21.3.1.2 Condenser. Between the field diaphragm and the condenser lens is a condenser iris diaphragm, and depending upon the specific type of specialized microscopy, there may be other additional components, for example, a polarizing filter in polarizing microscopy, Differential Interference microscopy (DIC), and Hoffman modulation-contrast microscopy, a beam splitter in Nomarski DIC, a center stop in dark-field microscopy, a phase annulus in phase-contrast microscopy, and an off axis aperture in oblique or anaxial illumination, or an excitation filter in fluorescence microscopy.

The quality and numerical aperture of the condenser is important to the overall image quality and resolution. Resolution of the microscope is

$$d = \frac{\lambda}{\text{NA objective} + \text{NA condenser}}$$

where d is the smallest distance between two resolvable points. The best condensers are achromatic-aplanatic condensers. However, Abbe condensers are also common. For condensers with NAs greater than 0.9, optimal results are attained if immersion oil is put between the front lens of the condenser and the specimen. The condenser must also be properly focused as there is a focal length, and the light must be focused at the specimen which will fill the back lens of the objective with even illumination when the iris diaphragm is properly adjusted. High-quality condensers should be free of chromatic and other aberrations. The lens elements should have high transmission properties to minimize light loss.

21.3.1.3 Stage. Next is the specimen which is held on a stage. Most microscopes have mechanical stages for precise positioning, and more sophisticated systems have X-Y computer-controlled positioning stages. Polarizing microscopes usually have circular stages for specimen orientation. Optical factors important in the specimen itself include the glass slide, coverslip, and mounting medium. Slides are usually glass, but in some special applications may be quartz. An especially important factor is coverslip thickness. The thickness of #0 coverslips is 0.1–0.13 mm, #1 is 0.13–0.17 mm, #1.5 is 0.15–1.20 mm, #2 is 0.17–0.25 mm, and #3 is 0.25–0.5 mm. Although some objectives have correction collars to adjust for different coverslip thicknesses, most objectives have a fixed correction factor for a 0.17 mm thickness. Usually, #1.5 coverslips should be used for optimal image quality. The refractive index of the medium that contains the cells and the medium between the coverslip and objective lens also are important factors because reducing the refraction of light as it passes from media of differing refractive indexes reduces light loss and background noise due to random scattering. Because the refractive index of glass is 1.52, the use of immersion oil in place of air between the slide and immersion objective lens allows for higher NAs and higher resolution and image quality. In fluorescence microscopy, the use of media without or minimal fluorescence is essential.

21.3.1.4 Objective Lens. Detailed knowledge of the characteristics, type, and quality of the objective lens is one of the most important aspects in microscopy. Having lenses free of aberrations, with high light-gathering and transmission characteristics and the highest numerical aperture possible are pivotal in attaining high-quality images. Furthermore in various specialized types of microscopy, additional components (e.g., phase plate in phase-contrast microscopy) are positioned in the back focal plane of finite tube length objectives. For in-depth coverage of objectives, refer to Refs 2,3, and 23. The following only skims the highlights and presents some of the terminology. Unfortunately, markings on objectives may vary among manufacturers.

Until recently, the vast majority of microscopes were fixed tube length of 160 or 170 mm (mechanical tube length from objective nosepiece opening to eyepiece opening). In such finite systems, the objective projects a real image in the microscope. The lens focuses convergent light in the interlens space. Most manufacturers have switched over

to infinity-corrected optics (2,3,23). Infinity objectives, marked ∞, are designed to project an image to infinity so that essetially there is parallel light between the objective and eyepiece. The advantage is that one or more optical components such as is needed in polarizing, phase, DIC, or fluorescence microscopy can be inserted without changing the functional tube length. One, two, three or more components can be introduced without affecting microscope performance. So multimode microscopy is easier to design without deleterious effects on image quality. But because the light rays are parallel to make the light convergent and project an image to the eyepiece, a second lens, or so-called tube lens, is needed between the objective and the eyepiece. Finite systems do not have a tube lens. Objectives cannot be interchanged between infinity and finite systems.

Beyond these two fundamental types there are other features important to know for proper selection and use of objectives. Most standard objectives are achromats (sometimes marked Achromat) with chromatic aberration correction for two colors (red and blue) and spherical correction in green. Apochromats are corrected for three spectral colors (blue, green, red). Plan indicates correction for a flat field. Fluorite objectives, often marked FL, fluor, Neofluar, etc., use fluorite glass and are ideal for fluorescence microscopy. Fluorite achromates have better spherical correction than conventional achromates. Etched on the objective could well also be the magnification, coverslip correction (usually 1.7), and numerical aperture (1.4 is highest presently attainable). In terms of final image magnification, a ballpark practical magnification limit should be around 500–1000 times the objective NA, preferably 750 or less. Objectives may also have coverslip thickness correction collars or diaphragms (useful in fluorescence microscopy to adjust image intensity). Some objects are high dry and are to be used in air, and others are designed to have an immersion fluid between the objective and specimen. The immersion medium is most frequently oil (marked oil, oel) but glycerine (gly), water (w), and other immersion objectives are also used. Individual manufacturers often additionally identify these with color-coded rings etched around the objective (see Tables 21.2–21.3 in Ref. 2). As the magnification of objectives increases, the working distance (distance between the objective and specimen when at the focal point) decreases as does the depth of focus. Objectives labeled LD are designed to provide longer working distances (useful for microinjection, manipulation, etc.). For polarizing microscopy, objectives must be strain-free and are often marked POL.

As will be dealt with later in the context of the specialized microscopy types, additional components can be incorporated either in the back focal plane of the objective or between the objective and ocular (depending on the type of system). Examples of such elements are Nicol or Wollaston prisms for Nomarski DIC, analyzer (polarizing filter) and compensator for polarizing microscopy and others, phase plate for phase-contrast microscopy, attenuation filter in single sideband edge-enhancement microscopy, barrier or emission filter in fluorescence microscopy, modulator plate in Hoffman modulation microscopy, etc.

Before moving on to the eyepiece or ocular, it is important to stress that using the highest NA objectives possible is essential for critical excellent microscopic imaging. The light-gathering capability, brightness, and resolving power are dramatically improved in higher NA objectives. The micrographs in Figure 21.1 illustrate that the detail resolved in the diatom test slide is much better with NA 1.4 versus 0.65. This becomes especially important when light intensity is limited (e.g., in polarizing microscopy, certain fluorescence). In addition to the importance of NA in image resolution and spatial frequency, according to Abbe (see Ref. 2), contrast transfer function (CTF) and modulation transfer function (MTF) are also affected. One can determine a specific optical transfer function (OTF) or MTF for any objective under a specific condition of use. The MTF specifies the performance system to image spatial detail. For three-dimensional image reconstruction and deconvolution routines used in image processing (particularly in fluorescence and confocal applications), the determination of the axial intensity distribution above and below the objective's focal point, expressed as a point-spread function, is needed. The axial intensity distribution of a point source above and below focus generates a three-dimensional diffraction pattern. One can calculate a point-spread function from a stack of serial optical sections of a point source (circular aperture or fluorescent bead). Suffice it to say that the quality of the objectives is at the heart and soul of the microscope's performance.

21.3.1.5 Eyepieces and Imaging. The eyepiece projects and magnifies the image formed by the objective lens. The power and diameter of field of view, as well as information on correction of aberrations and special features, are often indicated. CF indicates chromatic aberration free, W or similar markings indicate wide field, C or K indicates compensation, etched glasses are for high focal point, p or pl is for plan, and Kpl indicates a compensating flat field.

Conventionally observations are made by eye. However, increasingly, images are obtained by using a variety of video cameras, detectors, and photomultipliers with linkage to computer-based image processing and display systems. These will be covered in a subsequent section. Particularly useful are test slides to assess the overall imaging quality and spatial and axial resolution of the overall microscope system. Convenient test slides include diatoms with their precise repeat spatial patterns (e.g., *Amphipleura pellucida*—9.24 μM; *Pleurosigma angulatum*—0.62 μM),

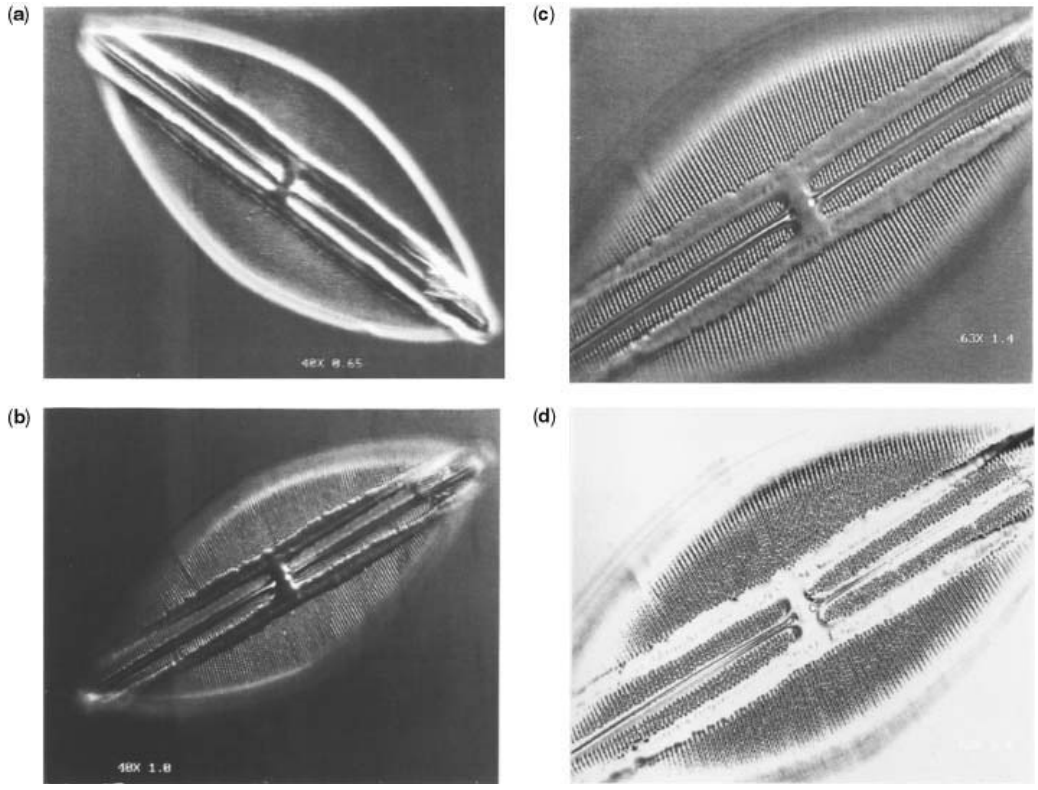

Figure 21.1. These Nomarski differential interference micrographs of a diatom illustrate the improved resolution with increasing objective NA (**a**) 40 × NA 0.65; (**b**) 40 × 1.0 NA; and (**c**) 63 × 1.4 NA; (**d**) this black and white image of a pseudocolored image of (c) reveals the fine structural detail resolvable.

butterfly scales, specially prepared pattern slides [e.g., Richardson slide (24), MBL-NNF slide (2)].

The preceding are the components that comprise a basic light microscope, including the possible variations in optical components and brief reference to concepts and practical aspects. Microscopes can be of the standard upright configuration or can be inverted with the light source in the upper vertical position, as one finds in inverted microscopes often used for examining cells in culture flasks or chambers.

21.3.2 Survey of the Variety of Light Microscopes and Cell Biology Usage

Visualization of structures in cells and tissues requires magnification because cells range from about 10–50 μM in diameter and are not resolvable by the naked eye. Along with magnification, which is achieved by the two magnifying systems (objective and eyepiece) working in tandem, structure can be discerned only by the presence of contrast within cells. The human eye cannot detect phase differences but can discriminate contrast differences in the range of 2–20% (18). Contrast can be achieved in various ways involving absorption, refraction, diffraction, reflection, light scattering, birefringence, and fluorescence. Central is the interaction between matter and light. In instances where this interaction results in phase changes, visualization is achieved only if these can be converted to contrast differences. Most living cells lack sufficient inherent contrast, so that bright-field microscopy reveals little without the use of stains to reduce the amplitude of certain wavelengths and render contrast differences preferentially. A number of different strategies have been developed to generate contrast thereby revealing structures in unstained or live cells and tissues (2,18,20,25–28). The following covers the highlights and uses of the array of light microscope types available for cell technology. A variety of useful contributions can be found in the Royal Microscopical Society Handbook Series (27) and Cell Methods Handbooks [28, also Ref. 20 (Vol. 3)]. A particularly good web site that covers various types of microscopes is the Molecular Expressions-Microscopy Primer (http://micro.magnet.fsu.edu/primer/webresources.html).

21.3.2.1 Bright-Field Microscopy. The fundamental components of the bright-field microscope are as indicated earlier. Live cells and tissues are poorly viewed with a bright field because only opaque or naturally occurring pigment granules absorb or refract sufficient light to

generate discernible contrast. Although there are a few classical vital dyes (e.g., Janus Green B, Evan's Blue) that reveal selected facets of live cells, the primary use of bright-field microscopy is on fixed cells stained with dyes that bind selectively to cell structures. Figure 21.2a shows a typical paraffin section stained for bright-field observation. There is a wide array of selective and semiselective dyes available for cytological, histological, and histochemical uses (20 (Vol. 3), 29). The limitation is that fixed cells are usually used, and the problem of fixation artifacts must be considered.

Contrast visible to the eye in bright-field microscopy is due almost exclusively to the selective absorption of light. Because of differential binding affinities to stains, certain cell components become distinguishable. The classic example is hematoxylin and eosin staining (Fig. 21.2a) which highlights nuclei in shades of blue, and the cytoplasm pink, depending on the protocol used.

21.3.2.2 Dark-Field Microscopy. This is one of the oldest and least costly forms of microscopy that renders contrast to living or unstained cells (30–32). It reveals cells (particularly edges and boundaries) in bright contrast against a dark background (Fig. 21.2b). During the past 20 years, this form of microscopy has received renewed interest because it provides high-contrast viewing of very fine structures below the resolution limit of the microscope (2,3). One can view bacteria, cilia, flagella, single cytoskeletal elements, like F-actin and microtubules, and isolated particles and cell components.

Dark-field microscopes (DF) have special condensers with a center stop which blocks out all of the central rays

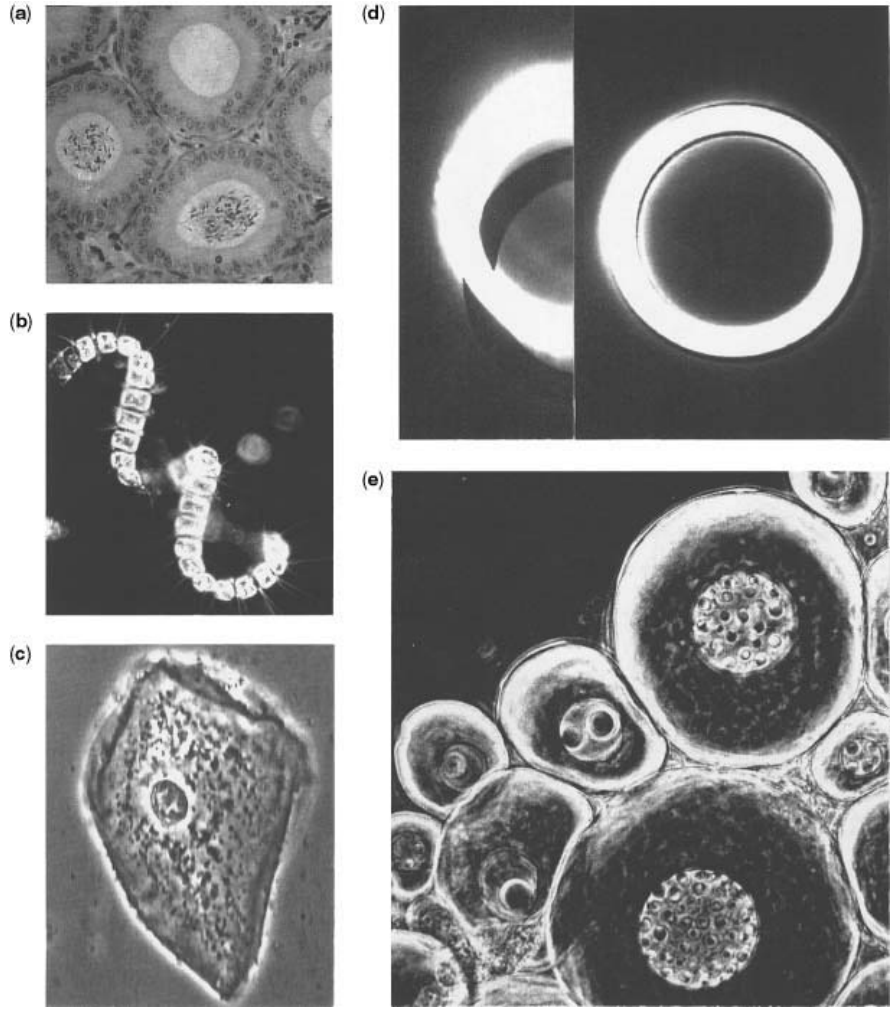

Figure 21.2. These micrographs provide examples of a bright-field and a dark-field on phase-contrast images. (**a**) an H and E stained epidymus section; (**b**) a live marine algal chain viewed in a dark field; (**c**) a live human buccal cell viewed with phase contrast; the two panels of (**d**) show the phase ring and annulus misaligned and aligned; (**e**) a phase view of live multicellular tissue (goldfish ovary) where nuclei and nucleoli are seen.

that create a cone of light. The ray diagrams in Figure 21.3 show dark-field microscopy compared to bright-field. Without a specimen in place and the condenser and objective properly focused, all of the undeviated light of this cone misses the objective. Once a specimen is introduced into the light path, some of this light is diffracted or refracted (deviated light) and enters the objective. So, only light scattered by the cellular components is seen, and the specimen appears as a bright extremely high-contrast structure against a black background. Dry DF condensers are usually used with objectives of NA <0.75. High NA objectives used for DF need a diaphragm to exclude undeviated light, some of which enters the objective. Not only is DF useful for looking at intact cells but has had renewed impact in visualizing exceedingly small structures. It is valuable in studies of cytoskeletal dynamics *in vitro* and cytoskeletal-based transport. In addition to these applications, DF is also very useful in autoradiography because the silver grains are highlighted as bright spots on a dark background making visualization and quantification clearer.

21.3.2.3 Phase-Contrast Microscopy. The absorptive light scattering differences between the variety of components in cells (due to refractive index and thickness differences) generate phase shifts. However, these are not detectable by the human eye or detectors. The interaction between light waves not deviated by cell components and deviated light is insufficient to generate amplitude differences large enough to give contrast. The invention of the phase-contrast microscope by Zernicke in 1935 (33) achieved the goal of producing a sufficient phase shift between undeviated light and specimen-deviated light, so that better interference occurred between the two wave fronts thereby providing sufficient amplitude change to give visible enhanced contrast. The interference between the two wave fronts provides a resultant brightness change (2,3,20,25–28,33). Now structures not visible in bright-field microscopy are easily seen. This provides an easy to use, cost-effective way of viewing live cells in culture and determining general cell features, nuclear shape, size, cell movements, etc. Figure 21.2c and 21.2e show phase-contrast images of both single cells and multicelluar tissue. The impact of phase contrast on cell biology was considered so important that Zernicke was awarded the Nobel prize in 1953.

A phase microscope has a special condenser with a series of phase annuli (each matched for its respective objective) (Fig. 21.4). The phase annulus allows a hollow cone of light (undiffracted zero-order illumination) to enter the objective and fall on a coincident donut-shaped region of a phase plate that is located in the back focal plane of the objective. This circular ring region of the phase plate (often coated by a dielectric) absorbs or attenuates 70–80% of the light and introduces a phase shift of one-quarter of a wavelength. Light scattered and altered by cellular components is deviated and passes through the other transparent regions of the phase plate (Fig. 21.4). The net result is that the introduction of the phase shift allows sufficient interference between the altered and unaltered light to generate visible amplitude differences, that is, contrast (can be negative or positive contrast). This reveals finer cellular detail (Fig. 21.2c, 21.2e). However, an annoying feature is the presence of halos surrounding contrasted structures because some of the diffracted light also passes through the ring area of the phase plate adding to the directly transmitted light. A

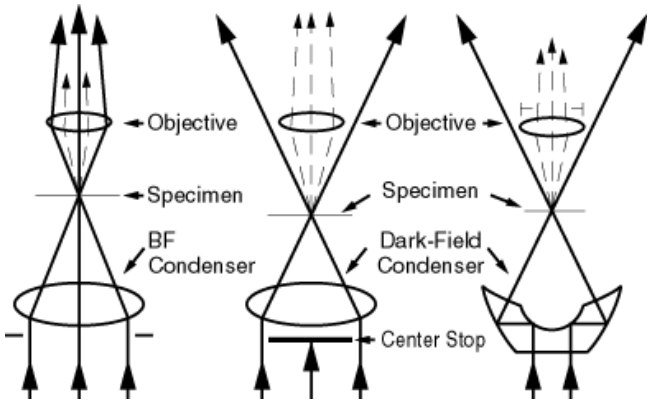

Figure 21.3. These ray diagrams contrast a bright-field microscope (left) with simple center-stop dark-field and dark-field condenser microscopes. A hollow cone of light is created by either the center stop or a dark-field condenser that has a central reflecting surface. This cone of undiffracted or zero-order light (solid line) bypasses the objective, and only the deviated refracted light (dashed line) enters the objective.

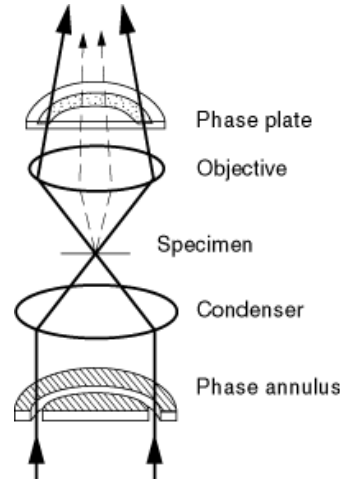

Figure 21.4. The essential components of the phase-contrast microscope. The condenser annulus produces the cone of undiffracted light that passes through the matched-phase ring or phase plate located at the back focal plane of the objective. The dashed lines represent the diffracted light.

second limitation is that one cannot do optical sectioning, so out-of-focus details limit the level of detail discernible.

Phase contrast works best on thinner objects (<5 μM thick), and proper images are obtained only if the correct phase annulus is used for each objective phase plate and if the annulus and ring in the phase plate are precisely aligned. This can be easily done with microscopes having a flip-in Bertrand lens (so the back focal plane of the objective can be seen) or by removing an eyepiece and using a phase-contrast telescope lens (Fig. 21.2d).

The invention of an aperture-scanning phase-contrast system by Ellis in 1988 (described in Ref. 2) uses a small circular fiber optic fiber that scans in a circle at the front focal plane of the condenser. This is conjugate with a phase plate in the back focal plane of the objective where there is a small dot that introduces the 1/4 λ shift instead of the usual ring. The result is improved imaging with less interference of out-of-focus image planes and no high-contrast halos. For detailed coverage of phase-contrast optics, the reader is referred to Ross (34,35), Bennett *et al*. (36), Inoué and Spring (2), Keller (3), and Sanderson (in Ref. 20 (Vol. 3)).

21.3.2.4 Oblique, Anaxial, or Asymmetrical-Illumination Microscopy. The use of oblique or even lateral illumination to yield contrast differences in unstained cells characterizes various modes of microscopy, as well as specially constructed microscope types.

21.3.2.4.1 Oblique or Anaxial (Asymmetrical) Illumination. This is achievable with a bright-field microscope set up for Köhler illumination and then by various means passing only the unaltered (undeviated, zero-order light) through one off-center region of the condenser and objective. Diffracted light passes through other areas of the objective. Oblique illumination can be produced by moving the lamp filament extremely to one side (37), by a variety of asymmetrical stops in front of the condenser or over the field diaphragm (38,39), or simply by offsetting the condenser diaphragm to one side (3) as Abbe did in the 1800s. Asymmetrical illumination due to uneven condenser illumination produces a contrasted differential image that usually has a shadow-cast appearance. This is caused by the components in the cells diffracting the light and creating other orders of diffraction which enhance interference and improve contrast.

21.3.2.4.2 Hoffman Modulation-Contrast Microscopy. This type of microscope developed by Hoffman (40) allows more precise control and refined imaging which is particularly useful for single cells. Shaded images with a three-dimensional appearance, high contrast, optical sectioning, and control of contrast result. The essential optical components are (1) a polarizer over the light source (2), a slit aperture with a rectangular polarizer covering about half of it in the condenser and a special amplitude plate called a modulator in the back focal plane of the objective (Fig. 21.5). The modulator is a trizonal plate with three different transmission regions (3%, 15%, 100%). The condenser slit/pol aperture must be aligned with the modulator. The clear slit is over the 15% zone, and the polarized half of the slit is over the 100% zone. The net result of this off axis illumination is that the small phase-gradient differences within the sample yield deviated or altered light that is converted to intensity variations giving the shadowing and optical sectioning effect.

21.3.2.4.3 Single Sideband Edge-Enhancement Microscopy. This related form of asymmetrical-illumination micrscopy was developed by Ellis (41) and utilizes a half mask (stop) in the condenser and a carrier attenuation filter in the back aperture of the objective. This attenuation or spatial filter is sandwiched between two polarizing filters (see Refs 2,41, for details). The images obtained are much like differential interference-contrast images and are

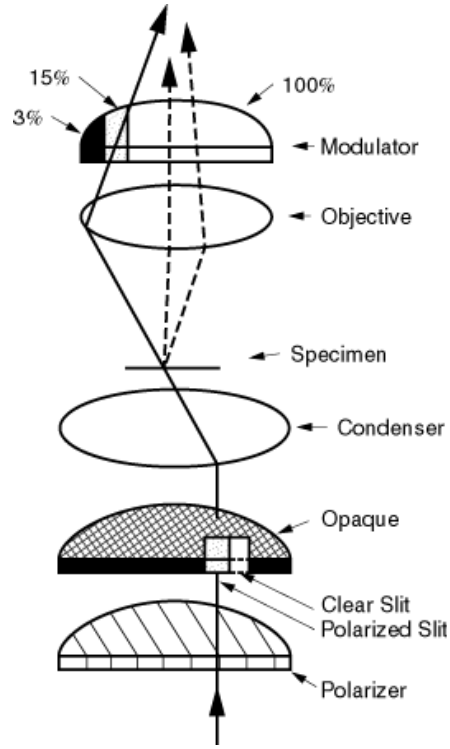

Figure 21.5. A simplified summary of the Hoffman modulation-contrast microscope (HMCM). Located in the front focal plane of the condenser is an opaque plate that contains an asymmetrically located rectangular slit half of which is covered by a polarizer strip. The back focal plane of the objective has a modulator plate with three zones of transmission. The condenser slit is aligned with the 100% and 15% areas. Diffracted light (dashed lines) passes through the rest of the modulator.

extremely rich in fine spatial detail. This is an ideal type of microscopy for viewing thin objects and where high spatial detail is required.

21.3.2.4.4 Multiple Oblique-Illumination 3-D Microscope. Three-dimensional images of cells, tissue slices, and live specimens can be produced by using a 3-D microscope that utilizes multiple (4) oblique fiber optic light polarized sources reflected by a pyramidal mirror. The microscope (3-D edge microscope, Edge Science Institute, Santa Monica) utilizes a field and relay lens to image the objective aperture on top of the optical path where it is split and channeled to the two eyepieces that provide a 3-D stereo image. See Greenberg and Boyde (42) for a general review of the optics and applications of this novel use of oblique illumination.

21.3.2.5 Polarizing Microscopy. Polarizing microscopy is a powerful qualitative and quantitative tool for examining cells and cell components that have structures with high degrees of molecular order. Structures such as filaments, microtubules, crystal arrays, extracellular matrix fibers, DNA, certain lipids, etc., can be viewed with sufficient contrast generated by polarization microscopy. Ordered structures appear as highly birefringent structures when ideally oriented. Anisotropy, the property of matter which has different values when measured in different directions in the same material, is the basis of polarizing microscopy. Polarizing microscopy has a long history dating from the first polarization microscope built by Smith in 1851 (43). Much of our current use of the polarization microscope in cell biology is heavily influenced by the extensive work of Inoué (2,44) and significant new developments introduced by Oldenbourg and Mei in 1995 (45).

A polarization microscope is basically an ordinary bright-field microscope equipped with a polarizer beneath the condenser and a second polarizing filter called the analyzer above the objective (2,46). Figure 21.6 shows a schematic of the components of a polarizing microscope. When light is propagated as a wave, it vibrates in two vectors at right angles to each other. When this passes through a Nicol prism (introduced by Nicol in 1860) or an anistropic structure such as a calcite crystal, the two beams (often called the e and o rays) are split. The polarizer preferentially passes light vibrating in a single plane, so that when the analyzer is crossed, little light is transmitted to the eyepiece. Only the alteration of polarized light by ordered structures in the cells placed in the optical path will generate birefringence (see Fig. 21.8f). The optics should be strain-free, and usually a rotating stage is used for specimen orientation. For analytical work, a compensator is often used between the polarizer and analyzer. This allows one to measure the degree of birefringence. When the polarizer and analyzer are crossed, one has extinction.

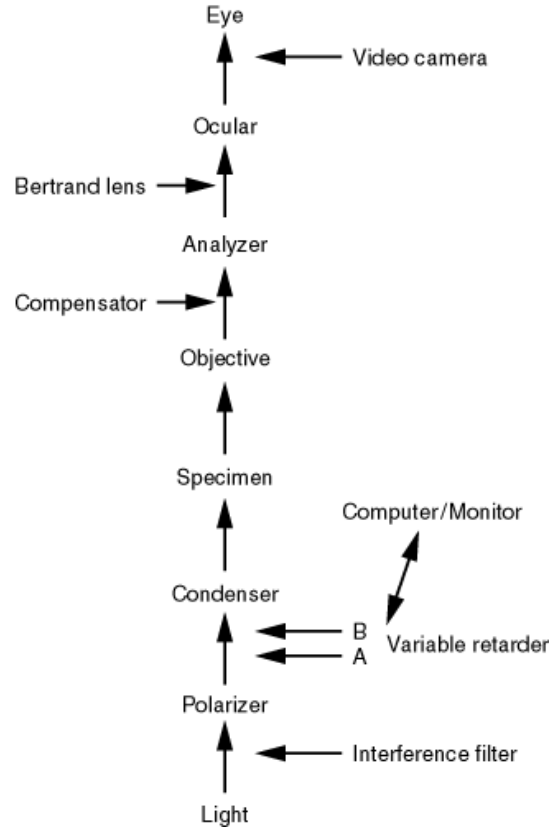

Figure 21.6. In the center is the sequence of components that comprise a basic polarizing microscope. On the left are optional elements (Bertrand lens, compensator frequently present). On the right are the additional components incorporated by Oldenbourg and Mei in their new Pol-Scope. A key component is the electrically controllable variable retarders (A and B). See text for details.

Extinction is a measure of the amount of stray light that is prevented from passing when the filters are crossed. To visualize anisotropic structures in cells and tissues, a high level of extinction is essential. Because the amount of light resulting from birefringent structures (e.g., microtubule arrays, mitotic spindles, DNA, etc.) is small, one needs to use bright light sources to overcome the significant amount lost by extinction. High NA objectives are used, so that maximum light capture is possible. Unfortunately conventional high NA objectives often reduce extinction. This can be corrected by using rectified optics (2).

With a polarizing microscope, anisotropic structures (e.g., microtubules, etc.) with their ordered molecular architecture appear as bright birefringent objects if extinction is high enough to yield a dark background. Birefringence occurs when the refractive index in one axis of the object is different in the orthagonal axis. This birefringence is measured as retardation (birefringence $\times$ thickness) and expressed in nM. Values less than 5 nM are hard to measure. However, this has recently been reduced to 0.02 nM by the introduction of a new innovative approach (45). The

Pol-Scope is a traditional polarizing microscope augmented by electro-optical devices and imaging algorithms to complete specimen birefringences. In a conventional Pol scope, only those anistropic structures in a certain orientation are displayed in a single image. The new Pol-Scope uses a precision universal compensator made of two electrically controllable liquid crystal retardation plates (B $\lambda/2$ 0°; A $\lambda/4$ 45°) that overcome the orientation problem. One can measure dynamically and non-destructively in live cells or isolated cell components with a high degree of sensitivity (as low as 0.02 nM) with excellent spatial resolution (0.2 nM). Recently (1997) Shinya Inoué (47) in conjunction with Hamamatsu and Olympus has added a new centrifuge polarizing microscope to the family of polarizing microscopes. This adds to the possibilities by allowing visualization of live cells and their organelles under centrifugation with high fidelity and resolution.

21.3.2.6 Interference-Contrast Microscopy. Like phase-contrast, interference-contrast microscopy exploits interference differences initially generated by local phase differences in the specimen and converts these to intensity differences. Perhaps the most widely used type of microscopy today to visualize live cells is the differential-interference microscope of which there is the Smith and Nomarski types (see Refs 3,20 (Vol. 3)). Surprisingly, interference microscopy was first introduced in 1893 by Sinks (see Ref. 48). However it was not until after the widespread use of phase-contrast microscopy that interference microscopes were designed and manufactured for general use. As reviewed in Inoué and Spring (2), there are essentially three types of interference microscopes *(1)* the Mach–Zehnder which involves two microscopes for separate reference and modified light paths; *(2)* beam-shearing types where the split beams are displaced laterally as in the Jamin–Lebedeff, Smith, and Nomarski types; and *(3)* the Mirau type where the reference beam is focused to a level differently from the specimen plane. The Jamin–Lebedeff interference microscope initially designed by Piller and built by Zeiss in the 1960s allowed quantitative analysis of live cells making it possible to measure cell volumes, mass of cell components, etc., based on calculations using optical path difference measurements. Such instruments are no longer available. The most widely used modern interference microscopes are the differential-interference microscopes (DIC) (2,18,26,48) developed by Nomarski in 1955 (48–50) and Smith in 1956 (48). In these, the beam splitter at the front focal plane of the condenser is a Wollaston prism that splits the polarized light into two paths displaced laterally relative to each other with shear. These two paths then pass through the specimen and are altered differentially depending on the refractive indexes of the cell components each encounters. At the back focal plane of the objective is another Wollaston prism (which can be adjusted in the Nomarski system) that recombines the two light paths. An analyzer crossed with respect to the polarizer (below the condenser) is next in the optical path. When the two beams are brought together, they interfere (Fig. 21.7). The phase shifts in each result from refractive index differences and thickness gradients in the cells being viewed. This exploitation of local phase differences results in a shadow-cast effect which reveals very fine cell detail and allows optical sectioning because of the very shallow depth of field. Figure 21.8c–21.8d shows DIC views of live cells. For comparison Figure 21.8a provides a HMCM image and Figure 21.8b provides a phase-contrast image.

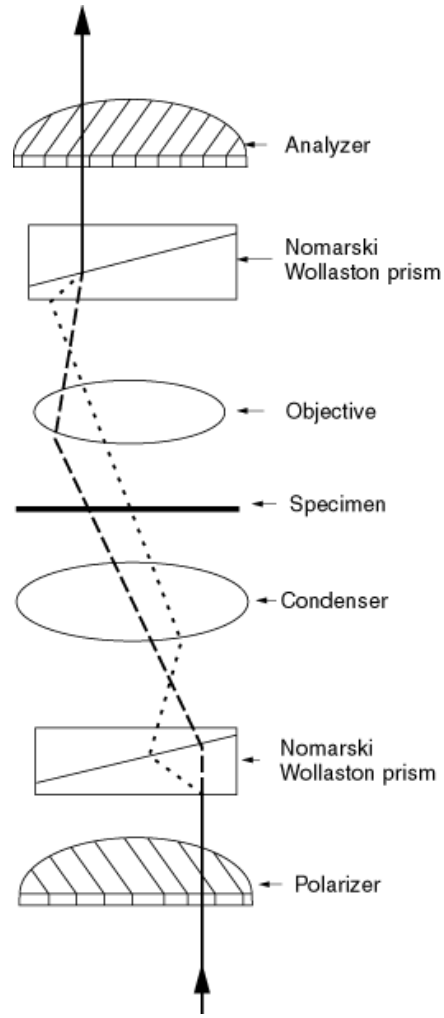

Figure 21.7. An example of one of the types of interference-contrast microscopes shown here is the Nomarski differential interference-contrast system (DIC). Plane-polarized light is split by Wollaston prisms into two paths separated by shear. These are indicated by the dashed and dotted lines. The final recombination of the two paths is via the second Wollaston prism. The interaction produces a differential-interference image with shading and high contrast.

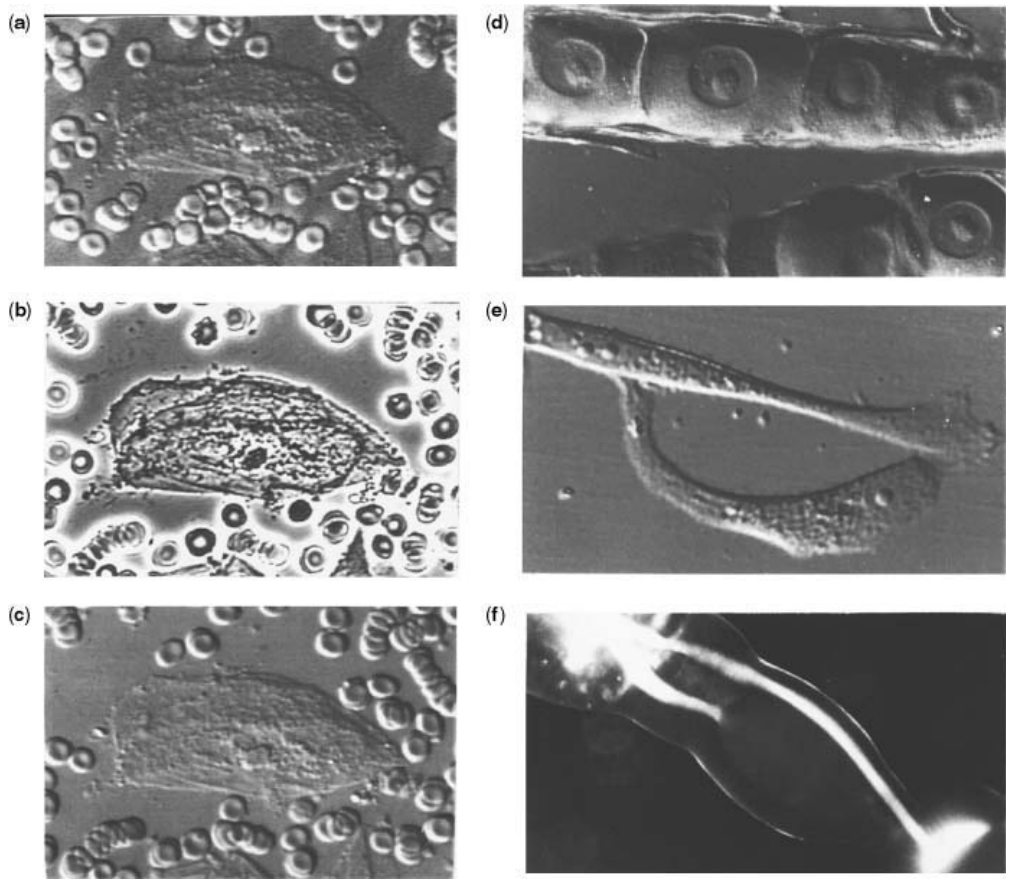

Figure 21.8. (**a–c**) HMCM, phase-contrast, and DIC views of a combined preparation of blood and a buccal cell. Note the graded shading in the DIC (c) and HMCM (a) images, and no halos, as are prevalent in phase image (b). (**d**) The optical sectioning ability of DIC of a praying mantis ovary. The oocyte's large nuclei and prominent nucleoli are delineated. (**e**) A DIC view of HeLa cells. (**f**) A live insect ovariole (of *Rhodnius proxlixus*) as seen in polarizing microscopy. The brilliant birefringent structures are the intercellular bridges or trophic cords that are packed with aligned microtubules.

Organelles and other cell structures appear in relief with variable contrast. For general viewing of cells in culture, this is widely used as the preferred method. However, it cannot be used with plastic culture dishes or plastic coverslips because these are anisotropic materials and affect the polarized light necessary in DIC. A recent improvement in DIC has been introduced by Holzwarth *et al*. (51) which is called polarization-modulated DIC (PM-DIC). This involves using a liquid crystal modulator that can switch the polarization from X to Y rapidly, coupled with a frame grabber and an imaging processing system. The result is a significant improvement in contrast, and with incorporation of background subtraction, one can resolve very fine spatial details of high contrast.

21.3.2.7 Reflection-Contrast Microscopy. Reflection-contrast microscopy (RCM; also sometimes called reflection-interference microscopy, RIM) can be used to study live cells, as well as fixed cells. In its simplest form, it involves passing light (usually polarized via an epi-illumination system with a dichroic mirror down through the objective, and reflected light from the specimen passes through the objective, the dichroic mirror, a polarizer at 90° to the first, and to the eyepiece (52). This was first used by Curtis (53) to investigate cell adhesion and improved by Ploem by placing a quarter λ coating on the front of the objective. Improvements in image quality result if special antiflex objectives are used (54). Izzard and Lochner (55) successfully used RCM (also called interference RCM or IRCM) to look at fibroblast cell substrate adhesion and interactions. Opas and Kalnins (56) also examined cell substrate local adhesion. In RCM, light waves reflected at the sample surface interfere with those reflected from the substrate. The result is an image that highlights contact and adhesion sites in high

contrast. Besides visualizing cell–substrate adhesion sites, RCM is very useful for visualizing nonradioactive *in situ* hybridizations where peroxidase or silver/gold labels are used (57).

Reflection microscopy has also involved using a scanning mode via a spinning Nipkow disk containing 24,000 small holes that produces and detects many points of light. These were first developed independently by Minsky and by Petrán in the 1960s (58–62). They are called tandem-scanning reflecting microscopes and are also used for examining cell–substrate adhesion, as well as cytoskeletal structures. The tandem-scanning reflecting-light microscope developed by Petran was the first use of a confocal microscope approach. For more in-depth information on reflection contrast microscopes, see Verschueren (52); Egger and Petrán (58), Curtis (53), Opas and Kalnins (56), Izzard and Lochner (55), Ploem *et al*. (57), and Bereiter-Hann and Vesely (in Ref. 20 (Vol. 3)).

21.3.2.8 Fluorescence Microscopy. The phenomenon of fluorescence was first discovered in 1833 by Sir David Brewster and named fluorescence by Stokes in 1852. In fluorescence, molecules in specimens absorb light radiation and per Stoke's Law emit light of a higher wavelength. The excitation light of specific wavelengths excites fluorophore molecules such that outershell electrons move to higher orbits. Within 10^{-7} seconds, these drop to lower orbits and lose the energy via emission of light at a higher λ. For a general description, see Refs 3,20 (Vol. 3), 63. A major impetus to use fluorescence in cell biology comes from the immunofluorescence studies of Coons in the 1940s who localized antigens in cells using antibodies conjugated to fluorescent dyes like fluorescein isothiocyanate (FITC). With the tremendous development of immunofluorescent approaches, the fluorescence microscope became a routine instrument in many cell biology and biotechnology labs during the past 40–50 years. Initially, instruments were transmitted fluorescence microscopes. However, these are rarely used today and have been supplanted by epifluorescence microscopes. A schematic of a standard epifluorescence microscope is presented in Figure 21.9.

The essential components of an epifluorescence microscope are a lamp that emits the appropriate range of wavelengths, a filter to select the excitation wavelength, a dichroic mirror to direct that wavelength through the objective to the specimen which will then emit light to be captured by the objective and passed through the dichroic mirror, a barrier or emission filter that blocks wavelengths below the emission λ, and finally imaging by the oculars. Basic information is available from a variety of texts [2,3,20 (Vol. 3), 63,64], as well as a number of web sites, particularly the Molecular Dynamics and Molecular Probes sites.

Various types of lamps are usable in fluorescence, depending upon the intensity and the spectral range needed. Tungsten halogen lamps produce a continuous white light and emit from about 350–1000 nM but of relatively low intensity particularly in the 350–400 nM range. Such lamps are usable for FITC and a number of newer fluorochromes excitable in the visible spectrum. With the advent of low-light and more sensitive CCD cameras, lower intensity is less of a problem. More widely used lamps are xenon arc lamps (e.g., XBO 75) which have high-intensity output over a fairly continuous spectrum from 250–1000 nM. These are preferred where fluorescence ratioing is needed and multiple λs are needed for different probes. Mercury arc lamps (HB050 and 100) are also widely used. They have high intensity but a more varied spectrum with distinct peaks of intensity at certain wavelengths (e.g., 366, 405, 436, 546, 578). Lasers are being increasingly implemented as excitation sources, each with their specific wavelength(s) rather than a broad spectral array. A heat filter is between the collector lens of the lamp housing and the optical path. Initially, excitation filters used were relatively broad (the UG, BG filter) but now most systems have excitation filters with a reasonably narrowly defined transmission window (this varies among manufacturers but, for, example a 450–490 nM range is common for fluorescein). The fluorescence microscope has an epifluorescence condenser. In some systems, the excitation filters may be located in a

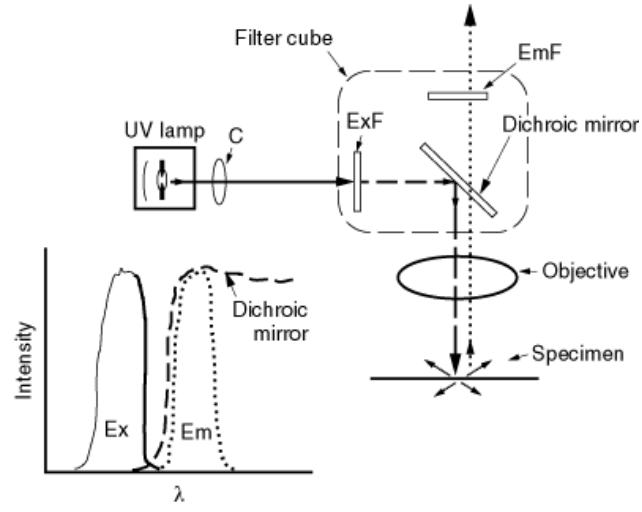

Figure 21.9. A schematic of a typical epifluorescence microscope with a lamp (usually HBO or XBO) that produces a spectrum of λ s. The λ of choice (depending on the stain used) is selected by the excitation filter (ExF). The selected excitation λ is reflected to the specimen by the dichroic mirror (dashed line). Fluorescence (higher λ) enters the objective lens and passes through the mirror with a final selection of the appropriate emission λ by the emission filter (EmF) or barrier filter. The generalized graph shows the spectral pattern for narrow band-pass Ex and Em filters and the dichroic mirror.

computer-controllable filter wheel, and in others the excitation filter along with the dichroic mirror and emission filter is located as a unit (filter cube) in the epifluorescence condenser (Fig. 21.9). The dichroic mirror will reflect the excitation λ into the objective but will transmit only the higher λ of the emitted light, and the higher λ will pass through to the eyepiece. Ideally, the emission filter would be a narrow band-pass filter and would transmit only the λ characteristic of the fluorochrome used. There is a tremendous range of filter combinations available (see the Omega Optical and Molecular Probes web sites, www.sover.net/∼omega and www.probes.com). The inset graph in Figure 21.9 shows a "generic" example of a narrow band-pass filter set. The terminology can be confusing. Dichroic mirrors may also be called chromatic beam splitters.

Because the image and its contrast come from emission of light from the specimen it is important that high NA, high transmission objectives are used, so that a sufficiently bright image results. As covered later, the use of low-light video cameras has opened up new vistas for fluorescence microscopy on live cells without the inherent problems of UV damage from the excitation beam or photobleaching because the intensity of the excitation illumination can be reduced with a neutral density filter or other means (13,14,16,20 (Vol. 3)).

The application of fluorescence microscopy is exceptionally far-reaching. Although there are relatively few endogenous fluorochromes (when present they often pose problems such as autofluorescence), there is an enormous array of fluorescent dyes now available for many applications relevant to cell technology. In-depth coverage of these is beyond the scope of this review, but there is a large and growing literature [3,20 (Vol. 3), 63–68].

The following highlights only a few of the applications of the fluorescence microscope.

A number of fluorescent dyes that selectively stain cell organelles (Fig. 21.10) [20 (Vol. 3), 68] are available. Mitochondria can be visualized in live cells with cell-permeant dyes like Rhodamine 123, Rhodamine 6G, $DiOC_6$, nonylacridine orange, JC-1 (Fig. 21.10a,b), and a range of MitoTracker dyes (Fig. 21.10c) (see Refs 69–71, and the Molecular Probes web site www.probes.com). Endoplasmic reticulum can be visualized (72,73) with labeled conA, $DiOC_6$, ER-Tracker Blue-White DPX (Fig. 21.10d); Golgi (74) with labeled C_5 and C_6 ceramide; DNA in nuclei with DAPI, Hoechst (Fig. 21.11d) or propidium iodide and so on. Fluorescent probes are used for tracking endocytotic uptake, cell to cell coupling, lysosome and lipid inclusions, and cytoskeletal elements, to name a few (75). There are also probes to quickly determine

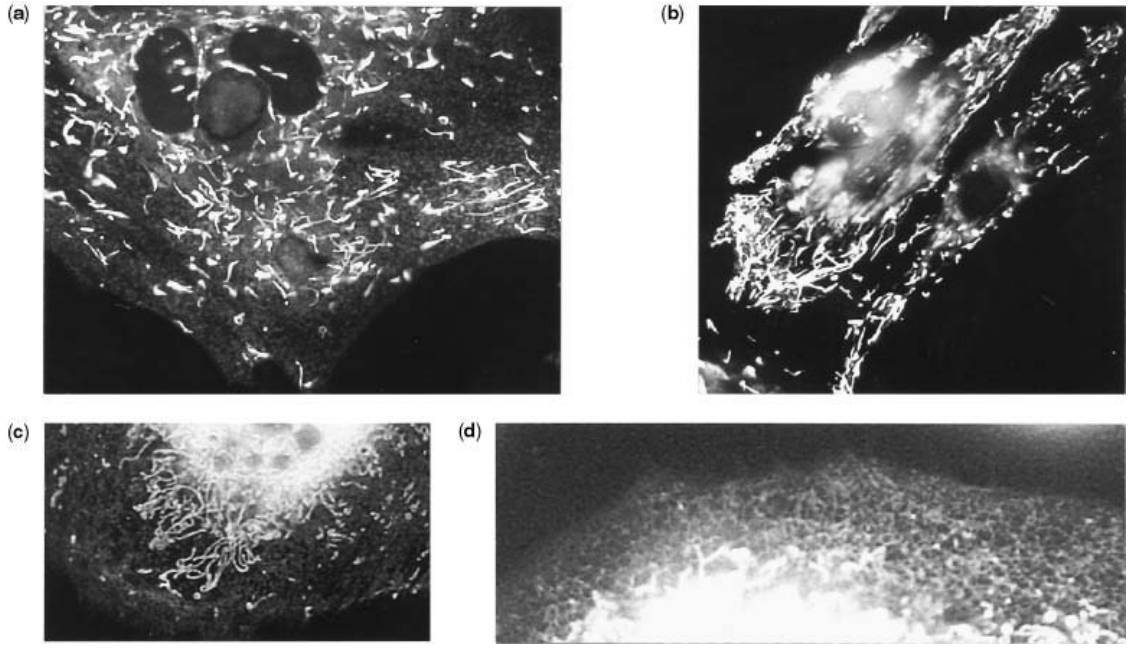

Figure 21.10. These black and white images of the original color fluorescence images show selectively stained organelles in live cells. The ER stains as a lacey network seen here in the thinnest peripheral area of a spread cell (E. Huebner and B. Hasinoff, unpublished data, 1999).

live and dead cells in culture and to measure levels of various ions, intracellular pH, and biochemical reactions (75–78). Fluorescently labeled probes are also used in *in situ* hybridization methods commonly known as FISH (fluorescence *in situ* hybridization). Immunofluorescence approaches to visualize cell structures, receptor sites, biosynthetic products, etc. is a major area of application [12–16,20 (Vol. B), 68]. Immunofluorescence has provided a powerful means for visualizing the cytoskeletal organization of cells. Figure 21.10 provides some examples of fluorescence microscopy of the microtubule and F-actin cytoskeleton using IF methods and a specific F-actin probe.

The introduction of new fluorescent probes and stains almost daily has resulted in an explosion of possible ways to study almost all facets of cell morphology and molecular functions of cells with fluorescence microscopy. Improved contrast and brightness is attained with newer dyes that are replacing the classical fluorochromes FITC (Fig. 21.11a) and tetrarhodamine isothiocyanate (RITC). Some of these are Texas Red, the Cy dyes (Fig. 21.11b), Bodipy, and most recently the Alexa dyes. Table 21.1 provides some examples of fluorophores. Some dyes require microinjection (e.g., the calcium-sensing cell, Fura 2) or some alternative physical cell loading method to introduce them into the cytosol. Increasingly dye-permeant forms (e.g., Fura 2 AM) have been produced. Although there are a number of sources of fluorescent dyes, Molecular Probes has become one of the major suppliers of new probes and continues to introduce an impressive array of new dyes.

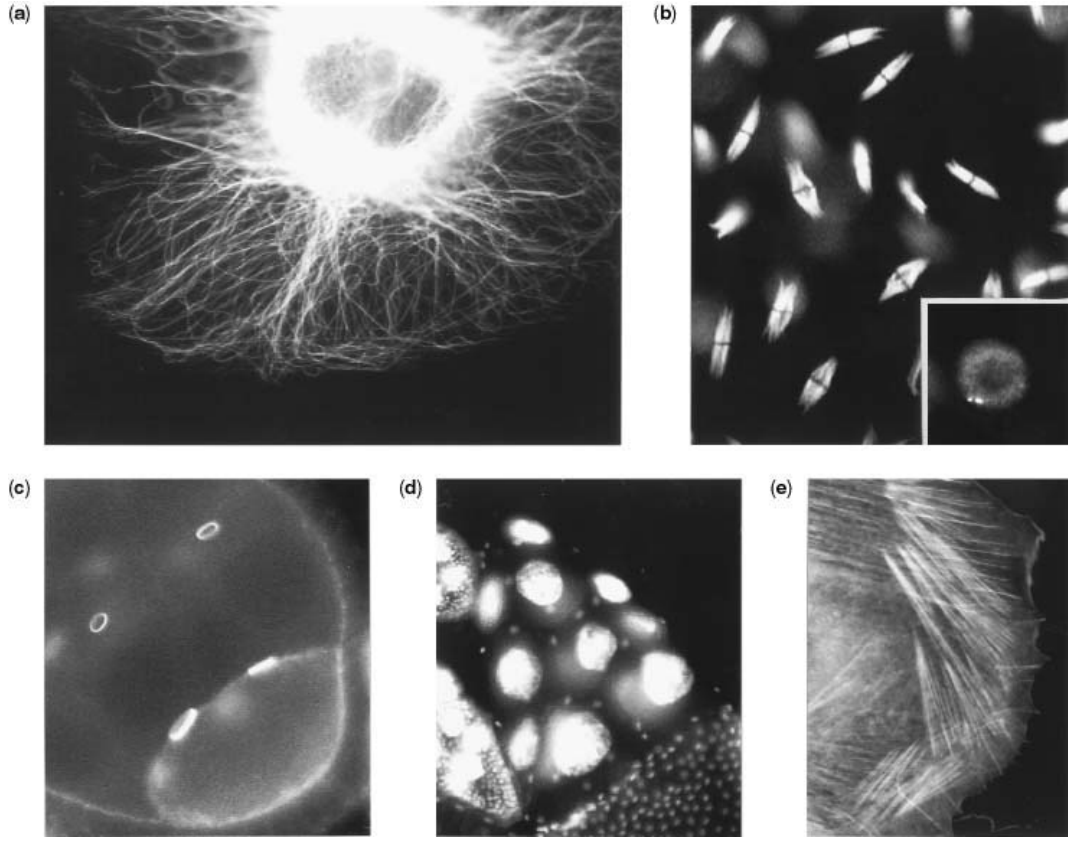

Figure 21.11. These black and white images of the original color fluorescence images illustrate immunofluorescence and other specific probes. (**a**) Dexrozoxane-treated CHO cells greatly enlarge in size. Their dramatic microtubule arrays are stained for acetylated tubulin using a fluorescein-labeled secondary antibody. (**b** and inset) Immunofluorescence of two stages of spermatogenic cells of the insect *Rhodnius*. The inset shows gamma tubulin labeling of the centrioles, and the main figure shows the tubulin of the spindles. The secondary antibody was labeled with Cy3 (E. Byard and E. Huebner, unpublished data, 1999). (**c**) The F-actin-stained ring canals of the *Drosophila* nurse-cell-oocyte cysts of the ovary. The F-actin-specific probe phalloidin is labeled with rhodamine. Wild-type green fluorescent protein (GFP) was originally isolated in the 1960s from jellyfish *Aequoria victoria* and cloned in the early 1990s. It absorbs at 395 (brighter) and 475 nM and emits at 508 nM. Chalfie showed that GFP can be linked as a reporter to other genes. This provided the catalyst for methods now routinely used to study gene expression in live cells using GFP fluorescence (79–83). Mutant forms of GFP generally called chameleons provide an array of GFPs as endogenous probes that monitor a variety of changes in pH and other factors (80). pH-sensitive GFP mutants called pHluorins are used to investigate endocytosis, for example (84). Recently, another family of fluorescent proteins, the phyofluors, which are much brighter than GFP, has been introduced (85). Fluorescent reagents can be introduced into cells in bound or caged forms and with appropriate wavelength irradiation are released and participate in reactions generating fluorescent molecules, thereby allowing one to study dynamic reactions at appropriate times [20 (Vol. 3), 86]. Suffice it to say, this is a rapidly advancing field.

A significant drawback in visualizing fluorescently labeled cells with conventional epifluorescence microscopy is the inability to visualize single focal planes. The fluorescence emanating from above and below focus plane levels contributes to the overall image, obscuring fine structural resolution. Image processing can improve visualization, but the introduction of laser scanning confocal microscopy dramatically improved and facilitated fluorescence optical sectioning (see Shotton in Ref. 20 (Vol. 3)).

21.3.2.9 Confocal Microscopy. This form of microscopy is part of the scanning microscopy family. In particular, confocal fluorescence microscopy has become popular as it overcomes the problem of out-of-focus plane fluorescence in fluorescence microscopy. Confocal has its origin in the 1950s and 1960s with its invention by Minsky in 1957 (58–62). Independently, Petran and co-workers in 1968 developed a Nipkow spinning-disc field-scanning or confocal microscope [2,20 (Vol. 3), 87–91].

A specimen can be scanned with the illumination beam by either stage scanning or the more widely used beam-scanning systems. Of these there are basically two common types, the disk-scanning confocals that use a spinning Nipkow or a modified Nipkow disk. In the Petran type the symmetrically placed pinholes alternatively provide the illumination pinhole and the imaging pinhole which are confocal. For current approaches in aperture scanning confocals, see Refs 28 (Vol. 3), 91–93. A newer modification developed by Kino in 1995 (2) uses a beam splitter that makes it possible for each pinhole to act both in illumination and imaging. The incorporation of a second disk with microlenses has further extended the use of the spinning-disk confocal microscope as a significant increase in image brightness was developed (94; also see 2,95). The laser-scanning confocal became the most prevalent confocal in the 1980s and 1990s. Figure 21.12a provides a simplified schematic of a laser-scanning confocal fluorescence microscope. Basically, a focused laser beam is scanned in raster fashion across the specimen. The laser light is directed through the objective via a dichromatic beam splitter, and fluorescence emission light passes through the beam splitter to a pinhole aperture that is confocal with the point source. Because there is fluorescent excitation along the excitation beam path, there is some out-of-focus fluorescence. So the pinhole aperture before the detector is necessary to collect only fluorescence from the in-focus plane. The illumination-focused spot in the sample and the detector pinhole are confocal with each other. The aperture ensures that only light from the confocal plane hits the detector. The net result is that out-of-focus plane fluorescence is minimized, optical sectioning can be done, and by collecting a Z axis series of images, 3-D reconstruction can be done. The advantages of removing obscuring glare, looking at thicker specimens without cutting sections, and the high degree of resolution

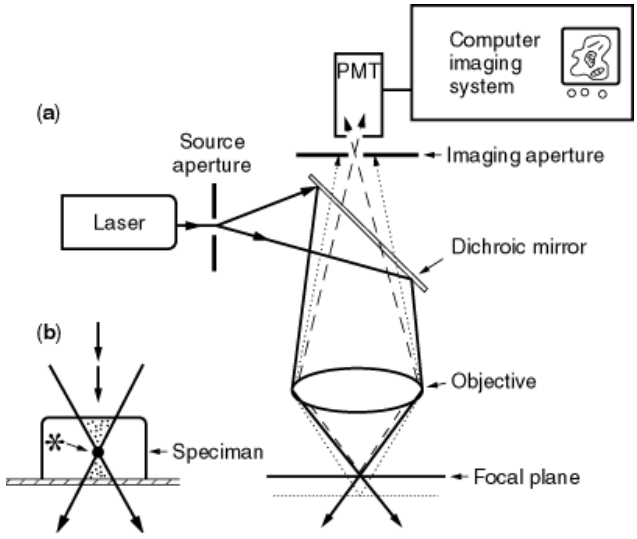

Figure 21.12. (**a**) A simplified schematic of a fluorescence laser-scanning confocal microscope. For simplicity, the excitation and emission filters routinely present in a fluorescence scope have been omitted (see Fig. 21.9 for their normal location). Also omitted is the scanning component. The excitation laser light (solid line) stimulates fluorescence in the sample. The fluorescence from the out-of-focus planes (dotted line) does not reach the detector (photomultiplier—PMT) because of the imaging aperture. Only the fluorescence from the confocal plane (dashed line) is deleted. (**b**) A simplified view of two-photon fluorescence in the specimen where two-femtosecond infrared laser pulses (depicted as two sequential arrows) simultaneously stimulate fluorophores at the focal point. Fluorescence occurs only in the small volume at the focal point (*pointing to solid dot). The stippled area shows, for comparison, the area where fluorophores are stimulated to fluoresce in conventional fluorescence and confocal-fluorescence microscopy.

has had a major impact in the cell biology literature. There are many excellent reference sources on all facets of confocal microscopy [2,3,20, (Vol. 3), 87,89,96–100] and also a number of valuable web sites (see end of chapter).

Figure 21.13 provides two examples of confocal images of an insect ovariole (*Rhodnius*). In normal fluorescence, detailed resolution is difficult (e.g., Fig. 21.13c) due to the fluorescence from multiple levels, but in confocal, as seen in an aqueorin-injected nurse-cell chamber (a) and in an immunofluorescence preparation of a plasma membrane calcium ATPase (PMCA) in the follicle (b), clear focus is acheived.

The significant development and impact of confocal has been aided by the refinement of scanning devices, detectors, varieties of lasers, and the improvements in computers necessary to handle the mass of data essential to 3-D imaging (14,16; Shotton in Ref. 20 (Vol. 3)).

An alternative approach to laser scanning confocals is the so-called digital confocals. These involve using deconvolution algorithms with a stack of serial optical sections obtained with a fluorescence microscope (see Shaw in Ref. 20 (Vol. 3); also see Refs 101–105). Each focal plane is sharpened by eliminating the blur from above and below the focal planes via such algorithms. Excellent optics, calculation of the point-spread functions, high-quality video cameras, and precise Z axis controllers are needed.

Particularly with single cells which are often fairly thin, the potential to resolve fine subcellular detail is now possible with conventional fluorescence microscopy in conjunction with video and image processing, confocal microscopy disk or laser scanning types, or computer deconvolution-based imaging.

21.3.2.10 Two-Photon and Multiphoton Microscopy. Despite all of the positive features of laser confocal fluorescence microscopy, there are some drawbacks (beyond the cost factor). The intense focused laser beam can cause significant photobleaching, and the laser irradiation can cause phototoxicity-generating free radicals and possible cell damage. Fluorescence eminates from all fluorchromes in the excitation pathway, including out-of-focus planes. This puts significant limitations on examining live cells. Two-photon microscopy was invented by Denk, Stickler, and Webb in 1989 (106,107). The suggestion of a two-photon microscope was first proposed in 1978 by Sheppard and Kompfner (108). The principle underlying two-photon and multiphoton absorption is based on the theoretical predictions of Maria Goeppert-Meier in 1931 and used in the field of spectroscopy. Imaging is similar to confocal microscopy except that photobleaching and damage are reduced. The excitation energy is concentrated temporarily and spatially, so that the saturation average power is small. For example, for Rhodamine B this would be 5 mW for a 100-fs pulse of 100 MHz (107). Excitation occurs only at the focal point, so that a pinhole aperture in the imaging path is not necessary because there is no out-of-focus plane fluorescence to remove. Figure 21.12b compares the area of fluorescence in two-photon versus conventional confocal fluorescence. Any damage to the sample that might occur is also restricted to the focal volume itself.

In two-photon microscopy, infrared wavelength high-energy ultrashort (femtasecond) pulsed lasers are used. These can be Ti: sapphire mode-locked lasers pumped by high-power argon ion gas lasers or diode-pumped 532-nM lasers. The excitation of a fluorescent dye molecule by one photon stimulates it to a partially excited short-lived virtual state from which it can be raised to its excited state if a second or more photons hit virtually simultaneously. Subsequently, thermal decay of the molecule yields fluorescence. The net result is that two or more photons of long wavelength create the same excitement normally achieved by short wavelength stimulation (in confocal), as long as they arrive almost simultaneously [for details,

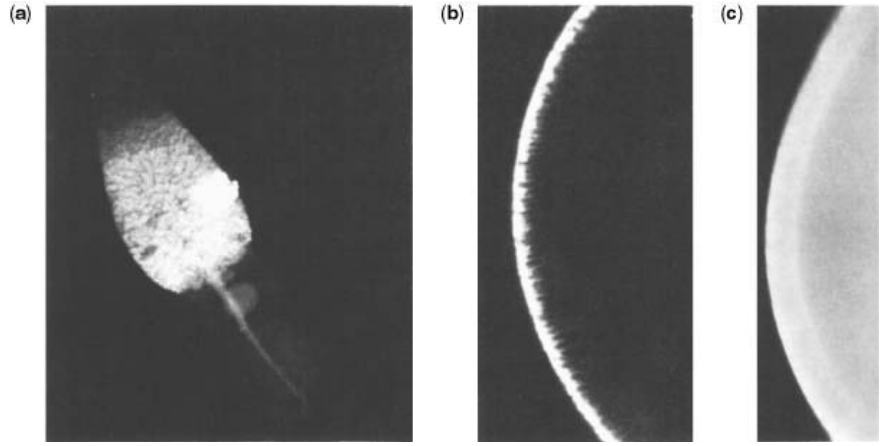

Figure 21.13. Examples of confocal single focal plane views of ovarioles of the insect *Rhodnius*. (**a**) Fluorescence in the nurse chamber and extending intercellular channels (trophic cords) of an ovariole that was injected with fluorescein-labeled aqueorin (Ca^{2+} sensitive photon-emitting protein) (E. Huebner, C. Bjornsson and A. Miller, unpublished data, 1999). (b) and (c) Micrographs of occytes with surrounding follicular epithelium that has been labeled via immunofluorescence for a plasma membrane calcium ATPase. The confocal image (**b**) shows that the label is localized in the outer follicle cell surface and (**c**) a similar preparation with conventional fluorescence microscopy where the out-of-focus plane fluorescence makes definitive localization difficult (Bjornsson and Huebner, unpublished data).

see Refs 28 (Vol. 3), 107,109–113]. Thus, unlike confocal and basic fluorescence microscopy, the excitation wavelength is greater than the emission wavelength. The red wavelengths penetrate deeper than UV so that the imaging range is extended, viability is improved, and there is no out-of-focus photo damage. Unlike confocal microscopy, the range of fluorescent probes that can be visualized is extended and excitation wavelength is not a problem because the excitation spectrum is much wider (113). The impact of two- and multiphoton microscopy is only now being felt with exciting work looking at intracellular pH, Ca^{2+} enzymes like glucose 6-phosphatase, ratio measuring of NAD and NADH, serotonin solutions, GFP, mitochondria, etc., in live cells (83,107,110–112,114,115, and web sites).

A major drawback to photon microscopy is the high cost of the femtosecond lasers and a potential problem of focal heating due to the absorption of infrared light. As manufacturers develop new instruments with improved technology and lower costs, multiphoton microscopy will become more accessible to biologists. The potential to study dynamic events in living cells at the light microscope level has been brought to single-molecule sensitivity levels.

A variety of additional types of microscopy have and are being developed that use not only light but other forms of electromagnetic energy for imaging. These include infrared spectromicroscopy, soft X-ray microscopy, laser Doppler microscopy, scanning acoustic microscopy, nuclear magnetic resonance microscopy, and others (116–119). These are beyond the scope of this chapter.

21.4 LASER TWEEZERS AND SCISSORS

Lasers have had an ancillary impact important in microscopy and cell technology in the form of laser tweezers and scissors that in combination with the light microscope provide a new noninvasive tool to measure forces operating in all processes like molecular motor-based transport and membrane characteristics, to isolate individual cells or cell components, and to do ultrafine microsurgery. Structures can be trapped and held by a laser beam-gradient force, and in essence particles are moved by light. A number of reviews and chapters cover the principles of laser trapping (120–124). A novel tool uses laser capture to isolate single cells from tissue sections thereby opening new frontiers for molecular analysis (125,126).

21.5 SCANNING-PROBE NEAR-FIELD MICROSCOPES

These are the newest microscopy tools impacting cell biology. They have the remarkable potential to resolve structure at the atomic level, thereby revealing structural detail normally seen only with electron microscopy. Involved is scanning of a small probe (1–10 nM) near the surface of structures with images generated as a result of the interaction between the probe and surface. Binnig and Rohrer revolutionized microscopy with the introduction of the scanning-tunneling microscope (STM) in 1981 (127) for which they received the Nobel prize in 1986.

Subsequently in 1986, Binnig, Quate, and Gerber (128) invented a related microscope, the atomic force microscope (AFM). Initially these instruments were primarily used in the physical sciences, but within the past five years they are increasingly being used in cell biology. These instruments represent one of the most important breakthroughs in analytical instrumentation technology in decades. Scanning probe microscopes work in a variety of environments (air, liquid, etc.). They magnify and resolve at the atomic level providing high-resolution, three dimensional morphology by "feeling and sensing" surface structures rather than using a photon or electron beam (129–134).

21.5.1 Scanning Tunnelling Microscopes (STM)

This type of scanning probe microscope requires an electronically conductive sample and is not generally applicable in biological systems. The probe tip scans the sample while being kept at a constant tip-to-sample distance of about 8 Å by an electronic feedback circuit. The tunneling current is kept constant, so that the rigid probe moves up and down indicative of the atomic surface contours being scanned. The probe uses an electron tunnelling current between the sample to activate a piezoelectric ceramide that supports the probe, raising and lowering it. Very sensitive measurements of 0.1 Å can be made.

21.5.2 Atomic Force Microscopes (AFM)

These evolved from STM, were introduced in 1986 (128), and are increasingly being used to study cells and cellular components (135–142).

In AFMs, the probe tip is positioned over the sample and then scans the selected area. The tip is mounted on a flexible cantilever arm. As the tip scans the cantilever, it is deflected, and the force of deflection is measured. A laser beam is usually used to detect cantilever deflection. The degree of deflection relates to the three-dimensional atomic structure of the surface scanned. Probe scans are sensitive to forces on the order of 10^{-12} N. Although care must be taken in interpretations by AFM of soft elastic surfaces that are easily deformed, recent applications to live and fixed cells have given dramatic images. Researchers have obtained images of chromosomes, cytoskeletal elements, whole cells, membrane surfaces, and membrane exocytosis (see web sites for images).

The development of three versions of AFMs and the combination of AFMs with other forms of optical microscopy has made the study of soft material (i.e., cells) and dual imaging more amenable (132,133,140,143). The three forms of AFM are *(1)* contact type, where probe tip friction and adhesion may be factors and bending in the lever is due to van der Waals forces; *(2)* noncontact type, where the probe hovers 1–10 nM above the surface causing less damage to delicate samples but with lower resulting resolution and *(3)* the newer tapping mode, which involves an intermittent contact oscillation providing for high resolution while minimizing mechanical distortion (138; also see the Life Sciences, Digital Instruments, and the merged Park Instruments/Topometrics web sites). These web sites provide examples of images.

Suffice it to say that this new form of microscopy is still in its infancy but growing exponentially as the impact on biological systems is realized. The ability to visualize cellular structures at submicron to atomic resolution is remarkable, particularly because live cells in natural media can be viewed and dynamic events recorded. The full range of applications in cell technology is still to be determined.

21.5.3 Scanning Near-Field Optical Microscopes

In 1928 Synge proposed a microscope without lenses that could circumvent the diffraction limit to resolution. This led to development in the 1990s of near-field aperture-scanning microscopes by Betzig and Trautman that gave super-resolution (144). Such microscopes are scanning near-field optical microscopes (SNOM) (145–148). High resolution is achieved by overcoming the far-field diffraction barrier by making an optical aperture much smaller then the λ of the light used and placing it close to the sample. With such a sub-λ aperture extremely close, the light emanating from the aperture illuminates a small area immediately below the aperture (the near zone), and this is scanned over the sample; the imaging is via a photodetecter multiplier system or, as in new instruments, a high NA objective relays the light to a photodetecter and ultimately, to a computer for image display. The light is carried to the scanning aperture via an optical fiber, and often lasers are used. Resolution depends on the size of the fiber (around 50 nM) and the distance from the sample (within 1 λ). New hybrid instruments that combine SNOM and AFM are becoming available (e.g., Nanomics Instruments) so that both a topographical and an optical image can be obtained. With high NA objectives and appropriate fluorescent dyes, high-resolution fluorescence microscopy is possible with SNOM. Until very recently, SNOM was mainly used on nonbiological material. The potential to use SNOM and continuous-wave two-photon SNOM on cells is in early stages of exploration (147,149–152).

21.6 VIDEO MICROSCOPY AND IMAGE PROCESSING

Along with the growing number of improvements and innovations in optical microscopes and the various scanning probe microscopes, the renaissance in microscopy is also due in large measure to the availability and

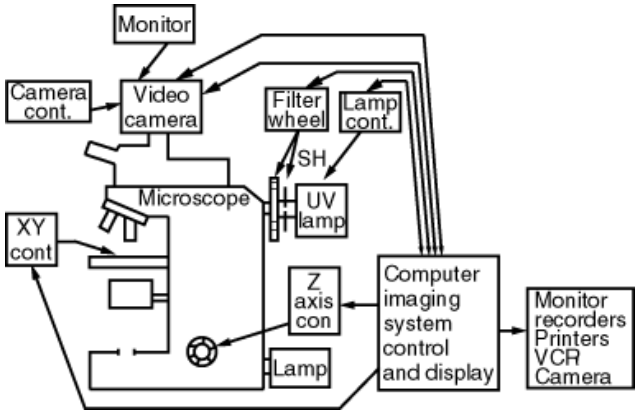

Figure 21.14. A block diagram of a typical system that integrates a computer and image processing with a microscope and peripheral devices. The system depicted has transmitted and epi illumination, X-Y stage and Z axis focus control, fluorescence with shutter and filter wheel, variable HBO lamp control for intensity, multiport head for various possible video cameras, video camera analog control, analog camera, display for video microscopy, computer image processing, computer control of peripherals, and various output options. The complexity of such systems depends on the applications.

improvements in video cameras, the use of computers, and digital processing. Video microscopy and image processing have become essential routine components of most laboratories in cell biology (2,14–16,20 (Vol. 3)). Figure 21.14 provides a block diagram with some of the components one might find in a typical microscope/computer workstation. Peripheral devices include X-Y stages, Z axis focus, filter wheels, shutters, lamps, liquid crystal filters, cameras, and recording devices, to name a few. The variety of cameras range from tube video cameras, CCDs, CMOS, intensified CCDs, cooled CCDs, and digital cameras. Image storage and recording components can also vary considerably.

An invaluable reference source that provides the historic perspective since TV was invented by Zworykin in 1934, the use of various types of video cameras, microscope interfacing and image processing is Inoué and Spring (2, also see 153). Both theoretical and practical aspects are covered. The work of Inoué and Allen in the early 1980s stimulated the widespread use of video microscopy in cell biology (154–157). In its simplest form, using a TV camera (with manual gain and black level control), high NA microscope optics, and a video monitor gives significant analog video enhancement and reveals excellent cell detail in live cells and allows analysis of fast dynamic events. The subsequent introduction of image processing with the use of A/D conversion of the video signal by frame grabbers in computers expanded the capabilities enormously. Image processing software routines made it possible for the cell biologist to do background subtraction, frame averaging, change contrast and brightness digitally, and a variety of other image-enhancement functions. The range of possibilities is broad. Figure 21.15 illustrates some of these using three different cell types (buccal cell, fish hepatocyte, and brain pyramidal neuron). Depicted is image enhancement (a), intensity representation (b,c), various manipulations (d–f), and 3-D integration and merging of stacked images. The cellular detail revealed can be astounding, allowing visualization of structures like microtubules, mitochondria, cytoplasmic movements, etc. [20 (Vol. 3), 157].

The end result is that video-enhanced microscopy is affordable and widely available, and when used on DIC, phase contrast, polarizing, and other forms of light microscopes provides excellent image quality and resolution extending our ability to study cells, live and fixed. Resolution of video systems and printers has improved often achieving photographic film quality. An array of video cameras, including Neuvicon tube cameras, charge-coupled cameras (CCD's), complementary metal oxide semiconductors (CMOS), and digital cameras are used [see 14,16, Shotton and Ladic, in Ref. 20 (Vol. 3), 158–161].

The development of ultrasensitive low-light video cameras has had a major impact in capitalizing on the use of fluorescence microscopy on living cells. Normal fluorescence microscopy uses levels of UV that cause significant cellular damage, making study of living processes difficult or impossible. Reduction of the level of excitation illumination generates a very weak fluorescent signal not detectable by eye or standard cameras. Low-light cameras such as silicon intensified cameras (SIT), intensified SIT (ISITS), intensified CCD (ICCD), cooled CCDs and cameras capable of integration on chip provide output signals of sufficient brightness that fluorescently labeled cellular structures can be studied in live cells without impairing function [14,20 (Vol. 3), 158,160,161]. Furthermore components that are not abundant (e.g., a small number of receptors) can become detectable because the sensitivity of detection is very high.

The combined benefits of video-enhanced contrast and video low-light microscopy makes video microscopy applicable to the full range of light microscope types and a broad spectrum of cell biology problems.

The implications of image processing of digitized images with computers adds an additional dimension in the potential to extract information and also for quantitative and morphometric analysis. Possibilities range from simple measurements such as counting objects, length and surface area measurement, and density profiles to intensity measurements in quantifying fluorescence, staining, etc. The microscope and image processing have become indispensable tools in many cell biology laboratories (14,16,20 (Vol. 3)).

In-depth details of the terminologies and technical aspects of video microscopy imaging is beyond the scope of this chapter. The reader is referred to Inoué and Spring (2), Shotton (in 20 (Vol. 3)), Ladic (in 20 (Vol. 3)), Oshiro (159), CLMIB (158), Lynch (162), Moomaw

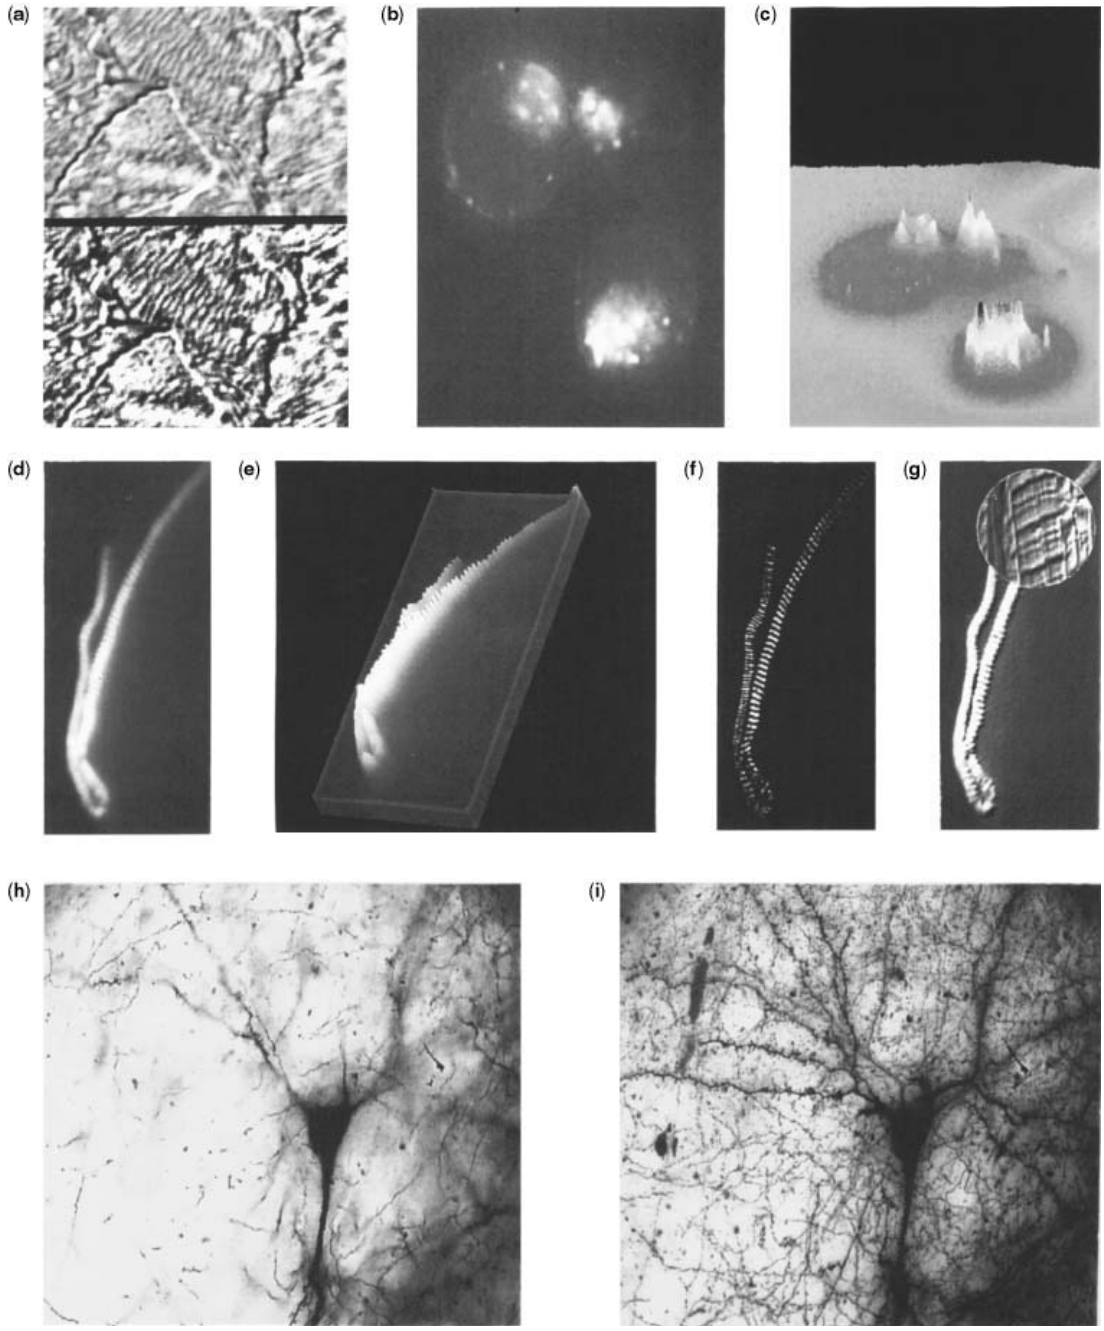

Figure 21.15. Some examples of image processing. (**a**) Contrast enhancement of the surface membrane feature of live buccal cells. (**b**) Trout hepatocytes that have endocytosed the fluorophore lucifer yellow; the relative brightness of the fluorescent areas is illustrated in this black and white image of a pseudocolored 3-D intensity profile in (**c**). (d–g) Various manipulations of a fluorescence image of an isolated insect striated muscle cell stained with rhodamine-labeled phalloidin (**d**). The F-actin of the sarcomeres fluoresces brightly. (**e**) An intensity profile (brightest areas as peaks). (**f**) Contrast enhancement. (**g**) A DIC-like image produced by subtraction of two images with shear. The inset is at higher magnification to show more clearly the DIC-like view of the sarcomeres (the original nonprocessed image was a fluorescence image). (h) and (i) 3-D reconstruction of a stalk of focal planes. (**h**) A single focal plane of a Golgi stained pyramidal neuron cell in a thick section of the cerebrum. Only part of the dendritic structure and the axon are seen. (**i**) Merging of a series of focal planes into a single image. On screen this can be viewed in stereo and rotated.

(161), Lockyer (160), and the web sites of manufacturers. An especially important aspect is the selection of the appropriate camera(s), particularly because new options are becoming available almost daily. There are many manufacturers (e.g., Apogee, Cohu, Cooke, Dage, Dulsa Fairchild, Hamamatsu, Photometrics and Princeton Instruments/Roper Scientific, Kodak, Video Scope, Xybion, RCA, Panasonic, Hitachi, Phillips, and others). Resolution, signal-to-noise ratio improvements, and sensitivity are continually improving, and costs are becoming affordable. The advances in thermoelectric cooling devices or Peltier cooling has allowed for excellent cooled CCD cameras. Digital video cameras are also becoming more commonplace. A broad selection of frame grabbers and imaging software is also available from many manufacturers.

So, on all fronts of video microscopy, this impact on cell biology is strong and growing daily.

21.7 ELECTRON MICROSCOPES

The golden age of electron microscopy was ushered in by the world's first electron microscope built by Knoll and Ruska in 1932 in Berlin (7–9). The first micrographs of biological specimens were produced in Belgium by Marton (163). The first North American EMs were built in Canada by Hall in 1936 and Prebus and Hillier 1983, and other microscopes were developed in the late 1930s in England (Martin, Whelpton, and Parnaim) and Japan (Sugata; Hibi) (see 9,10,164).

The excitement that characterized these early days of EM was based on deBroglie's discovery that electrons travel as a wave and Busch's discovery that they could be focused by electromagnetic lenses. One had the potential to exceed the resolving power of the light microscope. The first commercially available electron microscopes became available in the 1938–1940s first from Siemens in Germany and RCA in North America, and from Phillips, AEI, and various Japanese companies. Improvements in electromagnetic lens aberration correction, use of apertures, and vacuum system advances led to the transmission electron microscopes, that provide unprecedented resolution for cell biologists to determine the ultrastructure of cells and tissues. The first scanning electron microscope was developed in the 1930s by von Ardenne in Germany. The predecessor of the SEM, as we know it, was developed by Oatley in Britain (11) and first commercially produced by Cambridge Instruments. Since then there have been innumerable advances in EM with high voltage EMs, analytical EMs using scanning transmission EM (STEM), imaging based on energy loss spectroscopy, and others. Magnification attainable and routinely used by cell biologists ranges from 1,000 × to 500,000 × with resolving powers as low as to 1 Å or less. Some specialized new EMs in the 300 kV or more range can resolve single atoms. Ease of use has progressed from manual control with manual valves, geiger tubes, etc. to microscopes that are slick, ergonomically designed with microprocessor and digital control, and have sophisticated imaging capabilities. Perusal of the literature and web sites of the major manufacturers of EMs (JEOL, Hitachi, Phillips, Leo, and others) provides some insights into the state of EM technology available today. Many reference texts are available on the theory, principles, and uses of biological electron microscopy and tissue preparation techniques (165–169).

The application of electron microscopes to cell biological research also hinged on the development of specimen preparation methods and cutting sections thin enough for an electron beam to pass through to yield a transmitted image. The selection of fixatives that preserve cell morphology adequately was essential. Osmium tetroxide initially (used in the 1940s–1950s) and glutaraldehyde (introduced in the 1960s) provide excellent cell ultrastructural preservation and are still in use today. The ability to attain ultrathin sections of TEM rested on finding suitable knives and developing microtomes with ultrafine advance capabilities. The implementation of plastic resins (a wide range available today), the utilization of glass and diamond knives, and the design of ultramicrotomes have made biological TEM the widely used tool it is today. The selective enhancement of electron density in cellular components is achieved by using heavy metal stains such as uranyl acetate and lead citrate.

The light microscope was overshadowed from the 1940s to 1960s by an enormous explosion of literature based on electron microscopy that provided incredible resolution and led to new understanding of cell organelles and cell processes. It opened new vistas in cell biology. The electron microscope is still a powerful tool with important applications today, but as covered earlier, the advances in light microscopy and scanning probe microscopy have taken more of a lead role. The exciting prospects for a cell biologist is that there is now an arsenal of instruments available to reveal almost any facet of cell structure and function one wishes to visualize, and the TEM is one these tools.

The transmission EM shares a similar plan with a conventional light microscope. It has electromagnetic lenses in place of glass ones and a filament (either tungsten or lanthanum hexaboride) that emits a stream of electrons by thermionic emission upon heating (to 2700°K) into a vacuum (in the TEM column). In some newer instruments field emission (electrostatic) guns are used. Efficient vacuum is created by various vacuum pumps (e.g., diffusion types, ion getters, turbomolecular pumps). Figure 21.16 shows a simplified diagram (minus the vacuum system and electronic control systems) of a basic TEM, the components added to make it a scanning transmission EM, STEM, or a standard SEM, and compares them with an inverted light microscope ILM. The literature is replete with conventional electron-dense/electron-lucid images

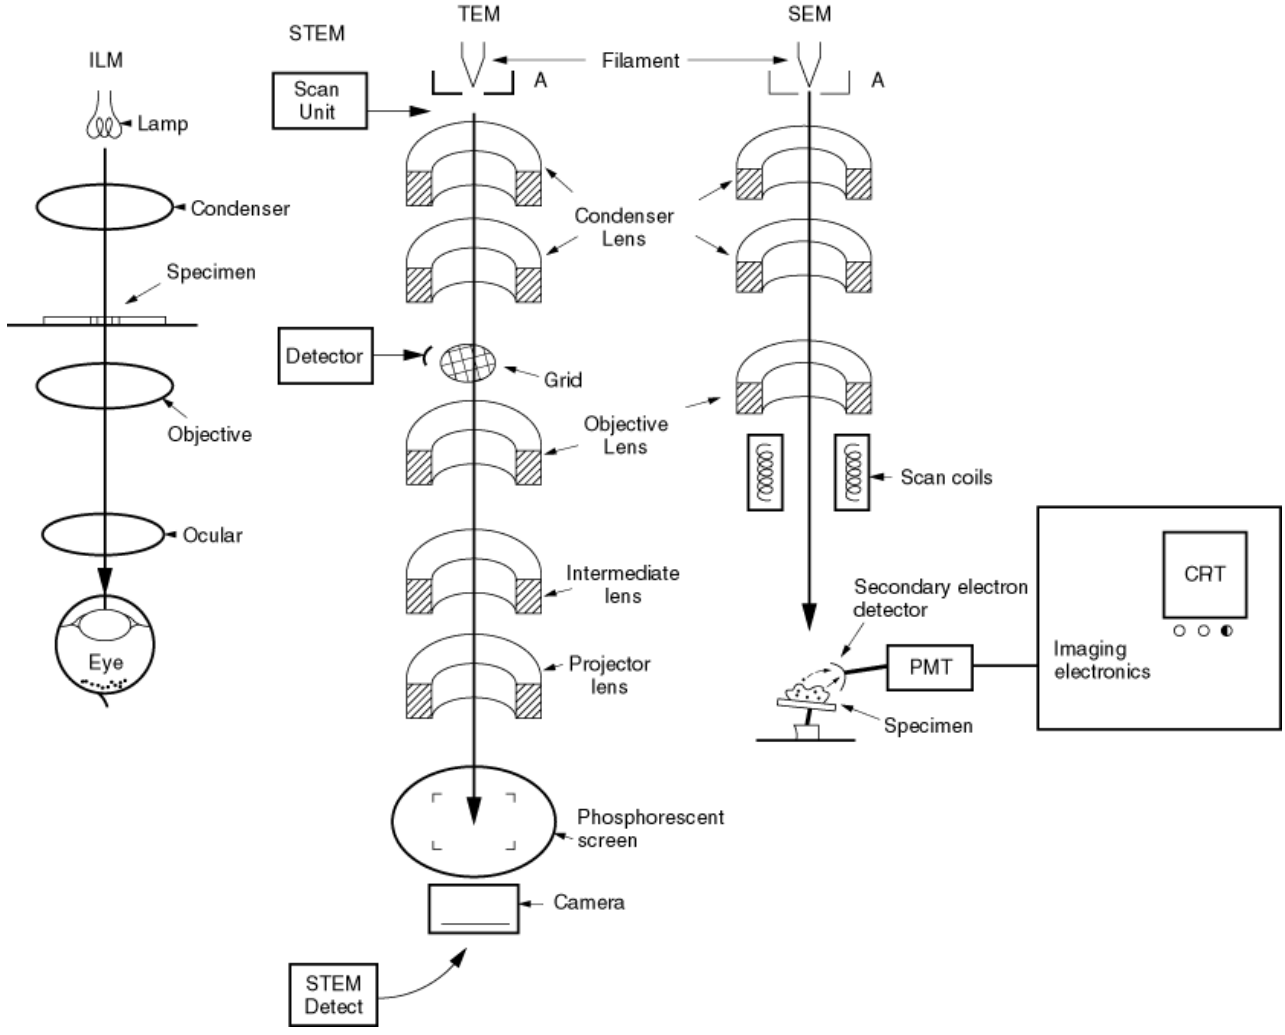

Figure 21.16. This simplified schematic illustrates the key components of electron microscopes (STEM, TEM, and SEM) compared to an inverted light microscope (ILM). The vacuum system and electronic control components are omitted. Presented is the sequence from the electron gun (filament and anode A) through the various electro magnetic lenses and viewing on a phosphorescent screen (TEM) or cathode ray tube (CRT) in SEM. Adding scanning coils and detectors near the sample (e.g., X-ray detector) or a STEM detector below the phosphorescent screen basically converts a TEM to an STEM and greatly expands its range of capabilities. STEM and other detector-generated images are viewed on a CRT via an electronic control unit (not shown).

provided in TEM micrographs that reveal fine cellular detail (membranes, mitochondria, cytoskeletal elements, labeled receptors etc.). The advent of peroxidase, colloidal gold, and other electron-dense labeling methods facilitates immunoelectron microscopy. When fixation interferes with immuno methods, ultracryosectioning and labeling methods can be used. With the addition of scanning coils to a TEM, one can position or raster a beam over a sample or selected area, and combining a host of X-ray microanalysis and other detectors, the TEM becomes a STEM (Fig. 21.16). This extends the EM's capability into the analytical range. Figure 21.17 provides an example of a conventionally stained TEM micrograph. Energy loss spectroscopy has also been used for electron microscopic imaging (170). Using electron spectroscopic imaging with an EM like the Zeiss CEM 902 makes it possible to image unstained sections based on their composition. Figure 21.18a shows microtubules imaged at the carbon edge.

Scanning EM also has major uses in cell biology (171). While utilizing electromagnetic lenses (condenser, objective and field lens), the beam is scanned across a sample, and secondary electrons given off by the surface are collected on a detector nearby converted to photons, which are transmitted to a photomultiplier and are displayed on a screen via the SEM electronics (Fig. 21.16). Usually samples are fixed, dehydrated, dried (critical point drying,

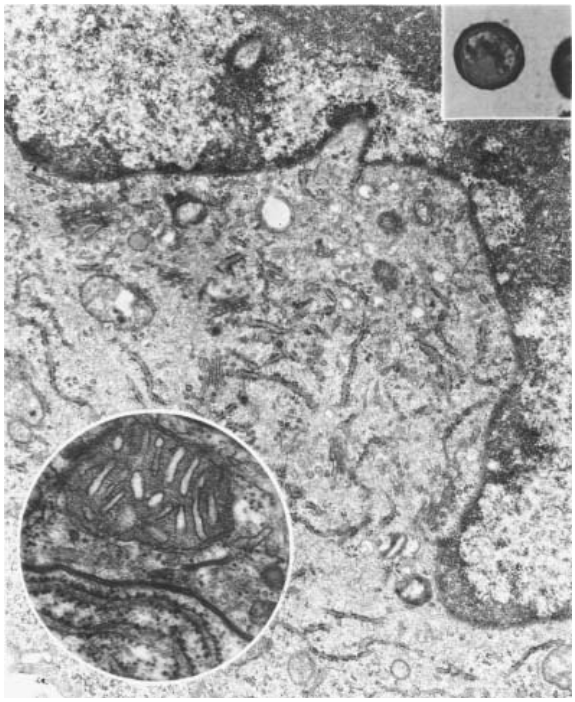

Figure 21.17. A typical TEM micrograph of a thin section of an ascites tumor cell (inset is LM view) depicting the nucleus and array of organelles and filaments stained with uranyl acetate and lead citrate. The circular insets shows a high magnification view of a mitochondrion and the rough endoplasmic reticulum of a gastric epithelial cell from a jellyfish.

freeze-drying, or other means) and have an ultrathin metal coating (gold or gold-palladium) on the surface (by a sputter coater). Now, whole cells (Fig. 21.18c, d), cut surfaces, and isolated organelles can be viewed with resolution at 1 nM or less. Three-dimensional images of high resolution can reveal cell surface specializations, as well as internal cell morphology (e.g., membranous organelles, the cytoskeletal cytoarchitecture, etc.) (172). Figure 21.18e shows an SEM view of a complex microtubular array isolated from an insect ovariole (Huebner, unpublished data).

Improvements in SEMs and innovative approaches have extended the range of the type of sample that can be viewed. Field-emission SEMs with ultravacuums can give magnifications of one million with high resolution. Another new category of SEM, the environmental SEM (ESEM), has removed the constraint of high vacuum. They operate in the range of 1–20 torr. This opens new avenues to examine unfixed hydrated samples without distortion and thus avoids artifacts due to specimen preparation inherent in conventional SEMs (CSEM) or in low-vacuum conventional SEMs (LV-CSEM). Cells and tissues can be imaged in hydrated form with no fixation under nearly natural conditions at EM resolution. The full impact of the ESEM in cell biology is yet to be realized. A variety of analytical probes can also be incorporated into SEMs making them analytical SEMs. Thus the cell biologist also has a variety of high-resolution instruments available under the SEM umbrella that can produce three-dimensional images of cells and cellular components.

A powerful cryomethod used to provide the molecular architecture of structures like membranes, cell junctions, and cytoskeletal elements, is freeze-fracture. Early workers such as Moor, Steere, and others in the 1950s provided the foundations for freezefracture replica methods (167,173–175). In essence, cells are frozen with ultrarapid cryomethods and placed in a freeze-fracture device which has ultralow temperature control, low vacuum, a cracking or fracturing device, and electrodes for carbon and platinum coating. The frozen sample is cracked or fractured leaving randomly cleaved surfaces (interior of membranes and internal cell components). This is followed by a time invacuo when sublimation of water from the frozen sample surface occurs (etching). This is normally a very short period but can be extended in deep etch procedures. Deep etching reveals internal cytoskeletal elements and membranes below the fractured surface. The exposed surface is then coated with carbon and platinum. The sample with its coating is removed from the freeze-fracture unit, thawed, and the tissue washed away leaving only the thin carbon–platinum coating called a replica, which is a cast of the fractured surface. Astonishingly, such replicas faithfully reveal the finest morphology of submembrane architecture (proteins within the bilayer) and molecular subunits of cytoskeletal elements (F-actin and microtubules), for example. Revealing this level of structural detail necessitates using ultrarapid freezing methods. The best molecular architecture is attainable with freeze-slam methods using a copper block cooled with liquid helium, as in the freeze-slam deep etch methods. More commonly in conventional freeze-fracture, immersion freezing with cryogenic liquids is used.

Freeze-fracture replicas are visualized in transmission EMs. The replicas are thin enough for the beam to pass. Due to the shadowing of platinum preferentially on areas due to their three-dimensional contours, one has a range of electron densities reflective of the differential amounts of platinum. Platinum is coated onto the sample from an angle and carbon is coated from above. The net effect is an image that shows high contrast, high resolution and has a shaded, contoured, three-dimensional appearance. Figure 21.18b and insets show a freeze-fracture image of an insect follicle cell. Depicted is the nuclear surface with the inner and outer envelopes and nuclear pores. The rectangular inset shows intramembranous particles of the cell membrane.

21.8 SUMMARY

It is difficult to do justice to the scope of the field of microscopy today in a few pages, but hopefully this

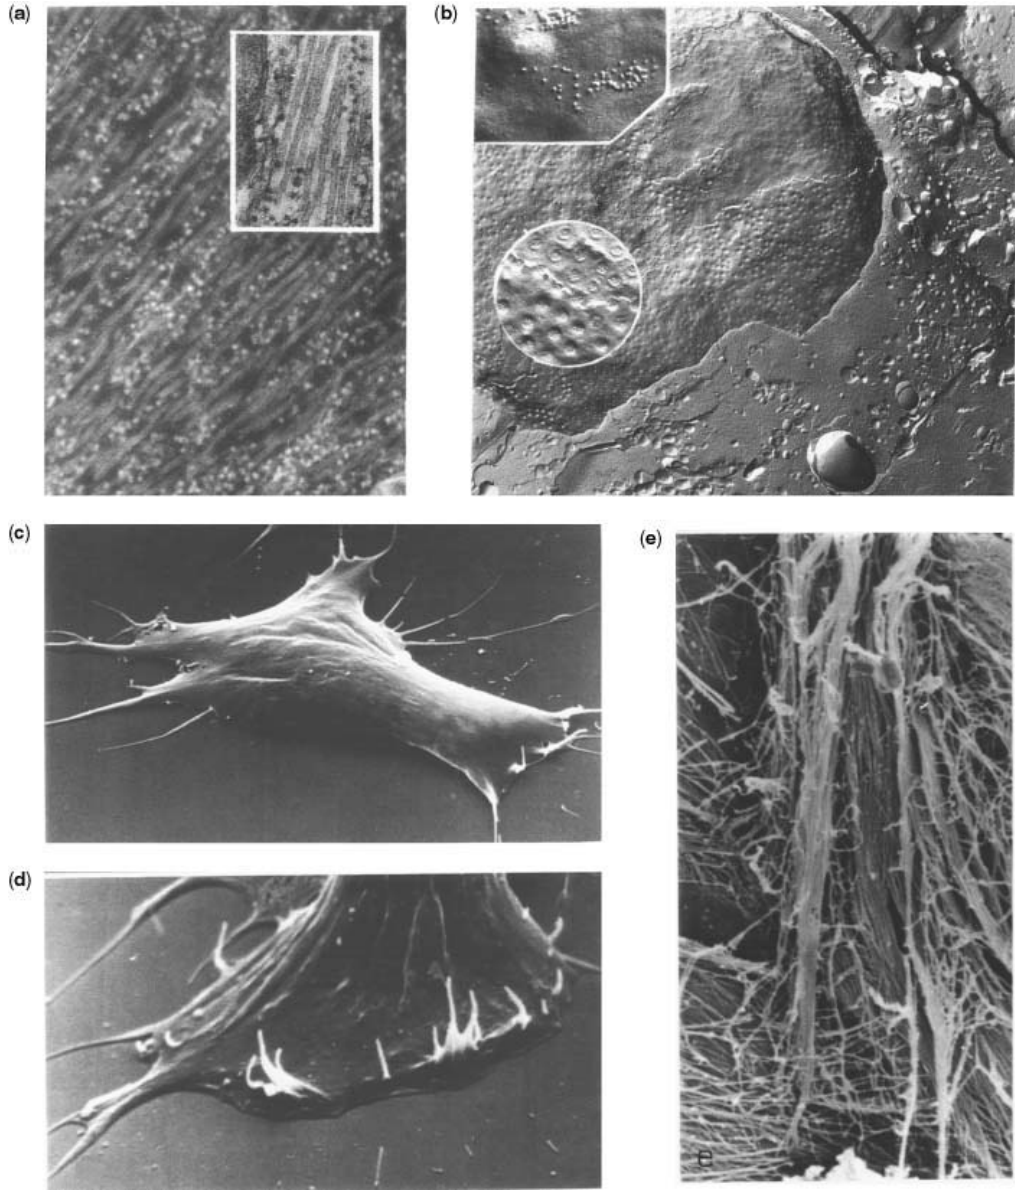

Figure 21.18. (**a**) A TEM view of an unstained section of insect ovary microtubules and ribosomes in the ovarioles of the insect *Rhodnius* imaged on the basis of their carbon content by electron spectroscopic imaging (U. Heinrich and E. Huebner, unpublished data, 1999). The insets show a comparable stained image in conventional TEM. (**b**) A TEM freeze-fracture micrograph of an insect follicle cell in the insect *Rhodnius*. The fracture plane reveals the nucleus with its many nuclear pores, the inner and outer nuclear envelopes, and vesicles and mitochondria in the cytoplasm. The upper inset shows intramembranous particles of the plasma membrane. (c–e) Examples of SEM of whole cell and cell components. (**c, d**) The surface filopodia and ruffles of isolated American lobster hemocytes. (**e**) Isolated microtubular arrays from the ovarioles of the insect *Rhodnius.*

presentation provides the reader with an introduction to the variety of microscopes available today to the cell biologist. The field is growing rapidly, and many exciting prospects undoubtedly await us in the future.

Biology in general and cell biology in particular will be front and center in the science of the next century. It is reassuring to anyone in cell biotechnology, who is exploring the intricacies of cell structure and function to

have such an arsenal of microscopical tools as already exists. The long history of microscopes since Janssen, Hooke, and Leeuwenhoek continues with renewed vigor as we explore the microcosm.

21.9 WEB SITES

The following provides some of the many web sites with microscopy content. Many of these have links to other sites within the list and outside. Included are various educational, personal, and vendor sites. The list is not all inclusive and is not intended to endorse any particular product or manufacturer. Addresses of web sites may change, companies may merge, new sites may appear and others may close, so the list provides some of the vast array of microscopy resources and information available at this time. Due to the nature of the web, it is not possible to predict the future content and details of any site.

21.9.1 Microscopical Societies

- http://www.rms.org.uk (Royal Microscopical Society)
- http://www.MSA.microscopy.com/ (Microscopical Society of America)
- http://www.ualberta.ca/~cherbur.msc (Microscopical Society Canada)

21.9.2 General Microscopy and Variety of Microscopes

- http://micro.magnet.fsu.edu/primer/webresources.html (Molecular Expressions—Microscopy Primer—M. Davidson, M. Abramowitz, Olymus & Florida State University excellent interactive tutorials on LM types)
- http://www.mih.unibas.ch/Booklet/overview.html (LM, EM, and SPM images)
- http://www.pharm.Zrizona.edu/centers/tox_center/swehsc/exp_path/m-i_onw3.html (D. Cromey, University of Arizona, many links)
- http://nsm.fullerton.edu/~skarl/EM/EMLab.html (R. Koch, California State University Fullerton, images, instruction).
- http://members.aol.com/BobCat54/index.links.html (many links to world sites, universities, suppliers)
- http://www.uq.oz.au/nanoworld/nanohome.html/ (University of Queensland, collection of microscopy resources)
- http://www.mwrn.com/ (collection of microscopy web resources, vendors' products)
- http://www.ou.edu/research/electron/www-vl/menu.shtml (University of Oklahoma)
- http://www.ou.edu/research/electron/www-vl/educatio.shtml (University of Oklahoma educational site, many links)
- http://www.ou.edu/research/electron/mirror (C. Jeffries, Bristol, United Kingdom, many links)
- http://www.microscopy-online.com (web magazine with resources, vendors, bulletin board)
- http://www.microrgc.demon.co.uk (microscopy and Analysis Publication, info, links to other sites)
- http://www.MME-Microscopy.com/education/ (national consortium of microscopy experts)
- http://www.yahoo.co.uk/Science/Engineering/optical_Engineering (list of web sites and many links)

21.9.3 Fluorscence Microscopy, Confocal and Multiphoton Microscopy

- http://www.mdyn.com/application_notes/applications.htm# Application Guides
- http://www.probes.com (Molecular Probes, Oregon, many links to journals and microscopy sites via/sites/
- http://www.Fluorescentprobes.com (TEF Labs, Texas)
- http://www.molbio.princeton.edu/facilites/index.html (J. Goodhouse, confocal images and biol. EM)
- http://www.bocklabs.wisc.edu/imr/home2.htm (D. Wokosin, University of Wisconsin. Institute Microscopy Facility, variety of LM, Em, and Imaging)
- http://www.caltech.edu/~pinelab/2photon.html (S. Potter and S. Fraser—excellent two-photon and confocal site)
- http://www.cs.ubc.ca/spider/ladic/confocal.html (Lance Ladic—excellent confocal site)
- http://www.vaytek.com (digital deconvolution, confocal)
- http://www.scanalytics.com (deconvolution, digital confocal)

21.9.4 Scanning Probe, SNOM, and Laser, Tweezers

- http://www.cellrobotics.com/cell (Laser tweezers—Cell Robotics Inc.)
- http://www.thermomicro.com (SPM—Park Instruments and Topometrix merged)
- http://www.di.com (Digital Instruments)

- http://www.molec.com (Molecular Imaging Inc.)
- http://www.omicron-instruments.com/ (Omicron—Twin SNOM)

21.9.5 Electron Microscopy

A number of the general sites listed above also include EM (e.g., University of Wisconsin IMR, Princeton Molbio, University Oklahoma, U.C. Fullerton etc.). The various EM manufacturers also have informative web sites eg. (Hitachi, JEOL, Phillips, Zeiss, etc.) http://www.mos.org/sln/sem/ (This Museum of Science, Boston, site has good SEM info and links to other sites.)

Acknowledgments

I am indebted to Everett Anderson for his mentorship and expertise in revealing the wonders of electron microscopy and to Shinja Inoué for exposing me to the world of analytical light microscopy and the power of light microscopy in his MBL course and since. Research funding from the Canadian Natural Sciences and Engineering Research Council and the University of Manitoba has been invaluable. I thank Madeleine Harris for secretarial help in preparing this chapter.

MYCOPLASMA CONTAMINATION OF CELL CULTURES

CORD C. UPHOFF AND HANS G. DREXLER
Department of Human and Animal Cell Cultures, DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

22.1 BIOLOGY AND NOMENCLATURE OF MYCOPLASMAS

22.1.1 Characteristics of Mycoplasmas

Mycoplasmas represent a large group of microorganisms that are characterized by their lack of a rigid cell wall, a standard attribute in all other types of bacteria. Therefore, a distinct class within the prokaryotes, appropriately named *Mollicutes*, was created. For historical and practical reasons, the trivial terms mycoplasmas and mollicutes are often used as synonyms; first, prior to the introduction of the taxonomical term *Mollicutes*, the designation *Mycoplasma* had been generally employed for this class of organisms; secondly, the members of the subsequently established genus *Mycoplasma* are the most common and pathogenically most important organisms of this class with regard to human and animal infections and malignancies. Thus, the trivial term mycoplasmas is still widely used in the broader sense and will be used here as well. The very first term for mycoplasmas was "pleuropneumonia-like organisms" (PPLO), the causative agent of the primary atypical pneumonia. For specific details regarding the biology and taxonomy of mycoplasmas, the reader is referred to specialist textbooks (1–3).

Besides their lack of a cell wall, mycoplasmas are (apart from the controversially discussed nanobacteria) considered to be the smallest self-replicating organisms known at present (Table 22.1). This notion refers not only to the size of these bacteria but also to the size of their genome and their cellular organization, and their physiological capabilities for synthesizing and metabolizing certain compounds. Mycoplasmas contain only the vitally important cell components including membranes, ribosomes, and the bacterial chromosome. The small size of 0.3–0.8 μm in diameter and the flexibility of their cell membrane allow mycoplasmas to pass through commonly used antibacteriological filters with diameters of 0.45 μm. The latter feature and their cohabitation with other organisms, their resistance to antibiotics known at that time as well as the difficulties to culture them without host cells prompted the initial assumption that mycoplasmas were viruses. In fact, the first established mycoplasma pathogen of humans (*Mycoplasma pneumoniae*) was initially believed to be a virus. As a result of their small size and the absence of a cell wall, mycoplasmas are pleiomorphic, varying in shape from spherical or pear-shaped cells, to branched-filamentous or helical cells. Since genome replication is not synchronized with cell division, filamentous forms and chains of beads are frequently observed (4).

The size of the genome ranges from 580 to 1300 kb (*Mycoplasma*) and up to 2200 kb for *Spiroplasma* species, quite in contrast to that of other bacteria with commonly more than 3000 kb (e.g. *Escherichia coli* with 5500 kb). Consequently, mycoplasmas possess only about one fifth of the numbers of genes that are found in other bacteria (about 500 to 1000 in contrast to 5400 in *E. coli*); mycoplasma can be considered to most closely represent the concept of a "minimum cell." This minimal genetic constitution corresponds to their commensalic and parasitic lifestyle, which allows them to minimize the metabolic pathways used. In contrast to other bacteria, the genome has also a rather low G+C content, accounting for only about 25%, which is

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

TABLE 22.1. Synopsis of Salient Characteristics of Mycoplasmas

Physical characteristics
Lack of rigid cell wall
Smallest self-replicating bacteria; size: 0.3–0.8 μm
Filterable through 0.2-μm filter; many mycoplasmas can pass through a 0.45-μm filter
Morphology: polymorph, spherical, pear shaped, branched, helical (*Spiroplasma*)
Biological characteristics
Replication: binary fission (budding forms, chains of spherical cells, branched filaments due to asynchronized genome replication and cell division)
Long generation times: 1–9 h
Genomic features
Genome size: 600 kb (*Mycoplasma* and *Ureaplasma*), 1700 kb (*Acholeplasma, Anaeroplasma*, and *Asteroleplasma*), and 2200 kb (*Spiroplasma*)
G+C content: 23–41%
Use of UGA as tryptophan codon, not as universal termination codon (*Mycoplasma* and *Spiroplasma*)
Number of genes/proteins: <500
DNA polymerase complex consists of one enzyme (*Mycoplasma* and *Ureaplasma*) or three enzymes (*Acholeplasma* and *Spiroplasma*)
Metabolism
Require sterol or cholesterol (except *Acholeplasma* and *Asteroleplasma*)
Require several basic components (e.g. vitamins, nucleic acid precursors, lipids, fatty acids, and amino acids) in species-specific compositions
Generation of energy
Fermentative organisms catabolize carbohydrates with acid production
Most nonfermentative organisms hydrolyze arginine producing ammonia
Ureaplasma hydrolyzes urea
Lifestyle
All mycoplasmas are commensals or parasites; many are pathogens
Extracellular cytadherence to eukaryocytic cells (but *M. penetrans* and others also intracellular)
Infect humans, animals, and plants
Detection
Mycoplasma infections are chronic and difficult to diagnose
Mycoplasmas form typical "fried-egg" colonies on agar (except fastidious "noncultivable" species and strains)

thought to be close to the minimum theoretical value to synthesize proteins with a normal amino acid composition. Only *Anaeroplasma*, *Thermoplasma*, and *M. pneumoniae* exhibit a higher G+C content (~40%) (5).

Another unique characteristic of *Mycoplasma* and *Spiroplasma* species is their use of the codon UGA, commonly representing a stop codon, as a tryptophan codon. They share this feature with mitochondria, which implies a phylogenetic relationship. On the other hand, certain mycoplasmas, for example, *Acholeplasma*, employ the normal codon composition, which suggests that the change in codon usage appeared after the evolutionary separation of the *Mycoplasma/Spiroplasma* from the *Acholeplasma*. Overall, the mycoplasmas display a great genetic diversity; this may be due to either phylogenetic diversity or a rapid evolutionary development of the mycoplasmas caused by their commensalic and parasitic existence, which is supported by the restricted DNA repair system.

Owing to their limited metabolic capabilities, mycoplasmas require a number of nutrients for survival: nucleic acid precursors, amino acids, vitamins, and other basic components. The growth of all mycoplasmas (except *Acholeplasma* and *Asteroleplasma*) depends on the presence of sterol and cholesterol. Moreover, they also need to take up lipids from the environment for the formation of cell membranes. Physiologically, mycoplasmas can be differentiated into two groups, the fermentative and the nonfermentative species. The fermentative strains gain energy and carbon by fermentating carbohydrates (hexoses, starch, and glycogen) mainly to produce lactic acid, pyruvic acid, acetic acid, and acetylmethylcarbinol, leading to a lowering of pH in the culture medium. In contrast, the nonfermentative species do not significantly decrease the pH of their environment, because they oxidize fatty acids and alcohols. But, they cannot metabolize carbohydrates via the glycolysis pathway. The nonfermentative and some of the fermentative species are able to hydrolyze arginine and produce adenosine triphosphate (ATP), CO_2, and ammonia, which is toxic for eukaryotic cells. *Ureaplasma* hydrolyze urea in order to generate ATP. These organisms are sensitive to pH changes which, in fact, they may cause themselves; this observation must be taken into account during attempts to culture them.

The above-described characteristics are presumably the reason for our inability or difficulty to culture many mycoplasma species thus far identified in chemically defined media. Clearly, we have failed to mimick *in vitro* the natural milieu provided by the host; consequently, not all of these fastidious organisms can be cultivated. Most successful culture methods use media that include beef heart infusion, peptone, or tryptone (as sources of proteins and amino acids); glucose, arginine, or urea (as sources of energy); yeast extract (as a source of vitamins and growth factors); and serum (as a source of sterol and cholesterol). Contrary to other bacteria, mycoplasmas grow very slowly, even under optimal conditions. The generation times usually range between 1 and 3 h, but there are also generation times of up to 9 h; in addition, mycoplasmas have a relatively long lag phase. Therefore, it may take more than 1 week to obtain visible colonies on agar. Also, mycoplasmas do not overgrow other organisms.

It has long been assumed that mycoplasmas are extracellularly located on the eukaryocytic cell membrane

(cytadherence). However, studies in recent years have unequivocally demonstrated the intracellular location of certain mollicutes (notably *Mycoplasma fermentans*, *Mycoplasma genitalium*, and *M. pneumoniae*), not only after phagocytosis by granulocytes and monocytes, but also in nonphagocytic epithelial cells. *Mycoplasma penetrans* was shown to be capable of entering a variety of human cells *in vivo* and *in vitro*. Mycoplasma cytadherence and invasion appear to be active, but separable processes. Extensive invasion of cells by *M. penetrans* eventually leads to cell disruption. The total number of mycoplasmas infecting the cells, as well as the percentage of the mycoplasma population able to invade the cells, depends apparently on the mycoplasma species and may be influenced by the eukaryotic cell type and culture conditions. Although the great majority of the infecting mycoplasma population is definitely extracellularly located, the intracellular location, even for only a short period, sequesters mycoplasmas and protects them effectively from mycoplasmacidal therapies. This phenomenon may also explain the difficulty of eradicating mycoplasmas from all infected cell cultures (6).

The dependency on many specific organic compounds force mycoplasmas to live in close relationship with other organisms. They can be found as commensals and parasites in almost all higher organisms including plants, insects, and vertebrates, but are highly host specific in their natural environment. Mycoplasmas are nearly perfectly adapted parasites, rarely killing their hosts. Mycoplasma infections are thus of a more chronic nature and are very frequently difficult to diagnose on the basis of the symptoms alone. In humans, mycoplasmas can be physiologically found on the mucous surface of the respiratory, gastrointestinal and urogenital tract, the eyes, mammary glands, and joints, whereas ureaplasmas occur solely in the urogenital tract. Most species can be regarded as part of the normal microbial flora, a minority, however, may cause diseases in humans and animals. *M. pneumoniae*, for instance, is the causative agent of the primary atypical pneumonia (prevalent particularly in children), while *Mycoplasma arthritidis* appears to be involved in the pathogenesis of arthritis. All farm animals appear to suffer from mycoplasma infections, leading to significant economic losses. For example, *Mycoplasma hyopneumoniae*, in combination with other respiratory bacteria and viruses, causes pneumonia leading to reduced weight gain. Vaccination of the animals is a common treatment to prevent infections. *Anaeroplasma* and *Asteroleplasma* are regularly observed in bovine and ovine rumen. These two genera are obligatory anaerobic. Insects are the hosts of a variety of mycoplasmas, including species from the genera *Mycoplasma*, *Acholeplasma*, and *Spiroplasma*, most of which also can cause diseases in their hosts. But all these species seem to be clearly distinct from those isolated from vertebrates.

Mycoplasmas also cause several hundreds of economically important plant diseases transmitted by insects. *Acholeplasma* and *Spiroplasma* are seen on or in plants. Some *Spiroplasma* species invade the sieve tubes of the plants possibly giving rise to diseases as a result of obstruction. Insects are known to transfer *Spiroplasma* into the plants. The *Acholeplasma* species detected on plants also seem to derive from depositions by insects. Although a large spectrum of various plant and insect infectious agents apparently belongs to the class *Mollicutes*, it is not possible yet to culture them *in vitro*; microscopic observations suggested a certain resemblance to mycoplasmas. These organisms were termed *Phytoplasma* and *Entomoplasma*.

Another most difficult diagnostic problem concerns the detection of mycoplasmas infecting human and animal cell cultures; such contamination is a rather frequent occurrence. Typical for mycoplasma contaminations is that the symptoms are rarely very pronounced as the infection takes a chronic course. Also in this field, the damage occurring in biological research and production owing to the use of contaminated cultures is scientifically and economically substantial.

22.1.2 Taxonomy of Mycoplasmas

Owing to fundamental differences as compared to other bacteria, the *Mollicutes* constitute a class of their own. The class is divided into 14 genera within four orders based on morphological and physiological criteria and on the size of the genome: Acholeplasmatales, Anaeroplasmatales, Entomoplasmatales, Mycoplasmatales (Fig. 22.1). Previously, the order Thermoplasma was assigned to this class on the basis of their lack of a cell wall. However, the members of this order are phylogenetically clearly separated from the other *Mollicutes* and are assigned to the kingdom Archeae. In 2007, more than 200 species within the class *Mollicutes* were recognized. The genus *Mycoplasma* contains the largest number of recognized species (>120); some of the best-studied species are further subdivided into a multitude of strains (2,7). The mollicutes that have already been characterized and taxonomically defined constitute only a part, apparently a minor one, of the mollicutes living in nature. With the advent of new microbiological and molecular biological methods in the field of mycoplasma taxonomy, it is likely that many more species will be detected.

Extensive research was performed in order to clarify the phylogenetic relationship of the mycoplasmas within their class to each other and beyond their class to the other bacteria. For instance, sequence analysis of the highly conserved 16S rRNAs documented that mycoplasmas are not "primitive bacteria" with poorly developed metabolic pathways, but that they apparently intentionally reduced their

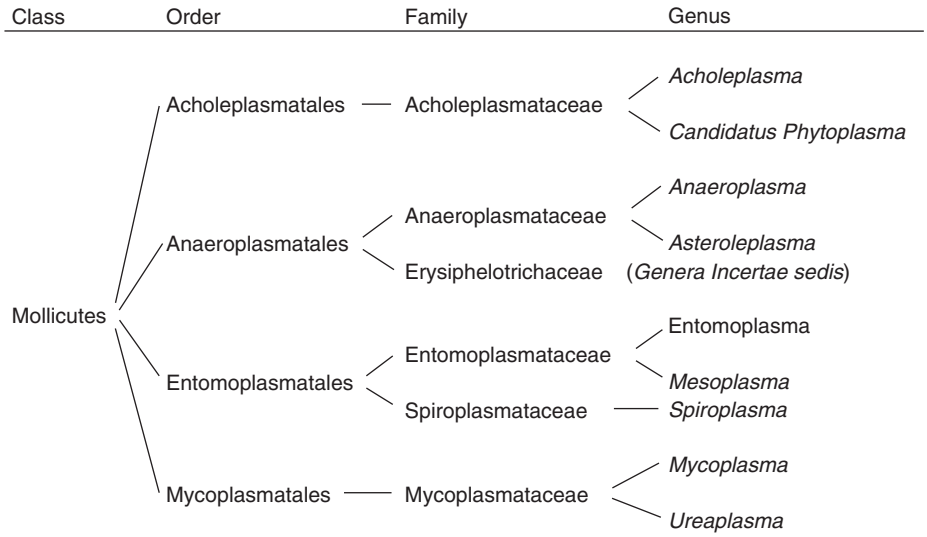

Figure 22.1. Taxonomy of mycoplasmas. For specific details see Refs 2–4.

genome size and their synthesizing properties during their adaptation to cohabitation with other organisms. The molecular investigations employing degrees of similarities in the nucleotide sequences suggested that the closest relatives of the *Mollicutes* are the Gram-positive *Clostridia*, *Bacillus*, and *Lactobacillus*.

22.2 MYCOPLASMA CONTAMINATION OF CELL CULTURES

22.2.1 Incidence of Mycoplasma Contamination

Cell culture of primary cells and continuous cell lines of human or animal origin faces several challenges affecting biological and biotechnological applications. Among these are infections with microorganisms and here in particular with mycoplasmas that may significantly hamper the use of these cells. Mycoplasmas were first isolated in 1956 from a contaminated cell culture. Ironically, during the investigations of the effects of a mycoplasma infection on cell cultures, it was found that the uninoculated negative control cell culture was already contaminated (8). Soon thereafter, it became well established that stable, continuous cell lines are frequently contaminated. Only one mycoplasma cell can grow up to 10^6 CFU/mL within 3–5 days in an infected cell culture. Frequently, there are from 100 to 1000 mycoplasmas attached to each infected cell (cytadsorption) (Fig. 22.2). Contamination may initially go undetected because mycoplasma infections do not produce overt turbid growth as commonly seen with other bacterial or fungal contamination. Often mycoplasmas can achieve very high densities in cell cultures without causing a change in the pH (and therefore without a color change of most culture media). Some mycoplasmas produce very little overt cytopathology, and covert contamination may remain undetected for months. Virtually all reports and research on mycoplasma contamination of cell cultures concern human and animal cells.

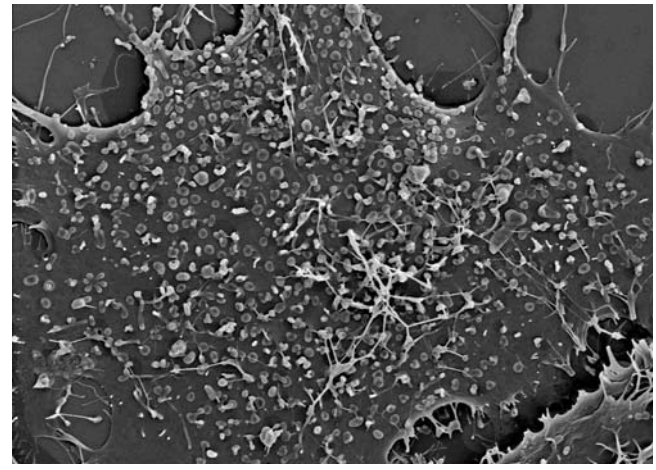

Figure 22.2. Scanning electron micrograph of a critical point-dried HeLa cell culture infected with *M. hyorhinis*. The mycoplasmas adhere to the cellular membrane of the eukaryotic cell; magnification 3000×.

While mycoplasmas have been shown to be present on or in fresh plants (see section titled Characteristics of Mycoplasmas), nothing has been published concerning the occurrence of mycoplasmas in plant cell cultures. It is not known whether mycoplasmas are truly not present in these cultures or whether such a contamination has never been studied in plant cell cultures. It is unlikely that human contact is the source of a possible contamination

as those mycoplasmas found in plants, namely members of the Entomoplasmatales or Candidatus Phytoplasma, do not infect humans. Furthermore, all media used in plant cell cultures are chemically produced and properly processed solutions, and vectors like insects are usually excluded from plant cell cultures. The primary plants from which the callus or suspension cultures are established are theoretically the primary source of mycoplasma contamination. Principally, no type of cell culture, vertebrate, invertebrate, or plant, is safe from mycoplasmal infection. Clearly, specific studies are required to provide some data in this unexplored area.

In general, primary cell cultures and cultures in early passage are less frequently contaminated than continuous cell lines: primary cultures and early passage cultures on the order of 1% and 5%, respectively, and continuous cell lines in the range of 15–35% (Table 22.2). Several large series, mainly in the United States, on tens of thousands of cell cultures analyzed over several decades (1960s–1980s) found an incidence of about 15%. However, more recent studies on smaller series and reports from other countries in South America, Europe, and Asia documented significantly higher infection rates of cell cultures, commonly in the range of 15–35%, but also as high as 65–80% (8–11).

The ever expanding application of cell lines in research and biotechnology (with the resulting exchange of nonauthenticated and mycoplasma-positive lines between scientists) and the increasing use of certain antibiotics (mostly penicillin plus streptomycin, which merely serve to mask but do not remove mycoplasmas) in routine culture have presumably led to this increase in mycoplasma contamination of cell cultures, which has now reached epidemic proportions. It appears that contamination rates are higher for cultures continuously grown with such "cell culture antibiotics."

TABLE 22.2. Incidence, Most Common Species, and Sources of Mycoplasma Contamination

Incidence
Continuous cell lines (15–35%)
Early passage cell cultures (5%)
Primary cell cultures (1%)
Most common species
M. orale (frequency 20–40%; natural host: human)
M. hyorhinis (10–40%; swine)
M. arginini (20–30%; bovine)
M. fermentans (10–50%; human)
M. hominis (10–20%; human)
A. laidlawii (5–20%; bovine)
Sources
Original (primary) tissue isolate (<1%)
Culture reagents (mostly bovine serum)
Laboratory personnel
Cross-contamination from infected cultures (most common source)

22.2.2 Most Common Contaminating Mycoplasma Species

As described in detail above (see section titled Characteristics of Mycoplasmas), mycoplasmas can be found nearly ubiquitously, as long as the given environment offers sufficient amounts of nutrients and the essentials compounds. Commonly, such permissive conditions exist in higher organisms. As the list of mammalian, insect, and plant hosts for mycoplasmas becomes longer, the number of isolated mycoplasma species and strains is also rapidly expanding. Most of the well-known and best-studied mycoplasmas are pathogenic infectants of humans, economically relevant animals (such as cattle or swine), or agriculturally important plants (such as grapevine, fruit trees, rice, and potato). Within the last two decades, mycoplasmas have been recognized as one of the major cell culture problems; consequently, their biology and physiology have become topics of intense research.

Although at least 20 distinct species have been isolated from contaminated cell lines, detailed investigations on the identity of the contaminating species showed that by far the largest portion of infections is caused by a relatively small number of *Mycoplasma* and *Acholeplasma* species: more than 95% of the contaminants identified were *Mycoplasma orale*, *Mycoplasma hyorhinis*, *Mycoplasma arginini*, *M. fermentans*, *Mycoplasma hominis*, or *Acholeplasma laidlawii* (Table 22.2). Depending on the study, the individual percentages of these six species may vary. Although many mycoplasmas are host specific *in vivo*, the various species are not restricted to cell cultures derived from their natural hosts. Species that are rather rarely found in cell cultures (generally <1%), but that are still consistently detected in the reported series, include the following: *Mycoplasma alkalescens* (natural host: bovine), *M. arthritidis* (rodent), *Mycoplasma bovis* (bovine), *Mycoplasma buccale* (human), *Mycoplasma canis* (dog), *Mycoplasma gallisepticum* (avian), *M. genitalium* (human), *Mycoplasma pirum* (bovine), *M. pneumoniae* (human), *Mycoplasma pulmonis* (rodent), and *Mycoplasma salivarium* (human).

Mycoplasmas from human sources are the most prevalent group and account for approximately one third to half of all strains isolated. Generally *M. orale*, which is the most common mycoplasma species in the oral cavity of clinically normal humans, represents the single most common isolate accounting for 20–40% of all mycoplasma infections in cell cultures (Table 22.2); in recent years the infection rate of *M. fermentans* seems to significantly increase. Other nonpathogenic mycoplasma species from the normal human microbial flora of the oropharynx seen in cell cultures are *M. fermentans* and *M. hominis*. *M. salivarium* and *M. buccale*, normally detected in the human oral cavity, have also, albeit rather rarely, been identified as cell culture contaminants.

The bovine group of mycoplasmas accounts for about another third of all strains isolated from cell cultures. Here the most frequent infectious agents are *M. arginini* and *A. laidlawii*. These two species have a relatively wide host range as they are isolated from cattle, sheep, goat, and so on, and from a variety of other mammals, birds, and insects. These cell culture contaminants are thought to be derived from bovine sources as in the early days of cell culture (1950–1970) the bovine sera were not routinely and as strictly screened for mycoplasma contamination as they are today. *M. hyorhinis*, a common inhabitant of the nasal cavity of the swine, accounts also for a high proportion of the infections. Trypsin is usually extracted from porcine pancreas, and via this indispensable reagent, swine mycoplasmas may have found their way into cell cultures. However, it appears that trypsin destroys mycoplasmas; furthermore, no mycoplasmas have been reliably detected in trypsin preparations. On the other hand, because swine and cattle are processed through the same abattoirs, the swine strain of *M. hyorhinis* may have been introduced into bovine sera; *M. hyorhinis* has often been isolated from bovine sera. The finding that mycoplasma infection of cell cultures is clearly limited to a small number of species suggests that specific interactions may exist between the eukaryotic cells and the mycoplasmas. This is supported by the finding that different mycoplasma species behave differently in various cell types.

22.2.3 Sources of Mycoplasma Contamination

Studies of the natural habitat of mycoplasmas implicate human technician, bovine serum and the primary cultures (Table 22.2). Tissue specimens used to initiate cell cultures are not the major sources of mycoplasma infection. The frequency of infection in primary cell cultures is low, on the order of 1% (8,10). Furthermore, murine, avian, and canine species of mycoplasma only account for 0.5–1% within the panel of mycoplasmas isolated from contaminated cultures—despite the wide use of murine cell lines.

The high incidence of bovine mycoplasma species, predominantly *A. laidlawii* and *M. arginini*, implicates the fetal or newborn bovine serum. Studies in the 1960s and 1970s showed that 25–40% of the serum lots provided by commercial suppliers were contaminated (8). In order to prevent contaminations and to eliminate those adventitious agents that are most frequently detected in bovine serum, namely mycoplasmas and bovine viral diarrhea viruses (BVDV), suppliers now apply more sophisticated sterility test procedures, use γ-irradiation and filtration, and have implemented stricter rules and controls at the abattoirs. Although bovine serum contamination has certainly significantly decreased over the last 10–20 years, owing to problems inherent in all sterility test procedures (for instance sample size of large lots), serum lots absolutely free from mycoplasmas cannot be guaranteed. However, the titer in modern serum lots is assumed to be very low and a contamination of all cultures grown with the serum is not likely. As there is no legal requirement for suppliers to provide mycoplasma-free products, bovine serum should still be considered as a possible source of contamination.

Because the largest percentage of mycoplasmas found in cell cultures are of human origin, it is logical to assume that the laboratory personnel is one of the major sources of contamination. If the human cell culturist, the bovine serum or the primary culture were the only sources of infection, then there should be random mycoplasmal contaminations in culture laboratories and only some cultures within a laboratory unit should be mycoplasma-positive. However, this is not the pattern of contamination that has been observed. Clearly, in laboratories with contaminated cells, most or all cultures are positive containing the same mycoplasma species (10). Thus, mycoplasma-infected cell lines are themselves the single most important source for further spreading of the contamination. This is due to the ease of droplet generation during handling of cell cultures, the high concentration of mycoplasmas in infected cultures (10^6 to 10^8 CFU/ml of supernatant), and the prolonged survival of dried mycoplasmas. Although mycoplasma-positive cell cultures account for more mycoplasma infections now than bovine sera and laboratory personnel together (4,8,10), the cell culture technician is of course involved in the propagation of the infection, as the mycoplasmas themselves do not "jump from culture to culture" on their own. Operator-induced contamination is a multifaceted problem (see section titled Routine Working Protocol for Prevention). Suffice it to mention here that mycoplasmas are spread by using laboratory equipment, media, or reagents that have been contaminated by previous use in processing mycoplasma-infected cells. One more finding argues for the operator-induced contamination of cell cultures with mycoplasmas: the high rate of cross-contaminations of cell cultures. At present, the rate of cross-contaminations is as high as 15% of all cell cultures (11).

22.2.4 Effects of Mycoplasma Contamination

The *in vitro* culture of cells has opened many doors in research; unfortunately, it has also brought new problems for the researcher. One of the biggest problems, mycoplasma contamination, resembles the opening of Pandora's box as mycoplasma infections can have a myriad of different effects on the contaminated cell cultures. However, this multitude of different effects does not affect the various cells in the same manner and to the same degree (Table 22.3). Many mycoplasma species produce severe cytopathic effects in some cell lines while

TABLE 22.3. Effects of Mycoplasma Contamination on Cell Cultures

General effects on eukaryotic cells
Altered levels of protein, RNA, and DNA synthesis
Alteration of cellular metabolism
Induction of chromosomal aberrations (numerical and structural alterations)
Change in cell membrane composition (surface antigen and receptor expression)
Alteration of cellular morphology
Induction (or inhibition) of lymphocyte activation
Induction (or suppression) of cytokine expression
Increase (or decrease) of virus propagation
Interference with various biochemical and biological assays
Influence on signal transduction
Promotion of cellular transformation
Alteration of proliferation characteristics (growth and viability)
Total culture degeneration and loss
Specific effects on hybridomas
Inhibition of cell fusion
Influence on selection of fusion products
Interference in screening of monoclonal antibody reactivity
Monoclonal antibody against mycoplasma instead of target antigen
Reduced yield of monoclonal antibody
Conservation of hybridoma

others may cause very little overt cytopathology. There can be qualitative and quantitative differences in the same parameter depending on the infecting mycoplasma species, the culture conditions, the type of the infected cell culture, the intensity and duration of the infection, an additional infection with viruses, and other parameters. Thus, contaminations can interfere with virtually every parameter measured in cell cultures during routine cultivation or in experimental investigations. Consequently, the mycoplasmas in these cultures cannot simply be ignored or regarded as harmless bystander organisms. Besides the loss of an important culture, in the worst case all experiments might be influenced by the infections and artefacts are produced. Because of the virtually unlimited number of reported mycoplasmal effects on cultured cells, only some of the most important parameters will be described here in order to highlight the diversity of possible effects. Clearly, the term mycoplasma infection is a rather general term similar to virus infection (12).

Mycoplasmas have an enormous spectrum of cytopathogenic effects on cells, ranging from no noticeable change in morphology to minimal alterations characterized by an increase in cytoplasmic granularity to a frank cytopathic effect with occasional cell lysis. A characteristic change in nuclear morphology often associated with mycoplasmal contamination is the appearance of condensed chromatin, nucleolar aggregation, and other signs of imminent apoptosis. These morphological effects can be reversed by changing the medium or by replenishing with fresh nutrients. As with morphology, the effects of mycoplasmal contamination upon cell growth are extremely variable, ranging from none to complete cessation of proliferation depending on the cell type, mycoplasmal species, and concentration of mycoplasmas. Even enhancement of cell growth has been reported. Strongly infected cultures are characterized by stunted, abnormal growth and rounded, degenerated cells with a macroscopically "moth-eaten" appearance at the edge of monolayers. Detachment of monolayers due to mycoplasma contamination has also been observed (4).

One of the most obvious reasons for these effects is that mycoplasmas consume the nutrients in the culture medium depleting glucose, arginine, nucleic acid precursors, amino acids, vitamins, and so on, thereby being direct competitors of the cultured eukaryotic cells. Often the concentration of the mycoplasmas in the medium or on the cells exceeds the number of eukaryotic cells by more than a thousand times. The depletion of medium nutrients results in profound effects on cell metabolism and function. The mycoplasmas usually metabolize the nutritional elements significantly faster than their hosts. They further induce the host cells to produce nucleotides, as has been demonstrated for infections with *M. orale* in which deoxyadenosine is highly increased and converted to ribonucleotides and these nucleotides are incorporated into mycoplasmal RNA.

Moreover, the metabolites can be harmful for the eukaryotic cells, for example, by acidifying the medium (fermentative mycoplasmas producing acidic metabolites) or by producing ammonia (arginine-hydrolyzing mycoplasmas). Ammonia is known to be a highly toxic agent and has been shown to inhibit cell growth in a variety of cell lines. In addition to this effect, the depletion of the basic amino acids, arginine and glutamine, may result in alterations in protein synthesis and inhibition of proliferation; they may also lead to chromosomal aberrations because these amino acids are used in high amounts in the histones of the eukaryotic nuclei. Depletion and alterations of nucleic acid precursors can produce mutations in the eukaryotic DNA; host cell DNA can be degraded by mycoplasmal nucleases and endonucleases. *In vitro* induction of chromosomal aberrations such as chromosome breakage, multiple translocation events, and numerical chromosome changes were seen in various cell cultures infected with different mycoplasma species (13).

A biotechnologically important effect of the nucleotide-transforming mycoplasmal enzymes is the activity of the uridine phosphorylase, which can inactivate the artificial bromodeoxyuridine (BrdU). This reagent is universally applied as a thymidine analog for the selection of cells with a thymidine kinase defect; the presence of this defect is exploited in cell fusion techniques. Thymidine kinase phosphorylates BrdU which is then incorporated

into eukaryotic DNA causing cell death. As the BrdU is metabolized by mycoplasmas, it may appear that cells growing in the presence of BrdU carry this enzyme defect (14). In hematopoietic cell cultures, several mycoplasma species are known to stimulate (or inhibit) activation, proliferation, and differentiation, enhance immunoglobulin secretion by B cells, and induce expression and elaboration of cytokines and growth factors, for instance interleukin-1β (IL-1β), IL-2, and IL-6, tumor necrosis factor, and various colony stimulating activities (12).

A final example of the detrimental effects of mycoplasma contamination concerns work with viruses. Some mycoplasmas have no detectable effect on viral growth while others may decrease, or even increase, virus yields in infected cultures. For example, the titer of the arginine-dependent DNA viruses is significantly reduced by mycoplasma contamination. In some cell lines, mycoplasmas can either enhance or block expression of interferon-γ, which inhibits propagation of viruses in cells. Certain virus-like cytopathic effects caused by mycoplasmas may be falsely ascribed to the presence of viruses. Like viruses, mycoplasmas are filterable, hemabsorbant, hemagglutinant, resistant to certain antibiotics, inhibited by antisera, able to induce chromosomal aberrations, and sensitive to detergents, ether, and chloroform (4).

22.3 DETECTION OF MYCOPLASMA CONTAMINATION

22.3.1 Various Detection Methods

Over the last four decades, a vast array of techniques has been developed to detect mycoplasma contamination of cell cultures (Table 22.4). Most of these methods are relatively lengthy, involve subjective assessments, and use measurements that are often quite complex in nature. The two classical detection methods DNA fluorochrome staining and microbiological colony assay together with the recently introduced and highly specific and sensitive methods RNA hybridization and polymerase chain reaction (PCR) are described in greater detail from section titled DNA Fluorochrome Staining to Polymerase Chain Reaction. Ideal detection methods should be highly sensitive and specific, but also simple, rapid, efficient, and cost effective. The evaluation of tests comprises the components' validity and reproducibility pertaining to the statistical parameters (operating characteristics): sensitivity (detection of true positives), specificity (detection of true negatives), accuracy (detection of true positives and true negatives—combination of sensitivity and specificity), and predictive value (probability of correct result). Further aspects of the evaluation of a test are technical reproducibility and interobserver reproducibility (concordance of interpretation of the results). Many detection methods rely on subjective reading and interpretation of the results, which obviously requires training, experience, and consensus (15).

Traditionally, mycoplasmologists discerned direct and indirect detection methods. While the term direct method referred to the classical microbiological colony growth of mycoplasmas on agar, indirect detection techniques included procedures that measure a gene product that is associated with mycoplasmas rather than with the mammalian cells in culture. Furthermore, tests may be performed directly on the specimen taken from a given cell culture or indirectly using the so-called indicator cell culture procedure whereby the specimen is inoculated into another cell culture known to be free of mycoplasmas (monkey cell line Vero and murine cell lines NIH 3T3 or 3T6 have been used with equal success). Use of an indicator cell culture promotes better standardization and allows appropriate positive and negative controls to be included in each assay (8,15). Mycoplasmologists advise identifying every cell culture mycoplasma isolate as identification presents a clearer picture of the nature of the infection and may be helpful in determining its source. Identification can be achieved with various immunological techniques [e.g. using species-specific antibodies in immunostaining or enzyme-linked immunosorbent assay (ELISA)] or nowadays' species-specific PCR primers. However, to the cell culturist, the chief concern appears to

be whether the culture is free from contamination rather than specific identification of the contaminant.

The first detection methods involved histological staining and light microscopy, applying the classical histological stains, hematoxylin-eosin, May-Grünwald-Giemsa, and acridine orange. Some of the larger cytadsorbing mycoplasmas, for example, *M. hyorhinis*, are observable as small pleomorphic bodies lining the infected cell membrane. Smaller organisms and mycoplasmas that do not readily cytadsorb to cultured cells, for example, *M. orale*, are more difficult to detect with histochemical techniques. Cell debris, organelles, surface structures, and so on, may mimic mycoplasmal bodies. An alternative method for the visual demonstration of mycoplasmas uses hypotonic treatment of infected cells, fixation, and orcein staining followed by phase contrast microscopy. The major limitation is the probable insensitivity of histological staining when small numbers of mycoplasmas are present.

Mycoplasmas have been studied extensively by electron microscopic techniques, both scanning and transmission electron microscopy. Mycoplasmas can usually be distinguished from viruses, yeast, rickettsiae, chlamydiae and other bacteria. Although these techniques are quite useful for mycoplasma basic research and certainly provide extremely interesting and beautiful pictures, the diagnostic value of electron microscopy for mycoplasma detection is, however, limited by the complex technology and the need for expensive equipment and trained staff. Mycoplasmas can often be confused with cytoplasmic blebs and a large number of possible artefacts; low-level contamination is essentially not detectable with electron microscopy; large numbers of cultures cannot be assayed. Clearly, electron microscopy cannot be regarded as a routine mycoplasma detection test.

A variety of biochemical detection methods have been developed, including colorimetric, chromatographic, and biological enzyme assays; separation of radioactively labeled DNA or RNA by density gradient or gel electrophoresis; and protein analysis (two-dimensional electrophoresis and isoenzyme analysis). The enzyme assays are based on the detection of an enzymatic activity present in mycoplasmas, but minimal or absent in tissue cells. The enzymatic activities exploited include arginine deiminase; thymidine, uridine, adenosine, or pyrimidine nucleoside phosphorylase; and hypoxanthine or uracil phosphoribosyl transferase. Arginine deiminase catalyzes the conversion of arginine to citrulline, which can be measured colorimetrically. Unfortunately, this enzyme activity is a property of nonfermentative mycoplasmas, and consequently most fermentative species that include common culture contaminants cannot be detected by this method. Nucleoside phosphorylase is responsible for the cleavage of thymidine to thymine with subsequent release of deoxyribose, which is measured colorimetrically. However, certain mycoplasma species gave negative results. A chromatographic technique measures uridine phosphorylase activity: cells to be tested are lysed and incubated with [^{14}C]-uridine; the lysate is chromatographed; the conversion of [^{14}C]-uridine to [^{14}C]-uracil is determined. Cleavage of other nucleosides (e.g. thymidine and adenosine) by mycoplasmal phosphorylases but not by mammalian cells has also been reported, taking advantage of the avid uptake of exogenous nucleosides by mollicutes. However, the difficulty with these approaches is that mycoplasmas vary widely in their ability to incorporate nucleic acid precursors (10,16).

A biological enzyme assay utilizes a purine analog, 6-methylpurine deoxyriboside (6-MPDR). This nontoxic analog of adenosine is converted by adenosine phosphorylase into 6-methyl purine and 6-methyl purine riboside, both of which are toxic to mammalian cells. Mycoplasmas generally have much higher levels of adenosine phosphorylase than do cultured eukaryotic cells and, accordingly, hydrolyze 6-MPDR more rapidly. The release of toxic products from 6-MPDR in the presence of mycoplasma is detected by including a sensitive indicator cell line (for instance murine cell line 3T6). However, the interpretation of the results is highly subjective. False-negative results can be explained by mycoplasma species and strains having either no adenosine phosphorylase activity or activities below the sensitivity level of the assay and further by differences between the cell lines regarding sensitivity to the metabolites (15).

Mycoplasmal RNA can be distinguished from mammalian RNA. One technique relies on the identification of [^{3}H]-uridine-labeled mycoplasmas after sucrose density gradient centrifugation, whereby mycoplasma-positive cultures give a distinguishable peak that is not observed in mycoplasma-free cultures. Another method measures uridine and uracil uptake by mycoplasmas. After polyacrylamide gel electrophoresis, results are expressed as the ratio of uridine to uracil incorporated. Several species were difficult to detect and a number of false negatives were reported. Taken together, positive biochemical results are based on arbitrary values making low orders of mycoplasma contamination difficult to detect. Not all mycoplasma contaminants possess higher distinguishing levels of enzymatic activity. Overall, the above-described biochemical detection methods give inconsistent results when comparing different cell lines and have lower sensitivities than, for instance, microbiological cultivation and DNA fluorochrome staining methods, making their use problematic (15,17). Recently, a new biochemically based assay was invented, which takes advantage of two enzymes from principal energy producing pathways of mycoplasmas: carbamate kinase used in arginine hydrolyzation and acetate kinase used in fermentation

of carbohydrates. The activity of these enzymes can be measured in a luminometric assay, which is very fast and is further described below.

Immunological methods use mainly species-specific polyclonal antisera and monoclonal antibodies to detect and identify mycoplasmas, applying immunofluorescence, immunoenzymatic, or radioimmuno-precipitation techniques, immunobinding onto nitrocellulose paper, or ELISAs. These specific immuno-assays are used primarily for mycoplasma speciation. Several ELISAs have been shown to produce false-negative results in mycoplasma detection as only certain species are addressed. Although ELISAs are easy to perform, their use is hampered by the relatively weak sensitivity of this technique (lowest detection level of 10^7 CFU/mL). A monoclonal antibody has been produced that recognizes a common antigen (elongation factor TU) shared by most mycoplasmas; this protein, essential for all prokaryotes, mediates the transport of aminoacyl-tRNA to the ribosomes. In theory, the approach using a "pan-mycoplasma" antibody with fluorescence staining has considerable potential, as it might be possible to detect single cells harboring few mycoplasmas. However, the interpretation of the stainings are very subjective and difficult to reproduce between observers (17). Autoradiography of infected cells previously labeled with [^{3}H]-thymidine or uridine reveals extranuclear localization (throughout the cytoplasm and cell periphery) of silver grains. This method suffers from a lack of sensitivity; another limitation of autoradiography is the exposure time needed. Finally, one method exploits the growth-inhibitory effects of mycoplasma contamination on eukaryotic cells: supernatant from the culture to be tested is added to an indicator cell line; the eventually resulting growth modulation is quantitated by [^{3}H]-thymidine β-scintillation counting. This method is certainly not very sensitive regarding low-level infections, very subjective, and time consuming.

22.3.2 Most Reliable Detection Methods

Until the arrival of RNA hybridization and PCR, DNA fluorochrome staining and microbiological culture had been regarded as the "gold standards" for detection of mycoplasma contamination (8,10). Although the classical methods certainly have kept their eminent place in the armamentarium of mycoplasma detection methods, the new approach to a highly sensitive, specific and rapid diagnosis of mycoplasmal infection is based on the development of gene or DNA probes, which were first introduced in the 1980s. The principle is simple as genes or genomic sequences, that are specific for a single species or a particular group of mycoplasma or universally for nearly all mycoplasmas, are identified and synthesized; these probes are used for DNA or RNA hybridization. The development of PCR enables the amplification of the target DNA in the specimen using specific synthetic oligonucleotides complementary to conserved rRNA sequences and increases the sensitivity by several orders of magnitude (18). Positive hybridization signals as dots on filters or scintillation counts and visual demonstration of the PCR amplicon in gels indicate the presence of the infectious agent. Another technique applying specific probes was adopted from cytogenetic methods. Mycoplasma-specific fluorescently labeled oligonucleotides are hybridized to ribosomal RNA and can be detected with a fluorescent microscope. The technique is more sensitive and specific than the DNA fluorochrome staining method. In the following sections, all six procedures, the classical and the modern molecular biological, biochemical, PCR, and fluorescence *in situ* hybridization (FISH) techniques, are presented in greater detail.

22.3.2.1 DNA Fluorochrome Staining. Fluorescent dyes binding to DNA were first used to detect mycoplasmal infection in the 1970s. The two primary DNA-binding stains are 4′-6-diamidino-2-phenylindole (DAPI) and bisbenzimide (Hoechst 33258); further, but rather rarely employed stains are the olivomycin fluorescent dye and a conjugated benzoxazinone kanamycin fluorescent probe. The fluorescent dyes rapidly and selectively bind to eu- and prokaryotic DNA, forming strongly fluorescent DNA–DAPI/Hoechst complexes with high specificity. Under fluorescence microscopy, an uncontaminated cell culture shows only nuclear fluorescence against a dark background. Mitochondrial DNA does bind the fluorochrome, but at levels imperceptible by routine microscopy. Mycoplasmas, however, that have approximately 10 times the DNA content of mitochondria are readily detected as bright foci over the cytoplasm, lining the cell membrane or in intercellular spaces (Fig. 22.3). This procedure is not diagnostic for mycoplasmas as other prokaryotic nonmycoplasma contaminants will also be detected. To overcome problems associated with the analysis of many different cells, to detect low-level contaminations, and to screen potentially infected sera, the use of an indicator cell line such as murine cell line 3T6 or monkey cell line Vero is recommended (the so-called indirect DAPI/Hoechst staining). Specimens to be analyzed are inoculated into the indicator cell culture known to be mycoplasma negative, and after an appropriate incubation period, the indicator cell line is examined under ultraviolet (UV) light.

DNA fluorochrome staining will detect titers of 10^5 organisms or greater per milliliter. False-positive results can be caused by staining artefacts or cell detritus. Particularly, apoptotic cells distribute their DNA fragments over a broad avenue in the intercellular region and might mimic infected cell cultures. Thus, the condition of the cell culture is crucial for the quality of the assay. This

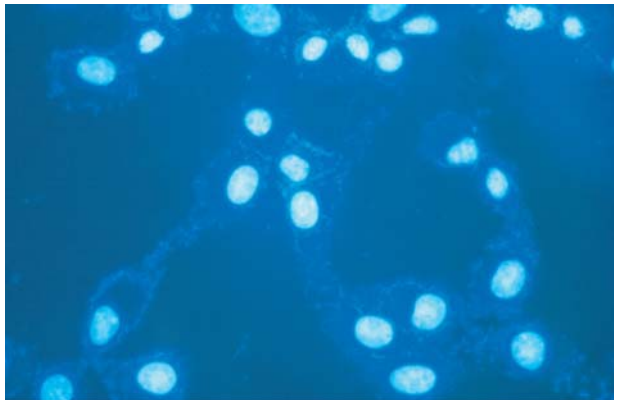

Figure 22.3. Detection of mycoplasma contamination by DAPI–DNA fluorescence staining. Fluorescent micrograph of the adherently growing cell line VERO-B4, which was inoculated with supernatant of a mycoplasma-contaminated cell culture and cultured for 5 days. The fluorochrome DAPI binds to any DNA present on the slide. The large fluorescent (blue) bodies are eukaryotic cell nuclei. The mycoplasmas are seen as dense clouds on the cells. For technical details see Ref. 17. Photographs were taken with a Nikon Labophot photomicroscope using a 60× objective. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Figure 22.4. Detection of mycoplasma contamination by colony growth on agar. Mycoplasmas (*M. arginini*) from the human suspension cell line U-937 were first enriched in a liquid broth medium and then plated on agar to allow for formation of characteristic colonies. A typical field of an agar plate incubated for 1 week is shown. Note the characteristic "fried-egg"-type mycoplasma colonies. For technical details see Ref. 17. Photograph was taken with a Nikon Diaphot inverted microscope using a 3.2 × objective. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

test is dependent on the intensity of the infection since only massively contaminated cultures can be identified, thus easily leading to false negatives. The majority of false-positive and false-negative readings are due to equivocal stainings with the ensuing difficulties in the (subjective) interpretation of the results and borderline decisions. Use of an indicator cell line significantly enhanced sensitivity, specificity, accuracy, and predictive value of the DNA fluorochrome assays (15). Here, the main disadvantage appears to be the necessity to carry permanently an adherent cell line (however, the cell lines Vero and 3T6 are relatively easy to maintain and have no or few background artifacts) and the extended incubation period. Advantages of the fluorochrome tests are that they are inexpensive, simple, and rapid, and can be applied for regular screening and long-term monitoring.

22.3.2.2 Microbiological Culture. For decades, the mainstay of mycoplasma detection was based on standard microbiological culture procedures. Specimens are inoculated into mycoplasma broth and subsequently onto agar both containing thallous acetate that inhibits the growth of conventional bacteria, but does not affect the growth of mycoplasmas. Broths are transferred to agar plates after 4–7 days of incubation. Most mycoplasmas produce microscopic colonies (100–400 μm in diameter) with a "fried-egg" appearance growing embedded beneath the surface of the agar (Fig. 22.4). Because the contaminants grow embedded, they maintain their morphological shape. Consequently, they are easily distinguishable from bacterial colonies. Certain mycoplasmas may produce a more diffuse, granular type of colony (8,10).

This procedure has the advantage of ease of manipulation and visual recognition of colonies. Some artifacts are occasionally seen on agar after inoculation of cell culture specimens: colonies must be distinguished from cell clumps by their eventual increase in size; pseudocolonies (e.g. calcium- and magnesium precipitates and air bubbles) can be a problem for the inexperienced observer since they can increase in size and can actually be transferred. There are wide variations in size, morphology, and speed of growth of the mycoplasma colonies isolated from different cell cultures. Colonies become usually detectable after an average of 3–6 days, but also later sometimes. In 1973, the existence of "noncultivable" mycoplasmas were reported and were recognized as *M. hyorhinis* (8). These contaminants grow poorly or not at all on well-standardized broth and agar media. A large percentage of *M. hyorhinis* strains does not propagate at all on cell-free medium. On the other hand, colonies of other bacteria can be distinguished by their different morphology or a PCR might be performed to confirm identity of the colonies and to exclude a bacterial contamination of the broth or agar plates.

Although the microbiological culture has the advantages of being inexpensive, highly sensitive with a high detection rate, and an established and important reference method, the

disadvantages are the long incubation time, the need for a subjective and experienced interpretation, and the fact that not all mycoplasmas can be successfully cultured.

22.3.2.3 Molecular RNA Hybridization. The assays of this category of mycoplasma detection are based on the principle of nucleic acid hybridization: complementary nucleic acid strands come together to form stable double-stranded complexes. The highest sensitivity is achieved in DNA–RNA hybridization that is commonly used, but also DNA–DNA hybridization would work satisfactorily. The availability of rRNA sequences in databases allows for the construction of species-specific, group-specific, or universal oligonucleotide probes to cover all mycoplasmas commonly isolated from cell cultures. Two unique features make rRNA the most suitable target for probes: the general organization of the molecule with conserved, semiconserved, and variable regions; and the high copy number of rRNA present in each mycoplasma cell (about 1×10^4). The probes represent sequences of the 16S or 23S rRNA genes. Some other bacterial species may also be detected by these tests. Importantly, RNA from eukaryotic cells will not hybridize with the probes.

The liquid solution hybridization (best exemplified by the commercially available kit "Gen-Probe", Mycoplasma Tissue Culture NI Rapid Detection System) uses an acridinium ester-labeled single-stranded DNA probe homologous to 16S and 23S rRNA sequences. After the rRNA is released from the organism, the chemiluminescently labeled DNA probe combines with the target rRNA to form a stable DNA–RNA hybrid. The acridinium ester of the single-stranded nonhybridized probe is then destroyed by addition of a hydrolysis buffer; positive signals are measured in a luminometer. The assay can be completed within approximately 1 h. The second method uses filter hybridization, whereby cell culture samples are simply heat fixed on the membranes, hybridized with the [^{32}P]deoxycytidine triphosphate (dCTP) labeled probe derived from 16S or 23S rRNA sequences, and incubated for autoradiography. The detection limits are in the range of 10^3 to 10^4 organisms; the filter method is reportedly more sensitive than the liquid hybridization.

The advantages of these assays are broad specificity, high sensitivity, convenient sample preparation, processing of large sample numbers, and rapid results. Validity and reproducibility of the Gen-Probe test are very high (15).

22.3.2.4 Polymerase Chain Reaction. The first reports on the application of PCR in the diagnosis of mycoplasma infections appeared in 1989. The PCR technique is based on repeated cycles of high temperature template denaturation, oligonucleotide primer annealing, and thermostable polymerase-mediated extension; the number of DNA molecules theoretically doubles after each cycle. Nearly all mycoplasmic 16S rRNA sequences have been determined and form the basis for a systematic phylogenetic analysis of mollicutes (see section titled Taxonomy of Mycoplasmas). Computer alignment studies of mollicute 16S rRNA sequences reveal regions with sequence variability or conservation at the species, genus, or class level allowing for the selection of appropriate oligonucleotides (primers) for detection and identification of mycoplasmas. The highly conserved regions of the genes enable the selection of primers of wide specificity ("universal primers"), which will react with DNA of any mycoplasma and even with the DNA of other prokaryotes; this is satisfactory for detection of mycoplasma cell culture infection where the goal is just to screen the cultures for contamination. Besides the conserved regions of mycoplasmal 16S rRNA genes, the 16S–23S intergenic regions are quite useful for mycoplasma detection (18,19). It is important that no cross-reactions with the DNA of cell lines occur.

As PCR can be performed with frozen and lyophilized material, this offers a means for a retrospective analysis and facilitates the transport, collection, and storage of samples. The amplification may be performed as a single-step PCR (Fig. 22.5) or as a two-step (nested) PCR; the latter approach not only considerably increases the sensitivity and specificity, but also increases the risk of contamination by DNA carryover. Southern blotting of PCR products and hybridization with a specific radio-labeled internal probe is another possibility to improve sensitivity. However, a very high sensitivity level may not usually be required in routine diagnosis as acute and particularly chronic cell culture mycoplasma infections involve a large number of organisms (commonly 10^6 per milliliter or higher). The very high sensitivity may be an advantage at a very early phase of infection or under conditions where mycoplasma growth is suppressed (e.g. in the testing and monitoring of cell cultures post treatment with antibiotics for elimination of the contaminants).

The detection limit using a set of nested universal primers was determined to be 1 fg mycoplasmal DNA which is equivalent to 1–2 genome copies of the 16S mRNA coding region (mollicute genomes carry only one or two rRNA gene sets). The ability to detect a single mycoplasma cell makes PCR the most sensitive detection method available, clearly more so than microbiological culture. In theory, a positive cell culture may be derived from a single mycoplasma cell (18).

The high sensitivity of PCR may cause problems in producing false-positive results due to contamination with target DNA. Another possible problem is false-negative data caused by the inhibition of the *Taq* polymerase by components in the samples. This problem can be overcome by performing a DNA preparation of the sample and by spiking an internal control DNA into the sample. Using a limiting dilution of the internal control DNA, the PCR reaction can

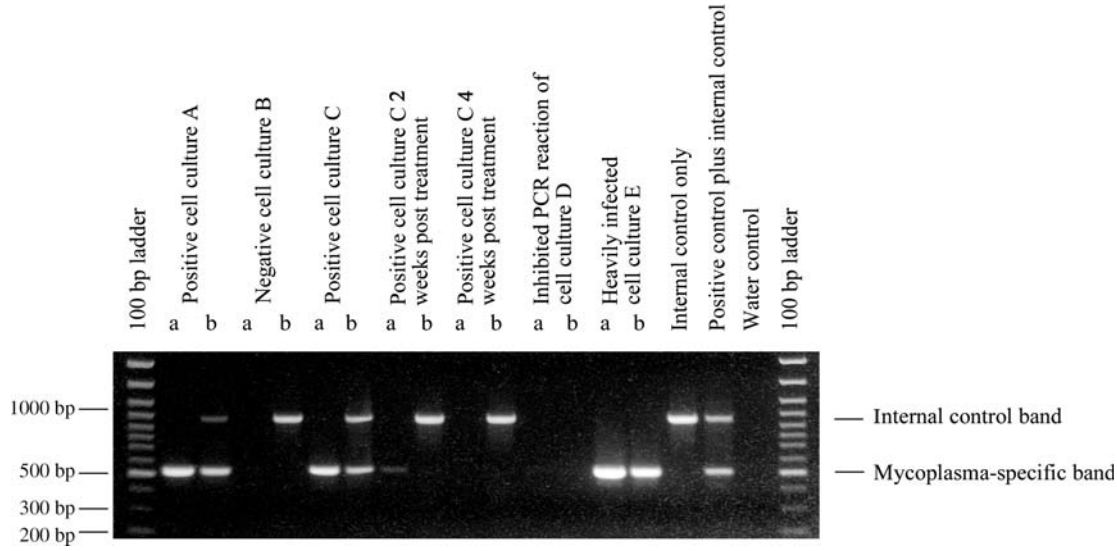

Figure 22.5. Detection of mycoplasma contamination by PCR. An ethidium bromide-stained gel containing the reaction products following PCR amplification is shown. Products of about 510 bp represent the contamination of the cell culture and the products of about 1000 bp derived from the internal control DNA added to the reaction b. For technical details see Ref. 20.

easily be standardized. Ideally, the internal control is amplified with the same primers as the wild-type mycoplasma DNA fragment. In this case, the control DNA should contain an insertion or a deletion to be distinguished from the wild-type PCR product. However, once all PCR-related problems are properly addressed, single-step or two-step PCR are clearly superior to other mycoplasma detection methods in many respects as this method combines simplicity and speed with high specificity and extreme sensitivity, in addition to objectivity, accuracy, and reproducibility (21). In particular, PCR is not limited by the ability of an organism to grow in culture; in certain areas, this molecular nucleic acid amplification may eventually replace biological amplification (i.e. growth in artificial media), a feature of paramount importance considering the fastidious nature of mycoplasmas (18).

Additionally, some PCR assays allow a simplified determination of the infecting mycoplasma species, provided only the limited number of usual cell culture contaminating mycoplasma species are present.

A further development of the conventional PCR method is the real-time PCR. This technique utilizes either SYBR green, which fluoresces when intercalated into double-stranded DNA. The fluorescence can be determined during each cycle of the PCR and the amount of newly amplified DNA can be continuously observed. This method does not discriminate between a mycoplasma-specific and a nonspecific PCR product. The identification of a mycoplasma-specific product requires a melting point determination of the PCR product. On the other hand, the reaction can be performed with a third quenched fluorescently labeled oligonucleotide, which can hybridize specifically to the amplified product emanating from mycoplasmal DNA. Hybridization abolishes the quench and the fluorescence can be determined during each cycle.

Real-time PCR offers the ability to quantify the amount of the target DNA when known standards are used in parallel reactions. But this is usually not necessary for the detection of mycoplasma contaminations. While the conventional PCR assay can be performed within approximately 2 h including sample preparation, PCR run and visualization of the PCR product on an ethidium bromide-stained gel, real-time PCR takes longer to be completed (4 h). Thus, PCR should prove to be a reliable technique of choice for mycoplasma detection in cell cultures. PCR protocols for the establishment of the tests in any laboratory (20) as well as several PCR kits are commercially available.

22.3.2.5 Fluorescence In Situ Hybridization. Another sensitive and rapid method to detect mycoplasma in cell cultures is the FISH. The advantage of the assay is the visualization of the mycoplasmas under the microscope. This allows to determine the intensity of the infection. A fluorescently labeled oligonucleotide is applied to cells fixed on microscope slides. The oligonucleotide hybridizes to a conserved region of the 16S rRNA. The high amount of ribosomes in the mycoplasmas leads to a multiplication of signals per cell. Owing to the specificity of the probe, only the mycoplasmas show fluorescence after hybridization and stringent washes. In contrast to the fluorochrome assays, the fluorescence is restricted to the mycoplasmas and no eukaryotic DNA or RNA influences

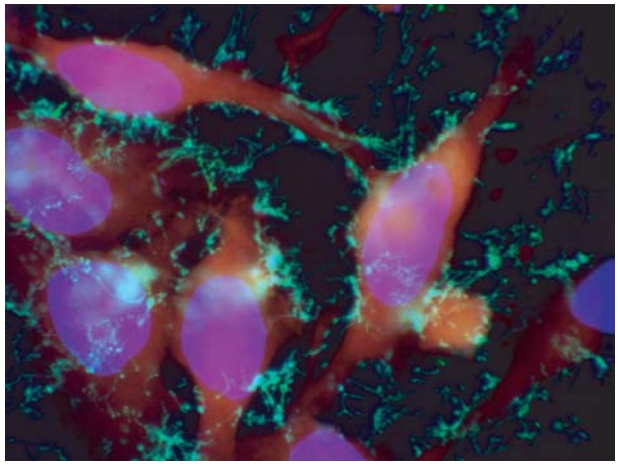

Figure 22.6. Detection of mycoplasma contamination by FISH fluorescent micrograph of an adherently growing HeLa cell line infected with *M. fermentans*. Cells were grown on slides, fixed with 4% paraformaldehyde, and exposed to fluorescein isothiocyanate (FITC) labeled oligonucleotides specific for mycoplasma (green). The cells were counterstained with tetramethylrhodamine isothiocyanate (TRITC) phalloidin to show the cytoplasma (red) and with DAPI to stain the nuclei of the eukaryotic cells (blue). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

the result (Fig. 22.6). The assay can be performed within 2–3 h including hybridization step.

22.3.2.6 MycoAlert. A recently launched assay for the detection of mycoplasmas is the MycoAlert test (distributed by Lonza). The method is based on the luminometric determination of two enzymes specific for certain microorganisms, presumably including all mycoplasma strains occurring in cell cultures. The enzymes are involved in two vital energy gaining processes: arginine metabolization and fermentation of carbohydrates. The carbamate kinases are specific for mycoplasmas hydrolyzing arginine. Arginine is metabolized into L-citrulline and ammonia, L-citrulline is cleaved with participation of inorganic phosphate into L-ornithin and carbamoyl phosphate, which is then used for the generation of ATP in the presence of carbamate kinase resulting in carbonate and ammonia. Acetate kinase is involved in the metabolization of glucose into acetate: acetyl phosphate and adenosine diphosphate (ADP) are converted into acetate and ATP. By adding the substrates of the enzymes to the mycoplasma-infected cultures, the generation of ATP can be measured luminometrically. Luciferin, luciferase, ADP, adenosine monophosphate (AMP), and inorganic phosphate are added to the cell culture supernatant in a cell lysing buffer and the background of ATP concentration is determined. Carbamoyl phosphate and acetyl phosphate are then added to the solution and the additional production of ATP is indicative for the contamination with mycoplasma.

The test can be performed within 30 min and is very reliable when applied in routine cell culture, although the background concentration of ATP is occasionally very high.

22.4 ELIMINATION OF MYCOPLASMA CONTAMINATION

22.4.1 Various Elimination Methods

Ever since mycoplasma contamination of cell cultures was first reported, attempts to develop methods for elimination of the mycoplasma have been made. It has been suggested that efforts to eradicate mycoplasmas from contaminated cells should be considered as a last resort (in order to prevent spread of the contaminant) and that it would be often far better to eliminate the problem completely by autoclaving the infected cultures and replacing them with fresh stocks known to be mycoplasma free (11). However, all, too often, cell lines are not replaceable with a mycoplasma-free aliquot, and purging of mycoplasmas from such cultures is a necessity.

Four general types of procedures have been used to eliminate mycoplasmas from infected cell cultures: physical, chemical, immunological, and chemotherapeutic treatment (Table 22.5). Many of the methods were shown to be unreliable. Some techniques may apply to some, but not all mycoplasma species; some of them are too laborious or simply impractical. Elimination is typically time consuming, often unsuccessful, and poses risks of secondary infection to other cell cultures. Methods of elimination should ideally be simple and easy, rapid and efficient, reliable and inexpensive, have minimal effect on the eukaryotic cell, and result in no loss of specialized characteristics; accidental cloning selection of treated cells also should not occur. However, there is clearly not a single method available that is both 100% effective and fulfills all the ideal requirements.

The effectiveness of some elimination methods has been investigated only in experimentally contaminated cell cultures, yet experimentally infected cultures may not realistically reflect the laboratory situation since chronic infections certainly result in complex interactions between mycoplasmas and cells. If a cleanup is attempted, it is imperative to closely monitor the effectiveness of treatment relative to mycoplasma elimination and eukaryotic cytotoxicity. A variety of procedures have been described and utilized. Administration of antibiotics is by far the most common and efficient approach and is discussed in greater detail in section titled Antibiotic Treatment as the Most Effective Method.

The physical elimination methods include prolonged heat treatment at 40–42°C and filtration through microfilters (100–200 nm). For obvious reasons, both approaches

TABLE 22.5. Various Mycoplasma Elimination Methods

Procedures	Applicable To
Physical procedures	
Heat treatment	Hardware and heat-resistant cell culture reagents or products
Filtration through microfilters	Heat-sensitive cell culture reagents and products
Induction of chromosomal or cell membrane damage with photosensitizing	Insensitive cell cultures and cell cultures reagents and products
Chemical procedures	
Exposure to detergents	Surfaces, hardware
Washings with ether–chloroform	Hardware
Treatment with methyl glycine buffer	Surfaces, hardware
Incubation with sodium polyanethol sulfonate	Surfaces, hardware
Culture in 6-methylpurine deoxyriboside	Hardware
Immunological procedures	
Cocultivation with macrophages	Cell cultures
In vivo passage through nude mice	Cell cultures
Culture with specific antimycoplasma antisera	Cell cultures, cell culture reagents, products
Exposure to complement	Cell cultures, cell culture reagents, products
Cell cloning	Cell cultures
Chemotherapeutic procedures	
Antibiotic treatment in standard culture	Cell cultures
Antibiotic treatment plus hyperimmune sera or cocultivation with macrophages	Cell cultures
Soft-agar cultivation with antibiotics	Cell cultures

do not seem to be very promising. Another procedure takes advantage of the nutritional requirements of mycoplasmas offering them 5-bromouracil (or 5-BrdU), which is then selectively incorporated into the mycoplasmal genome. Exposure to visible light induces chromosomal breaks leading to cell death; this photosensitivity was greatly enhanced by the binding of the fluorochrome Hoechst 33258 to the DNA (8). The method is labor intensive and time consuming (requiring several rounds of treatments and subsequent cloning), can be highly cytotoxic to the eukaryotic cells, may produce cellular mutants, and was reported to activate endogenous C-type retroviruses in murine cells. A variation of the latter method is the use of the lipophilic fluorescent probe Merocyanine 540 that is incorporated into the cell membrane of mycoplasmas. Again illumination with visible light of cultures incubated with Merocyanine 540 together with Hoechst 33258 leads to a significant degree of mycoplasma eradication. The relative merit of this technique is not yet established and the use for cell lines derived from leukemia, lymphoma, neuroblastoma, and some other solid tumors might be limited, because these cell types are also sensitive against photosensitization.

The more recently developed membrane-active peptides, for example, alamethicin, dermaseptin B2, gramicidin S, and surfactin, are highly efficient in pure mycoplasma cultures, but in the presence of serum their activities are decreased. Thus, the concentrations and treatment times required for the elimination of mycoplasmas from cell cultures are toxic to the eukaryotic cells (22).

The chemical procedures involve the exposure of the cultures to various reagents for a given period, once or repeatedly. Described are treatments with methyl glycine buffer, sodium polyanethol sulfonate, and 6-MPDR. Treatment with detergents such as Triton-X 100 were reported to be effective. Another method uses washings with 2:1 parts ether and chloroform overnight in the cold. Overall, these chemicals will hardly be selective in harming only the mycoplasmas without untoward sequelae for the eukaryotic cells.

Immunological elimination methods exploit the physiological mechanisms of the normal immune responses, using either cellular components of the immune system with their intrinsic abilities of phagocytosis (*in vitro* in culture dishes or *in vivo* in mice) or the soluble mediators of immunity, namely, complement and antibodies (immunoglobulins). Mycoplasma-infected cells were cocultivated with primary and purified human or murine macrophages extracted from the peripheral blood, bone marrow, or peritoneum; some protocols suggested the addition of antibiotics, others used pooled human immunoglobulin. Nude mice, which still possess macrophages, but cannot mount a full immunological response due to the lack of T lymphocytes, were used for the *in vivo* passage of mycoplasma-contaminated cell lines in the form of an ascites tumor. This method requires animal facilities. Culture with macrophages, *in vivo* or *ex vivo*, will reduce the mycoplasma content, although it does not appear to be sufficient to eliminate mycoplasma completely; furthermore, it carries the risk of introducing murine viruses (e.g. C-type viruses) from the murine host and the procedure will not eliminate intracellular mycoplasma.

Considerable efforts have been spent in producing high titer neutralizing antimycoplasma antisera in rabbits, guinea pigs, and cows. They clearly do not work in every instance and simply reduce the mycoplasma load temporarily; thus, their elimination efficacy is rather low. Incubation with complement contained in fresh human serum was suggested as a rapid and efficient procedure building on the destructive

interaction between components of the classical complement pathway and mycoplasmas.

Concerning the efficiency of immunological mycoplasma purging methods, it is of note that the mycoplasma membrane, being exposed to the external environment, is the cell organelle that comes into contact with components of the host immune system (in the mammalian organism). Lacking the protection of a rigid cell wall, mycoplasmas should be particularly sensitive to growth inhibition and lysis by antibodies and complement. Yet, despite this apparent exposure to a possible immunological attack, mycoplasma infections are usually chronic in nature, indicating the frequent failure of the host defense mechanisms to eradicate the parasites. Mycoplasmas may have certain mechanisms at their disposal for rapid adaptation to the microenvironment and thus can escape any immunological actions (5). These *in vivo* observations may explain the lack of success in using immunological approaches for mycoplasma decontamination of cell cultures. Finally, cell cloning of an infected culture in 96-well plates may lead to a mycoplasma-free culture, in the hope of selecting cells without any cytadsorbed contaminants. The success rate is generally very low while the amount of work involved is clearly very high.

The physical, chemical, and immunological methods are usually of restricted value since the mycoplasmas, although not detected for sometime afterwards, commonly reappear (low efficiency); some methods are time consuming or have detrimental effects on the eukaryotic cells and other techniques are complex or impractical as they require extensive resources or special equipment and knowledge. Considering the various advantages and disadvantages of any elimination procedure, chemotherapeutic treatment appears to be superior compared to the other mycoplasma eradication techniques and thus the method of choice. The simple addition of another reagent to a cell culture is within the technical and financial capabilities of every cell culture laboratory.

22.4.2 Antibiotic Treatment as the Most Effective Method

Mycoplasmas, which lack a cell wall and are incapable of peptidoglycan synthesis, are theoretically not susceptible to antibiotics such as penicillin and its analogs, which are effective against most other bacterial contaminants of cell cultures. However, it has been reported that several bacteriostatic antimicrobial agents inhibit the growth of mycoplasmas; thus, they may not eradicate the contaminants, but simply suppress the full-blown picture of an infection and tend to mask the presence of mycoplasmas. A number of different antibiotics have been explicitly used for mycoplasma control (Table 22.6). The contaminant strains, however, often developed resistance to certain antibiotics, which were thus completely ineffective. Other antibiotics (for instance some aminoglycosides and lincosamides) were moderately to highly effective in

TABLE 22.6. Various Antimicrobial Agents against Mycoplasma Contamination in Cell Cultures

Antibiotic Category: Specific Antibiotic	Mode of Action	Effect on Bacteria	Effectiveness against Mycoplasmas[a]	Cytotoxicity for Eukaryotic Cells[b]
Aminoglycosides	Protein synthesis inhibitor	Bacteriocidal		
Gentamicin			+	–
Kanamycin			+	+
Spectinomycin			+	+
Tetracyclines	Protein synthesis inhibitor	Bacteriostatic		
Chlortetracyline			+	(+)
Doxycycline			+	(+)
Minocycline			++	(+)
Lincosamides	Protein synthesis inhibitor	Bacteriostatic		
Clindamycin			+	+
Lincomicin			+	+
Macrolides	Protein synthesis inhibitor	Bacteriostatic		
Erythromycin			(+)	–
Roxitromycin			–	–
Tiamulin (pleuromutilin)			++	–
Tylosin			+	+
Quinolones	Nucleic acid synthesis inhibitor	Bacteriocidal		
Ciprofloxacin			++	–
Enrofloxacin			++	–
Sparfloxacin			–	–
Novobiocin	Cell wall inhibitor	Bacteriostatic	–	–

[a] ++ = highly effective; + = moderately effective; (+) = rarely or weakly effective; – = ineffective.

[b] Cytotoxicity at effective mycoplasmacidal antibiotic doses: + = cytotoxic; (+) = mildly cytotoxic or cytostatic; – = not cytotoxic.

eliminating mycoplasmas, but only at concentrations that had detrimental effects on the eukaryotic cells, such as marked cytotoxicity and genotoxicity.

Ideally, a basic procedure should involve isolating, speciating, and determining the antibiotic susceptibility of the contaminants to the arsenal of possible reagents to maximize success; then the cultures should be exposed to the effective antibiotics. However, this approach is extremely time consuming, labor intensive, and requires certain expertise. It might be fair to say that few scientists (for whom a cell culture is normally only a means to an end) would use this complex approach and would prefer a quicker solution.

The pharmacological and clinical testing and application of mycoplasmacidal antibiotics has shown that tetracyclines are generally effective antimycoplasmal agents; also quinolones were found to be highly effective against mycoplasmas. Recently, these antibiotics have been introduced for purging of mycoplasmas from cell cultures and are commercially marketed. Of note are, in particular, the fluoroquinolones ciprofloxacin (distributed as Ciprobay by Bayer), enrofloxacin (Baytril; Bayer), sparfloxacin (distributed by Sanofi-Aventis Pharma), and an unpublished reagent available as mycoplasma removal agent (MRA; Flow Laboratories ICN); the product BM-Cyclin (Roche) combines the macrolide tiamulin (a pleuromutilin derivative) and the tetracycline minocycline (Fig. 22.7); Plasmocin (InvivoGen) is a combination of a macrolide and a fluoroquinolone.

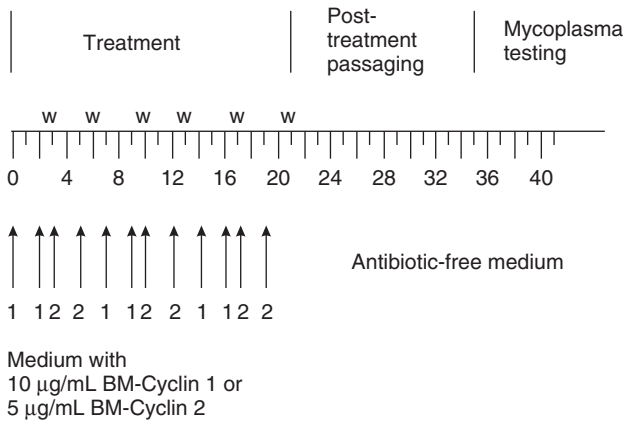

Figure 22.7. Treatment protocol for elimination of mycoplasma contamination using BM-Cyclin. BM-Cyclin containing the macrolide tiamulin (1) and the tetracycline minocycline (2) (Table 22.6) is added to the cell culture for 3 weeks in three alternating cycles (as indicated in this example by the arrows). Cells are thoroughly washed (W) prior to switching to the other reagent, at the beginning, and at the end of treatment. Post therapy, it is important to grow the culture in antibiotic-free medium. After a minimum of 2 weeks, mycoplasma testing is performed. Thereafter, cells are regularly monitored for reemergence of the contamination or for new infection. For technical details see Refs 23–25.

Tetracyclines inhibit protein synthesis by binding to subunits of ribosomes, thereby blocking peptide chain elongation. Tetracyclines inhibit both prokaryotic and eukaryotic ribosomal protein synthesis. Nalidixic acid is the prototype of a class of synthetic antibacterial agents, the fluoroquinolones, a subset of the quinolones. The mode of action of the quinolones involves the binding to and inhibition of the bacterial DNA gyrase that is essential for DNA replication, transcription, repair, and recombination. Despite their documented selectivity for prokaryotic enzymes, the quinolones may also exert an inhibitory effect on eukaryotic DNA polymerase α, topoisomerases, and DNA deoxynucleotidyl transferases; the activity of these enzymes is especially high in rapidly dividing cells. Indeed, high doses of quinolones induced double-stranded DNA breaks in human cells. Selectivity of the quinolones for the bacterial cell is at least partly due to the far greater sensitivity of the bacterial enzymes compared to the mammalian enzymes.

Antibiotic treatment of mycoplasma contamination in cell cultures has a high degree of efficiency as illustrated by the percentages of successful outcomes in various studies: 65–74% of the mycoplasma-positive cultures were cured with MRA, 74–100% with Ciprobay, 76–91% with Baytril, and 82–100% with BM-Cyclin (23); data on the treatment with Plasmocin are not yet available, but presumably they are similar to the ones found for the other antibiotics. Thus, two-thirds to three-quarters of all cultures treated can be cleansed by one of these antimycoplasma chemotherapeutic regimens. Besides cure, two other possible outcomes are loss of the culture and resistance. Culture death, occurring in 5–15% of the cases, is presumably caused by cytotoxic effects of the reagents. Not unexpectedly, BM-Cyclin (containing a tetracycline) shows the greatest growth-inhibiting effect, which may be either cytostatic or cytotoxic. Generally, 1 week after cessation of treatment, cell growth will return to normal. Cytostatic and cytotoxic effects of the antibiotics may be enhanced by the poor condition of cell cultures commonly found in chronically infected cells. This situation is clearly different from that of experimentally contaminated cell cultures. It was found that increasing the serum concentration and incubating the cells at higher densities (at or near clonal densities) were advantageous for the cell cultures.

With regard to resistance, the fluoroquinolones showed cross-resistance. This is not surprising given their basic structural similarity. Fortunately, sequential administration of BM-Cyclin to the same cells that were first exposed to a fluoroquinolone can still result in eradication of the resistant infectant. Higher concentrations of the antibiotics may be more effective in purging mycoplasma-contaminated cultures decreasing the rate of resistance, but this success would be counterbalanced by significantly higher cytotoxicity. It is not known whether the resistance of cell culture

mycoplasmas to antibiotics is acquired during treatment or exists already prior to exposure to these reagents. In any event, antimycoplasma antibiotics should be reserved for the specific situation of mycoplasma eradication in an infected cell culture and should not be routinely added as a common panacea to the culture medium as this would run a substantial risk of selecting resistant mycoplasma strains. The discovery of intracytoplasmatic mycoplasmas may explain the resistance of some cases where prior testing documented susceptibility of the particular contaminant to antibiotics. In these instances, the antibiotics mentioned above do not have physical access to the mycoplasmas. On the other hand, some antibiotics, for example, ciprofloxacin, were shown to be accumulated in the eukaryotic cells.

Antimycoplasma treatment conditions are certainly stressful to the eukaryotic cells. Thus, cells might no longer express the desired properties as a result of antibiotic administration. Outgrowth of a selected clone is another possibility. Some data suggest that cured cells generally preserve their characteristics. Still, any alterations to the cell lines induced by antibiotic treatment are obviously a matter of concern and require further detailed studies.

Taken together, the technically simplest alternative for mycoplasma decontamination with the most promising results is antibiotic treatment. The convenience of use and general availability of the reagents render it a reliable routine laboratory procedure. However, antibiotic mycoplasma elimination is laborious and time consuming as the duration of the treatment plus the minimum antibiotic-free posttreatment period ranges from 3 to 5 weeks depending on the protocol used. Furthermore, special attention must be placed on possible cytotoxic effects or effects that alter the characteristics of the cell line. Nevertheless, the effect of mycoplasma infection is in all probability greater than the effects of antibiotic treatment.

Finally, variations of the antibiotic eradication procedure involve the pretreatment or simultaneous exposure to surfactin, hyperimmune antimycoplasma serum, and coculture with macrophages (Table 22.5). The idea behind these techniques is to eliminate the bulk of the contaminants prior to the addition of the antibiotics or to combine different approaches that may complement one another in the efficacy with which they eliminate residual infectants. Another treatment model demonstrated improvement in the cure rate achieved with the use of soft agar and antibiotics over that obtained with antibiotics alone. The soft-agar technique consists of suspending infected cultures in soft agar containing appropriate antibiotics. The method is based on the survival of cells in soft agar and on the fact that the cells remain in suspension, thus facilitating exposure of mycoplasmas to the antibiotics. The advantage of the method lies in its speed and simplicity as only one cycle of treatment (indicated as 1–3 days) is adequate.

22.5 WORKING PROTOCOLS FOR DETECTION, ELIMINATION, AND PREVENTION OF MYCOPLASMA CONTAMINATION

There are three main components to be considered when regarding the problem of mycoplasma contamination of cell cultures: detection, elimination, and above all prevention of mycoplasma infection. In the following, several routine protocols are presented with regard to these three fundamental issues. Mycoplasmal contamination is now and will always be a potential threat to cell cultures. Overall, detection methods have dramatically improved in recent years and the availability of testing kits has also increased. Instead of discarding mycoplasma-infected cultures (without any possible clean replacement), elimination of the contaminants has become a realistic and practical possibility. Critical to maintaining cell cultures free of mycoplasma (and other adventitious organisms) is the establishment of routine operating and testing procedures by the cell culturist. The primary difficulty in controlling the epidemic mycoplasma contamination lies in convincing the culture operator of the necessity for validating the absence of these covert organisms and in creating a certain level of awareness for the dangers that lurk.

22.5.1 Routine Working Protocol for Detection

The high frequency of mycoplasma-contaminated cell cultures and the rapid spread of the infection within the laboratory impose a requirement for rigorous mycoplasma testing of any new incoming cell culture and also for regular screening of every permanently cultured cell line. The best test will fail if the sample submitted for testing is not representative or is not properly treated. Antibiotics can mask mycoplasma infection resulting in false-negative test results. Therefore, although it is highly desirable that cell lines always be cultured without any antibiotics, for mycoplasma testing purposes it is essential that cell cultures be maintained antibiotic free for several passages. Furthermore, cultures should be assayed a sufficient time after the last passage or exchange of medium; this allows organisms, if present, to grow to high titers. Although PCR is definitely the test of choice (see section titled Most Reliable Detection Methods), this method can also produce false-positive or false-negative results. Thus, conduction of at least two (better three) different techniques on the same sample is suggested to obtain a reliable diagnosis.

A routine working protocol for detection of mycoplasma contamination in the form of a flow chart is shown in Fig. 22.8. Newly arriving cell lines should be quarantined in a separate cell culture laboratory. The initial mycoplasma testing determines the mycoplasma contamination status of the cells. If the culture is contaminated and no clean replacement is available, decontamination might be

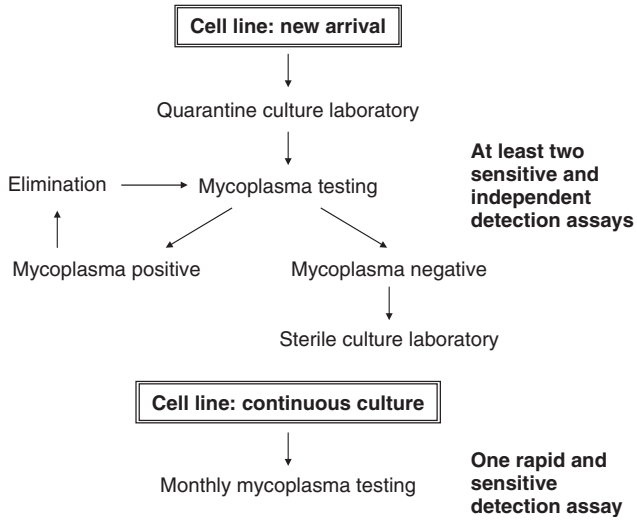

Figure 22.8. Routine working protocol for detection of mycoplasma contamination. A flow chart for mycoplasma testing of newly arriving and continuously cultured cell lines is shown. Use of at least two (better three or even four) different mycoplasma detection assays is suggested; best suited for determining the initial mycoplasma contamination status are PCR, RNA hybridization (Gen-Probe), FISH, biochemical assay (MycoAlert), and DAPI/Hoechst staining while for routine screening and continuous monitoring PCR, RNA hybridization (Gen-Probe), FISH, and biochemical assay (MycoAlert) are recommended; it is useful to check continuous cell cultures at monthly intervals. For technical details see Refs 15,17, and 19–21.

attempted followed by strict retesting post treatment (see section titled Routine Working Protocol for Elimination). It is absolutely mandatory that clean cultures also be regularly assayed for mycoplasma contamination, for instance, at monthly intervals. PCR with its extreme sensitivity, MycoAlert as very rapid and effortless assay, and DNA fluorochrome staining (DAPI/Hoechst stains) or FISH as inexpensive, simple and rapid methods can be applied for regular screening.

22.5.2 Routine Working Protocol for Elimination

If a cell culture is found to be infected with mycoplasmas, the advised procedure is to replace it whenever possible; frozen stocks can be examined or cell culture repositories can be contacted. An invaluable or irreplaceable cell line can be cured as decontamination with various methods has become a practical and highly successful endeavor. However, a number of factors should be weighed carefully. The treatment protocol plus the obligatory intensive monitoring thereafter is a laborious and time-consuming task. The possibility exists that upon exposure to potentially toxic conditions, the cell line will be subjected to selective pressure and the cured population might differ from the original. Also, the procedure entails extensive work with mycoplasma-positive cultures, thus carrying the risk of further spread of the contamination. We have had success with chemotherapeutic purging of cultures applying various antimycoplasma antibiotics. A flow diagram of the antibiotic treatment protocol is shown in Fig. 22.9.

As a general rule, if cell cultures are diagnosed as being positive for mycoplasma, as quickly as possible they should be either discarded, frozen, and stored in liquid nitrogen or treated with antimycoplasma procedures in order to prevent spread of the contaminant. The whole decontamination process should be undertaken in a quarantined culture laboratory until sterility is attained. It is advisable to freeze some cells for further elimination attempts in case the first treatment fails to achieve freedom from mycoplasma contamination. The basic principle of antibiotic treatment involves exposure of the positive culture to a recommended antibiotic concentration for a given number of days, followed by maintenance of the cells for at least 2 weeks in antibiotic-free medium, and then the close monitoring of the mycoplasma status by adequate tests to detect residual or new contaminants. Resistant cell lines may be rescued by subsequent incubation with a noncrossresistant antibiotic (for instance quinolone-resistant cells can be cured with BM-Cyclin). An alternative would be a second attempt with an untreated, mycoplasma-positive aliquot of the same culture using different antibiotics or higher concentrations. The application of elimination methods other than antibiotics remains a further possibility.

The recommendation that mycoplasmacidal antibiotics should be used as a permanently preventive measure to avoid contamination must be strongly rejected. Antibiotics, in general, and antimycoplasma reagents, in particular, should not be used as a substitute for good cell culture technique.

22.5.3 Routine Working Protocol for Prevention

Of primary importance in preventing mycoplasma contamination of cell cultures is an awareness of sources of infection combined with a program of cell maintenance, regular quality, and identity checks, and repeated characterization of the cells (27). The protocol for prevention of mycoplasma contamination should be designed to minimize risk of exposure of cells to mycoplasmas. As pointed out above (see section titled Sources of Mycoplasma Contamination), human sources and bovine serum constitute two of the main infectant reservoirs; undoubtedly, lateral spread from one cell line to another accounts for the majority of infections. A variety of specific steps can be adopted to prevent cell culture contamination with mycoplasmas (Table 22.7) (9–11).

Any sterile cell culture work should be performed in a vertical laminar flow biohazard hood. It is critical to

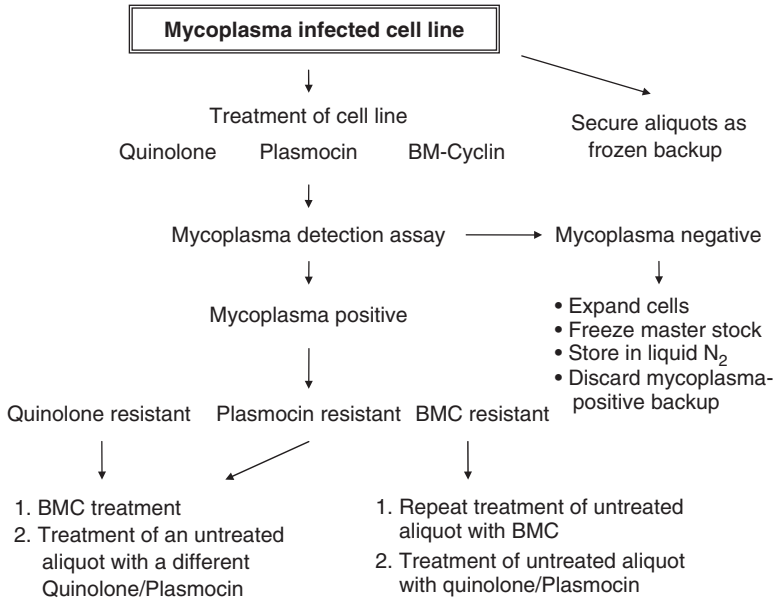

Figure 22.9. Routine working protocol for elimination of mycoplasma contamination. A suggested flow chart for planning antibiotic treatment of mycoplasma-positive cell lines is shown. It is proposed that aliquots of the contaminated cultures be frozen; these serve as a backup in case the initial antibiotic administration fails to achieve freedom from mycoplasma contamination. Cells may be treated with one, several, or all of the five regimens indicated, but in separate culture vessels as single agent treatment (the antibiotics should not be mixed). After an antibiotic-free phase of at least 2 weeks post treatment, cells must undergo several rigorous mycoplasma testings with at least two methods and must be examined afterwards at periodic short intervals (for instance monthly). In the case of antibiotic resistance, resistant cultures may be treated a second time with an effective, noncrossresistant reagent or backup (still contaminated) cultures may be treated in another attempt, or other purging methods may be used. For technical details see Refs 23 and 24–26.

disinfect all work surfaces before and after culture manipulations, including the various devices entering the laminar flow hood. Mycoplasmas are extremely sensitive to most disinfectants, but can show prolonged survival in a dried state. Thus, the main point is simply to keep the laboratory and its inventory as clean as possible. Clearly, nothing replaces good house keeping and good aseptic techniques in the control of mycoplasmal contamination. It is important that cell culture laboratories establish effective and scheduled mycoplasma testing procedures in the form of a routine screening program for all forms of microbial contamination, including mycoplasmas. Sera, media, and supplements (and also cell lines whenever possible) should be purchased from reputable suppliers that adequately test for mycoplasmal contamination.

All incoming cell lines should be quarantined until the contamination status is verified. Mycoplasma-free cultures should be separated in time and space from infected cultures. Reagents for the two sets of cultures should be separate. The general use of antibiotics is not recommended except in special applications and then only for short durations. Use of antibiotics may lead to lapses in aseptic technique, to selection of drug-resistant organisms, and to delayed detection of low-level infection by either mycoplasmas or other bacteria. Master stocks of mycoplasma-free cell lines should be frozen and stored to provide a continuous supply of cells should working stocks become contaminated. Mycoplasma-infected cell lines should be discarded or treated with mycoplasmacidal measures as quickly as possible in order to prevent lateral spread.

Strict adherence of the cell culturist to aseptic culture techniques is another fundamental aspect in mycoplasma control. Cell culturists should continually be aware of the danger of contaminating clean cultures with aerosols from mycoplasma-containing cultures manipulated in the same area. For example, the following procedures with liquid media generate droplets: pipetting, decanting, centrifuging, sonicating. These relatively large droplets do not remain airborne but settle within seconds into the immediate environment where they remain viable for days. Furthermore, mouth pipetting and unnecessary talking are not acceptable.

TABLE 22.7. Routine Working Protocol for Prevention of Mycoplasma Contamination

Cell culture facility
Facility should be designed and equipped for aseptic culture procedures
Certified laminar flow biological safety cabinets should be used and their function should be regularly examined
Work surfaces should be chemically disinfected prior to and following work, and thoroughly cleaned at regular intervals (monthly)
Incubators should be regularly controlled and cleaned (monthly)
Discarded glass and plastic ware and spent media should be carefully disinfected
Cell culture materials should be properly disposed of by central sterilization
Effective house keeping procedures should be followed to minimize contamination of the environment (e.g. floor, sinks, faucets, and water baths)
Unauthorized persons should not be allowed entry
Animals should not be kept in the cell culture room
Laboratory should be kept clean
Quality control
A defined quality and identity and characterization program should be established
Mycoplasma testing should be performed at the time of arrival of the culture and at regular intervals (monthly)
Reliable mycoplasma detection methods should be established and performed
Medium components (especially serum) should be tested for sterility before use
Strict aseptic techniques and good laboratory procedures should be followed
Cell cultures
Cell cultures should be obtained from reputable cell repositories
Incoming cell cultures should be held in quarantine until proof of sterility (or at least separated in time and space from sterile cultures)
Aliquots free of mycoplasma (and other adventitious agents) should be stored in a master and working stock system in liquid nitrogen
Antibiotic-free media should be used whenever possible
Periodic standardization checks of the cell culture (quality and identity program, characterization) should be made
Mycoplasma-positive cultures should be immediately discarded or treated with mycoplasmacidal measures
Cell culturist
Handwashing prior to and following work should be required
Mouth pipetting should be prohibited
There should be no unnecessary talking or traffic at the clean bench or in the immediate work area
Protective clothing should be used to protect both the culture and the culturist
Jewelry (rings, bracelets, and wristwatches) should be taken off
Written laboratory records for every cell culture should be made
The same medium aliquot should not be used for different cell lines
Medium should not be poured from bottles or flasks, but pipetted
Only one cell line should be handled at a given time

The prohibition of eating, drinking, smoking, or application of makeup in the laboratory is obvious. The recommendation to thoroughly wash and disinfect the hands, to take off jewelry (rings, bracelets, wristwatches), to wear protective clothing, and to tie back long hair (or use of head covering) are further precautions that are necessary to minimize the risk of contamination.

23.1 INTRODUCTION

With increasing numbers of glycoproteins entering the biotechnology pipeline as potential therapeutics, there is a growing need to understand what role glycosylation plays in the therapeutic effectiveness of glycoproteins and how best to select the host, culture environment, and possible modifications of the host for production of recombinant proteins. Therapeutic glycoproteins include thromobolytics, cytokines, blood-clotting factors, growth factors, and immunoglobulins. In 1993, four of the approved recombinant protein therapeutics were in the top 25 selling pharmaceutical products (1). Since 1996, more than 20 additional recombinant enzymatic glycoproteins and antibodies have been approved as therapeutics and diagnostics. Many of the recombinant glycoproteins (e.g., erythropoietin, colony-stimulating factors, and glucocerebrosidase) represent therapeutic breakthroughs, treating conditions that were previously untreatable (2). Still others are recombinant versions of proteins (e.g., clotting factors) that were previously purified from blood or tissues with the associated disease risks.

While the field of protein glycosylation has been reviewed extensively both from the perspective of the basic biology (3–7) and with a focus on the glycosylation of recombinant proteins (8–14), our knowledge of the field is evolving rapidly. In particular, there have been advances in the use of insect cells and fungi, efforts to modify rodent cell lines to present more human-like glycoforms, studies of *in vitro* glycosylation, and a deeper understanding of the effects of culture conditions on protein glycosylation.

The tools available for separation and characterization have also advanced dramatically. Routine use of mass spectrometry and LC–MS techniques in the biotechnology industry has made detailed glycan characterization possible as part of a routine quality analysis of recombinant glycoproteins. This chapter provides an overview of protein glycosylation, a discussion of the effects of glycosylation on the stability, activity, and clearance of glycoproteins, and then discusses techniques and strategies for separating and analyzing glycoproteins.

23.2 OVERVIEW OF PROTEIN GLYCOSYLATION

Protein glycosylation is the most common posttranslational modification. Among the proteins in the SWISS-PROT database, more than two-thirds of the proteins contain consensus sequences for N-linked glycosylation. On the

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

basis of the characterization of site occupancy of known glycoproteins, Apweiler and coworkers (15) estimate that more than half of the proteins in the database are glycosylated. Moreover, the mass of the carbohydrate added to proteins is substantial, between 10% and 60% of the molecular weight of a glycoprotein. All integral membrane proteins in higher organisms are glycosylated as are many secreted proteins. In addition, glycoproteins also exist in the cytoplasm and nucleus (3).

Carbohydrate modification falls into three general categories. N-linked glycans involve the amide nitrogen in the asparagine side chain; O-linked glycans involve the oxygen in the side chains of serine, threonine, hydroxylysine, or hydroxyproline; and glycosylphosphatidyl inositol (GPI) derivatization occurs on the carboxy-terminal carboxyl group. In addition, there are some unusual forms of glycosylation that have been recently discovered. A glycoprotein may have one or more glycosylation sites. Each putative glycosylation site may be always occupied, variably occupied (referred to as *macroheterogeneity*), or never occupied. In addition, the glycan attached to each site may vary from molecule to molecule (referred to as *microheterogeneity*) leading to a highly variable population of glycoproteins from a single polypeptide backbone.

The glycan diversity results from the large number of different sugars and linkages available to synthesize an oligosaccharide. A large number of hexose and some pentose sugars that can be incorporated into polysaccharides are available. The most common sugars, their structures, abbreviations, and symbols are given in Table 23.1. Each monosaccharide has a number of hydroxyl groups that can be linked to other sugars. Multiple linkages are possible, yielding a variety of branches. In addition, there are two anomeric forms available for each linkage, α- and β-forms.

23.2.1 N-Linked Glycosylation

In the case of N-linked glycans, the consensus sequence Asn-X-Ser/Thr where X is any amino acid except proline is necessary, but not sufficient, for glycosylation. It is estimated that between 10% and 30% of potential glycosylation sites are not occupied (16). N-Linked glycans can be grouped into three main categories all of which contain a common core structure ($Man_3GlcNAc_2$): complex, which contain no mannose residues other than in the core; high mannose; and hybrid, in which some of the branches are of the complex type and some are of the high-mannose type (Fig. 23.1). In each case, the GlcNAc is linked in a β-linkage to the amide nitrogen of the asparagine side chain. In the complex structures, each branch frequently terminates in a sialic acid although sulfated lactosamine is also seen, particularly in glycoprotein hormones such as LH, FSH, and TSH. Site analysis has shown that the distribution of different classes of N-linked structures is frequently specific for each site on a protein. For example, in the rat brain protein Thy1, site 23 has only high-mannose structures, site 74 has only complex and hybrid structures, and site 98 contains all three types (17,18).

Proteins targeted for secretion or membrane insertion are translocated to the endoplasmic reticulum by means of a 15–30 amino acid signal sequence comprising primarily hydrophobic amino acids during translation. The newly synthesized protein enters the lumen of the endoplasmic reticulum where it is subject to co-translational folding and N-linked glycosylation. N-Linked glycosylation occurs by the transfer of a lipid-linked oligosaccharide species ($Glc_3Man_9GlcNAc_2$–PP–dolichol) to an asparagine residue on the newly synthesized polypeptide chain. The oligosaccharide is trimmed by two glycosidases and one or more mannosidases in the endoplasmic reticulum and the protein is then translocated to the Golgi apparatus where it undergoes further modification of oligosaccharide chains and O-glycosylation, followed by packing and processing for secretion (Fig. 23.2).

N-Linked glycosylation and trimming also serves a quality control function and helps ensure proper folding. Monoglucosylated proteins (i.e., proteins with one terminal glucose remaining on the mannose core) are selectively bound by calnexin or calreticulin. This binding allows ERp57, a thiol-disulfide oxidoreductase, to bind to the glycoprotein and facilitate disulfide bond formation (19). Glycoproteins are released from calnexin and calreticulin by the action of glucosidase II which removes the terminal glucose from the glycan structure. If the glycoprotein is incorrectly folded, it is recognized by UDP-glucose:glycoprotein glucosyltransferase which adds a glucose back onto the glycan, allowing for another cycle of binding to calnexin/calreticulin to prevent misfolded proteins from leaving the ER.

23.2.2 O-Linked Glycosylation

The most common form of O-linked glycosylation is the mucin type which contains an α-glycosidic linkage between GalNAc (and sometimes GlcNAc) and the hydroxyl group of serine or threonine (Fig. 23.3). There is no clear consensus sequence for O-linked glycosylation; however, the serine or threonine acceptor amino acid appears to be preferentially surrounded by Ser, Thr, Pro, Ala, and Gly residues (7). O-Linked glycosylation of secreted proteins occurs in the Golgi apparatus, and hence is limited to residues present on the protein surface after the protein is completely folded in the ER. Currently, there are eight different core structures known to occur beyond the Ser/Thr-GlcNAc linkage (Fig. 23.3). There are a limited number of monosaccharides present in mucin-type glycans, namely GalNAc, Gal, GlcNAc, Fuc,

TABLE 23.1. Monosaccharide Nomenclature and Structures

	N-glycolylneuraminic acid	Neu5Gc		

[a]This symbol set represents the newly agreed upon symbols as established by the Consortium for Functional Glycomics and NLM/NCBI. See http://grtc.ucsd.edu/Essentials_Materials/EssentialsSymbols2ndEd.pdf for more information.

and sialic acid. Sulfation is also a frequent modification. In general, Glc and Man are not found in these structures. Biosynthesis occurs in a stepwise manner with individual nucleotide-activated monosaccharides added by site-specific glycosyltransferases. While the O-linked mucin structures are much more compact and generally smaller than the N-linked structures, they are also much more diverse. For example, human lung mucin contains more than 100 different glycans (7). A fairly common structure, particularly for cell surface glycoproteins, is the presence of many O-linked glycan in close proximity. These structures appear to serve both as passive and active barriers preventing proteolytic and infectious attacks.

23.2.3 Glucosylphosphatidylinositol (GPI) Anchors

GPI anchors are used to anchor surface membrane proteins to the cells in eukaryotes. They are particularly prevalent in mammalian cells and some parasitic protozoa, and are also found in other lower eukaryotes. Eisenhaber et al. (21) estimated by sequence analysis that ~0.5% of all eukaryotic proteins are GPI anchored. It is hypothesized that they allow the protein greater mobility than maintaining a transmembrane domain, but this has not been established. Proteins slated for GPI anchor attachment contain the usual amino-terminal signal sequence that directs them to the ER during synthesis. In addition, they contain a 15–30 amino acid signal sequence at the carboxy terminus. Like the amino terminal signal sequence, the amino acids are primarily hydrophobic. This signal sequence is cleaved when the GPI anchor is attached to the carboxy terminus of the resulting peptide. Three critical amino acids exist at the cleavage site, generally referred to as ω, $\omega+1$, and $\omega+2$. Cleavage occurs between the ω and $\omega+1$ amino acids and the ω amino acid becomes the carboxy terminus to which the GPI anchor is attached. The amino acid preference for the ω site is serine $\approx$ asparagine $>$ alanine $\approx$ glycine $\approx$ aspartate $>$ cysteine valine $\approx$ leucine. In the $\omega+1$ site, all amino acids are permitted except proline. At the $\omega+2$ site, the preference is alanine $\approx$ glycine $>$ serine $>$ threonine$>$ aspartate $>$ valine. (See Ref. 22 for a detailed review.)

The GPI moiety is synthesized on the cytoplasmic face of the ER and then translocated into the lumen. All GPI anchors appear to have a conserved core consisting of ethanolamine-phospho-6Manα 1-2Manα 1-6Manα 1-4GlnNα 1-6-myo-inositol-1-phospholipid. The lipid portion is very diverse and varies from species to species and within species (23). The GPI anchor is attached by the action of a GPI transamidase. This enzyme cleaves the peptide bond at the GPI anchor attachment site and creates an amide linkage between the ethanolamine of the GPI and the newly generated carboxyl group at the end of the cleaved precursor protein (24). The GPI-anchored protein is then sorted and transported to the cell membrane by a mechanism that is still unclear.

23.2.4 Other Less Common Forms of Glycosylation

In addition to the mucin form of O-glycosylation, a variety of other linkages exist between sugars and the hydroxyl groups of serine, threonine, hydroxylysine, and hydroxyproline. Xyl is β-linked to either Ser or Thr to link glycosaminoglycans (GAGs) to peptides to form proteoglycans. Epidermal growth factor (EGF)-like

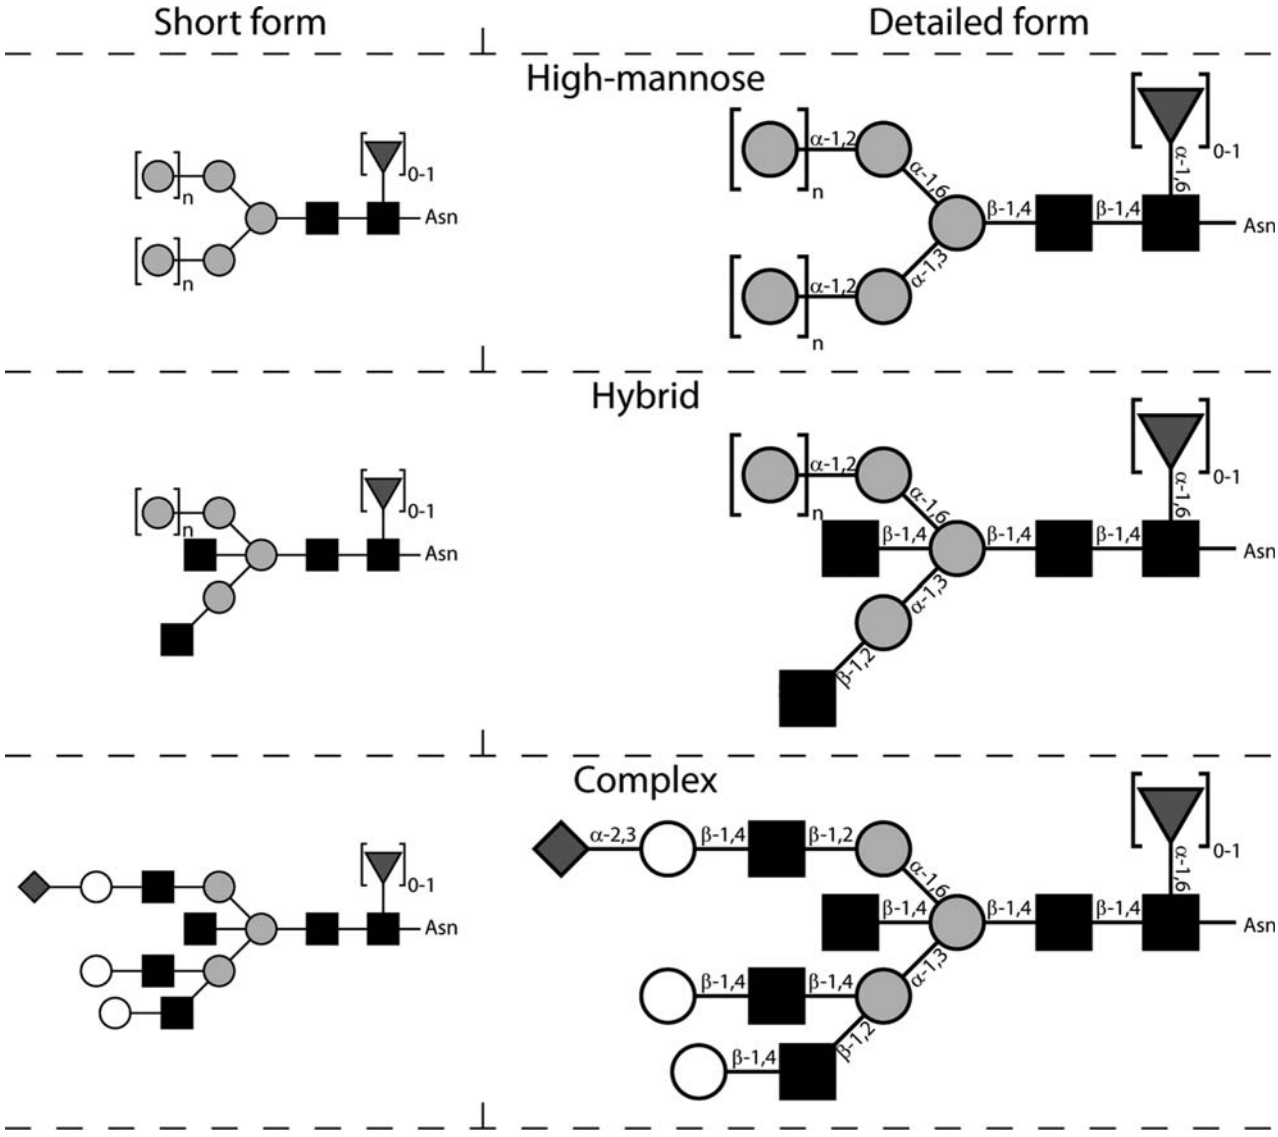

Figure 23.1. Overview of the three main types of *N*-glycans. The short form is an example of the notation described in Table 23.1.

domains of several proteins (including clotting factors) are modified by the addition of Glc or Fuc. Of particular interest is the addition of a single GlcNAc in a β-linkage to a variety of cytoplasmic and nuclear proteins. This modification is reversible and appears to serve a function similar to that of phosphorylation. Gal is bound in a β-linkage to hydroxylysine in collagen; yeast and other fungi exhibit Man α-linked to Ser/Thr, and a variety of other linkages are also seen (7,12). Some surprising linkages recently observed include a C–C bond between Man and Trp in human RNase 2 (7) and the discovery of phosphoglycosylation in which the oligosaccharides are linked to the peptide chain via a phosphodiester linkage (25).

23.3 EFFECTS OF GLYCOSYLATION ON PROTEINS

Protein glycosylation affects the structure, activity, immunogenicity, protease sensitivity, stability, and biological clearance of the glycoprotein. It also plays a role in protein trafficking and cell signaling. Our current understanding of these functions with specific examples, particularly for recombinant proteins produced in heterologous hosts, is described below.

23.3.1 Structure and Stability

Protein glycosylation affects protein structure in two ways. As the protein is glycosylated co-translationally,

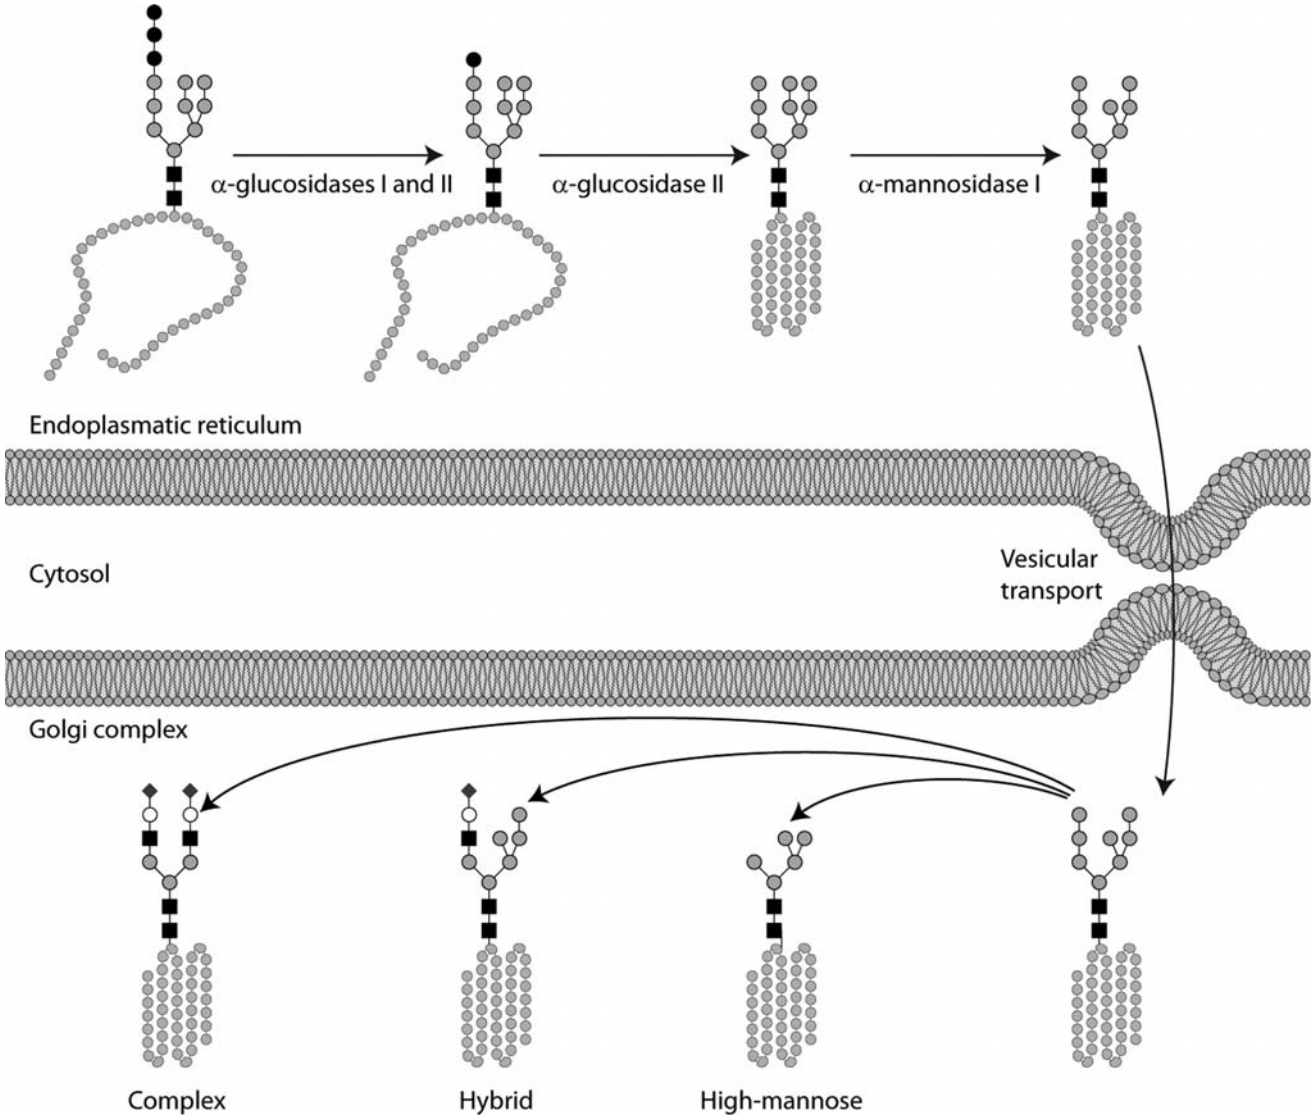

Figure 23.2. Schematic and simplified overview of the modification of *N*-glycans in the endoplasmatic reticulum and the Golgi complex, resulting in the three main types of N-glycosylation: high mannose (>3 mannose residues), hybrid (one antennae and >3 mannose residues), and complex (multiple antennae).

the presence or absence of the correct glycans can affect the nascent peptide's ability to fold correctly. When glycosylation is inhibited using tunicamycin or by removal of consensus sequences by mutagenesis, many proteins fail to fold correctly (26). The unfolded proteins aggregate soon after synthesis and are frequently bound noncovalently by BiP/GRP78, an ER chaperone. Frequently, the misfolded proteins are cross-linked by interchain disulfide bonds. The need for glycosylation varies dramatically with some proteins being unaffected and others very sensitive. In addition, it is sometimes possible to move the glycosylation site by site-directed mutagenesis and obtain correct folding, suggesting that oligosaccharides play a more global than local role in folding. In addition, as discussed above, the trimming of the N-linked glycans serves a quality control function in the ER. Incorrectly glycosylated and folded proteins are recycled for further processing. Ultimately, proteins that are incorrectly folded or glycosylated are targeted for degradation by the unfolded protein response (UPR).

Glycosylation enhances protein stability by a variety of mechanism. Wang and coworkers (27) examined five different glycoproteins, both in their native and deglycosylated forms. Deglycosylated proteins were less thermally stable and their thermal denaturation showed less reversibility than the native proteins. They found that the effect depended

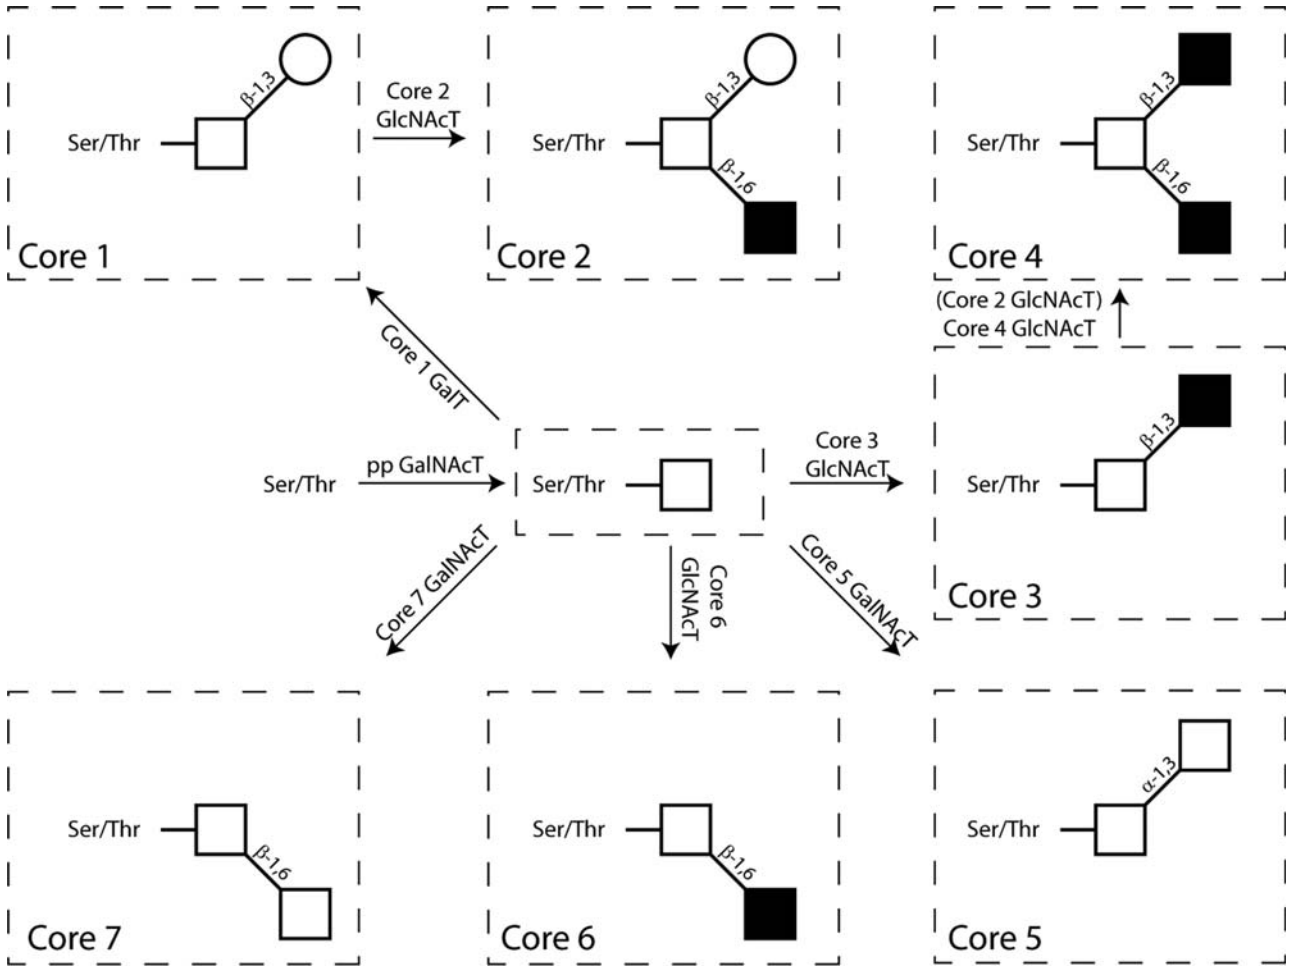

Figure 23.3. The seven core structures of mucin-like O-glycosylation found in humans. *Source:* Reproduced from information found in (20). GalNAc, *N*-acetylgalactosamine; GalNAcT, GalNAc transferase; GalT, Galactose transferase; GlcNAc, *N*-acetylglucosamine; GlcNAcT, GlcNAc transferase.

primarily on the amount of carbohydrate bound to the protein rather than the type of linkage. O'Connor and Imperiali (28) examined N-linked oligosaccharides attached to small peptides using NMR spectroscopy. They found that glycosylation causes the peptides to adopt more compact, folded conformations, particularly β-turns. Several investigators observed that glycosylated proteins had significantly less dynamic fluctuation, which appears to lead to increased stability (29).

23.3.2 Activity

Glycosylation can affect the activity of proteins using a variety of different mechanisms. The first mechanism is to alter the physiochemical properties including solubility and proper folding as described above (3). Alterations in glycosylation that affect protein folding are implicated in a number of diseases, including carbohydrate-deficient glycoprotein syndrome, cystic fibrosis, amyloid diseases such as Alzheimers, and lysosomal storage diseases such as Tay-Sachs (12). In addition, in a small, but significant number of cases, glycosylation can directly affect the biological activity of a correctly folded protein. Tissue plasminogen activator (t-PA), a serine protease produced recombinantly as an anti-thromobolytic, is one of the best known examples. t-PA contains four putative glycosylation sites, three of which are occupied (Asn-117, Asn-184, and Asn-448). It naturally occurs in two major molecular species, type I (glycosylated at all three sites) and type 2 (glycosylated only at Asn-117 and Asn-448). It is synthesized in a one-chain form and subsequently undergoes proteolytic cleavage by plasmin to a two-chain form. The occupancy of the Asn-184 site has been shown to affect the glycan structure at the Asn-448 site, the rate of conversion to the two-chain (more active) form, the affinity of t-PA for fibrin, and the fibrinolytic activity (16).

Similar effects were observed for both plasminogen and ribonuclease.

Hormone and receptor activities are also affected by their glycosylation. A number of glycoprotein hormones which activate adenylate cyclase exhibited drastically reduced activity on deglycosylation. In the case of hCG, the ability of the hormone to bind to its receptor was not inhibited; however, its ability to activate the signal transduction cascade was significantly impaired (3). Glycosylated receptors exhibited a variety of responses to changes in glycosylation. Leutenizing hormone receptor has six potential glycosylation sites; site-directed mutagenesis of three of them substantially decreased binding, while mutation of the other three sites had no effect.

23.3.3 Immunogenicity and Biological Clearance

Glycosylation plays a significant role in both immunogenicity and the rate of biological clearance both by the immune system and by the liver. Carbohydrate epitopes are responsible for blood-type determinants, indicating that even between humans, there is significant immune recognition based on carbohydrates. Moreover, close to half of the monoclonal antibodies (mAbs) generated against animal cells or cell membranes are directed against glycan groups. Plant glycoproteins are highly immunogenic, particularly because of the presence of xylose or an α-1,3-linked fucose (3). Many mammalian species, but not humans, contain a nonreducing terminal Galα 1-3Gal linkage. Antibodies against this epitope are present in all human sera and are the major reason for rejection of xenotransplants (30). Patients with rheumatoid arthritis, an autoimmune disease, exhibit a significant increase in serum IgG (immunoglobulin G) that is deficient in galactose and terminal *N*-acetylglucosamine. It is hypothesized that this alteration in glycosylation could lead to conformational changes in the Fc region of the immunoglobulin, creating new antigenic sites, leading to the autoimmune response (3). Of particular concern in the production of recombinant glycoproteins is the possible introduction of antigenic domains that could lead to severe allergic or immune responses.

Many recombinant glycoproteins exhibit rapid clearance, requiring frequent dosing to maintain biological activity. Desialylated glycoproteins are rapidly cleared by the liver via the hepatic asialoglycoprotein receptor, indicating that it is critical to maintain proper sialylation for recombinant proteins. Weikert et al. at Genetech demonstrated that overexpression of galactosyltransferase and sialyltransferase in Chinese hamster ovary (CHO) cells producing recombinant glycoproteins led to an increase in terminal sialylation with a resulting increase in mean residence time in a rabbit model (31). Insect cells have also been engineered to improve sialylation of recombinant proteins produced in insect cells, although the levels are still relatively low (32). Recently, significant efforts have been employed to glycoengineer recombinant proteins to improve their biological half-lives. Elliot et al. at Amgen demonstrated that recombinant human erythropoietin could be engineered to contain additional N-glycosylation consensus sequences. The engineered proteins were shown to contain an increase in N-linked glycans and molecules could be selected which maintained *in vitro* activity and receptor binding and showed increased *in vivo* activity because of decreased clearance rates (33).

23.4 TECHNIQUES FOR ANALYZING GLYCOPROTEINS, GLYCOPEPTIDES, AND THEIR ATTACHED GLYCANS

There are two major issues in characterizing the glycan structures on glycoproteins. One is referred to as *macroheterogeneity*, in which some glycosylation sites on glycoproteins are variably occupied and the other is referred to as *microheterogeneity*, in which glycan structures at each glycosylation site vary even with the same backbone peptide sequence. There are two possible approaches to characterization of glycans, analysis of the glycans while still attached to the peptide or hydrolysis and analysis of the released glycans. Since the amount of glycan and glycoprotein samples available is often limited, characterization of the glycan structures and the site occupancy simultaneously with the same sample (site-specific glycan analysis) conserves material and provides information about macroheterogeneity (i.e., variable site occupancy). While liquid chromatography/mass spectrometry (LC–MS) is well equipped to perform this characterization and is currently widely used to analyze glycan structures with the improved detection limits of MS technology (34,35), it is still unable to identify isomers that have identical masses. In this section, we first discuss techniques for analysis of intact glycoproteins and glycopeptides, and then discuss techniques for analysis of glycans that have been chemically or enzymatically removed from the peptide backbone. In the last several years, substantial advances have been made in both chromatography and mass spectrometry and, more importantly, in combining the two techniques that have permitted better assignments of glycan structures and assignments of structures at particular glycosylation sites (36–45).

23.4.1 Techniques for Characterizing Intact Glycoproteins and Glycopeptides

23.4.1.1 Lectin Affinity Capture. Lectins are plant proteins that specifically recognize a variety of glycan

structures. Lectins can have fairly narrow or very broad specificities, allowing them to be used for different applications. For example, concanavalin A (con A) has a broad specificity for high-mannose N-linked oligosaccharides and will also bind hybrid-type *N*-glycans and to a lesser extent bi-antennary complex glycans. It will not bind complex glycans with additional branches. In contrast, Sambucus Nigra lectin (SNA) binds specifically to glycans with terminal sialic acids, preferentially those attached to a terminal galactose in (α-2,6) linkage although to a lesser degree those attached with an (α-2,3), linkage. SNA lectin does not appear to bind sialic acid linked to *N*-acetylgalactosamine. Lectins with broad specificity can be used to chromatographically select a wide variety of glycosylated proteins or peptides from mixture of non-glycosylated and glycosylated proteins or peptides in a method termed *glyco-catch* (46). Alternatively, a lectin or a series of lectins with narrow specificity can be used to selectively capture glycoproteins with a particular glycan form, termed *serial lectin affinity chromatography* (47). More recently, these tools have been employed in conjunction with proteomic studies (e.g., mass spectrometry) to characterize glycans and glycoproteins (48,49).

23.4.1.2 LC–MS of Glycopeptides. The most common enzyme for generating glycopeptides for LC–MS analysis is trypsin. Trypsin is a serine endopeptidase, which specifically cleaves peptide bonds C-terminal to arginine or lysine. Depending on the glycoproteins that are to be characterized, other proteolytic enzymes such as chymotrypsin, Lysine C, and Glu-C can also be used. Sometimes, a combination of two or more enzymes is used to generate the appropriate size or sequence of peptides to facilitate the chromatographic separation of peptides.

In LC–MS analysis of tryptic peptides, there are three main steps. First, glycopeptides are generated with trypsin (usually modified trypsin to minimize autolysis of trypsin) after reduction and carboxymethylation of disulfide bonds (50). The peptide/glycopeptide mixtures generated with trypsin are then separated by HPLC on a hydrophobic column (often C_{18}). Usually, glycopeptides elute earlier than peptides because of the hydrophilic effect of the sugar moiety. In 2005, Wuhrer and coworkers reported using a hydrophilic column for separating and site-specifically characterizing glycopeptides (51), and this method has been increasingly used for analysis of both glycopeptides (37,42) and glycans (36,39). Finally, the glycopeptides in the peptide/glycopeptide mixtures are detected and the glycans are site-specifically characterized using mass spectrometry. Glycopeptides can be identified from among the peptide/glycopeptide mixtures by monitoring glycopeptide precursor ions such as *m*/*z* 204 ($HexNAc^+$), 274 ($[NeuAc-H_2O]^+$), 292 ($NeuAc^+$), and 366 ($Hex\text{-}Hex\text{-}NAc^+$) (52–56). Alternatively, chromatography can be used to enrich the sample for glycopeptides before mass spectrometry analysis (37,40). Depending on the properties of the samples, different types of mass spectrometry (nano-electrospray ionization MS, MALDI-TOF MS (matrix-assisted laser desorption/ionization time-of-flight mass spectrometry), etc.) can be used. With state-of-the-art LC–MS equipment, mass spectrometry can usually provide data-dependent multistage MS (MS^n), which can generate the fragments of oligosaccharides and peptides. This fragment information can be used to confirm the glycosylation site (peptide sequences) and the glycan structures and glycosidic linkages. This feature can be more powerful if combined with a method such as nano-electrospray ionization MS which consumes a very small fraction of samples (57). This significantly reduces the labor-intensive work and costs for characterizing glycans by eliminating extensive purification and other laborious tasks such as exoglycosidase digestion used in the conventional methods. As an example, Ivancic and coworkers recently used LC–MS to characterize α_1-acid glycoprotein (AAG). AAG has five N-linked glycosylation sites, each varying in its glycan structure. By using a high-low cone voltage switch during the analysis of the tryptic peptides, they were able to alternate between carbohydrate fragmentation for structural analysis (high voltage) and maintaining an intact oligosaccharide on the glycopeptide (low voltage) to determine the mass of each glycan structure (41). A similar approach was used to characterize a biosimilar mAb and compare the biosimilar with the innovator molecule (58).

One of the limitations of trypsin is that it is often unable to effectively cleave near a glycosylation site, presumably because of steric hinderance. To address this issue, several new approaches have been proposed. Segu and coworkers (59) explored the use of microwave-assisted digestion and found that the rate of tryptic cleavage (and, in general, the efficiency) could be substantially improved by microwave heating. Zauner and colleagues (42) reported the use of proteinase K, which leads to much smaller fragments improving mass spectral analysis.

23.4.1.3 Identification of Glycosylation Sites. Identification of glycosylation sites generally depends on enzymatic or chemical cleavage of the protein chain, separation of the resulting peptides and glycopeptides by reversed-phase HPLC, and detection by mass spectrometry (60).

The peptide fragments must be separated to identify the potential glycosylation sites because the analysis of unseparated enzymatic digests, commonly used for protein identification, cannot be used reliably since the glycopeptides may be discriminated against both because of their size and charge; sialic acid, phosphorylation and sulfation

may all introduce partial negative charges. In addition, glycopeptides are usually present in substoichiometric quantities because of the carbohydrate heterogeneity at any given site (61).

Glycopeptides are usually separated by HPLC on a hydrophobic column (C_{18}-reversed-phase HPLC), but either hydrophilic columns or capillary electrophoresis (CE) can also be used. Glycopeptides on the chromatogram can be identified by running the (partially) deglycosylated peptide mixtures and identifying the peak shifts (34,62). Enzymatic release of *N*-glycans using the endoglycosidase peptide *N*-glycanase (PNGase) F from the glycopeptides increases the mass by 1 Da by converting the asparagine residues at the glycosylation sites to aspartic acid residues. This 1 Da mass increase can be detected using MALDI-TOF MS, leading to the identification of glycosylation sites. If the incubation is performed in water containing $H_2^{18}O$, the labeled oxygen is incorporated into the aspartic acid resulting in doublet peaks separated by two mass units in mass spectra, further improving the detection (60). PNGase A can be used to release oligosaccharides containing α1,3-linked core fucose that is resistant to PNGase F digestion. *endo*-β-*N*-Acetylglucosaminidases D, F1, F2, F3, and H that cleave between the core GlcNAc residues can also be employed. Since the resulting peptides still bear an GlcNAc unit, the molecular mass observed after digestion should be higher than the predicted mass by 203 Da per glycosylation site for any given sequence stretch.

Site-specific information (site occupancy) can be characterized using glycopeptide mixtures. Proteolysis of glycoproteins is usually achieved with trypsin following reduction and alkylation of the proteins. The common method for the analysis of site occupancy is separating the glycopeptide mixtures on reversed-phase HPLC and analyzing the separated peptide masses on-line or off-line using mass spectrometry (LC–ESI MS, ESI-QqTOF MS, hybrid Q linear ion trap (LIT) MS, ESI-Q-TOF MS, and MALDI-TOF MS, etc.) This method can generate enough information to confirm the glycosylation sites (peptide sequence) and glycan structures (glycan fragments). In on-line LC–MS, glycopeptides eluting from HPLC can be identified by the appearance of oxonium ions such as *m*/*z* 204 ($HexNAc^+$), 274 ($[NeuAc\text{-}H_2O]^+$), 163 (hexose), 292 ($NeuAc^+$ sialic acid) or 366 ($Hex\text{-}Hex\text{-}NAc^+$) that appear at high source-orifice potential (selected ion monitoring method) (55). In the case of triple quadrupole MS (QqTOF, hybrid-Q-LIT LC–MS etc.), the oxonium marker ions can be more efficiently identified through collision induced dissociation cells (precursor ion scanning method) (53). In the precursor ion scanning method, the second quadrupole is set to pass the oxonium ion of interest and the first is scanned. Only compounds that fragment to produce the selected oxonium ion can be identified. Collision induced dissociation (CID) fragments reveal the identity of glycopeptides, as well as yield information on the carbohydrate structure (63). In MS^2 (MS/MS) of CID, fragments are rich in b-type oxonium ions of the nonreducing end of oligosaccharides (64) or y-type ions with peptides. These fragment information can be reconstructed to infer the oligosaccharide sequences. MS^3 of CID produces the extensive peptide bond cleavages that confirm the amino acid sequence of the peptides and thereby the glycosylation sites (65). The use of alternative fragmentation technologies such as electron capture dissociation (ECD) (66–68) and electron transfer dissociation (ETD) (69) provides for fragmentation of the peptide backbone, giving additional information about the sites of modification.

O-Linked glycans are not as amenable to these techniques because they are often grouped on adjacent or closely spaced amino acids, and it is not possible to acquire glycopeptides containing a single glycan from a known position of the protein chain. However, MS/MS spectrometry can provide some information as the masses of the b and y ions from the protein chain sometimes yield information on the location of glycosylation, but usually only when one site is occupied (70). The alternative fragmentation strategies, ECD and ETD, described above have also been employed to improve analysis of O-linked glycans (71,72).

23.4.2 Techniques for Deglycosylation

Among major protein glycosylation forms, N-linked and O-linked glycans have major impact on the proteins and have been extensively studied. In this section, the major techniques for releasing N- and O-linked glycans from glycoproteins are discussed. There are broadly two methods to release the glycans from the glycoproteins.

23.4.2.1 Chemical Methods. In order to release glycans, a general method is required that is independent of the protein to which the glycan is attached. For this reason a chemical method is used, which usually involves the use of hydrazine to cleave both N- and O-glycosidic bonds (73) (Fig. 23.4). Hydrazine releases both N- and O-linked glycans by cleavage of all peptide bonds in the glycoprotein. O-Linked glycans are released at 60°C, whereas incubation at 95°C is needed to release the N-linked sugars. The major advantages of the chemical method are that it releases glycans that are intact and with a free reducing terminus, it is nonselective (with respect to the glycans), and the process is amenable to automation (74). However, because all peptide bonds are destroyed in this method, all information related to the glycosylation sites on the proteins is lost. The acyl groups are cleaved from the *N*-acetylamino sugars and sialic acids and are normally

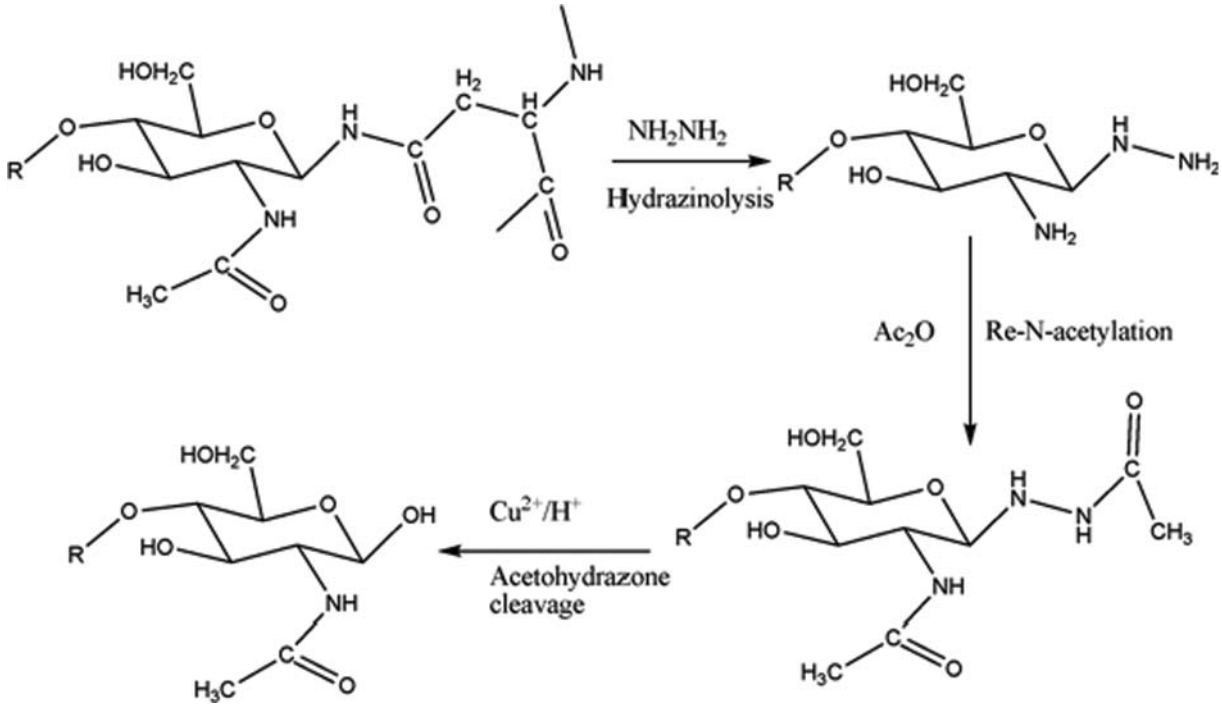

Figure 23.4. Hydrazine-based cleavage of glycosidic bonds.

replaced chemically (Fig. 23.4), with the assumption that they were originally acetylated, which is not always true, as with *N*-glycolylneuraminic acids (60). If the hydrazinolysis conditions are too harsh, some *N*-acetylamino groups or terminal GlcNAc residues can be removed (75).

O-Linked glycans are traditionally detached from the protein by β-elimination using strong bases such as sodium hydroxide or hydrazine (73). Recently, Yamada and colleagues have developed an automated method for releasing *O*-glycans coupled with MALDI-TOF MS to improve the speed and efficiency of *O*-glycan analysis (76).

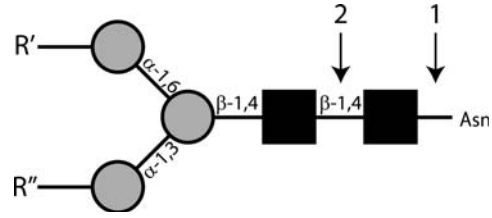

Figure 23.5. Common *N*-glycan cleavage sites on enzymatic treatment for glycan sequencing. Peptide *N*-glycanase (PNGase) F cleaves the glycan at the arrow marked with 1, whereas Endo D and H cleave at 2.

23.4.2.2 Enzymatic Methods. The most common enzyme for releasing N-linked glycans from glycoproteins is the peptide PNGase F, which is an amidase that cleaves between the innermost GlcNAc and the asparagine residue (Fig. 23.5, arrow 1). PNGase F hydrolyzes nearly all types of N-glycan chains except the ones containing fucose α-1-3-linked to the reducing-terminal GlcNAc from glycopeptides/proteins. In this case, PNGase A can cleave N-linked glycans containing α-1-3-linked core fucose.

Other useful enzymes are Endo D and H, which cleave between the two acetylglucosamine residues within the chitobiose (Fig. 23.5, arrow 2). Endo D releases all kinds of N-linked glycans while Endo H is limited to high-mannose- or hybrid-type N-linked glycans. Endo-β-*N*-acetylglucosaminidases F1, F2, and F3 are also often used. All three enzymes cleave within the chitobiose core (Fig. 23.5, arrow 2). While Endo F1 cleaves only oligomannose and hybrid glycans, Endo F2 cleaves oligomannose and bioantennary glycans, and Endo F3 is specific for bi- and triantennary *N*-glycans (77). Recently, Segu et al. (78) used PNGase F, Endo M, and a combination of Endo M and exoglycosidases on tryptic digests of fetuin in conjunction with LC–MS/MS to identify glycosylation sites and core fucosylation of bovine fetuin.

In contrast to the release of N-linked glycans, there are no universal *O*-glycans due to the lack of universal consensus sequence for O-linked glycans. Thus, enzymatic release of *O*-glycans from glycoproteins is limited by the high substrate specificity of *O*-glycosidases available (20,79). For example, the *endo*-GalNAcase D from *Diplococcus*

TABLE 23.2. Glycoprotein Oligosaccharide-Releasing Enzymes[a]

Enzyme	Source	Susceptible *N*-glycans
Endo D	*Diplococcus pneumoniae*	Some high mannose Some (few) hybrids
Endo H	*Streptomyces plicatus*	High mannose Most hybrids
Endo C_I	*Clostridium perfringens*	Similar to endo D
Endo C_{II}	*Clostridium perfringens*	Similar to endo H (narrower)
Endo F_1	*Flavobacterium meningosepticum*	Similar to endo H (narrower)
Endo F_2	*Flavobacterium meningosepticum*	High mannose Biantennary complex
Endo F_3	*Flavobacterium meningosepticum*	Biantennary complex Triantennary complex
Endoglycosidase	*Arthrobacter protophormiae*	Similar to endo C_{II}
Endoglycosidase	*Bacillus circulans*	High mannose
Endoglycosidase	*Bacillus alvei*	Similar to endo C_{II}
Endo S	*Dictyostelium discoideum*	Similar to endo C_{II}
Endo M	*Mucor hiemalis*	Similar to endo F_2
Endo B	*Sporotrichum dimorphosporum*	Similar to endo F_2
Endoglycosidase	*Aspergillus oryzae*	Similar to endo H
Endoglycosidase	Jack bean	Similar to endo C_{II}
Endoglycosidase	Human kidney (enzyme 1)	Mostly high mannose
Endoglycosidase	Human kidney (enzyme 2)	High mannose and complex (free oligosaccharides only)
Endoglycosidase	Rat liver	Similar to endo F_2
Glycoamidase A	Almond	Similar to Glycoamidase F
Glycoamidase F	*Flavobacterium meningosepticum*	All N-linked (except 1,3-core Fuc)
Glycoamidase	Jack bean	Similar to glycoamidase F
EndoGalNAcase D	*Diplococcus*	Gal-β-1,3-GalNAc only
EndoGalNAcase A	*Alcaligenes*	Gal-β-1,3-GalNAc only
EndoGalNAcase S	*Streptomyces*	Gal-β-1,3-GalNAc (plus larger structures)

pneumoniae cleaves only the disaccharide Gal β1-3GalNAc (20). Major glycan-releasing enzymes, their sources, and usages are summarized in Table 23.2 (80).

23.4.3 Strategies for Analysis and Characterization of Glycans

There are many strategies available for the analysis and characterization of released glycans from glycoproteins. The choice of methods or strategies depends on the properties of samples that are analyzed and information that is needed. A combination of the methods described below is often used to fully characterize the glycan structures on the glycoproteins.

23.4.3.1 Mass Spectrometry. Mass spectrometry has played a critical role in characterizing the glycan structures from glycoproteins. The most common mass spectrometry sources for ionization of oligosaccharides are either matrix-assisted laser desorption/ionization (MALDI) or electrospray ionization (ESI). A variety of detectors are combined with these ion sources. Popular combinations of ion sources and detectors for characterization of oligosaccharides are MALDI-time of flight (TOF), ESI-quadrupole ion trap (QIT), hybrid-Q-LIT MS, and ESI-Q-TOF MS, often connected to an HPLC on-line.

MALDI-TOF MS is the most commonly used mass spectrometry technique for characterizing sugar structures. The analysis of N-linked glycans and, to a lesser extent, O-linked glycans from glycoproteins is the area in which MALDI MS has had the most impact on carbohydrate analysis (60). The advantages of MALDI-TOF MS in characterization of glycans are that the mass spectra are relatively easy to interpret because most peaks represent singly charged species; hence, there is no need to deconvolute the mass spectra. In addition, to a certain extent, MALDI-TOF tolerates contaminants in the sugar samples, and it requires a very small amount of sample, unlike ESI MS. However, the automation is difficult; thus, it is most often used off-line.

The most critical part in MALDI-TOF MS for the study of glycans is to choose the right matrix for the samples. 2,5-DHB (dihydroxybenzoic acid) is the most popular matrix for the analysis of free carbohydrates (81). $[M + Na]^+$ ions are the dominant products in the positive ion mode. $[M\text{-}H]^-$ ions are the dominant form in the negative ion mode. When a 2,5-DHB sample solution evaporates, DHB tends to crystallize from the periphery of the target spot in the form of long needles that point toward the centre of the target. To overcome this problem, Super-DHB matrix (10% 2-hydroxy-5-methoxybenzoic acid added to DHB) was introduced (82). This matrix crystallizes more evenly than DHB and has been reported to enhance signal strength and resolution (48). 2,4,6-THAP (trihydroxyacetophenone) has been reported to effectively ionize sialylated glycans in negative ion mode (83) with

less loss of sialic acid during fragmentation than when DHB is used as the matrix. In addition to these matrices, 4-HCCA (α-cyano-4-hydroxy-cinnamic acid) and HABA (2-(*p*-hydroxyphenylazo)-benzoic acid) are also often used (60).

Derivatization of free oligosaccharides can increase the detection sensitivity and stability, simplifying the fragments in MALDI-TOF MS analysis. Thus, in certain cases, it can be advantageous to analyze derivatized sugars. Depending on the sample size, permethylation (>5μg) with methyl iodide or methyl esterification (<5μg) can be performed (84), and they can improve the sensitivity by about an order of magnitude. Reducing sugars are also often derivatized at their reducing end with chromophores or fluorophores, usually by reductive amination.

The composition of oligosaccharides can be inferred on the basis of the masses on the mass spectra. One of the popular web-based software tools for inferring the composition of glycans is GlycoMod. GlycoMod (http://www.expasy.ch/tools/glycomod/) is a software tool designed to find all possible compositions of glycan structures from their experimentally determined masses. The program can be used to predict the composition of any glycoprotein-derived oligosaccharide comprising either underivatized, methylated, or acetylated monosaccharides, or oligosaccharides with a derivatized reducing terminus (85). A typical mass spectrum of N-linked glycans isolated from secreted alkaline phosphatase (SEAP) produced by CHO cells is shown in Fig. 23.6; the glycan assignments made by GlycoMod are given in Table 23.3.

LC–MS/MS techniques with ESI have been increasingly employed in the analysis of glycans (36); the use of CID allows for identification of structures that cannot be elucidated with MALDI-TOF.

23.4.3.2 Chromatographic Profiling. A variety of chromatographic techniques can be used to separate and characterize glycans after release from the protein or peptide backbones. While individual techniques are useful, they are particularly powerful when combined in series as described in the section titled "Multidimensional Liquid Chromatography." With the exception of pulsed amperometric detection (PAD) which is generally applied with anion exchange chromatography, glycans separated chromatographically are most commonly detected by fluorescence labeling as described in the section titled "Detection Methods for Chromatography and Capillary Electrophoresis."

23.4.3.2.1 Anion Exchange Chromatography. High pH-weak anion exchange chromatography (HPAEC) is employed to separate glycans based on the number of

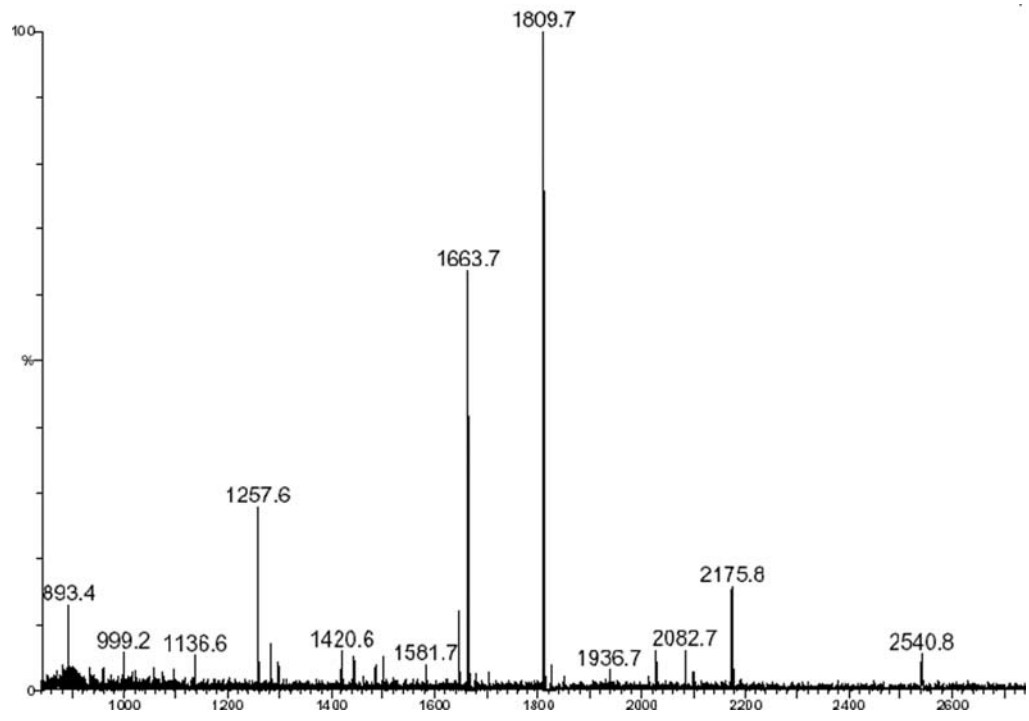

Figure 23.6. A typical mass spectrum of N-linked glycans isolated from secreted alkaline phosphatase (SEAP) produced by Chinese hamster ovary (CHO) cells. See Table 23.3 for the assignment of glycans to masses.

TABLE 23.3. GlycoMod Analysis of *N*-Glycan Compositions for Secreted Alkaline Phosphatase Produced in CHO Cells

			Positive Ion Mode
No.	Observed $m/z^{ab}[M + Na]^+$	Calculated $m/z^{a}[M + Na]^+$	Composition/Sequence
1	1257.6	1257.4	(Hex)2+(Man)3(GlcNAc)2
2	1282.6	1282.5	(HexNAc)1(Deoxyhexose)1+(Man)3(GlcNAc)2
3	1298.6	1298.4	(Hex)1(HexNAc)1+(Man)3(GlcNAc)2
4	1420.6	1419.5	(Hex)3+(Man)3(GlcNAc)2
5	1444.6	1444.5	(Hex)1(HexNAc)1(Deoxyhexose)1+(Man)3(GlcNAc)2
6	1460.7	1460.5	(Hex)2(HexNAc)1+(Man)3(GlcNAc)2
7	1485.6	1485.5	(HexNAc)2(Deoxyhexose)1+(Man)3(GlcNAc)2
8	1501.7	1501.5	(Hex)1(HexNAc)2+(Man)3(GlcNAc)2
9	1581.7	1581.5	(Hex)4+(Man)3(GlcNAc)2
10	1647.7	1647.6	(Hex)1(HexNAc)2(Deoxyhexose)1+(Man)3(GlcNAc)2
11	1663.7	1663.6	(Hex)2(HexNAc)2+(Man)3(GlcNAc)2
12	1809.7	1809.6	(Hex)2(HexNAc)2(Deoxyhexose)1+(Man)3(GlcNAc)2
13	1825.7	1825.6	(Hex)3(HexNAc)2+(Man)3(GlcNAc)2
14	2028.8	2028.7	(Hex)3(HexNAc)3+(Man)3(GlcNAc)2
15	2175.8	2174.8	(Hex)3(HexNAc)3(Deoxyhexose)1+(Man)3(GlcNAc)2
16	2540.8	2539.9	(Hex)4(HexNAc)4(Deoxyhexose)1+(Man)3(GlcNAc)2

[b] Some low-intensity peaks are not labeled in the mass spectrum (Fig. 23.6)

charged groups such as sialic acid, sulfate, phosphate, or uronic acid present on the glycan. Within the same charge group, large structures elute before small ones. In HPAEC, the column resin is a MicroBead pellicular resin in which small anion-exchange resin spheres are ionically attached to a larger cation-exchange resin sphere (86). The mobile phase is highly alkaline (e.g., 100 mM sodium hydroxide) often coupled with a gradient of sodium acetate. Anion exchange chromatography is frequently coupled with PAD which gives picomole (or lower) sensitivity without the need for derivatization. One limitation of PAD is that it gives a different response for each compound, making it difficult to compare quantities of different glycans within a sample. Recently, HPAEC has been employed with a capillary-scale column and both on-line PAD and on-line electrospray ion trap mass spectrometry (IT-MS), providing subpicomole sensitivity and the ability to characterize complex samples (87).

23.4.3.2.2 Reversed-Phase Chromatography. In addition to its application for separating glycopeptides, reversed-phase chromatography can also be applied to the separation of glycans. C-18 silica resins are most commonly employed (88); more recently, graphitized carbon has also been used (89). Underivatized oligosaccharides are generally separated with pure water in the mobile phase while gradient separations with increasing concentrations of organic solvents in the eluent are typically performed for derivatized glycans. The most common derivatization is reductive amination with fluorophores or chromophores as described in the section titled "Detection Methods for Chromatography and Capillary Electrophoresis."

23.4.3.2.3 Hydrophilic-Interaction Liquid Chromatography. Hydrophillic-interaction liquid chromatography (also known as *normal-phase chromatography*) is used to separate highly polar compounds and has been increasingly used to separate both glycopeptides and released glycans (39). In general, the retention of the glycans increases with increasing numbers of sugar residues. One of its main advantages is the ability to separate different structural isomers (38). Amide functional groups, using aminopropyl silica, are commonly employed as the stationary phase. The mobile phase usually consists of acetonitrile and water, although buffer salts are sometimes added. A recent modification, using zwitterionic sulfobetaine (ZIC-HILIC) functionality, has been used to separate sialylated glycans and glycopeptides as well as non-sialylated glycans from mAbs. This separation has been combined with ESI MS to characterize the glycans removed from mAbs (36).

23.4.3.2.4 Multidimensional Liquid Chromatography. Takahashi (90) have used sequential chromatographic steps to perform 2D and 3D mapping of neutral and charged oligosaccharides, respectively. In both cases, the glycans are derivatized with 2-aminopyridine (2-PA) before separation. Neutral glycans are separated initially by normal-phase chromatography on an amide column. As described in the section titled "Chromatographic Profiling," this separation is based primarily on glycan size. Each fraction is then subjected to reverse-phase chromatography on an octadecylsilica (ODS, C-18) column. The C-18 column provides separation based on the fine structure of the glycan. Each column can be calibrated with isomaltooligosaccharide mixtures to give a retention time in glucose units. The retention times of each

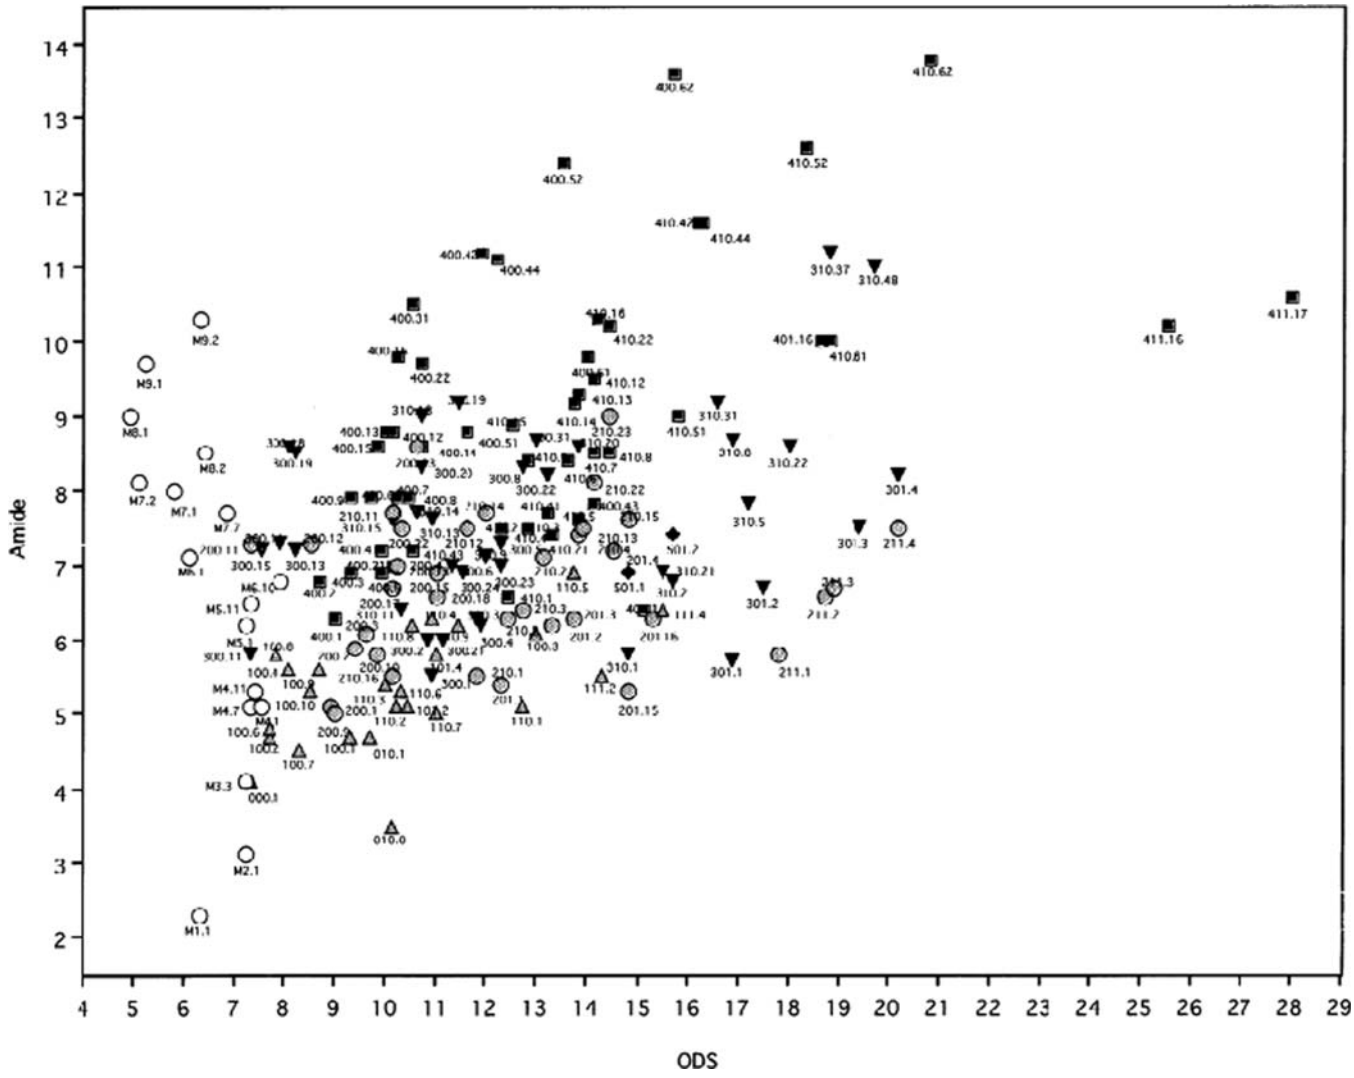

Figure 23.7. 2D plot of glycan liquid chromatography retention times. Retention time on a C-18 column versus retention time on an amide column. ***Source:*** Data originally from http://www.gak.co.jp/ECD/Hpg_eng/hpg_eng.htm. Symbols represent different types of *N*-glycans: (◯) high-mannose type, ( ) core and monoantennary, (◯) biantennary, ( ) triantennary, ( ) tetraantennary, and ( ) pentaantennary. glycan on both columns can then be represented in a 2D plot as shown in Fig. 23.7. For charged oligosaccharides, an initial separation is performed on a diethylamino-ethyl (DEAE) ion exchange resin to separate the neutral, mono, di-, tri-, and tetrasialyated sugars. Each charge group is then applied to the C-18 column, followed by the amide column, generating a series of 2D plots. By mapping known glycans, reference plots can be obtained and applied to identify mixtures of unknown glycans. In the case of glycans that do not correspond to a known position on the retention map, sequential digestion with glycosidases as described in the section titled "Sequential Enzymatic Digestion" can be applied to reduce the unknown structure to a common core structure. Gillmeister and coworkers have developed a modification of these 2D chromatographic analyses combined with automated sample spotting onto plates for conventional MALDI MS analysis that allows them to process a large number of very small samples ($<100\mu g$) rapidly. They have applied this approach to characterize the effects of culture conditions on the glycan profile of a recombinant therapeutic protein produced in CHO cells (91).

23.4.3.2.5 Frontal Affinity Chromatography. Frontal affinity chromatography (FAC) is a quantitative affinity method developed by Kasai and Ishii, which can accurately determine affinity constants between various biomolecules. To apply this method, an excess volume of an analyte (e.g., a glycan) is applied to a column on which an affinity ligand (e.g., a lectin) is immobilized. By comparing the volume of the elution front of an analyte that has no affinity for the ligand with the elution front of an analyte that binds to the ligand, the dissociation constant can be determined. Hirabayashi and Kasai have suggested that this method could be used for glycomics (i.e., the study of glycan structures from an organism or cell line) using a large number of lectins to probe various elements of glycan structures (46).

23.4.3.3 Capillary Electrophoresis. CE is a high-resolution analytical technique that has been widely used for the separation of oligosaccharides. It consumes an extremely small amount of sample and is capable of rapid, high-resolution separation, characterization, and quantitation of analyses. CE separates analytes under the influence of an applied electrical field as they migrate in a narrow capillary column spanning two buffer reservoirs and filled with a conducting buffer solution (92). The capillary column is made of fused silica, and invariably carries a negative charge on its inner surface because of the presence of silanol groups. At high voltage, the positive buffer ions migrate toward the cathode, and a narrow capillary provides a flat flow profile due to electro-osmotic flow. The electro-osmotic flow affects the mobility of analytes through the capillary. Separation is optimized by manipulating this flow, for example, by changing the pH of the operating buffer (93).

Normal-polarity mode is the most common mode of separation by CE. In normal polarity, the sample is injected at the anode and detected at the cathode and basic or neutral buffer is required. The normal polarity separation in basic borate buffer containing sodium dodecyl sulfate gives the best separation of mixtures of higher oligosaccharides (93). In reversed-polarity mode, the sample is applied at the cathode and detected at the anode, and an acidic buffer is required. This mode was successfully used for analysis of a variety of GAG-derived oligosaccharides (94). The resolution achieved by CE under a given set of conditions is dependent mainly on the charge, mass, and molecular mobility of the analytes present (93).

23.4.3.4 Detection Methods for Chromatography and Capillary Electrophoresis. Detection is typically performed by ultraviolet absorbance or fluorescence emission, although mass spectrometry is sometimes employed.

23.4.3.4.1 Derivatization and Fluorescent/UV Detection. Derivatization not only provides a useful method for sensitive detection by fluorescence and/or UV but also improves resolution of separation, through the introduction of charge and the alteration of the analyte. The most frequently used method for the derivatization of carbohydrates is reductive amination. The reductive amination reaction takes place between the aldehyde group at the reducing end of the sugar and the amino group of a labeling reagent employing sodium cyanoborohydride as a reductant. A number of labeling reagents have been used including 2-AP, 4-aminobenzoic acid (4-AB), 7-amino-1,3-naphthalenedisulfonic acid (AGA), 8-amino-naphthalene-1,3,6-trisulfonic acid (ANTS), and 1-phenyl-3-methyl-5-pyrazolone (PMP) (93). The various labeling agents and their detection wavelengths are summarized in Table 23.4.

23.4.3.4.2 Direct UV Detection Following Capillary Electrophoresis. On-column complexation of native carbohydrates with borate allows direct UV detection at 195 nm. Nanogram amounts of nonderivatized carbohydrates can be detected in this way. UV detection of glycopeptides is straightforward since the peptide bond gives rise to sufficient absorbance at 200 nm (95).

23.4.3.4.3 Indirect UV Detection Following Capillary Electrophoresis. Indirect detection methods are a viable alternative for compounds lacking a chromophore. The detection principle is based on the displacement of the chromophore in the background electrolyte by the analyte molecule, resulting in negative peaks (95). Buffers of benzene-1,2,4-tricarboxylic acid and of 5-sulfosalicylic acid are generally used (96).

23.4.3.4.4 MS Detection. On-line CE–MS has been performed using ESI MS, continuous-low fast atom bombardment ionization sources, and a time-of-flight mass spectrometer (97). Although ESI MS is the most convenient and promising method, MALDI-TOF MS has been evaluated as a fast detector that can provide excellent detection range from a low femtomole range to attomole range (97). The additional structural data obtained by MS reduces reliance

TABLE 23.4. Labeling Agents and Detection Wavelengths

	Fluorescent detection		UV detection
Agent	λ_{ex} (nm)	λ_{em} (nm)	λ_{max} (nm)
2-AP	320	380	237
4-AB	—	—	285
AGA	325	425	—
ANTS	325	520	—
PMP	—	—	245

on precise retention migration time measurements required by other methods that involve separations based solely on electrophoresis or chromatography (98).

23.4.3.5 Electrophoresis. Both isoelectric focusing (IEF) and fluorophore-assisted carbohydrate electrophoresis (FACE®) can be used to characterize glycans. In IEF, samples are applied to a gel with an intrinsic pH gradient. In the presence of an electric field, samples migrate until the pH equals the pK_a of the sample at which point they cannot migrate any further. IEF is very effective in characterizing the charge heterogeneity, particularly because of the degree of sialylation of the glycan.

Uncharged glycans will not migrate in an electric field; hence, they need to be derivatized before separation. Labeling with a negatively charged fluorophore (usually ANTS) at the reducing terminus by reductive amination permits electrophoretic separation as well as high sensitivity detection. FACE uses a polyacrylamide gel to perform the separation of glycans based on size; however, most glycans are relatively small (~1000 Da for oligosaccharides and ~180–300 Da for monosaccharides) requiring gels with a very high concentration of acrylamide (20–40% T acrylamide). These high percentage gels have limited stability and must be used as early as possible after casting or purchase. It is also important to cool the gel during electrophoresis as significant amount of heat is generated. FACE is often combined with sequential enzymatic digestion (described in the section titled "Sequential Enzymatic Digestion") to characterize both the glycan size and linkages.

FACE can also be used to characterize the monosaccharide composition of an oligosaccharide or of a glycoprotein. For monosaccharide characterization, the intact glycan (or glycoprotein) must be hydrolyzed to its component monosaccharides. Hydrolysis is generally performed at 100°C for 3–5 h in 2N trifluoroacetic acid (TFA) or 4N HCl for neutral or amino sugars, respectively. After hydrolysis, amino sugars require reacetylation before labeling. The monosaccharides are then labeled with 2-aminoacridone (AMAC) to permit visualization by fluorescence and to maximize the differential migration rates between the differential monosaccharides. After electrophoresis, the labeled monosaccharides can be visualized and quantitated using a long-wave (368 nm) UV light box as shown in Fig. 23.8.

23.4.3.6 Sequential Enzymatic Digestion. Exoglycosidase sequential digestion can be used to identify sugar structures, as well as glycosidic linkages, because exoglycosidases have specificity for cleaving only one kind of sugar and only in a single linkage position (61). A popular approach for glycan sequencing is the use of exoglycosidases in conjunction with the detection of respective reaction products by MS or HPLC. The underlying idea of this approach is that the substrate specificity of the employed enzyme defines the structural feature of susceptible glycans. Glycans can be treated either sequentially with single enzymes in order to establish their structure or the glycan pool can be divided into several portion and then treated with arrays of enzymes in parallel (99). The commonly used exoglycosidases for oligosaccharide sequencing are summarized in Table 23.5.

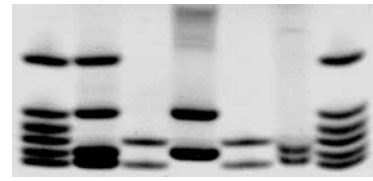

Figure 23.8. Monosaccharide composition analysis (using FACE® monosaccharide composition kit, ProZyme product code GK90100): AMAC (2-aminoacridone)-labeled monosaccharides released by two hydrolysis methods and analyzed on a monosaccharide composition gel against purified monosaccharide standards. FACE® is a registered trademark of ProZyme, Inc. (www.prozyme.com).

23.4.3.7 Sialic Acid and Monosaccharide Composition.

23.4.3.7.1 Sialic Acid Analysis. Terminal sialic acid residues on glycans play diverse biological roles in many glycoproteins. Sialic acids are key mediators in a plethora of cellular events, including cell–cell recognition and cell–matrix interactions. Incomplete sialylation of glycans that are normally sialylated leads to more rapid clearance *in vivo* through asialoglycoprotein receptors in the liver. Thus, the amount of terminal sialic acid is critical on the effectiveness of therapeutic proteins *in vivo*. On purified proteins, sialic acids are liberated either by hydrolytic procedures or by treatment with specific enzymes. Acidic hydrolysis with 2 M TFA at 80°C ensures the hydrolytic cleavage of all sialic acid linkages, deacylation, and decarboxylation of these residues. Many sialidases are commercially available and their specificity depends on O-acetylation, the occurrence of *N*-glycolyl groups, and the type of the glycosidic linkage (100). Sialic acids are typically quantitated using either a colormetetric or a fluorometric assay. In the colorimetric assay, the products of periodate oxidation of the sialic acid are coupled with thiobarbituric acid to form a red chromophore (λ_{max} 549 nm) (101). A modified thiobarbituric acid assay provides fluorometric detection of sialic acid with picomolar sensitivity. The fluorescence of the thiobarbituric acid

reaction product of periodate-cleaved sialic acid is readily detected by excitation at 550 nm and analysis of emitted light at 570 nm (102).

23.4.3.7.2 Monosaccharide Composition Analysis. Prior to monosaccharide analysis, monosaccharides must be released from the oligosaccharide chain by acidic hydrolysis. The choice of analysis method of monosaccharides depends mainly on the amount of material available. The most frequently used techniques are HPLC, CE, and FACE, all of which allow both quantitative and qualitative analysis of monosaccharide mixtures. More detailed information can be obtained by physicochemical method such as mass spectrometry and nuclear magnetic resonance (NMR) spectrometry (103). A mass spectrometer is often connected to the HPLC or CE apparatus which makes automated high-throughput analysis possible.

23.4.4 Bioinformatics Resources for Analysis and Assignment of Glycans

As the field of glycobiology has expanded, the bioinformatic and computational resources for the analysis of glycans have also expanded. These resources have been reviewed recently by Frank and Schloissnig (104). These resources include carbohydrate structure databases (Table 23.6), tools for glycan analysis (Table 23.7), and tools for prediction and analysis of glycosylation sites (Table 23.8). These tools are particularly useful for identifying carbohydrate structures from HPLC chromatograms and MS and NMR spectra. In addition, there are a variety of tools for molecular dynamics calculations and for determining carbohydrate–protein interactions. These are described in much greater detail by Frank and Schloissnig.

23.5 GLYCOSYLATION OF RECOMBINANT PROTEIN THERAPEUTICS

As of 2009, more than 165 recombinant protein pharmaceuticals have been approved for human use, with another 500 in preclinical and clinical trials. Of these, approximately 70% are glycosylated proteins (105,106), which correlates well with the estimate that more than 50% of the proteins in the human body are glycosylated (15). The glycans are well established determinants for the protein function, folding, serum half-life, and immunogenicity. As evermore complex recombinant therapeutic proteins are ectopically expressed in nonhuman host organisms, it will become increasingly important to produce products with more human-like glycosylation and to enhance their phamacokinetic properties through glycoengineering.

The structural information of the peptide chain of the recombinant protein is an important factor in directing glycosylation, but the glycan structures are also affected by

other factors, including the type of the host cell and the culture conditions. In this section, we, therefore, first present an overview of the native glycans for various potential hosts. This is followed by reviews of efforts to genetically modify the organisms to alter the glycans and modeling studies to address how specific glycans structures are produced for recombinant proteins. Finally, the effects of culture conditions on glycan structures, thus summarizing current knowledge of the effect of these factors, as well as an overview of the efforts in cellular and metabolic engineer targeted toward optimizing protein glycosylation, are discussed.

23.5.1 Effects of Host Cell Selection

The production of pharmaceutically active heterologous proteins is currently based on relatively few production platforms; mainly, hamster-derived cells (CHO and BHK) and mouse cells (SP2/0 and NS0). However, with the recent emergence of a number of new cell systems, for example, human PER.C6 cells, the bioreactor-grown moss *Physcomitrella patens*, and the glycoengineered yeast *Pichia pastoris* which all have reached the development and/or production phase (107–109), the scope of cell factories has been increased. The following sections present the typical glycosylation structures of the human system, and describe the glycosylation structures found in mammalian and nonmammalian cell-culture-based expression systems. In this context, we are also giving attention to the discussion on how non-human glycosylation patterns found in specific expression systems may affect the pharmacokinetics and, potentially, the immunogenicity of the recombinant protein. The sections titled "Insect Cells," "Plants," "Yeast and Filamentous Fungi," and "Bacteria" describe how these features have been engineered to facilitate the production of biopharmaceuticals with human-like glycosylation.

23.5.1.1 Mammalian Expression Systems. Within mammalian expression systems, the main types of cell lines employed are derived from human, hamster, and mouse cells.

23.5.1.1.1 Human Cell Lines. The glycosylation chemistry of the human cell can generally be seen as the ultimate goal of recombinant production of glycoproteins. It is desirable to obtain a glycosylation profile similar to the native protein in terms of pharmacokinetics, patient safety, and regulatory approval. However, human glycoproteins may contain quite a number of different glycosylation structures; a feature that other mammalian-derived cell cultures cannot fully emulate.

Human *N*-glycans generally have a core mannose structure, which in many cases will include a proximal α-1,6-bound fucose (10,110–112). Up to four antennae (110,113) and a bisecting GlcNAc (10,106,111,114) may be attached to the core structure. These antennae may be of type 1 (Gal-β-1,3-GlcNAc repeats) or type 2 (Gal-β-1,4-GlcNAc repeats) (111,113,115). The antennae may be capped in the nonreducing end with NeuAc-α-2,3-Gal (10,115) or NeuAc-α-2,6-Gal (10,110,114,116). The sialic acid residues may have further sialic acid residues added to them to form polysialic acid, [NeuAc-α-2,8-]$_n$NeuAc, where n may be greater than 55 (117). The antennae may also have fucose residues added as side groups to form the Lewis antigens; Lewis X (Le^X) (Gal-β-1,3/4-[Fuc-α-1,3/4-]GlcNAc) and sialylated Lewis X (sLe^X) (NeuAc-α-2,3/6-Gal-β-1,3/4-[Fuc-α-1,3/4-]Glc NAc) type structures (10,106,110,113). Finally, sulfonation of the antennae has been shown to occur, for example, in the form of sulfonated GalNAc residues (SO4-GalNAc-β-1,4-GlcNAc) (118) and keratan (SO4-Gal-β-1,4-GlcNAc) (119,120). For an overview, see Figure 23.9.

Human O-glycosylation is dominated by mucin-like-type *O*-glycans, especially in the context of heterologous proteins. This glycan type is initiated by the addition of GalNAc to a serine or threonine residue, which may then be extended in seven standard types, of roughly decreasingly abundance with core 1 being the most abundant (Fig. 23.3). Type 1 and 2 antennae, Lewis antigens, sialylation (121), or glycans of the ABH blood group type may then be added to additionally elongate these seven structures (122).

Owing to the potential complexity of the glycosylation structures described above, cell lines derived from human (cancer) tissue thus have the innate advantage of having the genetic basis for human-like O- and N-glycosylation. This said, a cancer cell line may display other glycans, simply due to genetic mutations, or the changed metabolism of the cell, making the glycosylation—to some extent—cell line and protein dependent. For instance, avian IgY expressed in HEK-293 cells has glycosylation similar to the native protein (123), but IgG from HEK-293 has an overly high content of proximal fucose (124). While widely used for research, the HEK-293 cell line is not widely applied in the production of biopharmaceuticals, although there is increasing interest in its use as a host for transient expression, both for preclinical materials as well as in the area of personalized medicine. Xigris® (activated protein C) has for a while been the only recombinant pharmaceutical protein produced in HEK-293 cells (106). Most recombinant protein pharmaceuticals from human cell lines are produced in the human fibrosarcoma cell line HT-1080, such as Elaprase® for the

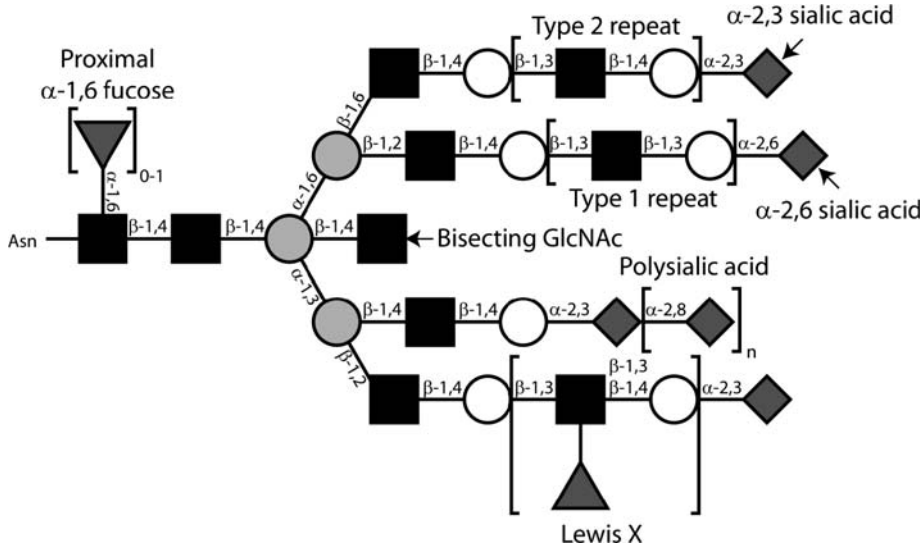

Figure 23.9. Examples of typical N-glycosylation features in human cell lines. The amount and extent of all the shown features may vary, including the number of antennae (horizontal branches). Sulfonation may also occur as sulfonated GalNAc residues (SO4-GalNAc-β-1,4-GlcNAc) and keratan (SO4-Gal-β-1,4-GlcNAc), but has not been represented here.

treatment of Hunters syndrome, and Dynepo (erythropoietin) (105,106). Some are also purified from cultures of cell lines naturally expressing the protein of interest, for example, interferons (106). The PER.C6 cell line, a cell line derived from retinal cells, has received increasing interest, partially because of its ability to provide correct glycosylation (125). Efficient protein production vectors have been presented for the system (126), and, in 2009, 14 products based on the PER.C6 cell line were in Phase I/II clinical trials (106).

23.5.1.1.2 Hamster Cell Lines. The varieties of N-glycosylation in the predominantly used hamster cell lines CHO and BHK-21 (Fig. 23.10) are generally viewed as being less complex than those found in human cells (Fig. 23.9). Owing to the broad variety of recombinant proteins expressed in these cell lines, the N-glycosylation potential is well known (Table 23.9). Both cell lines may generate up to tetraantennary structures (115,127–140), with proximal α-1,6-Fuc (10,128,130,132–135,138,141,142), NeuAc-α-2,3-Gal (10,129,130,132,134,136,138,139,141–144), and type 2 antennae (115,128,134,136,139,141,142,145). In addition to this, high-mannose-, hybrid-, and complex-type N-glycans as shown in Fig. 23.1 can be found (128,135,145). BHK-21 cell lines are also known to have at least two extra transferase activities not found in CHO cells, namely those resulting in the structures GalNAc-β-1,4-GlcNAc (138,140) and the immunogenic Gal-α-1,3-Gal-β-1,4-GlcNAc epitope. The α-1,3-Gal transferase creating this structure was shown to be inactive in CHO-K1 and DUKX-B11 (10,115,129,133).

A number of human N-glycosylation structures have been found absent in hamster cells, such as α-2,6-NeuAc (10,11,132), NeuAc-α-2,8-NeuAc, bisecting GlcNAc (162,166,169,178), and Le^X and sLe^X. However, in these cases, the genes have been found, but are only active in mutants (44,179,180). Finally, CHO and BHK cell lines may incorporate minor amounts of the immunogenic sialic acid Neu5Gc in the sialylation (10,106,152,157).

Studies of O-glycosylated recombinant proteins in hamster cells are mostly limited to erythropoietin and interleukins. *O*-Glycans on these are predominately of the core 1 mucin type with one or two sialic acid residues (136,138,139,141,170,172) as the core 2 transferase is normally not active in CHO cells (133,172,181).

Recombinant protein pharmaceuticals from CHO cells have a long history of regulatory approval, and the glycosylation structures produced by CHO cells are not known to elicit any serious immunogenic responses (106). Even so, the potential immunogenicity of the non-human structures is worth examining. Especially noteworthy is that the Gal-α-1,3-Gal-β-1,4-GlcNAc epitope is found in some BHK-21 lines. The epitope is not found in humans, apes, and Old world monkeys and is known to be immunogenic. More than 1% of human serum IgG recognizes this epitope (10,105). Another issue is the presence of Neu5Ac residues. A diverse antibody response to Neu5Ac residues in glycans is known to exist in humans (182). There seems to be a critical limit of Neu5Ac content needed to elicit a response, as fetuin with 7% Neu5Gc did give a significant response (152), but EPO with 1% Neu5Gc did not. The levels produced in CHO cells have been shown to vary between 1% and 15% (129), which makes it, in some cases, a possible point of concern.

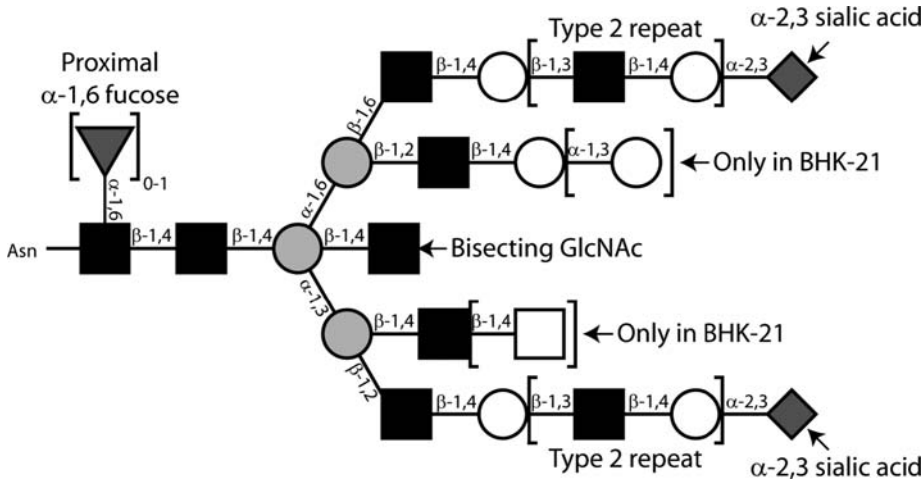

Figure 23.10. Examples of typical N-glycosylation features in hamster cell lines. The amount and extent of all the shown features may vary, including the number of antennae (horizontal branches). Note that two of the structures, GalNAc-β-1,4-GlcNAc and Gal-α-1,3-Gal-β-1,4-GlcNAc (on the center antennae), are only found in BHK-21.

While not strictly immunogenic, both the α-1,6-Fuc and the absence of bisecting GlcNAc have been shown to be problematic in terms of antibody production. It has been shown that the presence of α-1,6-Fuc on the core structure decreases Antibody Dependent Cell-mediated Cytotoxicity (ADCC) up to 50-fold (112). CHO cell lines add α-1,6-Fuc to a high percentage of the *N*-glycans in IgG (112). It has also been demonstrated several times that the absence of the bisecting GlcNAc decreases ADCC up to 10-fold (165,166). Furthermore, low *N*-glycan sialylation has been observed on IgG (see Table 23.9 and for example Ref. 169). This might decrease mAb effectivity as glycoproteins without sialic acids are cleared from the blood by the asialoglycoprotein receptor in the liver (183,184). Several engineering efforts have thus been targeted toward increasing the extent of sialylation (see the section titled "Mammalian Cells").

23.5.1.1.3 Mouse Cell Lines. Murine cell lines generally have some N-glycosylation features similar to human cells, but their glycans resemble those on human glycoproteins less than those of hamster-derived proteins. Typical cell lines used for the production of recombinant protein, such as C127 (10,11,185), ltk- (11), myeloma cell lines (NS0 and Sp2/0) (10), and hybridoma (10) cell lines, can all produce tetraantennary structures, with a proximal α-1,6-Fuc, type 2 antennae, and terminal α-2,3-NeuAc (10,11,129). This process is in many cases protein dependent. However, murine cell lines also have *N*-glycan structures not found in human cells, particularly Neu5Gc-α-2,3-Gal (11) and Gal-α-1,3-Gal (11,115,129,164,186). There are also a number of *N*-glycan structures that have not been reported in mouse cell lines, including Le^X (10,11), sLe^X (10,11), Fuc-α-1,2-Gal (10), Gal-β-1,3-GlcNAc (11), and GalNAc-β-1,4-GlcNAc (11). Finally, the choice of cell line, even within the same species, has a strong effect on the glycosylation. α-2,6-Sia is found in myeloma cells and C127 (11,115). Sulfonation has been seen in C127 (10), and a bisecting GlcNAc has been reported in C127 and ltk- lines (11). Polysialylation has been reported in ltk- cells (11). Hybrid or high-mannose structures are seen in myeloma and hybridoma cells (187,188). In summation, NS0 and Sp2/0 have quite similar N-glycosylation (10) as do different varieties of hybridoma cells (10,189), whereas C127 and ltk- cell lines have more disparate profiles (10,11,115). See Figure 23.11 for a summary.

In general, most of the detailed glycosylation studies in mouse cell lines have been performed on mAbs (162,164,189–193), possibly because of the production of the recombinant antibody Cetuximab in murine cell lines. This gives a bias on the reported murine N-glycosylation. Recombinant IgG produced in murine cell lines has *N*-glycans that are fairly independent of the cell line. The *N*-glycans are typically asialylated biantennary *N*-glycans with a proximal fucose and low galactose content as reported for NS0 (188,192), NS1 (191), and hybridoma cell lines (189–191). Slight variations are seen, such as no proximal fucose in *N*-glycans on IgG derived from NS0 (162), partial sialylation on IgG from a hybridoma line (193), and *N*-glycans of the Man_{5-9} type have also been found (188). One very significant observation is that some hybridoma cells glycosylate the light chain, often with α-1,3-Gal (10). α-1,3-Gal has also been found in recombinant IgG1 and IgG4 produced in NS0 cells (164).

While O-glycosylation in murine cell lines has been studied less than the N-glycosylation, possibly because of the absence of O-glycosylation on antibodies, it is reportedly largely similar to human *O*-glycans. The *O*-glycans of human IL-2 (interleukin 2) produced in mouse ltk- cells are the same as those added by the human T lymphocytes, namely core 1 glycans with one or two sialic acid residues (170). A study of recombinant human interferon

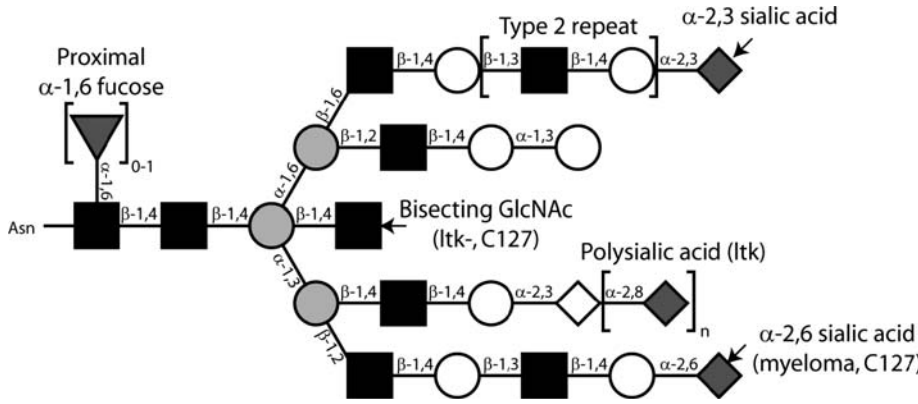

Figure 23.11. Examples of typical N-glycosylation features in mouse cell lines. The amount and extent of all of the shown features may vary, including the number of antennae (horizontal branches). Note that some of the structural features are only found in specific cell lines. Where nothing is marked, the structure may be found in all of the cell lines above and hybridoma cells.

α-2b expressed in NS0 also reported O-glycosylation at the same site as the human version (194).

The non-human epitopes found in murine cells have some potential effects on the pharmacokinetics and immunogenicity of heterologous protein produced in these cell lines. As described in section on hamster cell cultures (see section titled Hamster Cell Lines), the Gal-α-1,3-Gal-epitope is known to be immunogenic as more than 1% of human serum IgG recognizes this epitope (10,105). More specifically, up to 22% of patients have had a reaction toward the recombinant antibody Cetuximab due to the presence of this epitope (195). Additionally, the non-human sialic acid Neu5Gc is the most abundant sialic acid in murine myeloma cells (196) and in mouse cells (197). While the Neu5Gc-epitope is discussed in more detail above with the hamster cell lines, it is important to note that owing to the abundance of this epitope, the problem is more pronounced for murine lines. Other non-human glycans such as hybrid, or high-mannose structures (188), may also induce higher clearance through the mannose-specific receptors on the dendritic cells (198,199). In contrast to these reports, researchers from Novartis did, however, not find a significant negative effect of free mannose structures in IgG (200).

23.5.1.2 Nonmammalian Expression Systems. The use of expression systems, which are not based on mammalian cell cultures, has been historically limited for production of heterologous protein where N- or O-glycosylation effectively influences the protein function. Other eukaryotes, specifically yeast, insect cells, and plant cells, are often used for heterologous expression of proteins, but these all have (in their un-engineered states) limited capabilities in terms of protein glycosylation. Furthermore, the effect of the added glycans of the nonmammalian expression systems is often an immune response in the patient, as is described in the following sections.

23.5.1.2.1 Invertebrate Cells. Glycosylation in invertebrate cell lines has been reported to vary between cell lines for addition of both *N*- and *O*-glycans (11,201). A relatively large number of insect cell lines are used for the expression of recombinant protein. The most commonly used cell lines are/include *Spodoptera frugiperda* (*Sf9* or *Sf21*), and *Trichoplusia ni* BTI-Tn-5B14 (High Five™), but *Bombyx mori* SPC-Bm36 (11), *B. mori* BmN (202), *Mamestra brassicae* (11), *Estigmene acrea* (BTI-EaA) (11) are also used. The greater variety of insect cell lines utilization, compared to mammalian cell line usage, diversifies the picture somewhat. For N-glycosylation, the difference lies mainly in glycan size, extent of fucosylation, and absence of sialylation.

Generally, *N*-glycans are smaller in insect cells than in mammalian cell lines (Fig. 23.12). Insect cell lines have low activity of GnT I (203) and only trace levels of GnT II (203) and GalT (204–206) have been reported. Furthermore, insect cells posess an *N*-acetyl-*β*-glucosaminidase, which removes the GlcNAc transferred by GnT I after the

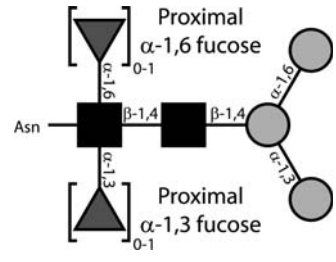

Figure 23.12. Example of typical N-glycosylation features in insect cell lines. Variations with 0 or 1 proximal fucoses and only 2 mannose residues are also seen.

action of mannosidases (207,208). Consequently, insect *N*-glycans are generally paucimannosidic with only 2–3 mannose residues and without antennae (11,209–213). However, BTI-EaA cells have been reported to produce Man_3 structures with up to three antennae (11).

N-Glycans from insect cell lines (11,202,214) and *Drosophila melanogaster* (215) may also have both a proximal α-1,6-Fuc and α-1,3-Fuc (di-fucosylation). The High Five cell line has a particular high percentage of di-fucosylation when compared to *Sf9*/*Sf21* (11).

The presence of sialylation has been discussed (213), but seems to be absent in insect cell lines (202,211,216,217). This is due to the almost complete absence of sialyltransferase activity (206,218), and the low activity of vital components of the biosynthetic pathway of the donor molecule in the sialylation reaction, and sialylation (CMP-Sia). Consequently, neither *Sf9, M. brassicae* SPCMb-92-C6, nor High Five show sialylation of *N*-glycans (201).

O-Glycosylation in invertebrates has mostly been studied in the model organisms *Caenorhabditis elegans* and *D. melanogaster* (209), but some reports have been made in invertebrate cell lines. Core 1 O-glycosylation is the predominant form and has been found in *D. melanogaster*, with a typical size of 1–3 sugar residues (219) as well as in *C. elegans* (220). In studies of *Sf9, M. brassicae* SPCMb-92-C6, and High Five, Gal-β-1,3-GalNAc-O-Ser/Thr (core 1) was found in all three cell lines (201,221). SPCMb-92-C6 and High Five also express an additional galactosyltransferase giving a Gal-α-1,4-Gal-β-1,3-GalNAc-O-Ser/Thr glycan (201,222). No sialyltransferase activity was detected in any of the cell lines (201), which seems to be a general feature (211,217).

The effect of the short insect glycosylation pathway is apparent on heterologous proteins. Kim et al. expressed human EPO in *D. melanogaster* cells, which resulted in significantly smaller *N*-glycans compared to those on EPO expressed in CHO cells. In the study, $Man_3GlcNAc_2Fuc_{0-1}$-Asn accounted for 60% of the glycans (212). This was also reported in another study for hepatocyte growth factor (155). As for the immunogenic effect of the insect epitopes, proximal α-1,3-Fuc is known to be immunogenic in rodents (223,224). Additionally, there may also be cross-reactivity with plants as serum from pollen-allergic patients has antibodies against α-1,3-fucose (224). The absence of sialylation also has a negative effect on serum half-life due to the increased clearance by the liver asialoglycoprotein receptor (183,184). Finally, the Gal-α-1,4-Gal-β-1,3-GalNAc-O-Ser/Thr has been speculated to be immunogenic in humans (201,222). Although efforts have been made to remedy these problems (see the section titled "Insect Cells"), no therapeutic proteins are currently produced in insect cells (106).

23.5.1.2.2 Plants. For plants, the N-glycosylation pathway is more or less similar to the mammalian up to and including the action of GnT I, which catalyzes the final step(s) in the formation of $GlcNAc_1Man_5GlcNAc_2Asn$. At this point, an α-1,3-fucose may be linked to the proximal GlcNAc as well as β-1,2-xylose may be linked to the innermost of the core mannose residues. These two sugar residues are widely found, and are also found on recombinant proteins expressed in plants (106,223–229). An advantage of utilizing plant hosts for IgG production is that the mammalian proximal α-1,6-fucose is absent from the product (202,230). Furthermore, the addition of a second terminal GlcNAc after the action of ManII has been demonstrated in several plants (202,230), for example, alfalfa (*Medicago sativa*) (225) and tomato (227), and is present in recombinant antibodies produced in tobacco (231), but no further GlcNAc transferases are known, thus allowing a maximum of two antennae (202,230).

As a result of the presence of *N*-acetylglucosaminidases, which remove GlcNAc residues from the nonreducing end after the action of ManII (208), many glycans are paucimannosidic (1–3 mannose residues). The paucimannosidic glycans may therefore have a core structure of $Man_{1-3}(Xyl)GlcNAc_2(Fuc)$-Asn (228). This structure with a proximal α-1,3-fucose and a core β-1,2-xylose is a consequence of the addition of the two sugars prior to the actions of ManII and the *N*-acetylglucosaminidase. All paucimannosidic, hybrid-type *N*-glycans, and complex-type glycans may be found, depending on the plant species, organ, and cellular organelle (202,232).

The elongation of the *N*-glycans is also limited. No β-1,4-galactose transferase activity or β-1,4-Gal residues have been found in plant *N*-glycans, and thus no type 2 elongation of the antennae is seen (233). The presence of sialic acids in *N*-glycans from plants has been discussed (234), but has now seemingly been disproved by the work of Zeleny et al. (235), who found that the levels found in plants were indistinguishable from the levels found in buffer blanks. The one type of elongation that has been shown to be present in a number of plants (236), including *Arabidopsis thaliana* (237), maize (226), cell suspension cultures (238), and alfalfa (225), is the Lewis a antigen (Le^a) (Gal-β-1,3-[Fuc-α-1,4-]GlcNAc). A summary may be found in Fig. 23.13.

The O-glycosylation pathways of plants are less studied than N-glycosylation, and are still partially in the dark (209). However, it is clear that it varies significantly from that of humans. A thorough review of *O*-glycan structures on plant allergens (239) shows a high *O*-glycan diversity. *O*-glycan backbones of GalNAc, similar to those typically found in humans, are seen, but also backbones of GlcNAc, mannose, arabinose, galactose and glucose are found with varying sugars attached as side chains. Some details are known on O-linked arabinogalactans commonly found on

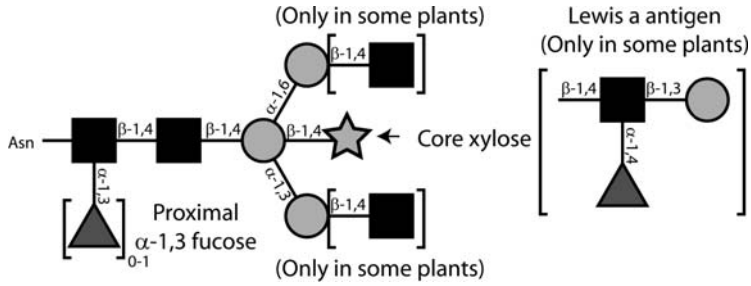

Figure 23.13. Example of typical N-glycosylation features in plants. Variations with 0 or 1 proximal fucoses and only 2 mannose residues are also seen.

plant cell surfaces. One example of this is the O-linked polysaccharide characterised by Tan et al. It has a galactose backbone, with side chains consisting of arabinose, glucuronic acid, galactose, and rhamnose residues (240). Another significant characteristic of plant *O*-glycans is that, in addition to serine and threonine linkages, plant proteins may also have O−glycans attached to a hydroxyproline residue (240,241).

What the effect of the plant-specific glycosylation is on the immune system, and what the clinical significance is, has been the subject of much debate. Especially the effects of proximal α-1,3-fucose and core β-1,2-xylose have received much attention as they are potentially immunogenic (239). Both epitopes are involved in pollen allergy (230,242,243). Even so, the reported effect varies. While mouse antibody expressed in tobacco plants have both α-1,3-fucose and core β-1,2-xylose attached (244), reports showed no immune response in mice to injection with antibody produced in plant cells (245). In contrast to this, Jin et al. (231) showed an immune response in rabbits to antibodies produced in *Nicotiana bethamiana*. An immune response was also seen when immunizing mice and rats with horseradish peroxidase (HRP) with these glycoforms (223). Injection of plant proteins into humans also elicits an antibody production targeted toward the glycans. However, the authors did not find it likely that this would have a significant clinical effect (246).

Even so, plant *N*-glycans can be allergenic. A study among blood donors showed that 50% of non-allergenic donors have antibodies for core β-1,2-xylose and 25% have antibodies for core α-1,3-fucose (223). 29% of pollen allergenic patients react positively to bromelian with *N*-glycans with both core β-1,2-xylose and core α-1,3-fucose, whereas 12.5% of the same patients reacted to defucosylated bromelian (239). A study by Bencúrová et al. (224) used a recombinant *P. pastoris* to test the effect of the fucose and xylose separately, and was unable to find a significant separate effect of the β-1,2-xylose, but did show a significant effect of α-1,3-fucose on its own. A de-fucosylation of bromelain also decreased the IgE reactivity in allergenic patients, but not to the levels of fibrin with neither fucose nor xylose in the *N*-glycans (239). Thus, it seems that both epitopes may elicit an immune response - especially in pollen-allergic patients - with a more significant response caused by α-1,3-fucose.

Effects are also seen in the absence of galactosylation and sialylation of the antennae also has detrimental effects, as glycoproteins without sialic acids are cleared from the blood by the asialoglycoprotein receptor in the liver (183,184).

The dicersity of *O*-glycan structures makes a generalization of the effects difficult. While some plant *O*-glycans have also been known to be immunogenic (239), the serum half-life of hGH has been increased by the addition of a hydroxyproline-O-glycosylation domain (241).

Despite the variations in glycosylation, recombinant glycoproteins produced in plants have not been known to elicit an immune response when applied topically, which makes the production of therapeutics and edible vaccines interesting (106,228,247).

A few plant derived therapeutics have been approved in the European Union, such as glucocerebrosidase, for the treatment of Gauchers disease, from carrot cells (106,248), interferon α (Locteron®) from duckweed (*Lemna minor)* (106), human intrinsic factor from *Arabidopsis* (228) and an anti-caries IgA (228).

23.5.1.2.3 Yeast. The main difference between N-glycosylation in yeast and mammalian cells lies in the processing of the *N*-glycans in the Golgi complex. In both cases, the predominant *N*-glycan entering the Golgi is $Man_8GlcNAc_2$. However, in mammalian cells; this structure is subject to trimming by mannosidases, leaving ultimately as few as three mannose residues (See Ref. 249 and the beginning of the section on "Mammalian Expression Systems"). In *Saccharomyces cerevisiae*, mannose residues are added to form a mannan core structure of 9−14 α-1,6-linked mannose residues (250). For some proteins, such as a yeast invertase, even larger structures of 30−54 mannose residues have been found (251,252). Additions to this high-mannose structure include α-1,2-Man sidechains as well as phosphomannose

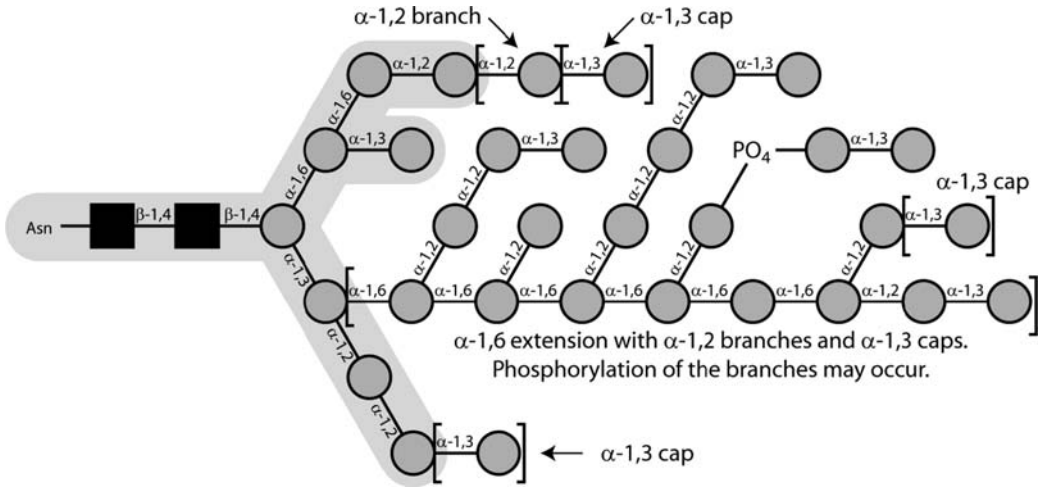

Figure 23.14. Example of typical N-glycosylation features in yeast. The length and branching of the chains may vary greatly, up to more than 50 mannose units (251,252). Pichia pastoris mannosylation is generally less extensive than that of *S. cerevisiae*.

groups, which both can be capped with α-1,3-Man residues (202,253). For a summary, see Figure 23.14.

The α-1,6-linked mannose chains of glycoproteins in the yeast *P. pastoris* are generally shorter (254) than in other yeasts (254). On one heterologous secreted protein, 85% of the *N*-glycans had 14 or less mannose residues in *P. pastoris*, while for *S. cerevisiae* this was only true for 20% of the *N*-glycans. This makes the *N*-glycans of *P. pastoris* more similar to those of mammals than those produced by *S. cerevisiae* (254,255).

There also seem to be differences in the occupancy of N-glycosylation sites with the common motif Asn-X-Thr/Ser. Human interleukin-1b has one possible N-glycosylation site, which is unoccupied when the protein is secreted from human monocytes, but the recombinant protein is N-glycosylated by S. cerevisiae (256).

Protein O-glycosylation in yeast seems to be restricted to protein O-mannosylation, which has also been reported in mammalian cells in a few cases (257). O-mannosylation differs from standard human O-glycosylation in that it is initiated in the ER with the attachment of one or two mannoses to a Ser or a Thr residue, followed by the addition of 1–3 mannosyl residues in the Golgi complex. The specificity of the O-mannosylation machinery also seems to be different. In one example, human insulin-like growth factor I is O-mannosylated when expressed in *S. cerevisiae*, while only the unglycosylated form is found in human serum (258). Furthermore, *S. cerevisiae* may have mannosylphosphate as a part of the O-mannosylation chain (257). *P. pastoris* does not seem to have this, and similar to what is seen for N-glycosylation, proteins expressed in *P. pastoris* generally have shorter O-mannosylation chains compared to those produced in *S. cerevisiae* (254,257).

Most interesting in the context of pharmaceutical proteins is the observation that O- and N-mannosylation of proteins increases the clearance rate of the protein. Even with the shorter mannosylation chains typically found in *P. pastoris*, mannose-sensitive receptors on the surface of dendritic cells initiate an immune response to the mannosylated proteins (198,199). This decreases serum half-life as well as the ADCC (259).

Due to the systemic differences in protein glycosylation, heterologous expression of pharmaceutically active proteins has been limited to unglycosylated proteins such as insulin, and growth hormone (106,260).

23.5.1.2.4 Bacterial strains. Bacterial N-glycosylation has been reported in some cases, but normally consists of only short chains. While some examples of N-linked GlcNAc residues have been reported - see below - the N-linked residue can be quite exotic with e.g. rhamnose or glucose bound directly to the peptide chain (10,261–264). A special case is the human-like N-glycosylation such as bi- and triantennary *N*-glycans found in some pathogenic bacterial species such as *Chlamydia trachomatis*, and *Campylobacter jejuni* (265,266).

Bacterial O-glycosylation has also been reported in several species. O-mannosylation occurs in pathogenic species such as *Mycobacterium tuberculosis* and *Chlamydia trachomatis* (257,267,268). and O-glycosylation in *Pseudomonas aeruginosa* (pili) and *Campylobacter jejuni* (flagellae) that differs significantly from human *O*-glycans by containing exotic residues such as 2,4-diacetamido-2,4,6-trideoxyhexose, N-acetylfucosamine, and pseudaminic acid (267,269). While a heptose residue has been identified in two *E. coli* proteins (267), no other

significant N- or O-glycosylation have been reported in industrial workhorses such as *E. coli* or *Bacillus subtilis*.

Due to the these reasons, the production of heterologous proteins in bacterial species have so far been limited to proteins without glycosylation, or proteins where the absence of the native glycosylation does not seem to have a noteworthy negative effect on the pharmacokinetics, such as the recombinant human insulin or human growth hormone produced by Eli Lilly in *E. coli* cells (260).

23.5.2 Genetic Engineering of Glycosylation Pathways

Genetic engineering of the glycosylation pathways has been applied both to the glycosylation machinery of mammalian cells as well as nonmammalian expression systems. The ultimate goal of metabolic engineering in the context of glycosylation is the construction of a host organism that which provides a consistent, "optimal" glycosylation of the heterologous protein it produces. For mammalian cells (see the section titled "Mammalian Cells"), approaching this is relatively uncomplicated focusing predominately on single-gene studies directed towards adding activities which improve pharmacokinetics (PK), and removing epitopes which cause immune responses and/or rapid blood clearance rates.

While mammalian cell culture provides a starting point where the glycosylation is closer to the native protein than any other expression systems, the relative complexity and cost of cultivating mammalian cells with high yields and titer are less attractive than systems featuring lower eukaryotes and bacteria. For this reason, genetic engineering has permitted significant advances towards using simpler organisms for production of human-like glycoproteins, with the promise of further improvements.

In this section we will describe the metabolic engineering efforts that have been applied to improve the glycosylation potential of mammalian cell cultures, plants and plant cells, insect cells, yeast and bacteria.

23.5.2.1 Mammalian cells. As described above, the glycosylation patterns of mammalian cell culture are quite close to those of the native human proteins. Most biosimilar are proteins produced in the human cell lines Per.C6, HT-1080 and HEK-293. The mouse cell lines (C127, ltk-, NS0, Sp2/0, and hybridoma cells) may all produce the immunogenic Gal-α-1,3-Gal-β-1,4-GlcNAc epitope, an epitope which may also be found in BHK-21-based hamster cell line. In this regard, the relatively smaller protein glycosylation repertoire of the CHO cell lines is an advantage, giving products a more uniform safety profile relative to mouse cells.

A literature survey of glycosylation engineering efforts in mammalian cells (Table 23.10) also confirms that the CHO based cell systems have received a special interest, as most of the studies that have been conducted in CHO cells with a small number in BHK-21 cells or/and human cells. In general, this may be explained by the rough generalization that human cell lines do not require glycosylation engineering, mouse cells do not present enough of an advantage over the hamster cell lines to attract the effort, and CHO cells, while making relatively harmless glycosylation, can benefit from having certain activities added or removed.

These glycosylation engineering efforts can be divided into two main sections, namely fucosylation engineering, and enhanced sialylation.

Fucosylation engineering is concerned with two main avenues: 1) expression of the α-1,3-Fuc transferase to form the Le^X and sLe^X structures in hamster or mouse cells and 2) removal of the core α-1,6-Fuc, which is found on almost all recombinant glycoprotein from CHO cells (See Figure 23.10). The core α-1,6-Fuc has been shown to have a detrimental effect on the ADCC of IgG (274,275), and removal of this residue has been shown to increase ADCC up to 100-fold (298), while having no visible phenotype (291). Due to the commercial interest in recombinant antibodies for therapeutics, de-fucosylation of antibodies is covered quite heavily by patents, e.g. WO00/61739, the first patent on defucosylated therapeutic antibodies (299).

Most approaches targeting the fucosylation pathway are based on the knock-out or RNA interference (RNAi) of CHO α-1,6-FucT (FUT8), or the knock-out or silencing of GDP-D-mannose-4,6-dehydratase (GMD) (Table 23.10). The latter approach is derived from the fucosylation-deficient Lec13 CHO-mutant which was shown to be deficient in this activity (300). A more indirect approach, which however, does not completely remove core fucose residues, is the expression of GnT III, the enzyme responsible for adding the bisecting GlcNAc in *N*-glycans. This residue blocks the addition of the core fucose and thus increases ADCC (165). An improvement on this strategy is re-localizing GnT III to earlier stages in the glycosylation pathway, which more efficiently blocks fucosylation (293). Another approach is the co-overexpression of GnT III and ManII to increase the competition for the substrate on which Fut8 is active (293).

A poor degree of sialylation is a relatively large issue for recombinant proteins produced in hamster cells. As mentioned in the section on "Immunogenicity and Biological Clearance", sialylation increases the residence time in serum (183,184). More than 20 studies exist where the α-2,3- or α-2,6-sialyltransferase has been overexpressed or expressed in CHO, BHK-21, or HEK 293 cells (Table 23.10). Mostly, the increase in sialylation gained from this strategy is modest (10-20%), but an increase in PK properties has been reported (285). It has also been attempted to improve sialylation by modifications up-stream of the sialyltransferase. A one-gene approach

TABLE 23.10. Overview of Glycosylation Engineering Efforts in Mammalian Cell Cultures.

Target gene(s)	Type	Method	Reported effect	Cell line	Protein	References
α-1,3-FucT	N	Expression	Synthesis of the sLe^X epitope in CHO DHFR-. No effect was seen in CHO Pro^-	CHO DHFR-	Surface protein	(270)
α- (1,3)-FucT	N	Expression	Introduction of the sLe^X epitope in BHK cells	BHK-21	β-TP	(11)
α- (1,3)-FucT	N/O	Expression	Addition of α-1,3-bound fucose, but not a fully active Lewisx antigen.	C127	PTA	(271)
α-1,6-FucT	N	siRNA	Decreased proximal fucosylation and increased ADCC	CHO DG44	IgG	(272)
α-1,6-FucT	N	siRNA	Decreased α-1,6-fucosylation to 28%	CHO DG44	IgG	(273)
α-1,6-FucT	N	Knock-out	Fucose removed. ADCC increased two orders of magnitude.	CHO DG44	IgG1	(274)
α-1,6-FucT	N	siRNA	Increase in de-fucosylation from 10 to 60%. More than 100-fold increase in ADCC.	CHO DG44	IgG	(275)
α-1,6-FucT	N	Mutant	Expression of IgG in this cell line gave a up to 50 fold increase in ADCC.	CHO Lec13	IgG1	(112)
α-1,6-FucT	N	Knock-out	Removed α-1,6-fucosylation. 100-fold increase in ADCC.	CHO DG44	IgG1	(276)
α-1,6-FucT+GMD	N	siRNA	Removed α-1,6-fucosylation.	CHO DG44	IgG	(273)
α-2,3-SiaT	N	Expression	Increase in sialylation from 6.7 to 7.5%. Increase in triantennary glycans.	CHO EC1	EPO	(277)
α-2,3-SiaT	N/O	Overexpression	Increased sialylation.	CHO	EPO	(278)
α-2,3-SiaT	N	Overexpression	Increased sialylation to >90%.	CHO	TNK-tPA	(31)
α-2,3-SiaT	N	Overexpression	33% increase in molar content of sialic acid, sialylation increased to >90%.	CHO	TNFR-IgG	(31)
α-2,3-SiaT	N/O	Overexpression	Increase in sialylation from 61 to 80%.	CHO	IFN-γ	(279)
α-2,3-SiaT + β-1,4-GalT	N/O	Co-expression	Increase in sialylation from 6.7 to 8.2%. Increase in triantennary glycans.	CHO EC1	EPO	(277)
α-2,3-SiaT+CMP-SAS+CMP-SAT	N/O	Co-overexpression	Synergetically increased sialylation.	CHO	EPO	(278)
α-2,6-SiaT	N/O	Expression	Added α-2,6-sialylation. 4% increase in sialylation. Improved the PK of the HP.	CHO DUKX-B11	IFN-γ	(280)
α-2,6-SiaT	N	Addition	39% α-2,6-sialic acid introduced	CHO UH	hTSH	(132)
α-2,6-SiaT	N	Expression	Introduction of α-2,6-bound Sia in BHK cells	BHK-21B	β-TP	(11)
α-2,6-SiaT	N/O	Expression	A-2,6-sialylation on 60% of the RP	CHO DHFR-	IFN-γ	(281)
α-2,6-SiaT	N	Expression	Added ability of α-2,6-sialylation	CHO	-	(282)
α-2,6-SiaT	N	Expression	Up to 60% Increase in sialylation	CHO DUKX-B11	IFN-γ	(283)
α-2,6-SiaT	N/O	Expression	Added ability of α-2,6-sialylation	BHK-21A	EPO	(284)
α-2,6-SiaT	N/O	Expression	Added α-2,6-sialylation. Improved PK.	CHO Pro-	EPO	(153)
α-2,6-SiaT	N	Expression	Added α-2,6-sialylation. 7% increase in sialylation.	CHO K1	IgG3	(285)
α-2,6-SiaT	N/O	Overexpression	Increase in sialylation from 61 to 80%.	CHO	IFN-γ	(279)
α-2,6-SiaT	N/O	Overexpression	Increased sialylation and serum half-life	HEK-293	rHuAChE	(286)
α-2,6-SiaT	N/O	Overexpression	Serum half-life increases with sialylation	HEK-293	rHuAChE	(287)
β-1,4-GalT	N	Overexpression	Decreased GlcNAc-termination from 6 to <1%.	CHO	TNFR-IgG	(31)

[a] AT-III, Antithrombin III; CMP-SAS, CMP-sialic acid synthase; CMP-SAT, CMP-sialic acid transporter; FSH, Follicle-stimulating hormone; GFT, GDP-fucose transporter; GMD, GDP-mannose 4,6-dehydratase; HP, Heterologously expressed protein; hTSH, Human thyroid stimulating hormone; IFN, Interferon; IgG, Immunoglobulin G; PDI, protein disulfide isomerase; PK, Pharmacokinetics; PLTA, polyoma large tumor antigen; PTA, Polyoma T antigen; rHuAChE, Recombinant human acetylcholinesterase; siRNA, Small interfering RNA; TIMP-1, tissue inhibitor of metalloproteinases 1; TNFR-IgG Tumor necrosis factor receptor–IgG1 fusion protein; TNK-tPA, Amino acid-modified tissue plasminogen activator; β-TP, β-trace protein.

has been the overexpression of the CMP-sialic acid transporter (CMP-SAT) which increased sialylation of IFN-γ. Jeong et al. (278) co-overexpressed α-2,3-SiaT, CMP-sialic acid synthase and CMP-SAT, and showed this to have a cumulative and even synergistic effect on sialylation of EPO.

As seen in Table 23.10, genetic knock-out studies are rare, mainly due to the previous lack of efficient gene targeting tools in mammalian cells as well as the lack of a genome sequence for hamster cells. However, fairly recently, zinc-finger-endonuclease-mediated gene knock-outs have been made commercially available through the CompoZr™ technology (301,302). We anticipate that this will have a large impact on metabolic engineering in mammalian cells in general, and specifically in glycoengineering.

23.5.2.2 Insect cells. As discussed in the section on "Non-Mammalian Expression Systems", the protein N-glycosylation pathway of insect cell lines is stunted compared to mammalian cells and produces primarily paucimannosidic structures with the possible addition of two fucose residues to the proximal GlcNAc. The main reasons for these truncated (relative to human glycoforms) structures are low activities of the GnT I, almost absent GnT II and β-1,4-Gal-T, and a dysfunctional sialic acid biosynthesis pathway. The native structure of insect cell N-glycosylation can be seen in Figure 23.15, along with the target enzymatic activities of N-glycosylation engineering.

Generally, the glycoengineering of insect cells attempts humanization by two main avenues:

1. Addition of mammalian glycosyltransferases to form antennae and elongate these.
2. Reconstruction of sialic acid biosynthesis and glycoform sialylation.

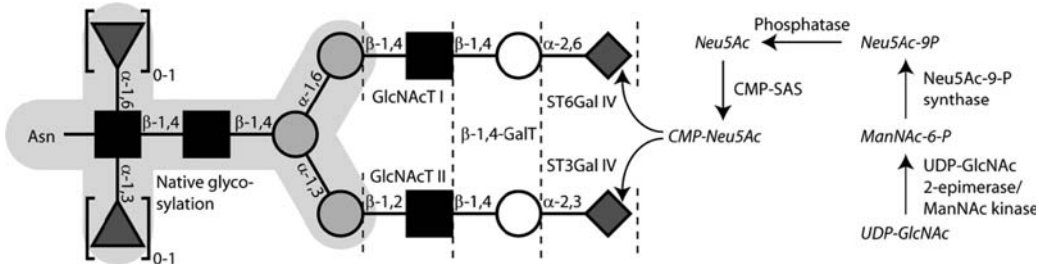

Figure 23.15. Enzyme activites targeted for glycoengineering of insect cells lines. The structure in light grey on the left shows the typical extent of N-glycosylation in insect cell lines; however the number of attached fucose residues may vary. On the right of the core structure are shown residues that have been added by genetic engineering. On the far right is the mammalian biosynthetic pathway for CMP-neuraminic acid, the precursor for sialic acid residues on N-glycosylation. Several of the enzymes of this pathway have been the target of engineering. See Table 23.10 for an overview of studies targeting each of the represented enzymes. Abbreviations: GalT: Galactose transferase. GlcNAc: N-Acetylglucose. GlcNAcT: GlcNAc transferase. Neu5Ac: Neuraminic acid. SAS: Sialic acid synthase. ST3Gal: α-2,3-(N)-sialyltransferase. ST6Gal: α-2,6-(N)-sialyltransferase.

Table 23.11 presents an overview of the studies employing these strategies. In general, the field has progressed from early pioneering work inserting single genes from the mammalian N-glycosylation pathway (303,304) to the concerted expression of seven mammalian genes (217). While the furthest advances were achieved in Sf9 cells, *Trichopulsia ni* has also shown to be a possible host for developing an insect cell-based alternative to mammalian cell culture for heterologous protein production.

23.5.2.3 Plants. By far the majority of glycan engineering efforts in plants in the context of heterologous protein expression have been targeted towards removal of the immunogenic core β-1,2-Xyl and α-1,3-Fuc (See Section on "Non-mammalian Expression Systems" and Figure 23.13). However, several strategies have been applied to achieve this.

One strategy to avoid the core β-1,2-Xyl and α-1,3-Fuc epitopes is the retention of the recombinant protein in the ER by the addition of the C-terminal amino acid motif KDEL or HDEL. This retention theoretically limits the glycosylation to high-mannose types ($Man_8GlcNAc_2$-Asn). Applications of this strategy include α 1-antichymotrypsinin produced in tobacco (BY-2) cells (310) and mAb in tobacco plants (311–314). All of these studies report high-mannose structures on the recombinant protein. Rademacher et al. applied the technique to mAb produced in maize endosperm, but reported the addition of GlcNAc addition (315). This has later been suggested to be an artifact (228). A minor disadvantage of this technique

is the increased clearance rates resulting from the mannose structures as described above for yeast systems. However, for some products, such as the glucocerebrosidase (GCD) produced by Protalix, which requires uptake through the macrophage mannose receptors, this may be advantageous (248). In the case of Protalix, the technique was modified to target GCD to the vesicles of the macrophages.

Another strategy to produce less immunogenic glycans in plants is to delete or silence the genes encoding the enzymes, core-XylT and core-FucT, which catalyze the formation of the core β-1,2-Xyl and α-1,3-Fuc epitopes. One such study in *A. thaliana* has produced a double-knockout line by crossing two single-knockout lines (316), which has been used for the expression of a mAb (317). Core-XylT and core-FucT have been knocked down in *M. sativa* (alfalfa) (318), *Nicotiana benthamiana* (319) and *L. minor* (320) using RNAi. A resulting antibody from one of the studies was demonstrated to have a 20–30 times higher ADCC than a reference mAb expressed in a CHO cell line (320).

Due to the presence of homologous recombination in the moss *P. patens*, the genetic knock-out of the core-XylT and core-FucT genes is possible in this organism. Cell lines with the double knock-out have been used to produce human vascular endothelial growth factor VEGF (321), EPO (322) and IgG (323). As a result of this modification, the IgG showed up to a 40-fold improvement in ADCC. With a similar objective, Huether et al. (324) rather elegantly disrupted the genes for core-XylT and core-FucT in *P. patens* by replacing it with a human β-1,4-Gal transferase. This removes the plant-specific residues from *N*-glycans, while adding the human β-1,4-Gal residue.

Yet another strategy to achieve a more human-like glycosylation and eliminate xylose and fucose from the core structures is based on the addition of glycosyltransferases. For this, the addition of bisecting GlcNAc to *N*-glycans by GnT III is favorable, as it enhances the pharmacokinetic properties of the protein and blocks the addition of Fuc or Xyl to the core of the *N*-glycan (228,325,326). Human GnT III has been expressed in tobacco plants by Rouwendal et al. (327), which added bisecting GlcNAc to more than half of the plant *N*-glycans. Frey et al. (328) expressed rat GnT III with and without a relocalization signal to the Golgi. Without the relocalization signal, results similar to those generated by Rouwendal et al. were obtained. The relocalization of rat GnT III to the Golgi improved the addition of the bisecting GlcNAc further and removed xylose and fucose from the *N*-glycans in app 60% of the glycans due, to out-competition for the core glycan substrate.

Another humanization strategy is to ectopically express GalT I. The terminal β-1,4-Gal (added by GalT I) blocks for the addition of both core β-1,2-Xyl and α-1,3-Fuc and gives a more human-like *N*-glycan. One example is the genetic transfer of human GalT I to tobacco BY2 cultures (329). This resulted in galactose being added to approximately half the total *N*-glycans as well as giving a virtual absence of both core β-1,2-Xyl and α-1,3-Fuc. A similar result was seen for the expression of HRP in the same cell line (330). At the same time, however, expression of mAb in this cell line seemed to be less effective in terms of both galactosylation, and the reduction of both core β-1,2-Xyl and α-1,3-Fuc (331). An application of this strategy in tobacco plants for mAb production has also been reported (233). An improvement of this technique has been an insertion of the GalT I earlier in the glycosylation pathway by adding targeting domains for the medial Golgi-cisternae to the transferase. Expression of a human GalT I fused with the targeting domain of *A. thaliana* core-XylT (332) in tobacco plants allowed the production of a mAb having *N*-glycans with undetectable xylose, very litte fucose and added galactose (333). A similar approach has been used in *T. benthamiana* (334).

A final target to be mentioned for engineering plant glycosylation is the recreation of the human sialylation pathway in plants. The insertion of the genes for the four biosynthetic enzymes and the transporter for the CMP-NeuAc precursor molecule has not yet been fully accomplished. References (335–337) all describe the insertion of two or more of the five steps in either plants or plant cells, but the full functional combination of all biosynthetic steps with a functional sialyltransferase has yet to be seen.

23.5.2.4 Yeast and filamentous fungi. This section will describe the immensely successful glycosylation engineering conducted in the yeast *P. pastoris*. However, minor efforts have also been undertaken in *S. cerevisiae* and filamentous fungi, for which we will also provide an overview here.

The methylotrophic yeast *P. pastoris* is a commonly used platform for heterologous protein expression due to its native ability to secrete properly folded proteins in high yields. The native *P. pastoris* generally adds a large number of mannose residues to *N*-glycans, producing *N*-glycans with a typical structure of $Man_{9-14}GlcNAc_2$, making it ill-suited for production of pharmaceutical glycoproteins (See Figure 23.14). However, a very successful series of genetic engineering studies by the company GlycoFi Inc. (now acquired by Merck & Co. Inc.) have reformed this to allow engineered *P. pastoris* to produce secreted human-like glycoproteins.

The first effort in glycoengineering was the deletion of the *och1* gene. Och1p is an a-1,6-mannosyltransferase, which initiates hypermannosylation. The *och1* deletion reduces yeast mannosylation to $Man_5GlcNAc_2$ sugar chains, which are compatible with the human immune system (First shown in S. cerevisiae (338,339)). A *P. pastoris och1* deletion strain formed the basis for the first

work of GlycoFi which, by the application of combinatorial genetics with a library of targeting sequences (340), achieved correct targeting of N-glycosylation enzymes to the organelles of *P. pastoris*. Applying this techology allowed for correct targeting of five eukaryotic proteins, namely mannosidases I and II, GlcNAcT I and II, and the UDP-GlcNAc transporter to achieve the production of proteins with a $GlcNAc_2Man_3Man_2$ structure (341).

Further improvement of the core *N*-glycan was attempted by the elimination of the Alg3p α-1,3-mannosyltransferase (342). This was shown to prevent the α-1,3- and α-1,6- mannose additions to the 1,6 arm of the dolichol-bound precursor, although with a slightly leaky phenotype, as some highly mannosylated glycoforms are still formed.

The strain of Ref. 341 was improved with the deletion more genes (Δoch1, Δpno1, Δmnn4B, Δbmt2, Δhis1), and the insertion of three more genes allowing for galactosylation of the *N*-glycans, namely galactose epimerase, a UDP-Gal transporter, and β-1,4-galactosyltransferase, giving $Gal_2GlcNAc_2Man_3GlcNAc_2$ $N-$glycans on mAbs (343).

The final step was the insertion of UDP-N-GlcNAc-2-epimerase/ManNAc kinase, N-acetylneuraminate-9-phos phate synthase, CMP−sialic acid synthase, a CMP−sialic acid transporter, and a library of chimeric sialyltransferases linked to yeast type-II transmembrane localization peptides to reconstruct the entire mammalian sialylation pathway in *P. pastoris*. The strain was validated by the production of recombinant human EPO with more than 90% terminal sialylation (108).

After the acquisition of GlycoFi Inc. by Merck & Co. Inc, the GlycoFi technology has been shown to give stable production of antibodies with human-like N-glycosylation under a range of cultivation process parameters (344), thus making it a very promising system for production of recombinant biopharmaceuticals.

The use of *S. cerevisiae* in glycosylation engineering has been limited, mostly due to the advantages of the *P. pastoris* system for heterologous protein production. However, a few successful attempts of engineering are to be found. Most notable is the *och1* deletion studies mentioned above as the basis for the further development of the GlycoFi technology (338,339). Another technique, which is complementary to the GlycoFi, is the reconstruction of the O-fucosylation pathway, including biosynthesis of the GDP-fucose precursor (345). This allowed the production of secreted recombinant epidermal growth factor domains with O-fucosylation.

Minor efforts have also been carried out in filamentous fungi. While filamentous fungi normally only produce mannosylated *N*-glycan, complex *N*-glycans have been achieved by the insertion of GlcNAcT I in *Aspergillus nidulans* (346) and *Trichoderma reesei* (347).

23.5.2.5 Bacteria. Mammalian glycosyltransferases are typically required to be glycosylated in order to be functional, which complicates the expression of the functional enzymes in bacteria. However, as discussed in above, a number of pathogenic bacteria mimic human glycosylation to support evasion of the human immune system. This allows for the transfer of glycosylation pathways into industrial workhorses such as *E. coli* or *B. subtilis* (262). The best example of this is the transfer of N-glycosylation steps from *C. jejuni* to *E. coli* (266,348). Zhang et al. (349) used an interesting strategy of tRNA-synthase evolution to introduce a first step of O-glycosylation to *E. coli* from *Methanococcus jannaschii*. Unfortunately, the authors could not reproduce the experiments, and the chapter was later retracted (350).

23.5.3 Modeling of glycosylation control

While some of the theoretical framework and quantitation required of modeling posttranslational modifications of proteins was established in the 1980's (351,352), and early 1990's (353−355), the actual modeling of N-glycosylation of proteins was not achieved until 1997 by the complementary studies of Monica et al. (356) and Umana and Bailey (357). Monica et al. focus on reactions occurring in the trans-Golgi network, and establishes and discusses the key assumptions for modeling a single compartment. Applying these assumptions within a mathematical framework based on ordinary differential equations allowed the authors to accurately model the extent of sialylation of secreted protein from Chinese hamster cells. Umana and Bailey published a multi-compartmental model accounting for 33 different glycoforms, which however does not account for sialylation. Here, assumptions for modeling multiple compartments were established. This more sophisticated model allowed the prediction of the effect of overexpressing of GlcNAc-transferase III.

Extending the principles of Monica et al and Umana and Bailey mentioned above, the most extensive model for an industrially relevant cell line was published by Krambeck and Betenbaugh (358), where the glycosylation modeling was extended to 7565 glycoforms generated by 22,871 enzymatic reactions. This model, together with an advanced model for human cells by the same authors (359) is currently the state of the art.

23.5.4 Effects of process conditions

It has long been known that protein glycosylation may be affected through the modification of culture conditions, both in terms of overall process parameters such as temperature, pH, dissolved oxygen, culture duration and mode of cultivation, and by the addition of small molecules to the cultivation medium. Typically, the changes made by

overall process parameters are not a part of a glycosylation design strategy (but not necessarily undesirable), while studies made with the addition of compounds are often seeking to directly improve glycosylation by shifting the chemical equilibrium of the glycosyltransferase reactions in the ER and Golgi. Overall, these effects are often both cell line and protein dependent.

In this section, we have compiled an overview of studies (Table 23.12). The overview is limited to mammalian cell cultures, both due to the abundance of work performed in this field, and due to the maturity of mammalian cells as production vessels of recombinant proteins. In the following, we discuss the effect of the most studied pertubations. For the effects of lesser studied manipulations, we direct the reader to Table 23.12.

23.5.4.1 Ammonium. Ammonium is typically formed from the degradation of glutamine, an essential medium component in most mammalian cell cultivations. However, even low concentrations of ammonium (2 mM), may disrupt the intracellular pH levels and inhibit cell growth and protein productivity (364,416). In studies of the effect on protein glycosylation (Table 23.12), it is clear that this detrimental effect of ammonium extends to both N- and O-glycosylation. Again, as little as 2 mM ammonium has been shown to decrease site occupancy, *N*-glycan branching, sialylation, and glycan size in general.

23.5.4.2 Butyrate. While the addition of sodium butyrate (NaBu), has been shown to cause growth arrest and induce apoptosis in mammalian cell cultures (417,418), it often improves the productivity (q_p) of cell cultures (386,402,404). However, the effects of NaBu on glycosylation are quite diverse. In some studies, the site occupancy, *N*-glycan extension and sialic acid content was increased, whereas in others, NaBu had a strongly detrimental effect on glycosylation (Table 23.12). This may be explained by the de-condensating effect NaBu has been described to have on chromatin (419), which one can assume will be very dependent on the genetic content of the individual cell lines.

23.5.4.3 Cell viability. It has been established in several studies that low viability of the cells may have a large effect on the glycosylation of the produced protein. Intracellular carbohydrate-active enzymes and sialylases may leak into the medium when cells die and decrease the value of the product (373,374,399).

23.5.4.4 Glucosamine and N-acetylglucosamine. The addition of glucosamine (GlcN) to the cell culture media is of special interest in protein glycosylation, as it is a precursor for UDP-GlcNAc, which is required in the Golgi as a precursor for *N*-glycan branching as well as for Type 1 and 2 extensions of the *N*-glycans. The intracellular level of UDP-GlcNAc may be increased by adding GlcN to the media, and more so by co-adding uridine (129). The effect of this has been shown in some cases to increase antennarity (Table 23.12). However, adding GlcN alone may decrease branching, galactosylation and sialylation. Substituting glucose for GlcN has been shown in one case to increase the biological affinity of the produced recombinant antibody ten-fold due to modification of the mAb light-chain *N*-glycans (388).

23.5.4.5 Glucose. Glucose is (along with glutamine) the main carbon source in mammalian cell cultures and thus the main source of carbon for protein glycosylation. While smaller changes in the concentration of glucose do not affect glycosylation notably (141), low concentrations decreased site occupancy. Furthermore, galactosylation and sialylation were also decreased (Table 23.12).

23.5.4.6 Oxygen. The level of dissolved oxygen (DO) in the culture is of great importance to the overall cellular metabolism and affects cell growth and overall metabolism directly. This sensitivity is also known to be cell line-dependent (420). Increasing DO has been reported to both increase (143,381,382), and decrease (385) protein glycosylation across a broad range of cell lines and proteins (Table 23.12). While these studies were limited mainly to investigation of sialylation or galactosylation, a study with a broader focus (384) found oscillation of DO to increase sialylation, branching, and galactosylation.

23.5.4.7 pH. The level of pH in the culture affects cellular metabolism greatly, even with small (0.1 pH units) variations (385). In the studies of the effect of pH on protein glycosylation, the effects are mostly determined for one specific level of pH, which makes generalization difficult. However, the observation of Borys et al. (408) that a pH below 6.9 and above 8.2 decreases glycosylation seems to be generally valid. Within this area, some variation in the results is seen.

23.5.4.8 Serum. While the addition of bovine serum traditionally has been an essential component of mammalian cell culture, concerns of contamination from the bovine source spreading to humans such as the Creutzfeldt–Jakobs disease, has decreased the use of serum to an absolute minimum. The effect of this change to serum-free growth medium is quite dependent on the cell line. In nearly all of the studies in Table 23.12, removal of serum increased the level of glycosylation, both in terms of site occupancy (396), and especially sialylation. One exception is for BHK-21 cells, where site occupancy dropped with the removal of serum.

TABLE 23.12. Effect of manipulation with process parameters and medium components on protein glycosylation. For the cell line, information is shown on the immediate progenitor (before transformation with the recombinant protein) if known.

Parameter	Reported effect	Cell line	Protein	Reference(s)
Amino acid supplementation	Adding glycine, threonine and proline increased α-2,3- and α-2,6-sialylation and galactosylation	CHO DUKX-B11	t-PA	(360)
Amino acid supplementation	Addition of depleted amino acids decreased glycosylation due to a bottleneck in β-galactosylation	CHO DHFR-	hEPO	(361)
Ammonium conc.	Adding >2 mM ammonium decreases α-2,6-sialylation of *O*-glycans	CHO	G-CSF	(362,363)
Ammonium conc.	Adding ammonium decreases glycosylation. The effect increases with pH.	CHO DHFR-	mPL-I	(174)
Ammonium conc.	Increasing ammonium concentrations decreases the expression of CMP-SiaT and α-2,3-sialyltransferase	CHO DUKX-B11	t-PA	(364)
Ammonium conc.	Sialylation is inhibited by ammonium.	Plasma cells	IgM	(365)
Ammonium conc.	Addition of ammonia decreases O-glycosylation and reduces sialylation in both O- and *N*-glycans	CHO-K1	hEPO	(366)
Ammonium conc.	Increased ammonium decreases tetraantennary structures and sialylation.	CHO-K1	hEPO	(367)
Ammonium conc.	The branching of the *N*-glycans decreased with increasing ammonium concentration	CHO	hEPO	(368)
Ammonium conc.	Increased ammonium concentrations may give increased branching due to an indirect effect of UDP-HexNAc pool size	BHL-21	IL-2	(369)
Ammonium conc.	Polysialylation decreases with higher concentrations	CHO MT2-1-8	NCAM	(370)
Ammonium conc.	20 mM NH_4Cl decreased polysialylation	SCLC N417	NCAM	(371)
Ammonium conc.	20 mM NH_4Cl decreased polysialylation	CHO MT2-1-8	NCAM	(371)
BSA addition	Decreases percentage of glycosylated protein	CHO DHFR-	IFN-γ	(157)
Calcimycin addition	Inhibits N- and O-glycosylation	CHO DHFR-	EPO, M-CSF	(372)
Cell viability	Sialidase, β-galactosidase, β-hexosaminidase, and fucosidase activities were found in cell lysates, potentially leading to degradation in the medium	CHO DHFR- (WB1), NS0, HEK-293, human-mouse hybridoma	-	(373,374)
Cell viability	Low viability correlates with lower sialylation and shorter glycans, possibly due to degradation	CHO DUKX	IFN-γ	(375)
Chloroquine addition	Sialylation is inhibited	Plasma cells	IgM	(365)
Cultivation mode	Sialylation may decline in the course of a batch cultivation relative to perfusion	CHO-K1	IFN-γ	(376)
Cultivation mode	Glycan content and sialylation was higher in perfusion than in fed-batch	CHO-DG44	SEAP	(377)
Cultivation mode	Galactosylation is decreased by: Lower chemostat dilution rate, hollow fibre cultivation (rel. to chemostat or batch), and low oxygen levels.	NS1	IgG	(191)
Cultivation mode	Fed-batch improved protein yields relative to batch cultivation	CHO DUKX	IFN-γ	(375)
Cultivation mode	Medium feeding increased glycosylation site occupancy	CHO	IFN-γ	(159)
Culture duration	Glycan truncation was shown to increase up to 52% of the RP after 240h	CHO	IFN-γ	(378)
Culture duration	The extent of glycosylation decreased with the cultivation period	CHO	IFN-γ	(379)

TABLE 23.12. (*Continued*)

Parameter	Reported effect	Cell line	Protein	Reference(s)
Cycloheximide addition	Increased the percentage of glycosylation protein from 20 to 80%	C127	Prolactin	(380)
Cytidine addition	Decreased polysialylation	CHO MT2-1-8, SCLC N417	NCAM	(371)
Dissolved oxygen (DO)	Sialylation increases with% DO.	CHO	hFSH	(143)
Dissolved oxygen (DO)	Reducing DO reduces galactosylation	Sp2/0	IgG1	(381)
Dissolved oxygen (DO)	No detectable effect of hypoxia, protein activity is decreased by anoxia	CHO DUKX-B11	t-PA	(382)
Dissolved oxygen (DO)	Glycosylation was similar from 3-200% air saturation with the exception of fucosylation which decreases below 50% and above 100%	CHO-K1	hEPO	(383)
Dissolved oxygen (DO)	Oscillating oxygen tension increases sialylation, branching and galactosylation	murine hybridoma	IgG1	(384)
Dissolved oxygen (DO)	Decreased sialylation with 100% DOT	CHO DUKX-B11	EPO-Fc	(385)
DMSO addition	Decreased sialylation	CHO	hIFN-β	(386)
Fructose addition	Glycosylation was lower than on a glucose-medium	human hybridoma	IgG	(387)
Galactose addition	Insignificant increase in *N*-glycan galactosylation	GS-NS0	IgG1	(188)
Galactose addition	Glycosylation was lower than on a glucose-medium	human hybridoma	IgG	(387)
Galactose addition	Did not increase sialylation	CHO	IL-CT	(171)
GlcN+Uridine addition	Increased antennarity	GS-NS0	TIMP-1	(129)
GlcN+Uridine addition	Increases the percentage of tetraantennary *N*-glycans	BHK-21	IL-2	(369)
GlcN+Uridine addition	Large decrease in polysialylation	CHO MT2-1-8, SCLC N417	NCAM	(371)
GlcN addition	No effect on glycosylation	CHO DHFR-	IFN-γ	(157)
GlcN addition	57% reduction in *N*-glycan galactosylation	GS-NS0	IgG1	(188)
GlcN addition	Decreases *N*-glycan site occupancy	CHO-K1	hEPO	(127)
GlcN addition	Decreases *N*-glycan branching	CHO	hEPO	(368)
GlcN addition	Decreased polysialylation	CHO MT2-1-8	NCAM	(371)
GlcNAc addition	Substitution of 20 mM glucose for 20 mM GlcNAc increased the biological affinity of the antibody 10x by modification of light-chain *N*-glycans	human hybridoma	IgG	(388)
Glucose concentration	N- and O-glycosylation is stable with changing concentrations	BHK-21	IgG-IL2	(141)
Glucose concentration	Glucose limitation led to decreased glycosylation site occupancy	CHO-K1 DHFR-	IFN-γ	(389)
Glucose concentration	Glucose limitation led to decreased glycosylation site occupancy	CHO	IFN-γ	(161)
Glucose concentration	Glycosylation was higher on glucose than on fructose, mannose or galactose	human hybridoma	IgG	(387)
Glucose concentration	Galactosylation decreases under low glucose concentrations	CHO DXB-11	IgG	(167)
Glucose concentration	Low concentration leads to decreased sialylation and increased presence of hybrid and high-mannose glycans	CHO DUKX	IFN-γ	(375)
Glucose concentration	Very low concentrations of glucose decreased glycosylation site occupancy	CHO	IFN-γ	(159)
Glutamine addition	Reduces degradation of the *N*-glycans	CHO-K1	hEPO	(127)
Glutamine concentration	N- and O-glycosylation is stable with changing concentrations	BHK-21	IgG-IL2	(141)
Glutamine concentration	Glutamine limitation led to decreased glycosylation site occupancy	CHO	IFN-γ	(161)

(*continued*)

TABLE 23.12. (*Continued*)

Parameter	Reported effect	Cell line	Protein	Reference(s)
Glutamine concentration	Low concentration leads to decreased sialylation and increased presence of hybrid and high-mannose glycans	CHO DUXK	IFN-γ	(375)
Glycerol addition	Improves the time-dependent de-sialylation	CHO	hIFN-β	(386)
Glycine betaine addition	Beneficial for polysialylation at high osmolality (>435 mOsm/kg), but decreases polysialylation decreases with higher concentrations at lower osmolality.	CHO MT2-1-8	NCAM	(370)
Growth phase	Sialylation was higher during the stationary phase (compared to exponential and death phase). This effect increases with temperature.	CHO DUKX-B11	EPO	(390)
Growth rate	Glycosylation site occupancy decreases at growth rates <0.014 h-1	CHO DHFR-	IFN-γ	(391)
Lipid supplements	BSA with a mixture of lipids increased glycosylation	CHO DHFR-	IFN-γ	(392)
Lipid+BSA supplements	Decreases percentage of glycosylated protein	CHO DHFR-	IFN-γ	(157)
ManNAc addition	Decreased sialylation	GS-CHO, GS-NS0	TIMP-1	(129)
ManNAc addition	Feeding 20 mM increased complete sialylation of bi-antennary *N*-glycans with 15%	CHO	IFN-γ	(393)
ManNAc addition	No effect on sialylation	GS-NS0	IgG1	(188)
ManNAc addition	Sialylation is decreased	Rat hepatocytes	total protein	(394)
ManNAc addition	Increased polysialylation	CHO MT2-1-8	NCAM	(371)
ManNAc addition	Slight increase in polysialylation	SCLC N417	NCAM	(371)
Mannose addition	Glycosylation was lower than on a glucose-medium	human hybridoma	IgG	(387)
Medium selection	Glycosylation was more complete on a protein-free medium than on a serum-free in batch cultures	CHO K1	IFN-γ	(395)
Microcarrier culture	Higher degree of branching in a suspension culture than in microcarrier culture	BHK-21	IL-Mu6	(396)
Microcarrier culture	Microcarrier culture had increased sialylation and decreased fucosylation relative to suspension	CHO-K1	SEAP	(137)
Microcarrier culture	No significant difference between microcarrier and suspension culture	CHO	β-IFN	(397)
Microcarrier culture	Glycosylation is unaffected by scale-up	CHO	EPO	(154)
Microcarrier culture	No significant difference between microcarrier and suspension culture	CHO	IFN-γ	(398)
Miscellaneous additives	Addition of 2,3-dehydro-2-deoxy-N-acetylneuraminic acid to the culture supernatant inhibits extracellular sialidases	CHO DUXB11	gp120	(399)
Mn^{2+} concentration	Increased galactosylation, site occupancy, and decreased branching		hEPO	(361)
Mn^{2+} concentration	Increased site occupancy with increased Mn2+ concentration	CHO DUKX	t-PA	(400)
Mn^{2+} concentration	Manganese addition partially counteracts the negative effects of calcimycin and Thapsigargin addition	CHO DHFR-	EPO, M-CSF	(372)
Mn^{2+} concentration	Manganese is essential for O-glycosylation	CHO DHFR-	EPO, M-CSF	(372)
NaBu addition	Increases *N*-glycan site occupancy	CHO DUKX	t-PA	(176)
NaBu addition	Sialic acid content increased	CHO	hFSH	(143)

TABLE 23.12. (*Continued*)

Parameter	Reported effect	Cell line	Protein	Reference(s)
NaBu addition	Increased extension of the *N*-glycan antennae with polylactosamine units. No effect on sialylation	HT1080	hEPO	(401)
NaBu addition	Increases *N*-glycan site occupancy	CHO DUKX	t-PA/GP2	(400)
NaBu addition	No change in glycosylation while production increased	CHO K1	IgG3	(402)
NaBu addition	Decreased sialylation	CHO	hIFN-β	(386)
NaBu addition	Dramatic decrease in sialylation	CHO DUKX	IACM	(403)
NaBu addition	Decreased sialylation, decreased biological activity	CHO DUKX-B11	hTPO	(404)
NaBu addition	Decreased fully sialylated biantennary *N*-glycans and increased branching	CHO	IFN-γ	(398)
NaCl addition	Polysialylation decreases with higher concentrations	CHO MT2-1-8	NCAM	(370)
NaCl addition	40 mM NaCl did not affect glycosylation significantly	CHO	IFN-γ	(398)
Osmolality	Galactose content decreased with increased osmolality	Sp2/0	IgG2a	(405)
Osmolality	Polysialic acid content decreases with higher osmolality	CHO MT2-1-8	NCAM	(370)
Osmolality	Increase only affects sialylation slightly	CHO MT2-1-8	t-PA	(370)
pCO_2	Neu5Gc proportion of total sialic acid content decreased under elevated pCO2. No other difference in glycosylation was seen	CHO MT2-1-8	t-PA	(406)
pCO_2	Elevated pCO2 increased glycan galactose content	Sp2/0	IgG2a	(405)
pCO_2	Glycosylation was not found to be dependent on pCO2	CHO DXB-11	IgG	(167)
pCO_2	Polysialylation decreases with increasing pCO2 and pH	CHO MT2-1-8	NCAM	(407)
pH	Glycosylation decreases outside the range of 6.9–8.2	CHO K1	mPL-I	(408)
pH	In the presence of 9 mM ammonium, increasing pH decreases glycosylation.	CHO	mPL-I	(174)
pH	Increasing pH decreases *N*-glycan site occupancy	CHO DUKX	GP2	(400)
pH	pH 7.4 increases the NeuAc/Neu5Gc ratio and increases galactosylation. Sialylation is higher at pH 7.2.	mouse hybridoma	IgG	(190)
pH	Reducing pH at decreased temperature (30 or 33 °C) counteracted decreased sialylation	CHO DUKX-B11	EPO-Fc	(409)
pH	No significant effect on sialylation	CHO DUKX-B11	EPO-Fc	(385)
pH	Sialylation decreased with increasing pH	CHO DUKX-B11	EPO	(390)
pH	Polysialylation decreases with increasing pH and pCO2	CHO MT2-1-8	NCAM	(407)
Serum addition/removal	Serum decreases terminal sialylation and proximal fucose as well as site occupancy.	BHK-21	IL-Mu6	(396)
Serum addition/removal	Serum addition decreases glycosylation	CHO DHFR-	IFN-γ	(157)
Serum addition/removal	Sialylation is higher in serum-free medium	CHO	EPO	(173)
Serum addition/removal	Sialylation is higher in serum-free medium	murine hybridoma	IgG1	(193)
Serum addition/removal	An osmolality-dependent decrease in polysialylation was lower on serum-free medium	CHO MT2-1-8	NCAM	(370)
Serum addition/removal	Removal of serum decreases glycosylation site occupancy	BHK-21	AT-III	(146)
Serum substitution	Addition of animal tissue hydrolysate decreased sialylation	CHO	IFN-γ	(131)

(*continued*)

TABLE 23.12. (*Continued*)

Parameter	Reported effect	Cell line	Protein	Reference(s)
Shear stress	*N*-glycan site occupancy decreases with shear stress	CHO DUKX-B11	t-PA	(410)
Temperature	32 °C was shown to be the optimal in terms of glycosylation complexity	CHO DUKX-B11	hEPO	(411)
Temperature	Decreased temperature (33 °C) increases *N*-glycan site occupancy.	CHO DUKX	t-PA	(176)
Temperature	Decreased temperature (33 °C) did not affect glycosylation	CHO-K1	hGM-CSF	(412)
Temperature	Sialidase activity was not affected by decreased temperature	CHO DUKX-B11	t-PA	(413)
Temperature	Decreased temperature (33 °C) increases *N*-glycan site occupancy.	CHO DUKX	t-PA	(400)
Temperature	Decreased temperature (33 °C) increased sialylation and decreased fucosylation	CHO-K1	SEAP	(137)
Temperature	Decreased temperature (30 or 33 °C) decreased sialylation	CHO DUKX-B11	EPO-Fc	(385,409)
Temperature	Decreased temperature had no effect on sialylation	CHO DUKX-B11	hEPO	(414)
Temperature	Decreased temperature had no effect on glycosylation	CHO	IFN-γ	(398)
Temperature	Cultivation at 21 degrees increases Golgi residence time and increases glycosylation	HL.-60	LAMP	(415)
Thapsigargin addition	Inhibits O-glycosylation	CHO DHFR-	M-CSF	(372)
Thyroxine	Increases *N*-glycan site occupancy	CHO DUKX	t-PA	(400)
Triiodothyronine addition	Increases *N*-glycan site occupancy	CHO DUKX	t-PA	(400)
Uridine addition	Decreased polysialylation	CHO MT2-1-8	NCAM	(371)

[a] ASB, human arylsulfatase B; AT-III, Antithrombin III; BSA, Bovine serum albumin; CSP, Cell surface protein; G-CSF, Granulocyte colony-stimulating factor; GlcN, Glucosamine; hGM-CSF, human granulocyte macrophage colony-stimulating factor; hEPO, Human erythropoietin; IACM, An immunoadhesion chimeric molecule; IFN, Interferon; IgG, Immunoglobulin G; IgG-IL2, IgG-IL2 fusion protein; IL2, Interleukin-2; IL2-GP, Interleukin-2 Mu6; IL-CT, IL-4/13 cytokine trap fusion protein; LAMP, lysosomal membrane glycoprotein; M-CSF, Macrophage colony-stimulating factor; mPL-I, mouse placental lactogen-I; NCAM, neural cell adhesion molecule; SCLC, Small Cell Lung Cancer; SEAP, secreted human placental alkaline phosphatase; TIMP-1, tissue inhibitor of metalloproteinases 1.

23.5.4.9 Temperature. Decreasing temperature from 37°C (typically to 33°C) during the production phase of the cultivation is often employed to increase q_p and arrest growth (106). In general, the hypothermic effect may increase protein glycosylation in terms of *N*-glycan site occupancy as well as glycan complexity, elongation and sialylation. Additionally, it has been reported that decreased core fucosylation may improve the PK of the heterologous protein (Table C). The increased glycan processing has been hypothesized to be due to a temperature-induced residence time in the cisternae of the Golgi complex (415).

23.6 CONCLUSIONS

As the number of glycoprotein therapeutics entering the biopharmaceutical market increases over the coming decades, there will be a commensurate need to identify the effects of glycosylation on the biological activity of the protein therapeutics and to characterize the glycosylation state of the recombinant protein products. We have described here a variety of techniques that can be used for that analysis. However, the bioseparations field is changing rapidly, and it is likely that new techniques will evolve which will allow higher-throughput, on-line characterization which will allow feedback to modify process conditions to improve glycosylation during biosynthesis or to improve purification by selecting more desirable glycoforms.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Dmitri Zagorevski of the Mass Spectrometry facility at RPI for assistance with mass spectrometry and Bo Larsen for constructive feedback on parts of the manuscript.

24.1 PROTEIN SECRETION VIA THE GENERAL EXPORT PATHWAY IN GRAM-POSITIVE BACTERIA

Positioning newly synthesized proteins at their site of action is a vital function for all cells. Secretion allows certain proteins to cross the various structures that give integrity to the cell, and to be subsequently released into the extracellular medium. There exist specialized cases of protein export where in addition to secretion, integration, and/or anchoring of the protein to the different cell envelopes occurs. These special cases will not be discussed in this review.

A multitude of studies focusing on protein secretion have highlighted that similar mechanisms exist among very divergent organisms. Generally, the secreted protein crosses a membrane barrier formed by a phospholipid bilayer: that of the endoplasmic reticulum in eukaryotes and the plasma membrane of gram-positive and gram-negative bacteria.

This review will focus on the secretion of proteins in the bacterium *Lactococcus lactis*, a model organism for the lactic acid bacteria (LAB). *L. lactis* is a gram-positive bacterium with distinct cellular compartments: (i) the cytosol, (ii) the plasma membrane, and (iii) the cell wall which forms a rigid exoskeleton protecting the cell against external aggression. This final structure represents, for secreted proteins, an additional barrier to overcome.

In gram-positive bacteria, several secretion pathways have been reported: (i) the general export pathway (GEP) or "Sec" pathway represents the primary pathway used for the majority of proteins, and on which this review will focus. More specific and rare systems, which will not be covered here, included (ii) the "Tat" pathway (Twin Arginine Translocation), targeted toward transporting proteins that have adopted their tertiary conformation along with their associated cofactors; (iii) ABC transporters (ATP-Binding Cassette); and (iv) the type IV prepilin system.

The secretion of proteins via the "Sec" or "Sec-dependent" pathway can be divided into three major steps (Fig. 24.1):

1. The synthesized protein is a cytoplasmic precursor (or preprotein) containing a secretion signal or signal peptide (SP) that is cleaved leading to the mature secreted protein. Comparative studies of SP primary sequences in prokaryotic and eukaryotic organisms have revealed a common overall structure (1–3): (i) an N-terminal region (N) carrying positive charges; (ii) a hydrophobic region with a helical fold (H); and (iii) a C-terminal region (C) carrying the cleavage site recognized by the signal peptidase (SPase) that releases the mature protein (Fig. 24.2). Compared

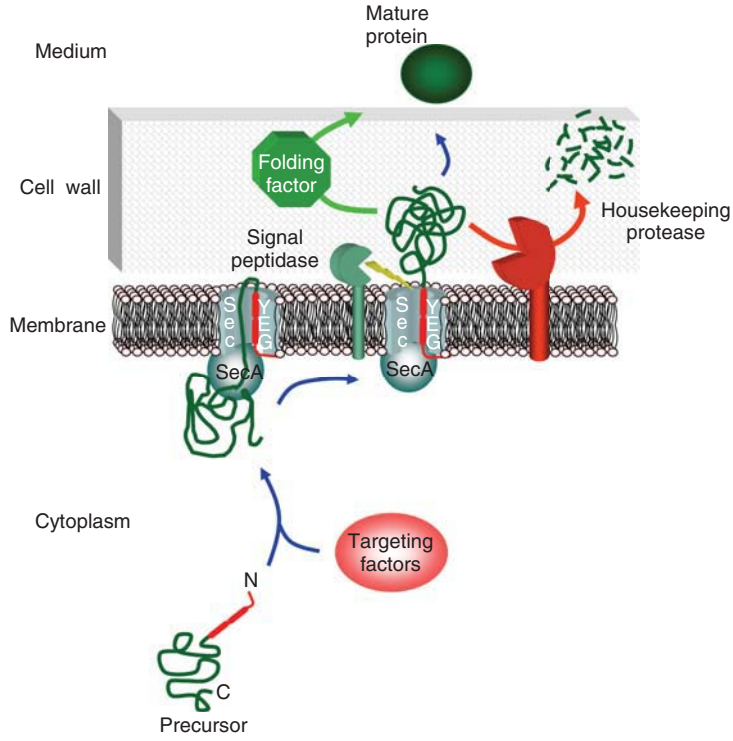

Figure 24.1. Protein secretion in gram-positive bacteria. The secreted proteins are synthesized as a precursor bearing a signal peptide at its N-terminal end. The precursor is recognized by dedicated factors which transport it to the secretion machinery. This machinery is composed of a motor protein, SecA, along with additional subunits, SecY, SecE, and SecG, which form a transmembrane channel permitting the precursor to translocate across membrane (Sec translocon). During or after translocation, the cleavage of the signal peptide by the signal peptidases releases the mature protein into the extracellular medium. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

with SPs of secreted proteins in *Escherichia coli*, the SPs of the gram-positive bacteria are generally longer in all three domains N, H, and C (1). During the synthesis of the precursor, the SP is recognized by cytosolic transport factors that can be general (chaperons) or dedicated to secretion. Their role is to maintain the precursor in an unfolded state which is able to be translocated and to direct it toward the membrane Sec proteins involved in translocation. In gram-positive bacteria, gene conservation and experimental data show that the addressing process via the complex signal recognition particle (SRP) and its receptor FtsY play a major role in the secretion of proteins.

2. Translocation of the precursor across the membrane involves several components. In most bacteria, SecA is the motor of protein translocation and SecY, SecE, and SecG form a hydrophilic transmembrane channel (Sec translocon) through which the precursor crosses the lipid membrane in an unfolded form (4–6). In some microorganisms, other proteins termed *accessory proteins* (some of them seem to be dispensable or not conserved, and their function is not as well established as that of SecA-SecYEG) can be associated with the Sec translocon and improve the secretion. Examples in *E. coli* include the SecDSecFYajC complex that has been shown to stimulate translocation (7) and YidC (8) that is mainly involved in the insertion of transmembrane proteins.
3. After crossing the plasma membrane, precursors undergo a maturation step in which (i) the SP is cleaved and (ii) proteins adopt their stable and active conformation. The cleavage of the SP involves the type I SPase that allows release of the secreted mature protein into the extracytoplasmic environment (periplasmic compartment of gram-negative bacteria, and extracellular medium in the case of gram-positive bacteria). The adoption of the active and stable conformation is subject to rigorous quality control in the cell envelope. This step may involve

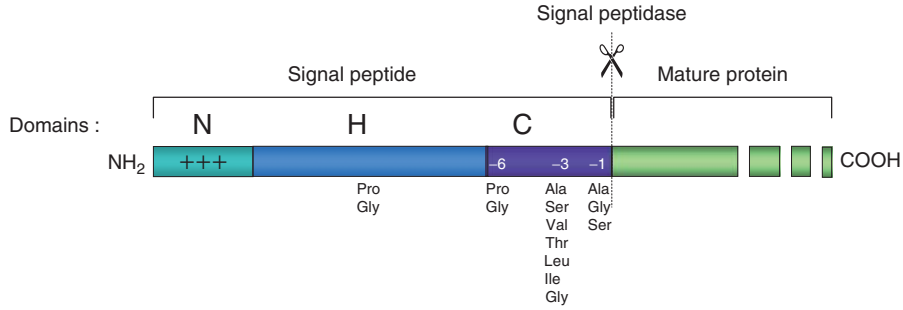

Figure 24.2. The three-part structure of the signal peptide (SP). The SP, fused to the mature protein, is composed of three domains: N, positively charged (+) N-terminal; H, hydrophobic; and C, C-terminal, containing the cleavage site of the SP recognized by the signal peptidases. Proline and Glycine residues are usually found in the middle of the H domain and between the H and C domains at position −6 with respect to the cleavage site: they allow for the disruption of the helix structure of the H domain. The signal-peptidase recognition site is composed of aliphatic residues, most commonly Alanine, at the −1 and −3 positions (3). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

exported folding factors (chaperons and folding catalysts) its role is to assist the secreted protein in the adoption of its functional conformation. Under stress conditions, in particular environmental (thermal) stress or biotechnological stress (secretion of heterologous overexpressed proteins), folding may be compromised leading to an accumulation of unfolded or misfolded proteins that are not functional and might be toxic. In response to such stresses, bacteria induced the expression of exported factors involved in protein quality control: folding factors to repair the damaged proteins and exported proteases to degrade them (9,10). Among these proteases, the HtrA family that is widely conserved in eukaryotes and prokaryotes (and in particular in gram-positive bacteria) (11), is the most studied, but other exported proteases are also involved in a similar housekeeping function (furthermore, in gram-positive bacteria, secreted proteases of broad specificity are known to degrade secreted heterologous proteins).

24.2 SECRETION OF HETEROLOGOUS PROTEINS IN *L. LACTIS*

An understanding of the secretion mechanism in *Bacillus subtilis* has allowed the development of effective strategies to construct and improve optimized expression strains (9–12). Currently, the genus *Bacillus* is widely used for the production of high yields of naturally secreted proteins (60% of enzymes commercially available) (9,12,13). However, secretion yields of heterologous proteins in this system are generally much lower (9,12,13). As a consequence, other gram-positive bacteria are proving competitive for the secretion of heterologous proteins. Among them, LAB possesses several natural advantages, such as their status of food component and optimized recombinant strains, which represent a particularly interesting alternative especially for the production of therapeutic proteins and peptides that are destined to human. To date, the optimized recombinant LAB are the subject of two major areas of advanced research (i) for the production of proteins in a fermenter and (ii) for the *in situ* delivery of therapeutic proteins such as interleukins, bacterial, and viral antigens (14).

Among the LAB, *L. lactis* is the most well studied and is considered as a model organism. It is a homofermenting mesophilic bacterium, which is divided into two subspecies, *L. lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris* (15,16). A number of genetic tools have been developed for this species, and the genomes of three strains have been sequenced (17–19).

In terms of heterologous protein production, *L. lactis* has several interesting characteristics that make it the species of choice when compared with other common bacterial systems, such as *E. coli* (20) and *B. subtilis* (12). Importantly, as *L. lactis* has safely been used in the dairy industry for years, and does not produce endotoxins, proteins produced in this bacterium should be GRAS (generally recognized as safe) according to FDA (Food and Drug Administration, USA) as in many other LAB. *L. lactis* is efficient for heterologous secretion and it naturally secretes a single protein, Usp45 (in significant amounts in the supernatant) (21,22), thereby limiting the downstream purification steps necessary to recover the heterologous secreted protein. Moreover, the strains used in the laboratory have only a single extracellular housekeeping protease, HtrA, and in *htrA* mutants, extracellular proteolysis of heterologous proteins is completely abolished (32–73). As extracellular protease-free strains, *htrA* mutants are very efficient hosts to improve protein

yield (23,26). In *B. subtilis* whose extracellular proteolytic system is much more complex, extracellular protease-free strains are not available: although nine extracellular proteases have been inactivated, four active surface proteases, including the three members of the HtrA family, are remaining (27,28). Finally, in *L. lactis*, the relatively simple fermentative metabolism ensures that optimized culture conditions, as defined in the laboratory, are easily transferable to an industrial scale (29,30).

Because of its advantages, many studies have used *L. lactis* to produce secreted recombinant proteins (Table 24.1) (31). The various strategies that have been used to improve the production yields of secreted proteins

are described in *L. lactis*. Most strategies involve developing effective expression systems (32) and optimized strains (31).

24.3 EXPRESSION SYSTEMS

In bacteria, expression systems for recombinant proteins typically use plasmids, which are easily manipulated. These plasmids carry the signals of expression and all the information necessary for the synthesis of the protein of interest. Most of expression systems available in LAB generally derived from those that have been developed in *L. lactis*. In other commonly used LAB, such as those belonging to the *Lactobacillus* genus, very few alternative expression systems have been developed (65).

24.3.1 Vectors

In lactococci, plasmids have been implicated in contributing to the plasticity of the genome by promoting the exchange of DNA between and within species. This plasticity allows the cell to adapt to a sometimes hostile environment, and can play a vital role in cell physiology by providing new properties. Some of these new properties have proven of technological interest (66). The natural plasmids of these bacteria present several advantages toward the development of genetic tools: (i) they are of limited size, facilitating extraction, and manipulation and (ii) many of them are easily selectable and transformable in large host range. Several types of vectors have been developed and characterized for protein production in *L. lactis*. The stability of expression vectors, related to their replication and selection, affects the efficiency of expression of the genes they carry (67).

24.3.2 Expression of the Target Gene

In prokaryotes, an understanding of the molecular mechanisms implicated in protein synthesis allowed for the characterization of signals. These signals are encoded in the gene sequence and modulate its expression through the transcription and translation steps. The optimization of these signals on expression vectors can thus enhance expression of heterologous proteins, particularly in *E. coli* (20,68–71).

24.3.2.1 Promoters. The transcription of a gene is a critical step in the synthesis of a protein. It defines, when factoring in degradation, the level of mRNA present in a cell. This process includes several steps: initiation followed by elongation and termination.

In *L. lactis*, the molecular mechanism of transcriptional initiation is considered identical to that which has been elucidated for *E. coli*, *B. subtilis*, and most other prokaryotes. This step involves two key elements: the promoter sequence or gene promoter and the RNA polymerase subunit which binds to the promoter sequence in order to initiate transcription (32,72). RNA polymerase is a protein complex comprising a main factor, encoded by the *rpoD* gene, which is homologous to the ρ^{70} factor of *E. coli* and ρ^{43} of *B. subtilis*. This main factor binds to the promoter, and to additional subunits 2 $\alpha\beta\beta'$, ω and $\tilde{\delta}$. The binding affinity of the ρ factor for the promoter regulates the strength of the promoter and thus influences the frequency with which transcription initiates. The model of the promoter region upstream of the +1 of transcriptional initiation includes two consensus hexanucleotide sequences, TATAAT (−10 box) and TTGACA (−35 box), with an optimal spacing of 17 nucleotides, although some promoters only include one extended −10 sequence: TGNTATAAT. In *L. lactis*, the promoters that are functional *in vivo* are consensual (32,73).

Most studies to identify or characterize promoters are based on the use of screening vectors carrying a reporter gene without a promoter. Many reporter genes have been described. They generally encode enzymes carrying an easily detectable and/or measurable activity such β-galactosidase (74,75), luciferase (76) or nuclease (Nuc) from *Staphylococcus aureus* (Nuc) (77). They may also confer a selective advantage such as antibiotic resistance (78–83) der van Rooijen *et al*., 1992.

In random screens, chromosomal DNA libraries are cloned upstream of the reporter ORF to create either transcriptional or translational fusions on an appropriate plasmid vectors. Alternatively, the reporter ORF is cloned into a transposon which is randomly inserted into the genome. In the second method, integration into the chromosome can be stimulated by inserting a transposon into the screening vector (74). Additionally, a large library of synthetic promoters has been generated by the cloning of degenerate oligonucleotides in which consensus sequences were conserved (84). In *L. lactis*, many promoters have been identified by targeted analysis of genes whose expression profile is linked to cellular metabolism (80,83,85–87).

Taken together, the results of these studies have identified two types of promoters: constitutive promoters and regulated or inducible promoters. Constitutive promoters, for which no regulation is described, allow for continuous and stable transcription under standard culture conditions. By contrast, regulated promoters modify the level of transcription of genes they control to allow the cell to adapt to environmental variables. These promoters involve regulators that interact with the promoter sequence and modulate the capacity binding of the RNA polymerase. In this section, we mainly describe the promoters used for recombinant protein production in *L. lactis*.

24.3.2.1.1 Constitutive Promoters. In *L. lactis*, a wide range of constitutive promoters of varying strength are

present. The most common of these have been isolated and characterized by Vander Vossen *et al*. (79). In this study, a genomic DNA library of strain *L. lactis* sp. *cremoris* WG2 was cloned into a screening vector carrying the reporter gene *cat-86* which confers resistance to chloramphenicol. This library allowed for the random selection and isolation of five genomic DNA fragments (P21, P23, P32, P44, and P59) which gave chloramphenicol resistance in *L. lactis* and *B. subtilis*. The differences in levels of measured CAT activity (from 0.2 to 5.1 U/mg) suggested the isolation of promoters of varying strengths: P59> P23> P21> P32> P44 where P59 is the strongest promoter. As has been observed in other bacteria, analysis of the nucleotide sequence showed that sequences driving the highest level of activity were those with −35 and −10 hexanucleotides which most closely resembled the consensus.

These promoters have been widely used and integrated into systems for the expression of food-related recombinant proteins (Table 24.2). Some of this work was used to compare the effectiveness of these promoters and yielded results that were sometimes in disagree with previously reported values (88). However, these studies directly compared the production of proteins whose genes had been placed under the control of these promoters, thus eliminating the bias introduced by differences in translation efficiency. No study has yet compared of the strength of these promoters by direct measurement of the amount of transcripts.

24.3.2.1.2 Inducible Promoters. In contrast to constitutive promoters, the level of mRNA for a gene of interest can be controlled using regulated/inducible promoters. These promoters are generally derived from genes whose regulated transcription allows the cell to adapt to its environment. Integrated into expression systems, these promoters allow fine tuning of transcription for the gene of interest in accordance with growth conditions. Regulators, positive or negative, bind to specific sequences on these promoters, influencing the efficiency of RNA polymerase binding and the frequency of transcriptional initiation. Inducible promoters are particularly interesting in instances where a protein toxic to the cell as higher yields can be achieved by allowing an increase in biomass prior to induction of the protein. A wide range of inducible promoters is described in *L. lactis* where induction can be induced (i) by exposure to different stresses such as changes in temperature, pH or phage attack and (ii) a change in cellular metabolism related to the chemical composition of the medium (32,98,99). However, the use of some promoters such as the heat-inducible promoter (100) or that induced by phage φ 31 attack (101) can be problematic during the processes fermentation and large scale production. Only well-defined systems will be of significant interest in these types of processes in *L. lactis*.

24.3.2.1.2.1 Nisin Promoter/NICE system. Nisin Inducible Controlled Expression (NICE) system was developed using the regulatory elements of the *nis* operon that is involved in the biosynthesis of nisin, an antimicrobial peptide naturally secreted by certain strains of *L. lactis* (102). The NICE system is based on the nisin promoter P_{nisA} and the two-component system *nisRK* that naturally regulates *nis* operon (103). NisK is a membrane sensor with kinase activity which activates the transcription factor NisR of the promoter P_{nisA} in the presence of nisin in the medium (Fig. 24.3). NICE system is widely used for the expression of heterologous proteins in *L. lactis* (31,104,105). A wide variety of expression vectors in which expression of a gene of interest is placed under the control of the P_{nisA} promoter have been developed

TABLE 24.2. Heterologous Proteins Expressed in *L. lactis* under the Control of Constitutive Promoters

Proteins	Species	Promoter	References
Chitinase	*Serratia marcescens*	P32, P59	89
M6	*Streptococcus pyogenes*	P23, P59	90

[a] From the library isolated by van der Vossen *et al*. (79)

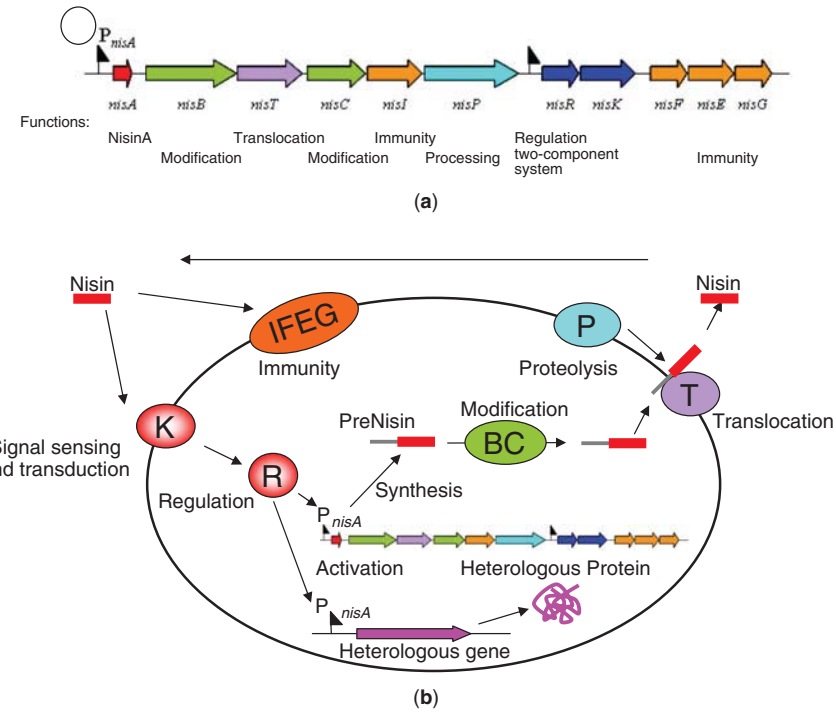

Figure 24.3. The NICE system. (a) Genetic organization of the nisin biosynthetic operon: *nisA* is the structural gene coding for nisin and *nisRK* genes are regulating the transcription of the whole *nis* operon. The products of the genes *nisBC* are implicated in the modification of the nisin precursor while *nisTP* translocates and cleaves it. The products of the genes *nisIFEG* play a role in nisin immunity. (b) Model of biosynthesis and regulation: The sensor, NisK, is autophosphorylated in the presence of nisin in the medium. The phosphate group is transferred to NisR, a transcriptional activator. The nisin precursor is modified by NisBC before being translocated by NisT and activated by NisP cleavage. The active nisin is then released into the medium. NisIFEG protects the cell against the bactericidal effect of nisin. At subinhibitory concentrations of nisin in the medium, only the presence of NisRK is required for activation of the promoter P_{nisA}. A protein of interest can be expressed and regulated if placed under the control of P_{nisA} in the presence of *nisRK* genes (106). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

and they are generally used in recombinant strains where *nisRK* genes have been integrated into the chromosome. The nisin inducible system and derivatives are the most widely used in LAB.

This system has many advantages including ease of use, tight regulation, and high expression levels. Furthermore, recent studies have described the use of this system in the industrial scale production of a cytoplasmic recombinant form of lysostaphin from *Staphylococcus simulans* biovar staphylolyticus. Optimized growth conditions and media composition during fermentation, including the amount of nisin added, can triple production yields of this protein (100–300 mg/L) (29). A follow-up study revealed that this production level is linear along production scales from 1–3000 L (30) demonstrating the strong potential of this system for industrial scale production. However, the use of nisin as inducer agent may be pose both technical and economic constraints due to high cost and the need for downstream purification and disposal.

24.3.2.1.2.2 P170 Promoter. The pH-inducible P170 system is another expression system compatible with large scale production. In *L. lactis*, P170 promoter controls transcription of or*fX*, a gene of unknown function, and it is induced by a decrease in pH at the stationary phase of growth (107). The growth of *L. lactis*, under classical culture conditions, in which glucose is the carbon source, causes the accumulation of lactic acid in the medium. This accumulation of lactic acid causes a decrease in pH (pH <6), activating the promoter during the transition from exponential growth to stationary phase (107). The P170 promoter is regulated by RcfB (108).

This system was also improved by defining (i) an optimal promoter sequence for the P170gx which permitted more efficient binding, and (ii) an optimized synthetic medium used to achieve high levels of expression (300 mg/L) while using Nuc as the protein model. Compared with other inducible systems, the P170 has the advantage of being autoinducible, limiting most intervention by the researcher.

Reproducibility is improved under this promoter as expression is induced for all cultured cells at the same time. Moreover, production tests carried out at scales of 200 L and 1 L showed comparable production yields, purity, and stability.

24.3.2.1.2.3 P_{Zn} PROMOTER. A new expression system has recently been identified and developed in *L. lactis*. It is based on the use of the ZitR-regulated P_{Zn} promoter, which naturally controls the expression of the *zit* operon *(zitRSQP)*. By homology with *adc* operons in streptococci, the *zitRSQP* is involved both in zinc uptake by the ABC transporter ZitSQP, and in the control of its own expression by ZitR, a repressor of the MarR family (99,109). An expression vector, pVE8062 was constructed, carrying the P_{Zn} promoter and its regulator *zitR* (99). Using two reporter proteins, a form of the secreted Nuc from *S. aureus* and a cytoplasmic galactosidase (LacLM) from *Leuconostoc mesenteroides*, it has been shown that heterologous expression controlled by ZitR-regulated P_{Zn} varies in response to the concentration of zinc cations in the culture medium (99,109,110): it is totally repressed by Zn^{2+} in a wide range of concentrations (from profusion to toxicity), and highly induced by severe Zn^{2+} starvation (after addition of a chelator of metals for example) [Fig. 24.4; (99,109,110)].

The addition of zinc to the growth medium could be useful to tightly repress heterologous expression during growth and allow for an increase in biomass before induction by addition of EDTA (a chelator of divalent cations) on exponentially growing cells. Moreover, if a low level of expression can be tolerated throughout culturing, a zinc-limited medium, such as the chemically defined SA medium (111) can be used. This allows for progressive spontaneous induction and requires no modification of culture conditions (99,112). This system is particularly interesting because the implementation of various culture conditions is simple, inexpensive, and totally compatible with large-scale fermentation and production of injectable therapeutic compounds.

24.4 PROTEIN SECRETION IN *L. LACTIS*

Of the 2597 putative proteins detected in the genome of *L. lactis* IL1403 (4107 for *B. subtilis)*, 188 proteins have a unique N-terminal TM segment that might correspond to an SP (284 for *B. subtilis)*. Among them are 39 lipoproteins (114 for *B. subtilis)* and 146 secreted proteins (166 for *B. subtilis)*. When comparing the size of their genomes, *L. lactis* secretes more proteins (handled by SPase I) than *B. subtilis* through Sec (5% against 4.3%, respectively) (Poster, G. (113), 7th Symposium on Lactic Acid Bacteria).

In *L. lactis* most components involved in secretion have been identified through homologies to those described in both the *E. coli* and *B. subtilis* models (Table 24.3). This sequence conservation allows us postulate that their roles in protein secretion are identical to those described in these model bacteria. Comparisons of the different systems do reveal some differences that will be identified by us. Work to improve secretion in *L. lactis* focuses on the modification of the precursor protein and the expression of genes involved in protein quality control. Based on numerous complete genomes of LAB that are currently available, it appears that most of LAB displays secretion machinery comparable to the *L. lactis* one (KEGG Encyclopedia website: http://www.genome.jp/kegg/catalog/org_list.html).

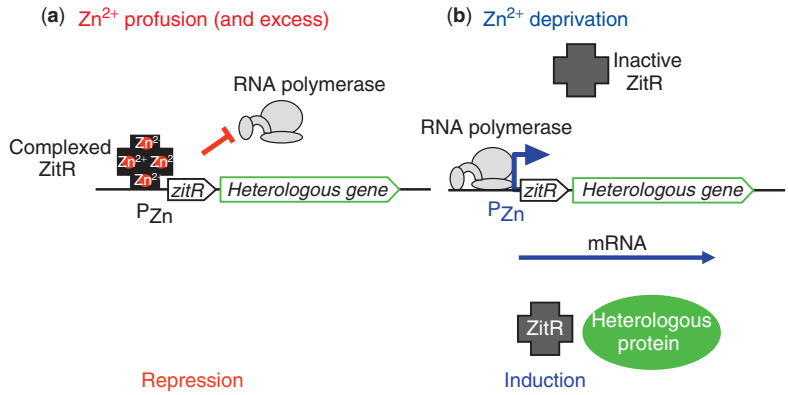

Figure 24.4. Model of regulation and expression of a gene under the control of ZitR-regulated P_{Zn} promoter. (a) Under conditions where zinc is present in sufficient amounts (profusion) or even in excess (toxicity), ZitR repressor is complexed to Zn and active as a DNA-binding protein: its binding on P_{Zn} promoter prevents the initiation of transcription by RNA polymerase. (b) When zinc is scarce in the medium, through use of a zinc-poor medium or by addition of a chelator, ZitR becomes inactive and is unable to bind to the promoter, allowing RNA polymerase to initiate transcription. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

TABLE 24.3. Comparison of Protein Secretion and Quality Control Machineries in *L. lactis* and *B. subtilis*

Components	*L. lactis*	*B. subtilis*
Secretion		
Intracellular chaperonnes and general targeting factors	GroEL, GroES	GroEL, GroES
	DnaK, DnaJ, GrpE	DnaK, DnaJ, GrpE
	Trigger factor	Trigger factor
Specialized targeting factors	Ffh, FtsY, scRNA	Ffh, FtsY, scRNA
		CsaA?
Translocon	SecA	SecA
	SecY, SecE, SecG	SecY, SecE, SecG
Accessory proteins	—, YwaB	SecDF, YrbF
	YbdC/YfgG	SpoIIIJ/YqjG
Type I SPases	SipL	SipS, SipT, SipU, SipV, SipP
		SipW
SPPases	—	SppA
		TepA
Extra-cellular Quality control		
Extracellular folding factors	PmpA	PrsA
	—	BdbA/B/C
Housekeeping surface proteases	HtrA	HtrA, HtrB, HtrC (YyxA)
	—	WprA
	—	CtpA
Secreted Proteases	—	AprE, AprX, Bpr, Epr, Mpr, NprB, NprE, Vpr

24.4.1 Optimization of Precursor

24.4.1.1 The SP. Among the numerous expression systems described for *L. lactis*, many have been designed to allow secretion of a protein of interest into the extracellular medium through GEP by fusing the protein of interest to an SP.

In bacteria, the conservation of the SP structure (described earlier) allows the export of heterologous proteins via their natural SP. Thus, the native form of Nuc of *S. aureus* is secreted in *L. lactis* (34,36). However, it is often assumed that the secretion of a heterologous protein will be more efficient if it is fused to an SP from the production host. To explain this difference, the implication of species-specific factors involved in the recognition of SP is possible.

As was the case for promoter identification, the identification and characterization of the SP is the result of both the study of specific genes encoding a secreted protein and of random strategies. The resulting SP used for the production of heterologous proteins in *L. lactis* comes from the gene *usp45* (21). Its function is unknown, but sequence homology suggests that it might be involved in cell segregation in the hydrolysis of the cell wall (114). SP_{Usp45} has been used in many expression systems combined with constitutive promoters such as P59 (33) or inducible promoters such as the nisin promoter (29–31,115). Moreover, the SP_{Usp45} has been successfully used in other LAB such as in *Lactobacillus plantarum* in which it allows to efficiently drive the export of the human papillomavirus type-16 E7 antigen (116). Furthermore, strategies employing random fusions in order to induce the secretion of a reporter protein have resulted in the generation of several collections of efficient SPs as AL1 (117) and cassettes for expression/secretion as ssx collections (35), PS_{Exp} (77) or SP310 (118,119).

In *L. lactis*, while the fusion of a protein to an SP does not necessarily ensure its efficient secretion into the extracellular environment, it may still confer protection against intracellular degradation (31). Production of the protein NSP4 (nonstructural protein 4) of bovine rotavirus (120), of BLG $\tilde{\beta}$-Lactoglobuline bovine) (51) and GroEL of *Brucella abortus* (121), where little or no secretion is observed, is nonetheless stabilized by their fusion to $SP_{Usp45.}$ The stabilization of these proteins by fusion to the SP could result from a conformational change induced either by interaction with accessory factors and/or intracellular chaperons (31) or by an intramolecular chaperon effect of the SP (122).

24.4.1.2 Propeptide Leisstcda. In *L. lactis*, the fusion of a synthetic propeptide, consisting of the nine residues, LEISSTCDA, between the SP and the mature part of the protein improves the efficiency of secretion of several heterologous

proteins. The protein Nuc (36), the L7/L12 antigen of *B. abortus* (37) and the α- amylase of *Geobacillus stearothermophilus* (31,36,123) are some examples. The effect of the peptide LEISSTCDA has been observed in various expression contexts using different promoters such as that for nisin (48,49,123) or the zinc promoter (GTP-Technology, unpublished) and various SPs such as SP_{Nuc} (123), and SP_{Usp45} (37,48,49) or SP_{Exp4} [(48,49), GTP-Technology, Labège, France, unpublished]. The positive effect of the fusion to this propeptide on translocation could be explained by the introduction of negative charges on the N-terminus of the mature protein, which would restore a balance of charges associated with SP-membrane interaction (31,36,123). Moreover, this positive effect on secretion is generally accompanied by an increase in the amount of protein, suggesting an indirect effect on intracellular proteolysis of the precursor (31). The use of the LEISSTCDA propeptide has also been shown to improve the secretion of Nuc and BLG heterologous proteins in *Lactobacillus casei* BL23 (124).

24.4.1.3 Carrier Proteins. In *L. lactis*, the fusion of a protein of interest to a protein known to be produced and secreted well by the cell can also help in stabilize production and improve secretion. The fusion of the protein L7/L12 to the secreted form of the Nuc from *S. aureus*, induced by SP_{Usp45}, improves the production rate by a factor of 2.5. This fusion also increases the amount of L7/L12 present in the supernatant in the form Nuc-L7/L12 (37). However, this stabilizing effect on protein production does not always lead to an increase in the amount of protein found in the supernatant. In the case of a Nuc-E7 fusion, the efficiency of secretion decreased from 95% to 5% despite increased expression (42). Secretion can be subsequently improved by factor 3 by inserting the LEISSTCDA synthetic propeptide (125).

In *L. lactis*, the different tools used to modify the precursor can also increase the level of total production (resulting from an improved synthesis and/or stability) and/or efficiency of secretion. The contribution of each effect toward improving the amount of protein found in the media varies and is difficult to predict.

24.4.2 Mechanism of Protein Secretion in *L. lactis*

24.4.2.1 Protein Targeting and Translocation. In *L. lactis*, no experimental data is yet available concerning factors involved in the targeting of the precursor to the membrane. *L. lactis* has the genes encoding for the ubiquitous intracellular chaperon systems GroEL/GroES (126) and Dna K/DnaJ/GrpE (127,128). The expression of GroES/GroEL is increased in response to various stresses such as temperature, acidity, ultraviolet irradiation, or concentrated salts (129–131). In response to heat stress, it was shown that expression is increased by a factor of 10 for *dnaJ* and *groEL* genes and of 100-fold for *dnaK* (132). Moreover, their overexpression increases the resistance of bacteria to stress (133). A homolog of *hrcA* from *B. subtilis* along with the CIRCE sequences was also detected in the genome of *L. lactis* (21,22,134). These proteins likely play a role similar to those described for *B. subtilis* and *E. coli* in protein folding. In contrast, in *L. lactis*, the effect of modulating the overexpression of these chaperons on the intracellular production of heterologous secreted proteins has not been the subject of any published studies.

Genomic analysis of *L. lactis* has detected genes encoding homologs of Ffh (*ffh*), HBsu (*hslA*), FtsY, and scRNA from the SRP system (17,135). Models of secondary structures of RNAs from *L. lactis, E. coli* and *B. subtilis* that associate with the SRP were constructed and compared. They show that the structure of the *L. lactis* RNAsc is closer to that of the 4.5 S RNA of *E. coli* than to that of *B. subtilis* (135). No homologs of *E. coli* SecB or *B. subtilis* CsaA have been identified in the genome of *L. lactis* IL1403. In this organism, it is thought that secretion is mainly cotranslational.

With regard to its mechanism of translocation and maturation of precursor proteins, SecA and SecYEG of *L. lactis* are highly homologous to the prototypes in *E. coli* or *B. subtilis*. Among the putative accessory proteins associated with this translocon, YbdC and YfgG, are homologous to SpoIIIJ and YqjG, respectively, of *B. subtilis* (17), and they all belong to the same protein family: Oxa1/YidC. In contrast, no protein homolog of SecDF protein from *B. subtilis* or both SecD and SecF proteins from *E. coli* can be identified by genomic analysis. Finally, *L. lactis* has only one type I SPase, SipL, and no SP peptidase has been identified (17).

The analysis of the genome sequence of the strain IL1403 of *L. lactis* shows that most proteins involved in secretion are present and may play an identical role to those described above. The influence of these different components on the secretion of proteins in this organism has not been reported in the literature.

A strategy of random mutagenesis was used to identify accessory genes directly or indirectly influencing the rate of secretion and/or production of a form of Nuc (136). A collection of mutants called *hypo- and hyper-secretors* were isolated. One of these, carrying a mutation in the gene *dltA* was identified as a hyper-secretor mutant. This study reported that the decrease in D-alanylation of the cell wall affects the release of Nuc into the media resulting in its retention in the cell (136).

On the other hand, the absence of certain factors such as SecDF, which can be regarded as accessory proteins associated with the translocon, and the simplicity of the mechanism of maturation, suggest that the capacity of translocation and precursor maturation in *L. lactis* is limited compared with that of the gram-positive model bacterium

B. subtilis which has a high capacity secretion. Complementation of the *L. lactis* translocation machinery by SecDF from *B. subtilis* allowed to improve the production of both *S. aureus* Nuc protein and *B. abortus* L7/L12 antigen (136).

24.4.2.2 Quality Control of Exported Proteins. As we have seen in this second part, the folding of proteins has a major influence on the process of secretion. It involves many factors, intra- and extracellular, for protein quality control. *In L. lactis*, such a network exists and functions on both sides of the membrane.

24.4.2.2.1 Folding. A network of proteins involved in quality control of the surface is also present in *L. lactis*. The lipoprotein PmpA, homologous to PrsA of *B. subtilis*, belongs to the parvuline family of PPIases, although it lacks the PPIase motif. Depending on conditions, its expression is induced by exposure to salt stress (62). Its overexpression influences the rate of production of a heterologous secreted protein, the lipase of *Staphylococcus hyicus*, suggesting that PmpA could be a chaperon protein (62). The overproduction of the PrsA factor from *B. subtilis* in *L. lactis* can also improve the amount of secreted heterologous proteins such as AmyL when they are overproduced (138).

L. lactis has no homologous counterpart to *B. subtilis* disulfide-bond-oxydo-reductases that are involved in the formation of disulfide bonds, although the formation of disulfide bonds in a secreted heterologous protein (murine interleukin 12) has been described (48,49). However, the low proportion of proteins in which bridges are formed between the two subunits p35 and p40 suggests that they may form spontaneously.

24.4.2.2.2 Degradation of Exported Proteins. For protein quality control at the cell surface, *L. lactis* has the advantage of possessing a single extracellular housekeeping protease, HtrA (23,26). Its inactivation confers a thermosensitive phenotype, probably resulting from the toxic accumulation of misfolded proteins at the cell surface (23). *htrA* expression is induced by exposure to different stresses (heat, salt, and ethanol) (25). The mechanism of *htrA* regulation is not yet known: one of *L. lactis* two-component systems could be involved in this regulation, as in *B. subtilis*, CssRS two-component system is responsible for *htrA* and *htrB* induction in response to thermal or secretion stress. HtrA was also shown to process AcmA, the major autolysin in the cell wall (23).

As part of the production of heterologous secreted proteins, inactivation of the protease is of interest as demonstrated for the lipase of *S. hyicus*. The production of this lipase, which is normally degraded by HtrA, is increased fourfold in the *htrA* mutant (23,24,26,110). This drastic stabilization effect makes *htrA* mutant strain a very attractive host for the production and secretion of stable heterologous proteins (23,26).

24.5 CONCLUSION

Among the broad host range available to produce heterologous protein in bacteria, LAB emerged as very interesting host cell factories. These bacteria naturally offer several advantages compared to other bacterial expression system, their food-grade property being one of the major one. This is of a major concern in the case of therapeutic proteins or peptides especially for human applications. Limited production yields led to many studies aiming to improve yield productions. Numerous tools including expression and secretion systems as well as engineered strains have then been successfully developed in the model LAB *L. lactis* making it an attractive and efficient cell factory to produce heterologous proteins. Based on this knowledge, efficient expression system could be provided in many other LAB such as lactobacilli. It has to be noticed that compared to *L. lactis*, some lactobacilli may offer additional natural advantages such as probiotic activity, better production yield and in some cases, mucosal persistance and/or immune system stimulation (14,116,139). Together, all these studies enlarged LAB scope mostly in production of heterologous proteins and mucosal delivery of therapeutic and prophylactic molecules. Depending on the application, LAB should be now considered as important host production candidates.

SOLUBLE PROTEIN EXPRESSION IN BACTERIA

Catherine H. Schein

Departments of Biochemistry & Molecular Biology/Microbiology & Immunology,
Sealy Center for Structural Biology and Molecular Biophysics, Member, Sealy Center for Vaccine Development,
University of Texas Medical Branch, Galveston, Texas

25.1 INTRODUCTION

My first publications on techniques to avoid the formation of inclusion bodies (IBs) in *Escherichia coli* (1,2) were met with a stream of positive responses from workers in the field. Many others had experienced the problems summarized in the second column of Table 25.1 and were tired of dealing with "solutions of renatured proteins" that contained particulate microdispersions of inactive protein. They also shared my concern that proteins treated with strong denaturants were not the best starting point for biophysical studies, especially in cases where the specific activity had not been determined previously. Spectral techniques such as Fourier transform infrared spectroscopy (FTIR) (1,2,16) and nuclear magnetic resonance (NMR) (3) revealed different folded forms in preparations from IBs. This indicates that there are differences in structure of proteins isolated from IBs compared to those expressed solubly (4). While correctly folded protein is present in IBs (5,6), purification procedures require complete unfolding. The great recent challenge, the structural genomics initiative, further emphasized the need for better methods for soluble expression (7,8). As renaturation from IBs has to be optimized for each protein, one of the first criteria used for targets for structural characterization was whether it could be expressed solubly in *E. coli* (9). However, even after lowering the growth temperature, many proteins are not expressed properly, or aggregate, requiring additional modification of the expression methods. Cell free growth (in lysates), or expression in yeast, insect cells or transfected mammalian cells are all possible alternatives. While expression systems in yeast (10,11) such as *Pichia pastoris* (12–15) and the baker's yeast *Saccharomyces cerevisiae* (16) are inexpensive and well developed, eukaryotic or insect cell culture methods are significantly more expensive than bacterial. Stably transformed higher eukaryotic cell lines are given to variability, tests for expression tests are time consuming, and the scale-up can be quite difficult.

There are numerous illustrations of how difficult it is to prepare proteins from IBs (17). Obtaining an apparently pure protein in solution after renaturing is no guarantee of activity. For example, human tyrosine kinase Lck was completely inactive if expressed insolubly in *E. coli* and renatured from IBs. The protein was active, however, as measured by autophosphorylation, if solubly expressed by coproduction with either gro ESL or TRX (18).

Further, even for proteins that renature well from IBs, point mutations can differ in their solubility as well as their specific activity. Ribonuclease A is probably the most common model for protein refolding experiments. However, a graduate student with experience in expressing RNase A mutants in *E. coli* and isolating them from IBs was unable to obtain an active form of a mutant that represented the ancestral protein of the hooved animals (the gene contains 16 amino acid changes chosen by evolutionary considerations) (19). Undergraduate students in a lab course recloned the gene into an *E. coli* secretion system (20), expressed the mutant protein in a soluble form, and were able to

TABLE 25.1. A List of Perceived Advantages and Actual Disadvantages of Expressing Recombinant Proteins as Inclusion Bodies in *E. coli*

Advantages of IBs	Disadvantages
Many mutants of a single protein can be tested by using an individual shaker flask (or wells of a multiplate) for expression.	Mutants of proteins can differ greatly in their specific activity and ability to refold.
	Shaker flasks do not allow good control of growth conditions.
High expression level means reduced fermentation costs.	Refolding shifts problems and costs downstream.
Production can be monitored with PAGE or immunoblotting.	Production cannot be monitored directly by activity.
Cytoplasmic proteins are washed away, simplifying purification. "95%" purity can be quickly achieved.	The other "5%" contaminants are hydrophobic, insoluble membrane proteins and cell wall fragments.
Removal of cytoplasmic proteins early means less proteolysis.	Significant proteolysis accompanies refolding in dilute solution.
The major contaminants are oligomers and misfolded or proteolyzed forms of the desired protein.	Separation of multiple forms of the same protein is the most difficult purification step.
Protein in inclusion bodies is often the only way to get problem proteins or those toxic to bacteria	If the protein does not refold well, another expression system will still be needed.

determine its specific activity with respect to that of the modern protein (unpublished results).

Most researchers wish to obtain their protein in a soluble form with a minimum amount of work. I thus begin by suggesting alterations in growth conditions which can be tested with most expression systems. The section titled "**Altering the Host Strain and Vector to Direct Soluble Expression"** then discusses alternative host strains and plasmids that are better for directing soluble protein expression. The section titled **"Altering the Protein Sequence for Solubility**" is devoted to discussing ways of altering the protein itself to avoid IB formation. One can try many of the suggestions for expressing a given protein by using robotics (21).

Today, bacterial culture and cloning techniques are used by many whose specialties are far from the area of microbiology. For this reason, the section titled "**Growth Conditions and Variables that Affect Yields of Soluble Protein**" contains detailed suggestions for preparing and maintaining stock cultures and inocula as well as a phage-free environment. One must stress the importance of good sterile technique, a topic that is never presented in other areas of the physical sciences. The last section includes tips on maintaining solubility during harvesting and the preliminary washing/lysis steps. Co-solvents for retaining solubility of proteins in solution are discussed in more detail in the accompanying review ("Protein Aggregation, Denaturation").

25.2 ALTERING GROWTH CONDITIONS TO INCREASE SOLUBLE EXPRESSION

25.2.1 Lowering Growth Temperature

For intracellular production, simply lowering the growth temperature (T) (22,23) can greatly increase the soluble fraction of protein. This result has been generalized now to many different recombinant proteins, eukaryotic to bacterial in origin, all of which are more soluble when expressed at a lower growth T in bacteria (Table 25.2 gives a partial list). Others have found a similar temperature effect in two strains of yeast, *Pichia*, and *Saccaromyces* (i.e. higher protein production if the induction temperature was reduced from 28°C to 19°C) (24).

Although most of the examples in Table 25.2 used 25−30°C for production, there is evidence that one can go much lower in T to increase the yield of soluble protein (see e.g. section **titled "Choice of Promotor"** on cold shock expression vectors). The vaccinia virus large subunit of ribonucleotide reductase (vvR1, 87-kDa) was completely insoluble in *E. coli* when expressed at 37°C (0.4 m*M* isopropyl β-D-thiogalactopyranoside) but was partly soluble if induction was at 15°C (51). The quantity of soluble and insoluble human androgen receptor (AR) fusion protein occurring at different times following induction at 12°C, 22°C, and 37°C, suggested there are numerous steps in the folding of the AR hormone-binding domain to a conformation that is both soluble and able to bind hormone (67). Six different areas of the protein were converted to insoluble protein at the higher temperature. Cold shock vectors (see below) can also be induced by low T in the range of 12−18°C.

There is a lower limit of about 8−10°C below which *E. coli* will not grow at all. In general, K12 strains grow very slowly below 23°C; at 10°C only a few dozen proteins are produced (68). There are additional problems with induction at very low temperatures. While one can move a shaker into the cold room to reach lower temperatures in the lab, industrial scale fermentors require special (and expensive) cooling to maintain temperatures below 25°C while agitating.

TABLE 25.2. A Few of the Proteins Listed in the Literature that are More Soluble When Produced in *E. coli* Grown at 30°C or Less. Where no Reference is Cited, the Data are from (23). This List only includes Proteins that are Produced in a Soluble Form at 30°C or lower for which Comparative Data is given in the Reference on Solubility at a Higher Growth T

Proteins more soluble at growth temperatures <30°C
Animal/Mammalian
Apurinic endonuclease (25)
Aplysia Attractin and related Pheromones (26–29)
Bovine heart mitochondrial ubiquinol-cytochrome-C reductase (fusion protein) (30)
Bovine pancreatic procarboxypeptidase A (31)
Chick brain ß-tubulins, 33kD (32)
Chicken riboflavin carrier protein (21)
Cystic fibrosis transmembrane conductance regulator (fused to glutathione-S-transferase) (33)
Apoglobin (34) and hemoglobin (34)
Human androgen receptor (AR) fusion protein 12
Human initiation factor-4E (35)
Human Interferon-α2
Human Interferon-β(36)
Human Interferon-γ
Human indoleamine 2,3-dioxygenase (37)
Human transforming growth factor-β(38)
Human testes antigen (39)
Human triose phosphate isomerase double mutant(M14Q/R98Q) (40)
Mouse DNA polymerase delta (41)
Murine cAMP-dependent protein kinase (catalytic subunit) (42)
Murine Mx
Rabbit muscle glycogen phosphorylase (43)
Rat phosphatidylinositol transfer protein (44)
Regulator of chromosome condensation (RCC1) (45)
Xenopus Cu,Zn Superoxide dismutase (46)
Fish
Herring antifreeze protein 13
Plant
Amylase (47)
Radish 3-OH-3-methyl glutarylcoenzyme A reductase (48)
Rice lipoxygenase L-2 (49)
Viral
Herpes simplex thymidine kinase fusion protein (50)
Vaccinia virus large subunit of ribonucleotide reductase (vvR1, 87-kDa) (51)
Yeast/Fungal
Cephalosporin-C acylase from Pseudomonas N176 (52)
Isopenicillin-N-synthases (53)
Streptomyces pro-transglutaminase (54)
Streptomyces jumonjinensis isopenicillin N synthase (56)
yeast α-glucosidase P1 (56)
Bacterial
β-galactosidase, (of Thermus thermophilus!) (57)
Carbamoylase and hydantoinase (58)
Diphtheria toxin and fusion proteins thereof (59)
Heparinase II and III from *Flavobacterium heparium* (60)
Lycopene cyclase from *Erwinia uredovora* (61)

Point mutations may make a protein more or less prone to temperature induced aggregation. For example, human triose phosphate isomerase is soluble at 37°C during production in *E. coli*. Two mutants of this enzyme, Met14Gln and RArg98Gln, are partially and completely inactive, respectively. A double mutant with both alterations was inactive, T-sensitive, and could only be produced in a soluble form at a growth T of 28°C (40).

While in some cases the production of soluble protein may appear to be the same at both growth temperatures (69), lowering the growth temperature has two additional great advantages. The first is that at lower temperature, the O_2 solubility in the growth medium is much higher. Thus the cell density can be increased as the culture is not forced to grow anaerobically as quickly. Anaerobic growth and particularly the production of acetate has been shown to limit cell growth and the production of protein (70).

The second advantage is that several plasmid expression systems have been shown to be more stable when bacteria are grown at lower temperatures. This may be due to the fact that the half-life of the antibiotics used to select plasmid bearing bacteria during the cultivation also have a longer half-life at the lower temperature.

Higher growth temperature can also inhibit processing. When chicken riboflavin carrier protein, a phosphoglycoprotein, was expressed in the T7 system at 37°C, two products were seen in whole cell lysates for protein with and without the pelB leader sequence encoded in the pET20b vector. The signal sequence was correctly cleaved in soluble protein expressed at 22°C, and that isolated from IBs (!) (71). This brings up yet a further point: even the aggregated protein formed at lower temperatures may be in a more active conformation (16).

Low growth temperature can also be combined with other modifications to achieve more soluble protein. For example, coexpression of certain proteins and foldases may be of use (section titled "Coexpressing other Proteins"; Table 25.3). Many of the proteins in Table 25.2 are fusions with common linkers that facilitate purification and may promote solubility, as discussed in the section titled "**Selecting Signal Sequences or Fusion Partners**" and Table 25.4.

There is one area where higher growth temperature may be an advantage. Secretion of RNases from *E. coli* was improved by growing the bacteria at 37°C (20). However, this phenomenon might better be referred to as *periplasmic shedding*, rather than true secretion, as indicated by the increase in total medium protein. Production of antibodies in secretion systems, for example is still done at lower growth temperature to maintain the product as much as possible within the bacteria. This avoids having to use ultrafiltration to concentrate the medium as well as the deleterious effects on the protein itself from aeration (as discussed later in this chapter).

25.2.1.1 Possible Reasons for the Effect of Temperature.

The reasons for the effect of lowering growth temperature are hard to pinpoint. The effect is not simply due to slowing the production rate of the protein or to a decreased growth rate. The protein Mx was sequestered into IBs at 37°C, regardless of the absolute production rate (which was controlled by varying the distance between the Shine Dalgarno and the initial ATG in otherwise similar expression plasmids) (23). The rate of synthesis of a particular protein does not necessarily increase with temperature. Further, decreasing the growth rate in other ways does not increase soluble expression; on the contrary, substrate limitations lower recombinant protein expression. A direct effect between protein folding and temperature has been detected in several studies, for example, the viability of phage produced at temperatures above 37°C decreases sharply (80). Others have found correct folding within IBs formed at the lower, but not higher temperatures, using FTIR (16,81).

It is possible that compartmentalization of protein production is more efficient at the lower growth temperature. For example, RNase A was insoluble at 37°C when produced cytoplasmically, but soluble at this temperature when directed to the periplasm/medium in a secretion system (20). In mammalian cells, proteins expressed in the nucleus were more susceptible to thermal denaturation *in situ* compared to those expressed in the cytoplasm (82).

Another possibility is the presence or lack of some proteins important for folding or aggregation at different temperatures. Postranslational modifications also affect solubility. Phosphorylation may occur at the higher temperature, thus altering the characteristics of the protein, as has been shown for GroEL (83). Proteolysis increases at higher temperatures, as does the catabolism of amino acids in central metabolic pathways such as serine (84). Studies of the expression of various heat shock proteins, which are induced by growth at higher temperatures, has indicated that their presence alone cannot mimic the effects on cell growth of increasing temperature. Indeed, as we will see in the section titled "**Altering the Host Strain and Vector to Direct Soluble Expression"**, coexpression of some of these proteins can selectively increase the amounts of

TABLE 25.4. Linkers that Improve the Solubility of Fusion Proteins or Allow More Specific Purification

Linker	Comments
Calmodulin (72)	Calmodulin binds to phenol sepharose tightly.
E. coli maltose binding protein (MBP)	Purify fusion protein by binding to amylose beads and eluting with maltose. The linker may be cloned at either end. Reported to be quite effective at rendering problem proteins soluble (73–75).
Glutathione-S-transferase	Purify fusion protein by binding to glutathione beads.
Hexa- (or more) poly histidine linker	Allows purification with metal chelate columns; may render proteins more soluble as well (32); usually does not interfere with activity although there are exceptions reported (76).
Thioredoxin (TRX)	Very commonly used linker system 78 useful for many proteins (33,57,58). Antibodies to thioredoxin may be useful in purifying the fusion proteins (78).
Ubiquitin (79)	Easily cleavable fusion protein.

soluble recombinant protein. Possible explanations for the effect of primary sequence on IB formation is discussed in the section titled "**Altering the Protein Sequence for Solubility**".

25.2.2 Medium Composition

Generally a defined medium that will allow high density growth is preferred for purification purposes (85). Batch feeding during induction has been shown to increase yield considerably. Glycerol may be a better carbon source than glucose as less acetate is produced when it is metabolized (86). In general, growth limitations should be avoided, with the exception of expression with negatively regulated induction systems, such as those based on the tryptophan promotor. Mathematical models have also been developed to aid in increasing cell density (87).

Adding compatible co-solvents during the culture may help maintain solubility, whereby in some cases their effect may actually be during harvesting (section titled "**Growth Conditions and Variables that Affect Yields of Soluble Protein**"). Increasing medium osmolarity by the addition of nonmetabolizable sugars may also increase protein solubility at higher temperatures: 0.4 M sucrose added to the growth medium increased the production of soluble ß-lactamase protein (88). There are relatively few examples, however, where compatible co-solvents have been tried, perhaps because of the large amount of solutes that must be added to the culture, that becomes especially prohibitive on scale-up. Solubility of bovine heart mitochondrial ubiquinol-cytochrome-C reductase, expressed as a fusion protein with glutathione, was greatly improved by adding 2.5 m*M* betaine and 440 m*M* sorbitol to the growth medium. Presumably, the increased osmolarity of the growth medium forced the uptake of betaine and a corresponding increase within the cells of glycyl betaine (31). Addition of detergents such as the Tween series to the growth medium may increase yields in secretion systems (however, these may simply change lower the amount of secreted protein associated with the cell membrane; so, addition of detergent should not be used by those who prefer to harvest the cells with the protein rather than directly from the medium) (20). Adjusting the growth medium may also compensate for the effects of higher growth temperatures (89).

Before eliminating casein hydrolysates from the growth medium, one should insure that their presence is not essential for controlling protease activity. Addition of protease inhibitors to the growth medium, in the form of an ill-defined extract of potato, was essential for production of interferon in *Bacillus subtilis* (90) and addition of 0.2 m*M* EDTA inhibited *Vibrio* exoproteases (91). Specific inhibitors of toxic enzymes may also be added to the growth medium. Yields of vvR1, for example, were improved by adding the ribonucleotide reductase inhibitor hydroxyurea (51).

Proteins induced under stress conditions may serve to control the production of acetate. The universal stress protein (USPA), a 13.2 kDa protein, is induced by a variety of stress conditions. This protein's role during stress may be to control the pathways of glycoslysis, as mutants in its gene secrete large amounts of acetate (92).

25.2.3 Induction Conditions

The timing of addition and amount of inducer should be strictly controlled. Many have found it advantageous to induce at low cell density in shaker flask culture to avoid growth limitation by the medium. The concentration of inducer may also be important; several authors have reported better yields of soluble protein if the isopropyl-D-thiogalactopyranoside (IPTG) inducer concentration was reduced from the usual 1 m*M* (44,45,93).

Yields of vvR1, for example, were improved by inducing at a low cell density, and using a low concentration (0.05 m*M*) of the inducer IPTG (51). A higher cell density

may be preferable with induction at very low temperatures, as for example, when using a cold shock promotor, as the cells will grow quite slowly after that point.

25.3 ALTERING THE HOST STRAIN AND VECTOR TO DIRECT SOLUBLE EXPRESSION

25.3.1 Choice of Host Strain

25.3.1.1 Strain Choice for Expression versus Transformation. Correct host strain selection is also essential. Table 25.5 lists the phenotypes of a few commonly used *E. coli* strains. Although some of their markers may determine how well a strain produces protein, several of them are potentially undesirable leftovers added for the use for which the strain was originally designed. For example, *sup*E is an amber suppressor that inserts a glutamine at UAG codons. This was incorporated into strains of *E. coli* for replication of M13 vectors that were required, according to NIH guidelines that no longer apply, to contain amber mutations (94). As the effects of these additions on overall expression levels are not clear, strains with fewer markers may be preferable for production purposes (95).

Careful cultivation and preservation of host strains is essential for optimal production. As host strains for protein production often do not transform well, strains such as JM101 or HB101 are used for transformations after ligation or for vector propagation. Choose a host strain that is suitable for the problem at hand. Many commercial vector systems come with a recommended host strain that should be optimal.

25.3.1.2 Low Protease Strains and those with Better Redox Characteristics. Protease minus strains of *E. coli* are particularly valuable for production of soluble proteins and those expressed from secretion vectors (101). For example, *E. coli* BL21(DE3), a protease-deficient strain, was used to express bacterial glutamyl-tRNA reductase (102) and is often used for expression of other proteins. A lon-htpr-strain (lacking the lon protease of *E. coli* (103)) significantly increased the production of RNases in a secretion system (20) and the strain SG21173 (lon-, htpR-, clp) was used to express the human T cell receptor V β 5.3 under the control of the hybrid trc promoter containing the *E. coli* heat-stable enterotoxin II (STII) signal sequence for protein secretion (104).There are also strains that facilitate the formation of disulfide bonds in the reducing environment of the cytoplasm (105). These should be considered for expression of proteins with multiple cysteine cross-links.

25.3.1.3 Coexpressing other Proteins. Co-cloning of molecular chaperones, can include such diverse molecules as thioredoxin reductase (106); for membrane proteins, phospholipids (107) can be of help, but they must be selectively chosen. Coexpression of *E. coli* heat shock proteins gro ESL has solubilizing effect only on certain mammalian proteins. For example, coexpression of gro ESL increased the solubility of four of eight eukaryotic proteins (mammalian c-myb, CRE-BP1, p53 and the *Xenopus* protooncogene Mos), while coexpression of thioredoxin increased the solubility of these and the other four tested (SnoN, c-Myc, adenovirus E1A, and the human tyrosine kinase Lck) (108). Thioredoxin also increased the production of antibodies (109).

There is also a report that association with GroEL decreased the solubility of the cystic fibrosis transmembrane conductance regulator (expressed as a glutathione-S-transferase fusion protein). A 60 kD protein co-eluted from affinity columns with the protein and was shown by sequencing to be GroEL. The authors were able to break up the complex and purify the protein (which was induced at $25-28^\circ$C) by adding 5 m*M* MgATP to the bacterial extract and incubating at 37°C (110).

Other reports indicate that Gro ESL may only have a solubilizing effect at certain temperatures. The aggregation of Pre-S2-S′-β-galactosidase, a three-domain fusion protein in the cytoplasm of *E. coli*, was reduced three- to sixfold by co-overexpression of the DnaK and DnaJ molecular chaperones over a wide range of growth temperatures ($30-42^\circ$C), while an increase in the concentration of the GroEL and GroES chaperonins had a significant effect only at 30°C. Co-immunoprecipitation experiments

confirmed that pre-S2-S′-β-galactosidase formed a stable complex with DnaK, but not with GroEL, at 42°C. When the intracellular concentration of chromosomal heat shock proteins was increased by overproduction of the heat shock transcription factor sigma, or by addition of 3% ethanol (v/v) to the growth medium, a two- to threefold higher recovery of active enzyme was observed at 30 and 42°C, but not at 37°C. The overexpression of all heat shock proteins or specific chaperone operons did not significantly affect the synthesis rates or stability of pre-S2-S′-β-galactosidase and did not lead to the disaggregation of preformed IBs. Rather, the improvements in the recovery of soluble and active fusion protein resulted primarily from facilitated folding and assembly. Titration of the DnaK–DnaJ early folding factors may trigger the formation of pre-S2-S′-β-galactosidase IBs (111).

Coexpression of proteins that improve solubility or the overall growth of the bacteria can also be useful. For example, coexpression of *Vitreoscilla* hemoglobin can increase the total cell protein of various common *E. coli* cloning strains (JM101, pRed2, and W3110) and *B. subtilis* (112). Their production characteristics should also be improved as the point of oxygen limitation is delayed (113). There are now several versions of these vectors to choose from, allowing expression of different hemoglobin forms (114). The role of another regulator of iron homeostasis, in *E. coli*, the small noncoding RNA RyhB, in bacterial growth and protein expression, is also being investigated (115). Cocloning demonstrated that the function of at least one of the six homologous insulin-like growth factor binding proteins is to assist in the formation and maintenance of the native disulfides of IGF-I (116).

Cocloning of specific antibodies to the protein may increase yields. For example, the heat induced aggregation of carboxypeptidase A could be greatly reduced *in vitro* in the presence of monoclonal antibodies that did not inhibit its activity (117). In addition, coexpression of tRNA genes for the preferred mammalian codons may increase the expression of mammalian genes in *E. coli*. For example, the expression of argU tRNA enhances expression of interferon (coded from the mammalian sequence) in *E. coli* (118).

25.3.1.4 Alternative Hosts to E. coli. There are millions of different bacteria yet very few are used currently as hosts for protein production. *E. coli* itself, isolated originally from infant diarrhea, was chosen as an experimental strain by Monod soon after World War II as it was relatively non pathogenic and grew quickly. In general, alternative bacteria tested for recombinant enzyme production were selected because they had some previous industrial application, and usually were approved for use in foods. Lactobacillus, found in cheese cultures, is a possible expression host.

B. subtilis is one of the earliest alternate hosts for recombinant proteins, as there was a history of successful industrial level expression of enzymes, and the bacterium was known to secrete proteins into the growth medium. Early strains were mostly suitable for the production of stable, protease resistant proteins (119). If the basic problems of protease degradation, and processing problems that may lead to insoluble product (120,121) can be avoided, there are several possible expression vectors (122), including one based on the α-amylase signal sequence and promoter (90) and, more recently, a cold shock expression system (123). The physical properties of the protein itself greatly affect expression in *B. subtilis*, however. IFN-γ, which has a stretch of positively charged amino acids at the *C*-terminus, accumulated as an uncleaved precursor in the cells and was hardly secreted, while we managed to obtain a few milligram per litre of soluble IFN-α, which is more negatively charged (124). Other Bacilli may also be useful; the vaccine strain *Bacillus Calmette–Guerin* has been used to produce a *Schistosoma mansoni* antigen (125).

As *E. coli* does not grow well at low T, an alternative bacteria has been suggested: *Rhodococcus erythropolis*, which can grow from 4 to 35°C. Successful expression in this bacterium was reported for several proteins that could not be expressed in *E. coli* (126). Other suggested hosts include *Staphylococcus carnosus*, used for surface display of a malaria antigen (127) and a secretion/expression system in *Salmonella* has been suggested for vaccine production (128). There are "shuttle vectors" available that can function in both *E. coli* and various alternative host bacteria.

Various *Vibrio* species were used to express the nontoxic B subunit of *E. coli* heat-labile enterotoxin linked to a 27-residue C-terminal fragment of Pol, the catalytic subunit of DNA polymerase of herpes simplex virus type 1. The highest yields were reported to be 3.5 mg/l. 0.3 m*M* EDTA added to the growth medium blocked proteolysis of the secreted protein (91).

25.3.2 Altering the Vector

25.3.2.1 Choice of Promotor. Having accepted that one should induce recombinant production at a lower culture temperature, there are a variety of promoter systems that can be used. Another factor, particularly important for potentially toxic recombinant proteins, is that transcriptional control should be tight, so that the protein is first produced in the cell after induction. Expression levels in the T7 system can be increased by tighter transcriptional control before induction (129). The most commonly used vectors for protein expression in *E. coli*, such as the pET series (130,131) have promoters that can be induced below 30°C (there are now many versions of the pET vectors that can be purchased from various vendors, that

allow one to select the linkers and other characteristics). After induction, expression temperatures as low as 18°C (over a 24 h period) have been used to enhance soluble production.

25.3.2.2 Cold shock vectors. The effect of temperature on solubility, as discussed above, is still a puzzle. The simplest explanation, that lowering the temperature slowed the absolute production rate of the protein, was proven to be incorrect by our initial experiments. Matthieu Noteborn cloned protein genes behind a weak (low producing) and strong (production levels 10–100 times better) promoter. Both the high and low expressing plasmid produced IBs at 37°C and soluble protein at 28 – 30°C (23). Our results indicated that the folding state of the protein or some other function of the bacterial metabolism must change at higher temperature.

Other authors explored the effects of cold shock on the bacterium. They found that while most bacterial proteins cease to be produced when the culture temperature is lowered to below 20°C, a whole group of *E. coli* proteins are *induced*. The promotor for one of these genes, cold shock promotor CspA (132), became the basis for a recombinant protein expression vector that could be induced by lowering the growth temperature (133). The cspA protein, when expressed, represses the synthesis of other proteins (an effect referred to as Low temperature-dependent Antibiotic effect of cspA Expression (LACE) (134). Normally, cspA expression reaches its peak about 1 h after cold shock, and then is reduced to basal level. Most of the increase in cspA can be attributed to enhanced stability of the mRNA at the lower growth temperature (136). Other members of the cspA family aid in transcription antitermination by "melting" the secondary structure of RNAs, thus permitting translation at the lower temperature (18). Initial tests of the cspA promoter indicated that it would direct the overproduction of recombinant protein upon cold shock and was a promising way to express toxic proteins (135). However, similar to cspA protein expression, there was pronounced repression of the synthesis of the recombinant proteins after a few hours at the lower temperature. Although production time could be enhanced by temperature cycling (33), the production levels for most test proteins were not better than those using the pET vectors.

Inouye's group discovered nonsense mutants of cspA that, when induced, would inhibit cellular protein synthesis, leading to cell death by LACE. This effect, which requires the 5′-untranslated region (UTR) of the cspA gene, is due to sequestration of ribosomes at the initiation site of the cspA mRNAs, thereby enhancing their stability. A new series of cold shock expression vectors were designed based on this data. These contain the cspA promoter, modified 5′UTR and 3′ transcription termination site, a translation enhancing element, and a lac operator after the promoter to maintain tight transcriptional control during bacterial growth (136,137). Synthesis of the recombinant protein, induced by adding IPTG and downshifting the temperature, continues for at least 48 h. We have successfully used these commercially available vectors to express several proteins in the soluble fraction of *E. coli*, including pheromones from Aplysia (26–29), and viral proteins (unpublished), and generally found that 24 h expression at 12 – 15°C gives substantial amounts of soluble protein that is relatively easy to purify. An additional advantage may be that, if production is induced after the bacteria are transferred to suitable labeling medium, the whole cell lysate can be used to do NMR analysis of the recombinant protein.

Many other common promotors, such as those based on the tryptophan operon, are useful for low temperature expression, as is a modified tryptophanase promotor (138). Secretion of specific proteins from *E. coli* is already possible using a variety of vectors (20,139). Secretion expression systems are particularly suited to mutant analysis (146), as the culture supernatant can be directly analyzed. *Pichia* systems are also useful for secretion at lower T (11,141). Further study of the factors affecting protein transport is needed for more general secretion systems.

25.3.2.3 Selecting Signal Sequences or Fusion Partners. The sequence of the protein itself can be altered by adding linkers, or stretches of amino acids with distinct properties. Many of the commonly used linkers (Table 25.4) were initially added to improve the purification of proteins, but later proved to improve protein folding, solubility, protease resistance, and/or overall yield. Adding signal sequences can be used to achieve secretion into the culture medium. Individual domains of the same protein, such as the carboxyl-terminal region of α hemolysin, may be required to achieve correct folding and soluble expression (142). In the same fashion, expressing a protein in series with a specific linker, or adding stretches of positively charged residues (143), may be a general way to achieve better folding. For example, DNA polymerase delta could be expressed as a glutathione-S-transferase conjugate (41). Indeed, expression of small proteins or fragments of a larger protein may only be possible if the desired sequence is expressed as a fusion protein (144). For example, domains of the rotavirus VP4 protein could be produced to 27%–35% of the soluble protein in *E. coli*, if they were fused to the Hepatitis B core antigen (145). Interleukin-2 was expressed in a nonaggregating fashion by expression as a fusion protein on a phage (146). Thioredoxin fusions of many proteins are soluble, especially if produced at lower growth T. These are, in some cases, active even before removal of the thioredoxin portion, and may be purified by heating lysates to 80°C. A DDDDK linker, the recognition site for mammalian intestinal protease

enteropeptidase, allows removal of the thioredoxin moiety (147). IGF-1 was >100 times more soluble when fused to one or two *Z*-domains from *Staphylococcus* protein A, and the solubilizing effect could also be seen during *in vitro* refolding (148). Although several linkers have been reported, the choice should be optimized depending on the protein (149).

Several linkers, such as hexa-histidine (His6), can aid in the detection and purification of recombinant proteins. Indeed, a recent survey of researchers involved in the structural genomics initiatives showed that these groups overwhelmingly use a T7 RNA polymerase based expression system and a 6-His affinity tag, because this allows the use of immobilized metal affinity chromatography (IMAC) to purify the recombinant proteins (131). Many vectors also include a protease site between the linker and the protein, to permit isolation of the natural protein [as there are reports of negative effects on activity if the histidine tag is left on the protein (150)]. This expression system has the advantage that the protein can often be expressed without an *N*-terminal methionine, but the disadvantage that yields are reduced due to the additional processing step and that the protease may cleave the protein itself. Yields may be low but sufficient for characterization. The 54-kDa subunit of the canine signal recognition particle (SRP) was expressed in *E. coli* using a T7 expression system with an amino-terminal extension encoding an initiating methionine and 10 histidine residues followed by an enterokinase cleavage site; 0.3 mg of HIS-SRP 54-kDa was purified to give a single band on SDS-PAGE in 20% yield from 500 mL of cultured *E. coli* (151). The hexokinase of *S. mansoni* has been expressed in *E. coli* as a fusion protein including an *N*-terminal polyhistidine tag and enterokinase cleavage site. The enzyme was purified by metal chelate chromatography to >95% homogeneity, based on analysis by SDS-gel electrophoresis and isoelectric focusing (152). Recombinant vvR1 was purified from a high salt extract of the *E. coli* lysate in four steps, the last utilizing an affinity column consisting of the carboxyl-terminal seven amino acids of the vvR2 protein linked to an insoluble resin (57).

The *E. coli* maltose-binding protein (MBP) is a handy fusion partner that allows simple purification and secretion of the chimeric proteins. Pollen major allergen Bet v 1 from *Betula verrucosa* (White Birch) has been cloned and expressed in *E. coli* as a fusion with MBP and a Factor Xa proteolytic cleavage site. A generally applicable cloning strategy based on polymerase chain reaction was designed to position the Factor Xa proteolytic site so that the authentic amino terminus of Bet v 1 was generated after cleavage. The fusion protein was isolated by amylose affinity chromatography and enzymatically cleaved by incubation with Factor Xa (153). The kringle V domain of the lipoprotein apolipoprotein (a) from human liver was solubly expressed in *E. coli* as a MalE fusion protein and purified by amylose–agarose affinity chromatography by eluting with 10 m*M* maltose (154). Human osteocalcin (hOC), a 49-amino acid peptide produced mainly by bone osteoblasts could be expressed as a glutathione-S-transferase (GST) fusion. The protein was soluble, and could be affinity-purified and then cleaved with activated protease factor X releasing the rhOC portion (155).

25.3.2.4 Altering the Gene Sequence of the Protein. Bacterial codon usage is often significantly different from mammalian. Genes for several proteins have been synthesized to reflect the bacterially preferred codons for degenerate amino acids and eliminate elements in the noncoding region of genes that lower productivity. One of the first examples was RNase A, where much more recombinant protein was obtained; the protein was synthesized from a synthetic gene that reflected bacterial codon usage than was produced from its murine counterpart expressed from the natural mammalian gene (20). Several companies now offer custom gene synthesis for such recloning purposes. There may also be specific mammalian codons in the cDNA that may inhibit translation in bacteria. For example, 4.9% of the adult isoform of human cardiac troponin (288 amino acids) is arginine, and in the native gene is encoded by AGG and AGA, codons rarely used in *E. coli*. Changing two areas where these codons occurred consecutively [AGG(165) AGG(166) and AGG(215) AGG(216)] to the bacterially preferred codon CGT increased expression 10-fold when one pair of the rare arginine codons was replaced and a 40-fold increase when both pairs were replaced (156). One can also use strains that express tRNAs for the mammalian preferred codons, as discussed above. Another study has indicated that AT rich regions in the cDNA should be avoided in *Pichia* expression (157).

A combination of methods may be necessary, especially for proteins that interact with hydrophobic substrates (63,158) or membranes (159). For example, the aggregation of the vaccinia virus large subunit of ribonucleotide reductase (vvR1, 87-kDa) (51) was prevented by lowering the induction temperature (to 15°C), lowering the cell density during induction, and the concentration of the inducer (to 0.05 m*M* IPTG). Addition of hydroxyurea, an inhibitor of ribonucleotide reductase, further increased production of soluble vvR1 in a dose-dependent manner.

25.3.3 Cell Free Expression Systems

Although often considered too expensive for large scale production of proteins, the need to express large amounts of protein in a quality good enough for characterization by the structural genomics initiative (160) has stimulated many groups to develop efficient cell free systems to produce soluble proteins. The least expensive but potentially

most versatile is an extract of wheat germ (161,162), which can be made in the lab or purchased commercially. As a eukaryotic system, wheat germ offers the potential for correct protein glycosylation, and often contains factors that can aid in the correct folding of multidomain proteins. Correct disulfide bond formation can also be favored in such systems (163) and special systems have been designed to express membrane proteins (159).

25.4 ALTERING THE PROTEIN SEQUENCE FOR SOLUBILITY

25.4.1 Why Do Inclusion Bodies Form?

This has been the subject of much debate since the phenomenon was first observed. Lowering growth temperature to achieve more soluble protein does not work for all proteins; further, we do not understand the physical characteristics that account for why some proteins are perfectly soluble even at 42°C while point mutations thereof can render them insoluble at all temperatures. Even very large proteins (e.g. heparinases II and III, Table 25.2, are over 700 amino acids long) can be expressed in soluble form.

Although even point mutations can render proteins more or less soluble (164), specific effects cannot be directly related to hydrophobicity (Gravy scores (53)) and effects of individual point mutations cannot be easily explained (55). While one multifactorial analysis (165) could not relate sequence to solubility, some correlations have been found in other studies (166). For example, the content of the individual amino acids Asn, Thr, and Tyr, and certain tripeptides correlated well with its solubility (167); another systematic study suggested replacing Asn, Gln, and Thr with Asp, Glu, and Ser to enhance solubility (168). The context is also important, however. In carbonic anhydrase, a Glu117Gln mutation caused aggregation, while Glu106Gln gave a soluble but inactive protein (169). There may also be a correlation between thermostability and *in vivo* half life of the protein (167), and secondary structure tendency may also be important (170). Another analysis related fibril formation to the isoelectric point (IP) of the protein, as of course the protein is least soluble at its IP (171). Please see the accompanying review of aggregation phenomena *in vitro* for more details on this point ("Protein Aggregation, Denaturation").

The sequence may also affect which system one should use to produce a protein. As noted above, positively charged proteins probably will not be secreted well in *Bacillus*. Analysis of 78 human proteins produced in *P. pastoris* revealed a correlation with only three factors: the presence of AT rich regions in the cDNA and a high IP of the expressed protein were both negative indicators for expression, while the existence of a native protein in yeast that was similar usually indicated that the protein could be produced there (157).

The effects of mutations throughout a protein on aggregation have been explored, for example, for Aβ1−42. This protein fragment, the protein accumulates as "amyloid plaques" in the brain of Alzheimer's disease patients. Here, the effect of mutating each residue in Aβ to Pro or Ala on fibril formation and peptide denaturation curves (172,173) and found that many proline mutations enhances solubility and destabilized fibril formation. On the other hand, mutating Asp23, which, in the solid state NMR structure of the fibril is in a salt bridge with Lys28 (174), to alanine rendered the protein completely insoluble.

25.4.1.1 Role of Proteolysis. Protein preparations from IBs often contain misfolded protein and proteolytic fragments. IB formation in *E. coli* was probably first observed when cells were treated with amino acid analogues (175); this relationship between abnormal protein and aggregation has been born out by other studies. In general, proteolysis accompanies IB formation (23); indeed, several authors attributed the effects on solubility of a lower growth temperature to reduced proteolytic cleavage of their protein (36,93,176). Further, the proteins seem to assume certain intermediate states that are difficult to define but can be identified by some techniques (177).

Two observations may shed some light on the process of aggregation. The first is that protein aggregates, as viewed by PAGE, appeared identical in the presence or absence of another protein. Thus the protein appeared to aggregate only with itself and not to co-aggregate with a potential partner (178). Of course, the authors could not analyze the more insoluble, larger molecular weight aggregates which did not penetrate into the gel, but the results strongly suggest that aggregation follows a very specific pathway.

The second observation is that the oligomers seen in many crystal structures are not due to the monomers aligning themselves at surface exposed hydrophobic sites. Rather, the monomers exchange a whole section of the protein to form a compact structure. Requirements for the swapped domain are that it have both a hydrophilic and hydrophobic face and that it be joined to the rest of the protein by a flexible linker. "Domain swapping" is one possible mechanism for aggregation that accounts for many of the observations about IB formation (179), in particular:

- *Specificity.* The swapped domain is connected to the oligomeric partner in much the same way as to the original monomer.
- *Speed.* Thermodynamically speaking, the major barrier to overcome during the initial formation of the dimer molecule is the barrier toward opening two monomers simultaneously that lie within a permissible distance

of one another. Once a dimer has formed, however, addition of another monomer requires only the opening up of one more molecule at a time. Thus aggregation will proceed quite quickly once the initial template has formed.

- *Proteolysis.* If one assumes that a long flexible linker joins the swapped domains, this essentially unstructured area would present a good site for the attack of proteases. The domains liberated by hydrolysis might serve as fragments to participate further in aggregate formation.
- *Association with synthesis.* Pulse labeling studies with *E. coli* overexpressing the *Salmonella typhimurium* gene CheY have shown that newly formed protein aggregates more quickly than existing protein (65). However, preexisting protein can also become involved in IBs if incubation is continued for a sufficiently long time (23). This makes sense if one assumes that protein immediately after synthesis is not yet completely folded. Possibly the stable domains fold first, followed by folding of the whole protein. A protein in solution exhibits a certain amount of folding out (so-called "breathing") that can be observed by techniques such as hydrogen exchange. Presumably, new protein whose secondary structure is formed but is still unfolded at the tertiary level can exchange domains easily, while existing protein can only join the aggregate at the appropriate stage in its breathing state. As the breathing rate increases with temperature, this can also account for the observed temperature dependence of aggregation. Aggregation would thus be one aspect of the protein solution half-life, which can be related to temperature by an Arrhenius plot (lnk vs 1/T, where k is an intrinsic instability constant and T is the temperature in $^{\circ}$K.) (180)
- *Irreversibility.* As the area of the domain that is swapped is substantial, the energy required to form (and hence to separate) oligomers is very large. Presumably the energy to form the aggregate is kinetic in nature. It has been calculated that the ΔG_0 for domain swapping is as high as 40 kcal/mol, an impressive barrier to overcome spontaneously.
- *Other miscellaneous observations.* These observations include the presence of active protein in IBs (16,181), the ability of some IBs to be separated by ion exchange, and the lack of a general relationship between protein sequence and aggregation. To some extent, the influence of heat shock proteins and chaperonins on solubility can also be explained by this mechanism, as they may bind to the partially unfolded protein and prevent proteolysis or reduce its ability to join the aggregate.

Domain swapping accounts quite neatly for the effects of specific point mutations (182) and their corresponding suppressors on the solubility of proteins (183). If one accepts that domain swapping is involved in oligomer formation, designing peptides to prevent aggregation may be a greatly simplified process, especially if a crystal structure is available or one has knowledge of interacting faces within the protein. One can direct changes in the protein itself to inhibit its aggregation or design peptides that will bind reversibly to these sites and prevent the initiation of aggregation (176).

These peptides need not be very large; for example, a simple tetramer, Arg-Gly-Asp-Ser, from fibrinogen, was sufficient to inhibit the aggregation of platelets (184). A change in a few discrete amino acids at the end of the B-chain of insulin considerably reduced the oligomerization state (185). Several different peptides have been designed to inhibit the aggregation of amyloid proteins, including that of the Aβ protein implicated in Alzheimer's disease (186–188). One can also internally encode a binding sequence. A monomeric λ-cro protein was made from the homo-dimer by duplicating the dimer interface region (six amino acids) at the *C*-terminus of the molecule. The monomeric mutant was more thermostable and appeared from NMR studies to have a solution structure similar to that of the dimer (189).

25.4.2 Mutation to Increase Solubility

Single point mutations may greatly improve solubility, whereby the mutations may also affect stability to proteolysis or improved interaction with a chaperone (190). A double mutation (Gly32Asp/Ile33Pro) in a turn/loop region between two helices rendered *E. coli* MBP insoluble (191). The solubility and stability to proteolysis during production in *E. coli* of a 101-amino acid fragment from the human respiratory syncytial virus (RSV) major glycoprotein (G protein) was significantly improved by altering several phenylalanine residues. Two Cys to Ser changes did not affect the solubility or stability of the gene product. The mutant G-proteins appeared antigenically similar to the parent and had similar secondary structures (192).

Destruction due to proteases can be minimized by identifying degradation "hot spots" in proteins (193). Some of these sites have been discussed elsewhere (2,165). It should be noted that such sites in mammalian proteins may be one mechanism for controlling the activities of enzymes and even cytokines. For example, proteolytic cleavage of the *C*-terminal of human interferon-γ, which also occurs in blood, can increase activity several fold. Efficient production of this cytokine in *E. coli* was only possible if the *N*-terminal residues Cys-Tyr-Cys, which are also not found in serum isolates, was removed from the coding sequence (194).

25.5 GROWTH CONDITIONS AND VARIABLES THAT AFFECT YIELDS OF SOLUBLE PROTEIN

The following is a brief accounting of more general growth conditions that can affect the amount and quality of recombinant protein.

25.5.1 Inoculum Preparation and Storage

One of the greatest causes of variation in the production of proteins in bacteria is plasmid and host strain instability. The plasmid should be checked periodically during large-scale cultivation. Loss of plasmid or alterations (including changes in the sequence of the desired protein or even deletion of the whole segment and insertion of unrelated DNA into the plasmid) can occur. Several different "insertion sequences" are known in *E. coli*. Correct preparation of inocula to minimize variation is essential.

Most strain stability problems are not discussed openly in papers dedicated to studying the proteins themselves (with notable exceptions (195))

The following general recommendations are made for the start of culture:(i) larger inocula are preferred; and (ii) glycerol cultures should be made from the first culture after a transformation, be stored at temperatures below -70°C and should not be reused. Study the restriction digest carefully after preparing stock cultures. Remember that 1 μl of a commercial EcoRI or BamHI preparation will cut an entire miniprep of plasmid completely in a matter of minutes. Unexplainable high molecular weight bands are probably not residual host DNA and may indicate either latent bacteriophage contamination or insertion sequences in the plasmid. When in doubt, throw it out (i. e. the culture) and do another transformation. For consistency, cultures should be stored in numbered boxes and a file kept of their location in the -70°C or liquid nitrogen storage. Excess glycerol cultures of strains no longer in use should be weeded at regular intervals (usually done when the compressor needs replacing or the contents of the freezer must be moved) (196).

A good plasmid library of minipreps of vectors is the ultimate backup. Some short cuts may be taken if using a reliable kit; for example, if one is sure that a sufficient number of bacteria will be transformed, it may be possible to prepare glycerols directly from the initial transformation mix.

25.5.2 Trouble Shooting Protein Producing Recombinant Bacteria

Most host *E. coli* strains carry a portfolio of mutations that may or may not be essential to their success in producing protein. Some of several cloning and expression strains and their genotypes are listed in Table 25.5. The requirements for a cloning strain (basically high efficiency of transformation) are different from those for a good expression host. The latter should grow vigorously on minimal media and be low in proteases, while the former, such as HB101, should have few host restriction systems and high sensitivity to the selection marker. Do not store host strains on agar plates in the cold room; the best method to preserve the phenotype is to lyophilize the cells or prepare glycerol cultures and store at -70°C or liquid N_2 temperature.

It is vital to continuously monitor the quality of these host strains, especially when several researchers share stock cultures. When performing a transformation, a control plate of competent cells with no DNA added should be used to test for unwanted development of antibiotic resistance. Look for differences in the characteristic color, size, and odor of host strain colonies plated out on nonselective agar.

If necessary, one can test the host strain for the presence of markers. Reversion to a protease producing phenotype can be detected by plating on casein agar. A complete listing of the meaning of various markers for *E. coli*, with alternate notation possibilities, can be found on the Internet (197) (http://www.uni-giessen.de/~g×1052/ECDC/ecdc.htm).

25.5.2.1 Protecting Your Cultures from Contamination. Most labs limit work with phages to discrete areas as they are recognized to be invasive. A widespread M13 phage contamination can be caused from one shaker accident that is not adequately cleaned up after, and months and even years of subsequent work can be wasted if the problem is ignored. The best method is to prevent the original contamination.

Frequent hand washing with antiseptic hand soap and wearing disposable gloves is essential to avoid cross contamination of cultures when handling plasmids and other replication competent nucleic acids. Surfaces should be covered with absorbent paper and changed regularly, preferably at the end of every experiment. Isolation precautions such as those used throughout the medical field and the food preparation industry should be automatic during work with recombinant organisms. One should avoid touching hair or face during work; long hair should be tied back. Protective coats should be removed at the door to the lab and never worn in public areas, especially lunchrooms.

On shakers, all cultures must be stoppered properly and the stopper should be properly fixed so it will not fly off during culture. Flasks should be removed from the shaker area or room to make additions. The shaker should be cleaned often with an antiseptic solution. The shaker room can be periodically sterilized by using a UV-light (one with a time switch can be installed in any area for very little money). Do not use a light for >300 h operation and/or leave it on for more than 15 min at a time. Note

however, that improperly used UV irradiation is worse than no sterilization at all, as a weak light can select for mutant bacteria that will be resistant to most killing methods. An easy way to determine if the lamp is still in order is to inoculate a plate with 1 mL of a dense culture of bacteria (preferably a spore former such as *Bacillus* or *Clostridia*) and leave it open under the lamp for 15 sec (time accurately!). If any colonies grow on the plate after 24 h incubation at 30−37°C, install a new fluorescent bulb.

25.5.3 Shaker Flask versus Fermentor Cultivation; Effect of Aeration

Expressing recombinant proteins solubly does not necessarily require great expertise. However, unlike expression in IBs, which can be done under relatively uncontrolled growth conditions, high level expression of proteins in a soluble form requires control over many variables during growth and induction. These include temperature, medium pH, oxygenation, and concentration of essential nutrients such as glucose (or glycerol) and toxic by-products of the bacteria, including acetate and carbon dioxide. Several industrial biotechnology groups have developed elegant solutions for all the problems encountered in soluble expression (95,198). In general, fermentor cultivation is to be preferred, as one can easily control all of the growth variables. Presumably because of stability problems with respect to both the host strain and plasmid, continuous culture methods are generally not used. The highest yielding processes to date are based on fed-batch technology, which is also standard for antibiotic production.

The medium during growth in shaker flasks, especially at higher temperature, rapidly becomes anaerobic and acidic, meaning that the bacteria are struggling to grow and are not able to produce optimal levels of product. Under these conditions, significant production requires completely subverting the bacterial metabolism into recombinant protein production, which usually means the use of induction methods such as temperature shock that favor IB production.

Good aeration, even beyond the O_2 uptake requirements of the culture, can increase production of proteins in *E. coli*. Rapid aeration reduces the concentration of CO_2 and acetate, both of which can be toxic. High acetate production has been implicated in reducing yields, especially in shaker flasks, even when the pH is controlled by using highly buffered media. Strains that produce less acetate have been created by metabolic pathway engineering; however, these may grow too slowly to be useful. Controlling the growth conditions of a prototrophic strain so that it did not experience anaerobiosis or stress has been shown to be a more useful way to reduce acetate production in large scale, high density culture (6).

Heavy aeration can, however, lower the yields of secreted proteins. For example, surface aeration with supplemental O_2 was used to produce interferon-α in *B. subtilis* as large activity losses were found when nitrogen was bubbled through a solution of medium and the purified protein (120). Antifoam can also seriously lower yields, especially for secreted proteins, and should be used sparingly.

To determine plasmid stability as a function of culture time, one can compare the specific plasmid content of the bacteria at the end of a large-scale fermentation to that of the inoculum. The easiest way to do this is to prepare plasmid minipreps and determine the colony forming units (CFUs) of a transformation into HB101, or some other high frequency of transformation strain, at various culture points. Alternatively, comparing the amount of DNA and its restriction map on an agarose gel can be done in a semiquantitative fashion.

25.5.3.1 Stability of Selection Stress. Most antibiotics, in particular, penicillin derivatives, should not be stored in frozen aqueous solution, nor should antibiotic containing agar plates be stored before use. The half-life of the closed ß-lactam ring is extremely short in aqueous solution, particularly at neutral pH. Ampicillin should be dissolved in sterile water, filter sterilized, and added to the growth medium as close to time of inoculation as humanly or mechanically possible.

Before ignoring this caveat, note that frozen ampicillin solutions have lost their ability to lyse bacteria but may inhibit growth of nontransformed bacteria. Week old refrigerated antibiotic containing plates used for transformation selection will show no colonies for the control Ca^{2+} cells. As the transformed bacteria grow, they secrete ß-lactamase that, coupled with the instability of the antibiotic itself at 37°C, will rapidly eliminate any selective pressure in that area of the plate (or in the vessel during a large-scale cultivation). Colonies picked from the transformation plates will contain nontransformed but viable bacteria. The initially inhibited nonproducers will be able to grow, diluting the plasmid bearers and lowering yield. If the plasmid confers any negative growth characteristics, the plasmid containing bacteria will rapidly become the minority in the vessel. Additional proteins from all those nonproducing bacteria will render the purification even more difficult.

25.5.4 Maintaining Solubility during Harvesting and Cell Lysis

If one is fortunate, the protein to be isolated has distinct characteristics that separate it from most of the host proteins in the lysate. Unfortunately, the majority of naturally occurring proteins are moderately hydrophobic, with a pK_a of between 6 and 7. This means they will elute from hydrophobic interaction columns at salt concentrations between 0.1

and 0.5 N, and from ion exchange resins with the vast majority of bacterial proteins. Thus a typical protein, if expressed at low concentration in the bacterial cytoplasm, will be difficult to separate by general methods of purification, and may be destroyed by proteases before ever being seen on a gel. This problem can be alleviated by using linkers that aid in purification (Table 25.4).

IB formation would appear to confer an enormous advantage in these initial stages, as the protein is clearly visible on a polyacrylamide gel and an apparently purified preparation can be quickly obtained. The denaturants used at the early stages of preparation inhibit most proteases and the overall yield, estimated visually, would seem to be very high. However, the protease problem returns when the protein is dialyzed in dilute solution to remove the denaturants (199). Thus a variety of methods have been used to modify the solution conditions during refolding (73,200–203).

The ability to wash away contaminants from IBs is often a Trojan horse. Membrane fragments and proteins that are equally insoluble persist through many detergent washes (indeed, there is a report that protein is rendered insoluble by these agents, particularly Triton X-100 (204)). These proteins are not always visible on gel electrophoresis as they "stick in the slot" or do not stain with silver stain reagents or Coomassie blue. An even greater problem arises: the protein is contaminated with proteolytic fragments, alternate folded forms and oligomers of itself. If solubly expressed protein required isolation from bacterial proteins with similar characteristics, the problem in IB schemes comes down to isolating the protein from what is essentially the same protein. This is the hardest of all purification steps.

Even proteins that are initially soluble in bacteria may be induced to aggregate, sometimes irreversibly, during cell breakage and washing. Aggregation and proteolysis can be minimized by adding a proteolysis inhibitor to the cell culture at the end of growth and maintaining a low temperature during centrifugation. Especially on the large scale, this may require special cooling equipment for centrifuges, and small batch processing using machines such as Manton/Gaulin or French presses.

In addition, it has been reported that detergents such as Triton X-100 and Nonidet P-40 can render proteins insoluble when added during cell washing/breakage steps. In one example, the solubility of two different forms of tubulin was increased by addition of 1 M NaCl to the extraction buffer (204). However, others have noted that extraction with 1% Triton X-100 was necessary for obtaining high yields of bovine heart mitochondrial ubiquinol-cytochrome-C reductase (fusion protein with glutathione). They solved later aggregation problems by resolubilizing the protein in the detergent dodecyl maltoside in 300 m*M* NaCl; the resultant protein appeared active as it gave a blue shift in the visible spectrum when incubated with ubiquinone (31). The preliminary breakage steps to maintain the solubility of T7 RNA polymerase had to be done in buffer containing large amounts of glycerol and detergent to prevent the protein precipitating. Once its extremely narrow salt range for solubility was determined (205), the purification was straightforward.

Even the pH of the extraction buffer can have a profound effect on solubility. For example, UMP-kinase from *E. coli* was insoluble if extracted from cells with a pH 7.4 Tris buffer, but was soluble if 1 m*M* UTP was added to this buffer or if 100 m*M* borate buffer pH 9 was used for the extraction. Reversible aggregation could be induced by adding Mg^{2+} to the UTP containing solutions or lowering the pH. A point mutant, D159N, was soluble at up to 5 mg/mL at pH 7.4 (206).

25.6 CONCLUSIONS AND OUTLOOK

As described above, there are a wide variety of choices available to enhance the production of soluble protein, ranging from vectors to bacterial strains to new methods for growing and inducing the bacteria. All aspects of the process must be considered to optimize protein quality, as well as quantity. For the first steps, a recent review, with many authors, also contains suggestions for "what to try first" (131). The tables here suggest a variety of ways that can be tried, if the first attempts at expression in bacteria yield too little protein, or if most of the protein is found in the insoluble pellet. Changing the bacterial strain and growth conditions can be first attempted. Many times it may be necessary to alter the sequence of the expressed protein, either by direct mutations in the primary sequence or adding linkers to enhance the solubility. Optimizing and controlling the growth and induction conditions are central to insuring a high yield of recombinant protein.

Finally, many of the problems of expression and solubility are also encountered if an inclusion body purification scheme is chosen. As outlined above, producing soluble proteins in *E. coli* requires no more work than producing insoluble proteins, and the researcher will be rewarded with a protein preparation that is considerably easier to work with than the product of most refolding methods.

26.1 INTRODUCTION

Animal cell culture technology has advanced significantly since the preliminary investigations on nutritional requirements for cell growth (1). Since the approval of Tissue Plasminogen Activator (tPA) in 1987, the majority of biopharmaceuticals, including monoclonal antibodies, vaccines, growth factors, and hormones, have been produced using mammalian cell culture (2). While Chinese hamster ovary (CHO) cells are the primary workhorse of cell culture technology, hybridoma, mouse myeloma (NS0 and Sp2/0), Madin–Darby canine kidney (MDCK), human (PER.C6®), baby hamster kidney (BHK), and human embryonic kidney (HEK) cells may also be used (3–7).

Challenges facing the industry today include the optimization of volumetric productivity to minimize capital investment and to increase plant throughput, the rapid development of "platform" processes especially for molecules in early stages of development and the greater understanding of cell culture processes and their effects on the quality of the biopharmaceutical products produced (8,9). In addition to significant advances in cell line engineering to develop highly productive cell lines, development and optimization of cell culture media and feeding strategies continue to be a requirement for accomplishing these challenges.

Designing cell culture media requires a good understanding of cell metabolism as well as knowledge

gained from empirical experimentation. While earlier formulations benefitted from the presence of serum and protein hydrolysates, there is a growing trend toward removing these undefined components to mitigate safety concerns, increase reproducibility, and to gain greater fundamental knowledge about the process. Well-developed cell culture media should be capable of supporting good growth and productivity and should be applicable across clones expressing different recombinant proteins for implementation in a platform process. Media should be robust, especially during preparation and storage, and support consistent performance across multiple scales of operation in manufacturing facilities. To meet the demands of fast timelines for early stage process development, the cell culture medium is often standardized as part of a robust platform technology applicable to multiple cell lines. However, both culture media and feeding strategies need to be customized for specific cell lines when there is a need to achieve high titers (for example for high commercial product demand). Since accomplishing these objectives with serum-free and peptone-free media continues to be a major challenge, this chapter will focus primarily on development strategies for chemically defined media.

While animal cell cultures may be operated in batch and perfusion modes, fed-batch cell culture processes in which depleted nutrients are supplemented periodically through the course of the process have emerged as the standard platform technology (10–12). Recent advances in cell line development and in the design of culture media have significantly increased both the volumetric and specific productivity of fed-batch processes (13–16). While design of the basal media is important for achieving high growth and productivity, design of the feed media is essential for sustaining performance over the course of the production culture. Designing media requires an understanding of practical and business-related constraints. The developed media should not only work in the lab environment at small-scales, but also not pose any problems during scale-up to clinical or commercial scales. The liquid media should not have any solubility concerns, should have a relatively long shelf life and be stable under any heat treatment that may be required for reducing the risk of viral contamination (17). This chapter will briefly discuss the common nutrients found in cell culture media and focus on approaches to the optimization of the chemically defined basal and feed media, as well as the practical considerations during experimentation and industrial implementation of the developed media.

26.2 NUTRIENTS IN CELL CULTURE MEDIA

In this section we draw upon published literature and our own experiences to discuss the role of the various components included in the typical culture medium used for industrial-scale production of biopharmaceutical proteins. While this applies specifically to CHO cell culture processes, it should be applicable across many animal-derived cell lines used for protein production.

26.2.1 Carbohydrates

Glucose is generally used as the primary carbohydrate source. Glucose metabolism in CHO cultures is generally very inefficient resulting in significant by-product formation in the form of lactate. In an effort to constrain the conversion of glucose to lactate and to influence product quality attributes, other carbohydrates such as galactose and fructose are frequently added to the culture medium (18,19). While growth rates of CHO cells are significantly reduced when galactose or fructose is used as the sole carbon source, cells will proliferate freely given some amount of initial glucose. CHO cells are also able to metabolize and grow on mannose as the sole carbon source (20). Pyruvate, which is the key branch point of glycolysis and the citric acid cycle, is also often present in cell culture media formulations (21,22).

26.2.2 Amino Acids

Amino acids not only provide the building blocks for protein synthesis but may also serve as a source of energy through amino acid catabolism (23,24). Depletion of essential amino acids may lead to immediate cessation of growth and loss of viability via apoptosis (25). The required amino acids for growth of cells *in vitro* include the physiologically essential amino acids arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. For most CHO cell lines which are proline auxotrophic, proline supplementation is also required. Even though glutamine is considered a nonessential amino acid, it becomes essential to CHO cells in culture if asparagine is depleted, since asparagine can only be synthesized from aspartate and glutamine through transamination. Similarly, asparagine becomes essential under glutamine depletion. Careful experimentation is required for determining the levels of amino acids since we have observed inhibitory effects at high levels of serine, tryptophan, tyrosine, cysteine, glutamine, glutamate, asparagine, and aspartate (unpublished results).

Since the enzymatic reactions for the synthesis of cysteine and tyrosine occur only in the liver, these two physiologically "nonessential" amino acids become essential for the culture of most animal cells. Many cell culture formulations contain either cysteine or its dimer cystine or a combination of both, and media derived from the popular DMEM/F12 medium contain both forms (26). Cystine is widely used due to the fact that, in this form, the amino acid is more readily transported into the cell where it is

rapidly reduced to cysteine (27). Since cystine has low solubility at neutral pH, it may have to be predissolved in acidic stock solutions prior to addition to the final culture medium. Alternately, salt versions of cystine could be substituted to improve solubility. Because of its superior solubility, cysteine is often used in place of, or in addition to, cystine. However, media formulations containing only cysteine invariably contain a proportion of cystine since cysteine is readily oxidized into cystine in the presence of copper and/or iron (28).

26.2.3 Vitamins

Eagle showed in 1955 that choline, folic acid, nicotinamide, pantothenate, pyridoxal, riboflavin, and thiamine are essential for cell growth (1). Care should be taken while choosing storage conditions for media containing these vitamins since high concentrations of riboflavin could lead to the formation of cytotoxic photodegradation products (29). The fat soluble vitamins A, D, E, and K do not seem to confer any advantage. It appears that ascorbic acid is not essential for growth or productivity, even though it may be added in some cell culture media for its potential antioxidant properties (30,31). Biotin is often added to cell culture medium in small quantities, but may also be present as a contaminant. Biotin is a cofactor in the metabolism of fatty acids and enhances cell growth and protein synthesis (32). Assays for many of the vitamins are readily available and can provide useful information about vitamin limitation. In some instances, since these vitamins are recycled within the cells and often not readily excreted, intracellular accumulation may occur even while supernatant concentrations appear limiting.

26.2.4 Other Inorganic Salts, Metals, and Trace Elements

Cell culture medium is often supplemented with Na^+ and K^+ ions, supplied as chloride salts (33). These are primarily present to supply an appropriate osmotic balance for the cells, but all three (Na^+, K^+, and Cl^-) regulate membrane transport of many nutrients and macromolecules into and out of the cells, as well as maintain the appropriate ionic strength for the functionality of many enzymes or directly participate in enzymatic reactions. The normal physiological Na^+/K^+ ratio of blood is of the order of 25–40, whereas in our experience, production media with this ratio between 1 to 5 seem to work well (22). For both sodium and potassium, there seems to be a lower limit below which cell growth is not supported to any major degree (below 40 m*M* Na^+ in our experience) though this may be cell line–specific and dependent on other factors of the medium composition.

Iron can be provided in various forms, typically as ferrous or ferric salts and as chelated ferric iron combined with citrate or EDTA (34,35). In most cases, no additional benefit of ferric forms or chelated iron over sufficient ferrous iron has been observed. The other inorganic salts and metals that are required such as calcium, copper, magnesium, and zinc are often provided as their sulfate salt. They play crucial roles in energy metabolism and as enzyme components, cofactors or catalysts, as well as regulators of membrane transport. Other components required in trace amounts, hence their moniker of "trace elements", include selenium, manganese, molybdenum, and vanadium (36). A number of trace elements, 19 in all, were added to the commercially available Ham's MCDB 301 (37). Even though 15 of these were subsequently removed from MCBD 302, a medium devised specifically for the growth of CHO cells, fibroblasts, and cell lines with less stringent nutritional requirements, they are often included in many commercially available and other production media. Their concentration needs to be carefully optimized since they could be toxic above certain concentrations (38–40).

26.2.5 Other Cofactors or Substrates

Putrescine, the polyamine precursor of spermidine and spermine, acts as a cofactor for DNA elongation, and is crucial for cell division in CHO cells and a number of other cell types (41,42). Spermine and spermidine derivatives are important in stabilizing the helical structure of DNA. Some media contain either spermidine or spermine or both, rather than putrescine, although the presence of putrescine alone seems to suffice.

Reduced glutathione (GSH), which is a tripeptide synthesized from the amino acids L-cysteine, L-glutamic acid, and glycine, is often added to cell culture media. In most instances, the amount of GSH present in the medium formulation is greatly surpassed by that produced by the cells. GSH participates as a coenzyme in cellular oxidation–reduction reactions and protects the cells from the oxidative damage related to those reactions and other free radical damage (43). The requirement for selenium as a medium component is tied to the activity of GSH, as selenium acts as a catalyst in many of these reactions (44,45). It has recently been reported that selenium could also function as an iron carrier (46).

26.2.6 Lipids and Lipid Precursors

Choline chloride and inositol, which primarily function as substrates, are usually added to cell culture media (36). While supplementing choline appears to be imperative, we do not find much evidence for the supplementation of inositol, although it may be beneficial in an osmo-protective

capacity. Lipoic acid is an eight-carbon, sulfur-containing fatty acid that is synthesized by eukaryotic cells like inositol, but it is often incorporated into many cell culture media for the numerous functions it performs. It is required for pyruvate metabolism as a cofactor in the pyruvate dehydrogenase complex along with thiamine, and possesses antioxidant properties (47,48). Linoleic and oleic acids are sometimes included in the formulation (22), even though substantial growth can be achieved in the absence of these lipids provided that the medium is rich enough in precursors. Many media employ lipid mixtures, often of soy origin and provided as emulsions or complexed with cyclodextran, to supply a raw source of lipids (36,49,50). Most are dominated in composition by cholesterol. These, along with ethanolamine may be useful, even essential, in some instances, especially in hybridoma/NS0 cell lines, but appear not to be necessary for CHO cells.

26.2.7 Nucleosides

The purine nucleoside hypoxanthine, the pyrimidine nucleoside thymidine, and potentially glycine are required for the survival and growth of cell lines suffering from folic acid deficiency. This is particularly true of mutants with defective dihydrofolate reductase (dhfr) activity (51). Satisfactory growth of such parental cell lines often requires supplementation with folinic acid (a synthetic version of active tetrahydrofolate) to facilitate DNA synthesis and, thus, adequate growth in the absence of serum. None of these precursors or other nucleosides appear necessary for the growth and productivity of cell lines reconstituted with a fully functional *dhfr* gene, though they may provide some benefit in lessening any metabolic burden coincident to their production by the cells. Many nucleosides may have either desired or unwanted impacts on product quality by influencing nucleotide pools within the cell.

26.2.8 Growth Factors and Carrier Proteins

Many medium formulations used for commercial production do contain some amount of insulin or insulin-like growth factor (IGF-1) (52). Both facilitate glucose uptake and lipid metabolism. In the case of CHO cells, while their benefit to growth is obvious at low cell density, it appears that they can often be dispensed at higher cell densities. It is observed that for certain cell lines, removal of insulin from the production medium significantly reduces cell growth in the production culture and the resultant titer in the culture media. In such instances, adaptation over a few passages may alleviate this dependence. Transferrin was traditionally used to facilitate iron uptake and serum albumen was often used as a safe transport mechanism for lipid supplementation (53). In the absence of recombinant versions of these carrier proteins, many cell culture media have forgone them and instead, have significantly higher concentrations of iron and free fatty acids or their salts. The current availability of recombinant versions of these growth factors may see a resurgence of their use in production-scale cell culture media should their benefit be cost-effective.

26.2.9 Other Media Additives

Even though a variety of pH control strategies have been tested, sodium bicarbonate is usually still added to the culture for its buffering capacity (54). The culture pH is controlled at a value close to neutral pH using a combination of CO_2 sparging to lower pH and the addition of sodium hydroxide or sodium carbonate to increase pH. Phosphate, along with some amino acids, can provide additional buffering to the medium. Bicarbonate could be used with other buffers such as HEPES, when additional buffering capacity is required in smaller culture scales where there is no active pH control. In sparged cultures, Pluronic F68, methylcellulose or polyvinylalcohol are usually added to reduce cell death associated with bursting bubbles (55–60). Due to ease of use, Pluronic F68 (Lutrol®) is most typically used (61–63).

26.2.10 Osmolality

In general, cell growth is most rapid at osmolalities around 280 mOsm/kg. The osmolality of the basal media in which the production cultures are initiated, is initially set around this value while the feed media usually have much higher osmolalities since they are prepared in concentrated formulations and then diluted when added to the culture. Osmolality outside of physiological ranges has often been exploited to enhance or retard cell growth and control loss of viability due to apoptosis. This can often lead to significant increases in volumetric productivity (64,65). The upper limit that cells seem to tolerate appears quite variable, since there seems to be a threshold upper osmolality at which there is a detrimental impact on culture viability.

26.3 BASAL MEDIUM DEVELOPMENT

The term "basal medium" refers to the medium that is used at the beginning of a culture, as opposed to the "feed medium" which is added to the culture after the initial growth phase. Basal media should contain all essential nutrients that are required to support and promote culture growth, whereas feed media mainly serve to support high cell density and prolonged culture viability, as well as maintaining good productivity. A robust and productive basal medium is a prerequisite of any medium development effort and essential for successful feed

medium development and overall cell culture process development.

The history of systematic basal medium development dates back to the 1950s, where Harry Eagle pioneered the concept of minimally required nutrient categories for mammalian cells and introduced the "Minimal Essential Medium (MEM)" (1,23). The MEM medium contains 29 components, including 13 amino acids, 8 vitamins, 6 ionic species, glucose, and serum protein with appropriate pH, buffering capability, and osmolality. Serum protein was an essential element of the basal medium developed at that time. Evolution of the basal medium formulation started soon after the MEM medium was published. The various efforts can be grouped to two categories: one for removing serum and replacing it with defined, specific nutrients; and the other for achieving higher cell density in the presence of serum (66). Among the well-known formulations derived from the MEM formulation are Dulbecco's Modified Minimal Essential Medium, or DMEM (67), which has higher levels of many of the MEM components like vitamins, glucose, and choline chloride; Iscove's modified DMEM or IMDM (68), which has supplemental buffering capacity and supports even higher cell densities. Additionally, the RPMI (Roswell Park Memorial Institute) media series was developed to achieve high density lymphocyte proliferation (69). In contrast, Ham's Nutrient Mixtures (F−12 and F−10) (70) offered substantially different formulations than that of MEM and support the low density growth and maintenance of many cultured cell types. An exhaustive list of media formulations is given in Burgener and Butler (22). A break-through was achieved when Sato and his coworkers reported on the DMEM/F12 formulation by mixing the two formulations at a 1:1 ratio (26). The resulting formulation combined favorable properties of both formulations and quickly became very popular.

Most of the earlier formulations were supplemented with serum. Development of serum-free basal media dates back to the 1960s. Although effective, the complex chemical compositions of serum limited the ability to improve the understanding of cellular needs. In addition, issues related to cost, source availability, lot-to-lot variability, and potential adventitious contaminants have fueled the desire to develop serum-free media (71,72). However, despite substantial development efforts, serum-free media often suffered decreased growth and reduced recombinant protein production. To compensate for the lack of serum, animal- or plant-derived hydrolysates (peptones) were successfully introduced as an alternative nutrient source and are widely used for commercial manufacturing processes (73). Peptones are generally acid hydrolyzed or enzymatically digested, boiled, and dried preparations derived from various protein sources, and are primarily used by the food and cosmetics industry. In recent years there has been widespread abandonment of animal-derived peptones for bioproduction use, especially those of bovine origin or containing animal-derived enzymes in their production, due to the risk of transmissible spongiform encephalopathy (TSE) contamination. Replacement with commercially available peptones from soy, wheat, rice, cottonseed, or others of plant origin has been a first step in many instances, but this has drawbacks due to the risk of plant mycoplasma in some preparations (74). Animal-derived peptones, which are a potential source of viral contamination in cell culture, will require either heat treatment (Code of Federal Regulations, 9CFR, for use in human products) (75) or extensive adventitious agents testing to reduce any potential viral introduction. Hydrosylates are also a significant source of endotoxin in the medium as well as the toxic Maillard reaction products (caramelization of sugars and amino acids such as lysine) due to the heat used in their processing. They can, however, provide a source of salts, metals, trace elements and act as a reserve amino acid supply, both through the free amino acid content and that bound in peptides (76). This offers an additional benefit due to the reduced osmotic contribution offered by adding amino acids sequestered in peptides rather than entirely as free amino acids, along with improved solubility due to the nature of the preparation of the hydrosylates. Numerous efforts have been taken over the years to elucidate what factors seem to contribute the beneficial effects attributed to peptones. In addition to their nutritional benefit, certain peptone fractions have also been identified to have growth-promoting effects (77,78). Because they contain a milieu of both growth-promoting and inhibitory components, individual peptones demonstrate an optimum concentration, beyond which they become inhibitory. This may be both media and cell line–dependent and requires empirical determination. Due to their undefined nature and potential lot-to-lot variability, they are often scrutinized when growth, titer or product quality issues arise; hence the drive to replace them with defined components. More importantly, use of peptones or serum greatly limits the evaluation of cellular nutrient needs, and therefore can become a bottleneck for further improvement of growth and productivity. Due to these concerns, a number of biopharmaceutical companies are in the process of transitioning from peptone-containing media to chemically defined media (13,15,16).

26.3.1 Chemically Defined Basal Medium Development Strategies

Medium development is historically referred to as both art and science. However, advances are rooted in sound scientific study. It usually requires a synergy of approaches that combine understanding of cellular nutritional needs and metabolism with trial and error experimental approaches.

Given the complexities of cell metabolism and phenotypic variations observed between cell lines, a universal procedure for media optimization probably does not exist. Rather, the presented techniques should be viewed as a tool-kit with specific experimental details and strategies that need to be developed based on the specific needs and the stage of medium and process development.

The first challenge in basal medium optimization is to choose the starting formulation. The starting formulation should ideally be chosen after a thorough evaluation of available candidates, which might include formulations derived from literature, in-house formulations and their blended derivatives (22). Most likely, a peptone(s) supplemented basal medium already exists, as is the case for many established companies. In such cases, the existing basal medium after removing peptone(s) should be considered as one of the leading candidates. The main advantages of using the existing peptone-free medium is the familiarity and experience with various aspects of the existing medium, such as medium powder manufacturing, medium preparation, heat treatment, and scale-up. Because of the undefined nature of peptones, replacing them with chemically defined components and achieving satisfactory performance is not a trivial task. This may include addition of many new components that are present in peptones, and reoptimization of concentrations for some of the existing components (76). The in-house peptone-free formulation should be evaluated with other formulations derived from literature or their derivatives in an appropriate scale-down model using representative cell lines. The results of one such study conducted with CHO cell lines derived from dhfr-DUKX CHO host (51) is presented in Fig. 26.1. The formulations screened included several in-house chemically defined media, various commercially available media, and differing concentrations of these formulations. The screenings were conducted in batch mode shake flask cultures and used glucose feeds to prevent the depletion of glucose. After the superior growth and volumetric productivity of the best formulation from these studies was confirmed in well-controlled small-scale bioreactor experiments, it was designated as the prototype basal medium. It was used as the starting point to design subsequent optimization studies for the basal and feed medium.

In general, subsequent experiments for optimizing basal medium should use design of experiment (DoE) principles. DoE has gained increasing popularity in many disciplines, as a way to maximize knowledge gained from the experimental studies conducted with limited resources

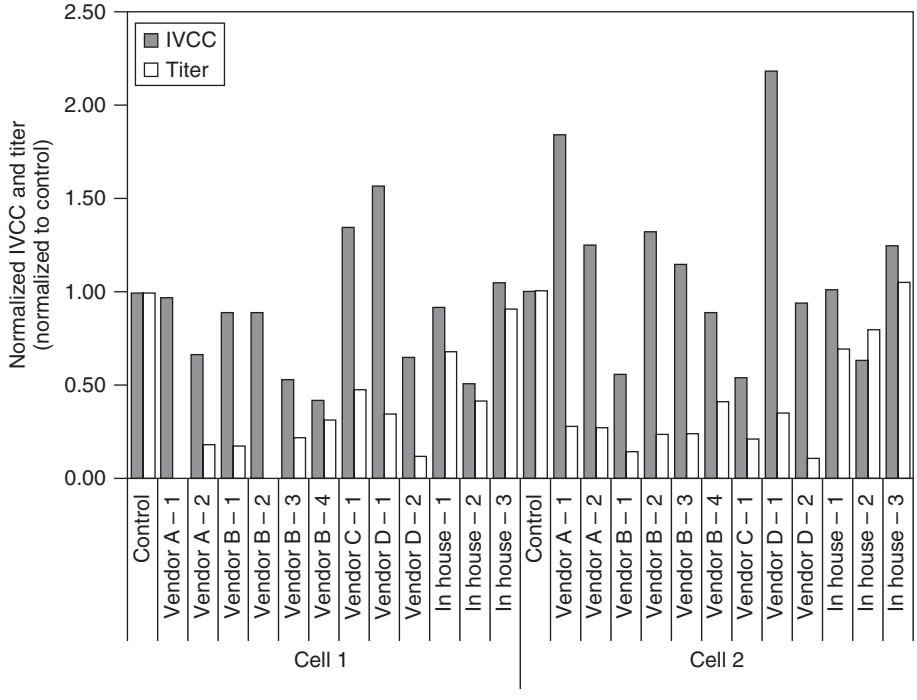

Figure 26.1. Normalized integral viable cell concentration (IVCC) and titer results for the various vendor media and in-house media. IVCC, which is a measure of cell growth, is the integrated, viable cell concentration (VCC) over time, $\int_0^t VCCdt$, and it is an indicator of the total product synthesizing capacity of the culture. Results were normalized against the peptone-containing medium, as the goal was to replace it with a chemically defined medium. Note that several of the vendor media supported better growth than the control, but titers were far lower.

(79–81). Due to the complex nature of mammalian cell metabolism and nutrient requirement, which can be further complicated by cell line and host specific needs, it is impractical to design a basal medium that has each of the 60–80 components optimized. Furthermore, many of the components have interactions with each other, and therefore experimental efficiency may improve by employing statistical design and analysis.

There are several well-documented approaches for basal medium development (22,71,82). Although many of the approaches were initially described for development of serum-free medium from serum-containing medium, they are still relevant for development of chemically defined medium. In general, these strategies can be classified as the "top–down" or "bottom–up" approaches. The bottom–up approach evaluates the concentration effect of individual components on culture performance. A classic example of the bottom–up approach is component titration, where one aims to establish dose responses for the components and appropriately adjust media composition. This approach may be very time-consuming and labor-intensive and might not be feasible if tight timelines are required for process development. The top–down approach focuses less on individual components and their roles in the formulation, and relies more on screening various formulations or component subgroups to find the best combination for culture performance. For example, media blending is an approach that has been proven to be very effective in combining synergistic effects of different formulations. The popular DMEM/F12 medium (26) is the best example of such an approach. An example of such an approach conducted at Genentech, Inc. is illustrated in Fig. 26.2. In this instance, the existing basal medium was subdivided into component subgroups and various medium formulations were derived from these subgroups based on fractional factorial screening design principles. However, all the derived basal media were evaluated in fed-batch mode using the same platform feed medium. These experiments identified that the trace element subgroup in the basal medium was limiting. When the concentration of the trace elements was increased five-fold based on the results of a response surface design study, the volumetric productivity of the process is improved more than three-fold from 0.6 g/L to 2.2 g/L.

Another decision that needs to be made during the optimization of the basal medium is whether to evaluate the test basal media in batch or fed-batch mode. Experimentation with batch mode cultures for basal media optimization enables the evaluation of the relative merits of the basal media in isolation and has the advantage of simplicity of experimentation. However, if a standard feed medium is available, it might be useful to evaluate test basal media in fed-batch mode with the feed medium included. Since batch cultures would invariably lead to depletion of amino acids or vitamins during the course of the culture, they would not be representative of a typical fed-batch process. Furthermore, use of the fed-batch mode could lead to immediate optimization of the existing process without further confirmation experiments. Generally, in early stages of medium development, when the medium is being developed *de novo*, no viable feed medium is available. In these instances, the batch mode experimentation with glucose feeding alone is appropriate. However, when a viable process with both batch and feed media is available, it might be appropriate to conduct basal medium optimization experiments in fed-batch mode with the feed media included, except when a complete overhaul of the existing process is desired.

26.4 FEED MEDIUM DEVELOPMENT

The aim of bioprocess development is the maximization of volumetric productivity without compromising the quality of the product. Cell growth is often limited in batch culture due to the depletion of essential nutrients such as glucose and amino acids. Excessive initial addition of these nutrients in the batch medium can increase osmolality to inhibitory levels and/or cause the accumulation of metabolic by-products such as lactate or ammonia. To overcome such limitations, industrial mammalian cell cultures generally use a fed-batch culture strategy for maximizing culture growth and productivity. The culture is initiated in the batch medium by inoculation with a seed culture and after a certain number of days, feeding is initiated using a feed medium that supplies depleted nutrients at appropriate levels. The constituents of feed media are usually glucose, amino acids, vitamins, and phosphate while trace elements and salts are usually not included. The feed medium is more concentrated than the basal medium to prevent loss of volumetric productivity due to dilution during feeding. The feed medium and the feeding strategy need to be optimized such that essential nutrients are supplied without overfeeding which might increase osmolality and have detrimental effects on cell growth. Feed medium optimization significantly affects the overall volumetric productivity of the process since the majority of the product is synthesized during the latter half of the culture when feed medium is likely to have the most impact. As with basal media, the demands imposed on process development due to rapid timelines require that two different approaches are used for the development of feed media. There is an industry-wide emphasis on the development of platform approaches for feed composition and feeding strategy development that would be applicable to multiple cell lines and easily transferred among multiple facilities and equipment. Intensive optimization of this platform is usually required for enhancing productivity for specific cell lines (83).

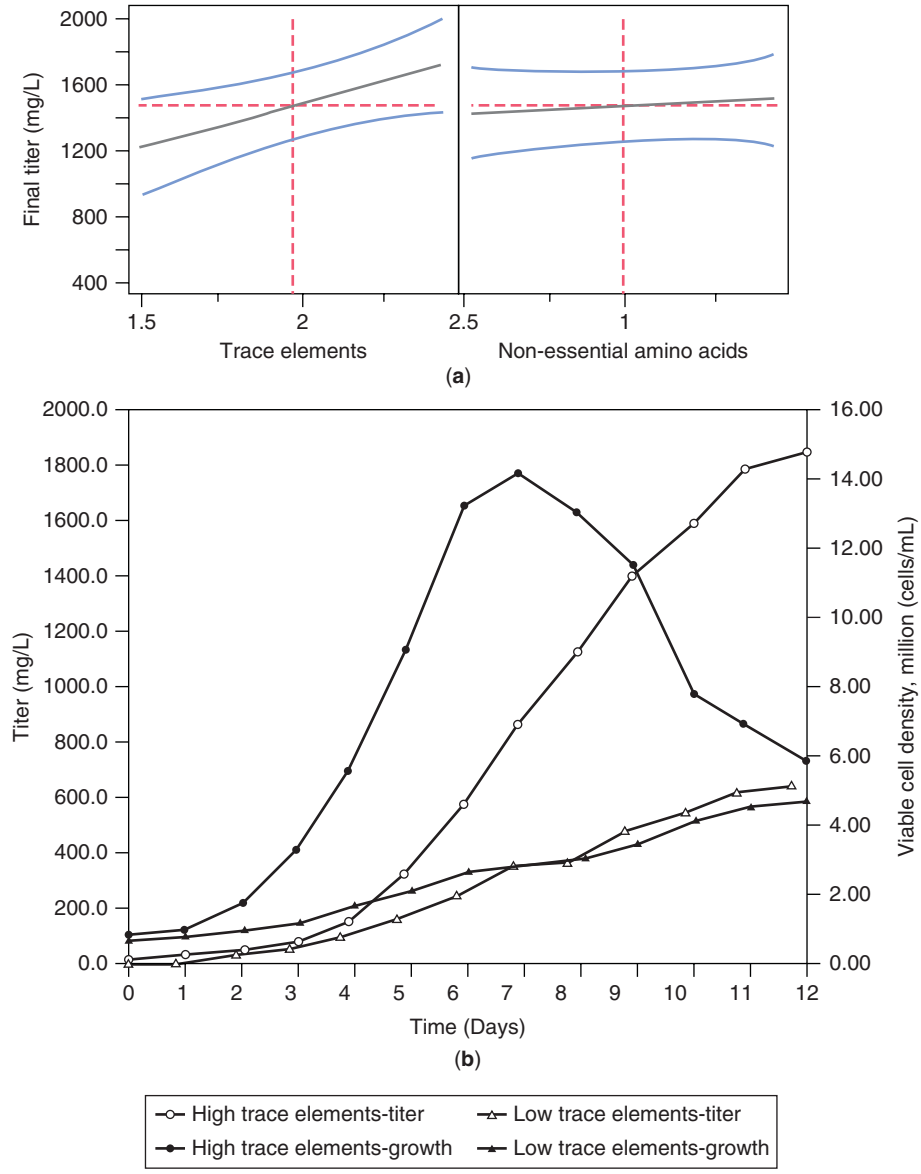

Figure 26.2. These experiments were conducted to optimize the basal medium. The basal medium was divided into subgroups and the concentration of the subgroups were varied using successive DoE experiments. The initial experiment was a fractional factorial design to screen the effects of the various nutrient subgroups (data not shown). The results from this experiment were used to design the subsequent experiment, which tested various concentrations of the trace elements and nonessential amino acid subgroups using a response surface design. (a) The results of the regression model between factor values and final titer for the response surface experiment is plotted. (b) Confirmation experiments conducted in controlled 2-L bioreactors confirmed that the final titer increased from 0.6 g/L to 2.2 g/L. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

26.4.1 Feed Medium and Feeding Strategy Development

The primary purpose of feed medium is to increase cell growth, extend viability, and enhance the volumetric productivity. It is well-known that depletion of nutrients could induce apoptosis and this is avoided by appropriate supply of nutrients in the feed medium (25,84). Feed medium composition and feeding strategy need to be optimized such that the nutritional demands of the cells are met without the synthesis of harmful metabolic by-products, namely lactate

and ammonia. Lactate metabolism in industrially cultured animal cells is similar to the "Warburg effect" observed in cancer cells (85). In growing cells, the majority of the energy demand is met by the generation of ATP in glycolysis. Regeneration of NAD^+ from NADH, which is critical for the continued use of glycolysis for the synthesis of energy, is accomplished by the conversion of pyruvate to lactate. In contrast, when cells stop growing, ATP is primarily synthesized through oxidative phosphorylation in the mitochondria. Except in specific lactogenic cell lines, the stationary phase is characterized either by the cessation of lactate synthesis or by lactate consumption. In addition to glucose, mammalian cells utilize glutamine as an energy source and while majority of the lactate is generated from glucose through glycolysis, it is also known that lactate is generated from glutamine (86–88). Ammonia is primarily produced during the catabolism of glutamine (88). While there are reports that lactate itself could cause both growth and productivity to decrease, its effects are magnified due to the increase in osmolality that accompany lactate accumulation in pH-controlled bioreactors (89). It is believed that ammonia detrimentally affects the culture by impacting the metabolism of UDP-*N*-acetylgalactosamine and UDP-*N*-acetylglucosamine (90). While there are varying reports about the extent of growth and productivity inhibition caused due to the accumulation of lactate and ammonia (91–93), there is a general consensus about the desirability of limiting their accumulation. Accordingly, limiting their accumulation has been the focus of feed medium and feeding strategy development.

Early studies reported that culture viability and productivity can be extended by simply feeding glucose to prevent its depletion and limiting the supply of glutamine. Since ammonia is a by-product of glutamine catabolism, limitation of glutamine supply was suggested as a strategy to limit ammonia (88). It was shown that the constant feeding of glutamine at a rate that was lower than the culture's maximum consumption rate led to reduced accumulation of ammonia (94). In addition, biomass yield on glucose, glutamine, and other essential amino acids was increased. Bushell *et al*. (95) designed their feed media based on measured uptake rates of various amino acids to show that both, the final titer and the culture viability can be improved. However, designing a feed medium based on measured uptake rates of nutrients can be difficult since these rates change during different phases of the culture. Recognizing that uptake rates can vary during the course of the culture, they formulated their feeds based on rates measured at different phases of the culture and showed that productivity is maximized when they designed the feed based on uptake rates measured in the growth phase. Zhou *et al*. (96) used on-line oxygen uptake rate measurement as a proxy to estimate the nutritional demands of the culture and designed their feed based on measured amino acid uptake rates. The feeding strategy was coupled to on-line measurements of the oxygen uptake rates to achieve enhanced cell growth (97). Xie and Wang took a more rigorous approach and proposed a stoichiometric model that related the consumption of glucose, amino acids, and vitamins to cell growth and product formation.

$$\theta_{glc}[glu\ \cos\ e] + \sum_i \theta_{a,i}[\text{amino acid}]_i + \sum_i \theta_{v,i}[\text{vitamin}]_i = [\text{cell mass}] + \theta_p[\text{product}] + \theta_{ATP}[\text{ATP}]$$

They estimated the stoichiometric coefficients based on the known roles of these nutrients in metabolism and measured cell composition and used them to rationally design feed medium composition and feeding strategy (98). They showed that such a strategy reduced the specific synthesis rate of lactate and ammonia as well as increased both cell growth and productivity. It was further shown that the supplementation of the above feed medium with serum and trace metals further enhanced growth, indicating that factors other than carbon source, amino acids or vitamins might be limiting (99).

Another strategy commonly used for reducing the accumulation of toxic by-products is the substitution of glucose and glutamine with alternative energy sources. Substitution of glucose and glutamine by galactose and glutamate was shown to decrease the levels of lactate and ammonia (19,20). Since galactose is transported more slowly than glucose, it was observed that substitution of glucose by galactose led to net consumption of lactate. Similarly, substitution of glutamine by glutamate had the effect of reducing the levels of ammonia since glutamate has only one amino group and it is metabolized slower than glutamine. It has also been established that the substitution of glutamine with pyruvate could have the same effect of reducing ammonia accumulation (21). Similarly, stable expression of the GLUT5 fructose transporter in CHO cells enabled the replacement of glucose by fructose (18). Since fructose is transported slower than glucose, lactate was also synthesized at a lower rate.

26.5 PRODUCT QUALITY

While culture media are commonly optimized for the purposes of increased productivity of the process, it is essential to ensure that such changes do not affect the efficacy and safety of the product. After any major changes to the culture media, it is necessary to ensure that the product quality has not changed significantly and if it has, that the changes do not adversely affect the safety or efficacy of the product (9). Factors that are considered to be part of the product quality profile include integrity of amino acid sequence, glycosylation (100), aggregation, deamidation of asparagine or

glutamine (101), methionine oxidation (102), and removal of C-terminal lysine (103). The quality profile of the therapeutic product could influence efficacy, immunogenicity, and *in vivo* clearance (104–107). Product quality is usually characterized using methods including peptide mapping (sequence integrity), ion exchange chromatography and capillary isoelectric focusing (acidic, basic variants), capillary electrophoresis (glycosylation), size exclusion chromatography (aggregation), and other techniques based on specific needs (e.g., HPLC or high performance liquid chromatography for sialic acid analysis).

Glycosylation is typically a product quality attribute that may be most dependent on culture media. Glycosylation is a posttranslational modification that involves the covalent attachment of oligosaccharide chains to the protein. The pattern of glycosylation can vary depending on the expression host. Bacterial cells generally cannot glycosylate proteins, and the primary reason many therapeutic proteins are produced in mammalian cells is that they need posttranslational modifications that microbial cells are unable to perform. Glycosylation is classified as one of two main varieties, *N*-linked and *O*-linked. In *N*-linked glycosylation, the oligosaccharide is linked to the asparagine residue with the consensus sequence Asn-X-Ser/Thr, and in *O*-linked glycosylation, the oligosaccharide is attached to serine or threonine through an *O*-glycosidic bond. No consensus sequence has been identified for *O*-linked glycosylation. The IgG class of antibodies is *N*-glycosylated at an asparagine residue in the CH_2 domain. This is typically a complex biantennary type with the core composed of two *N*-acetylglucosamine residues and three mannose residues. The oligosaccharide is composed of further additions of mannose, fucose, galactose, sialic acid, and *N*-acetylglucosamine to the core glycoform. Figure 26.3 shows some commonly observed *N*-linked glycoforms in CHO cells. This oligosaccharide is essential for the antibody to display functionality beyond antigen binding and the pattern of glycosylation can affect antibody function (108).

Heterogeneity in glycosylation can result from "Macroheterogeneity" or "Microheterogeneity". Macroheterogeneity can result from the presence or absence of the oligosaccharide at a specific site in the protein. Iron, manganese, butyrate, triiodothyronine, and thyroxine had the effect of increasing site-occupancy for tPA (109). It was shown that site-occupancy in tPA was inversely correlated with growth rate (110). In contrast, nucleoside precursor molecules uridine and guanosine decreased site-occupancy by 2%, while mannose and dolichol phosphate did not have an effect. Microheterogeneity can result due to variable additions of sugars to the core glycoform since the synthesis of the oligosaccharide is not template-driven, but through a series of enzyme-catalyzed addition and trimming reactions (100). Controlling the

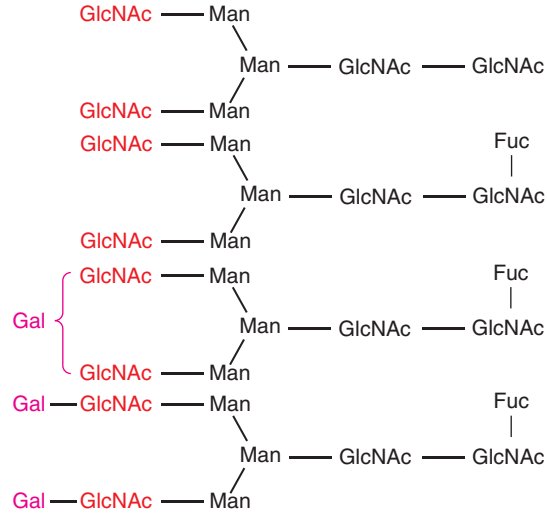

Figure 26.3. *N*-linked oligosaccharides commonly observed in monoclonal antibodies produced in CHO cells. GlcNAc: *N*-acetylglucosamine, Man: Mannose, Gal: Galactose, Fuc: Fucose. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

concentration of glucose and glutamine at low levels, which is a strategy used to reduce metabolic by-products, was found to decrease sialylation and increase the level of high mannose glycan species (111). Increasing culture time, which is commonly used to enhance volumetric productivity, led to increase in truncated and oligo-mannose structures, potentially in response to glucose starvation (112,113). Truncated and high mannose glycans were also observed in fed-batch cultures with culture time exceeding three weeks even though metabolite depletion was not a factor (114). Increased levels of sialylation and core fucosylation were observed in the absence of serum for cultures of BHK-21 cells producing a human interleukin-2 variant (115). Inclusion of glucosamine and *N*-acetylmannosamine increased the antennarity of glycans by increasing the pools of UDP-*N*-acetylhexosamine and CMP-sialic acid (116). Glucosamine addition in the media also had the effect of decreasing galactosylation by increasing UDP-*N*-acetylhexosamine levels and decreasing UDP-galactose levels (117). Decrease in UDP-galactose was believed to be due to the entrapment of cellular uridine in UDP-*N*-acetylhexosamine. Supplementation of *N*-acetylmannosamine, a precursor of sialic acid, was found to enhance sialylation of interferon-γ in CHO cells (118).

Culture media are often enriched with amino acids with the aim of enhancing volumetric productivity. Enhanced levels of amino acids could lead to the formation of ammonia, which could affect product quality. Ammonia is incorporated into UDP-*N*-acetylglucosamine, which is a precursor of oligosaccharides linked to proteins (119). Ammonia and glucosamine increased the intracellular

levels of UDP-*N*-acetylhexosamines which increased the antennarity of glycans and reduced sialylation (120). Increasing concentration of ammonium chloride also decreased the *N*-linked glycosylation of mouse placental lactogen-I produced in CHO cells (121). The effect of ammonium chloride was exacerbated by increasing pH, indicating that glycosylation was affected by the level of ammonia (NH_3) species. Increasing concentrations of ammonium chloride were also implicated in the decrease in galactosylation and sialylation (122).

Even though there is a significant amount of information in the literature about the general effect of certain medium components on product quality profile, the qualitative and quantitative impact on specific molecules and cell lines may vary. Hence, the product quality profile should be separately evaluated for each cell line after any changes, especially if they involve the transition from hydrolysate containing to chemically defined medium. The product quality assessment is also based on the then current stage of clinical development for a specific molecule (9). Culture medium changes are generally of less concern if they are proposed at an early stage of development before clinical and nonclinical studies. In fact, major modifications to the platform culture media, applicable to multiple cell lines in early stages of development, could be proposed based on new knowledge about productivity gains. In such a scenario, the impact of the change on product quality should be elucidated in small-scale bioreactor experiments based on its effect on multiple cell lines with different characteristics of growth and productivity. If the change is proposed for commercial products or for products in stages of development when no additional clinical studies are planned, a thorough comparability assessment should be performed. The product quality profile before and after the change should be elucidated. If the product quality profile is not adequately comparable, additional nonclinical or clinical studies might be required depending on data available about the product or its product class. Hence, major changes in culture media that affect product quality are usually avoided for commercial therapeutic products.

26.6 USE OF APPROPRIATE SMALL-SCALE MODEL AND HIGH THROUGHPUT SYSTEMS

An area that is often overlooked is the use of appropriate small-scale models during experimentation to optimize cell culture media. The media are usually developed for use in large-scale bioreactor cultures with working volumes ranging from 100–25,000 L. Since it is impractical to develop cell culture processes at this scale, small-scale models are used to mimic large-scale cell culture performance. The most commonly used models are small-scale bioreactors with working volumes ranging from 1–5 L. Even though the cellular microenvironment in these bioreactors do not exactly mimic the conditions at the large scale, the appropriate design and operation of these reactors can generate data comparable to larger scales. However, due to the large number of experimental conditions that need to be tested especially at early stages of media development, higher throughput than those offered by liter-scale bioreactors is required. To accomplish this objective, 96-well plates, microbioreactors (123), shake flasks (124–126) and Tubespins™ (50 mL conical bottom tubes with vented caps) (127) can all be effective smaller scale models.

Use of these smaller scale models also enables the construction of high throughput cell culture systems that can screen a large number of culture conditions simultaneously. Two common high throughput systems that have been developed are (i) reduced working volume "bioreactors" (hundreds of microliters to a few milliliters working volumes) and (ii) shaken container systems using flasks, tubes, and plates (hundreds of microliters to hundreds of milliliters working volumes). The reduction in working volume provides the potential to increase the throughput of the experiments particularly if the reactor vessels lend themselves to easy automation of unit operations required for the inoculation, sampling, control, and harvest of the reactors. Small volume reactors in hundreds of microliters to a few milliliters capacity have been developed with some form of control systems in place. A 24-well system using working volumes of 4–6 mL was developed by MicroReactor Technologies, Inc. (Mountain View, CA) for microbial applications (128). This system was then adapted for cell culture work but required modifications for foaming and pH control that resulted in the need for manual base addition (129). This system allows the control of temperature, dissolved oxygen, and pH at the individual well level but still needs to be inoculated, sampled, and harvested manually. Using their proprietary robotics technologies, Hudson Control Group (Springfield, NJ), have developed a system that automatically loads, samples, and feeds cells growing under 24 independent reaction conditions simultaneously. The entire unit is placed in a standard biosafety cabinet to allow aseptic feeding and sampling. The samples can be transferred to chilled microtiter plates for further analysis and users can input triggered automated feeding using multiple feeds and/or sampling of the wells based on measured events and/or time. This system is relatively "low" high throughput since consumers would have to purchase multiple 24-well plate systems to compete with shaken systems offering more vessels and greater automation. Another promising high throughput system is the SimCell™ microbioreactor platform from Seahorse Bioscience Inc. (North Billerica, MA). This is a cassette-like system with biocompatible, gas-permeable materials containing six reactors per cassette. The handling

of the reactors is highly automated and includes functions such as set-up, culture control, monitoring, and sampling (130). This system is capable of running ~1000 cultures simultaneously (131,132). A potential drawback of these systems is the cost, which may range from tens of thousands to millions for set-up and implementation in addition to the cost of consumables. For a potentially low cost solution, shaken container systems can be used for screening cell culture conditions including conditions for medium development. Automated systems for the shaken tubes have been developed as an alternative between shake flasks and automated shaken plate systems (133). Finally, shaken deep well–plate cell culture systems that are also easily automated have been described and are capable of executing 1500 cell culture runs per month (130).

For medium development, it should be noted that many of the smaller scale model systems do not offer a pH-controlled cell culture environment and hence, are not ideal scale-down models. It has been postulated that the qualitative effects of different medium components could be accurately investigated in these noncontrolled small-scale shaken systems (134). To test this, we performed studies comparing productivity and growth characteristics for a specific cell line in shaken TubeSpins™ (133), shaken flasks, and pH-controlled stirred tank 2 L bioreactors with three different media formulations. Figure 26.4, which shows the final titer from each of these cases, indicates that all these systems give similar qualitative results even though they differ quantitatively. This indicates that screening for qualitative performance deviations from appropriate control conditions could be representative even in systems that are not ideal scale-down models. We observe that this conclusion is true for medium components that have large effects across the majority of cell lines tested. Since cell lines display varying levels of sensitivity to pH changes, care should be taken to not interpret reduced growth or productivity of pH-sensitive cell lines in smaller scale shaken models as due to nutrient limitation or other medium effects. It is unavoidable that early stages of medium development are usually conducted in these smaller scales due to the large number of screening experiments required. It is recommended that bioreactor studies be conducted for verifying major conclusions drawn from such smaller scale screening studies. We believe that automated shaken systems could offer a viable high throughput methodology for medium formulation screening if the data is carefully interpreted.

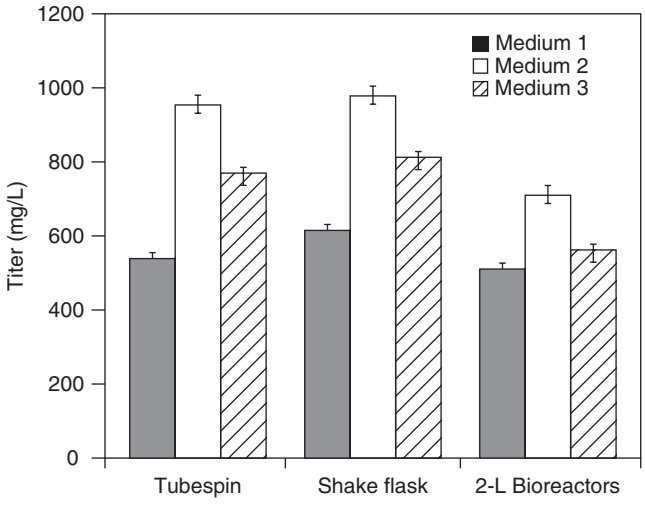

Figure 26.4. Three formulations designated as medium 1, 2, and 3 were evaluated in shaken tubes, shake flasks, and 2-L stirred tank bioreactors. The end-of-run secreted antibody titer data for cultures are plotted.

26.7 INDUSTRIAL CONSIDERATIONS FOR THE OPTIMIZATION AND IMPLEMENTATION OF BASAL AND FEED MEDIA

26.7.1 Platform and Customized Processes

While the focus of the literature has been primarily on the reduction of toxic waste products and enhancement of growth and productivity, several other considerations arise in the industrial setting for optimizing and implementing fed-batch cell culture processes. A "platform" process that is applicable across multiple cell lines expressing different products is highly desirable, especially for early stages of clinical development. Process development for new molecular entities in early stages of clinical trials when there is a high likelihood of failure, tends to be rapid. During such early development, the process platform is implemented with minimal changes; changes to the composition of the media are rarely made. In early development, the only changes made to the media are usually the concentrations of glucose, glutamine, and peptone. Optimization of volumetric productivity is more critical for molecules that are more likely to be commercialized. Since molecules in the later stage of clinical development have a greater probability of being approved, late stage process development tends to be more extensive with greater emphasis on process optimization and robustness. However, even in later stages of process development, a major overhaul of medium composition is not recommended because it is desirable to maintain consistency between processes developed at the same company and to facilitate scale-up and technology transfers across multiple clinical/commercial sites. Thus, the basal and feed media developed as part of this platform need to be appropriately optimized such that minimal modifications are required.

The platform feed media should be applicable to many cell lines with different growth characteristics. Different

cell lines expressing the same or different molecules, even when derived from the same parental cell line, could have different growth and metabolite profiles. For example, feed medium composition that is determined based on nutritional demands for a high growth/productivity cell line might overfeed another cell line with lower nutritional requirements due to slower growth. Hence media developed for the platform process are usually tested with multiple representative cell lines, which display different profiles of growth, metabolism, and productivity. A set of three to four model cell lines can generally satisfy this need for platform medium development. Two "typical" cell lines, which display growth and productivity characteristics typically observed in the existing process, could be used along with two "outliers", spanning high and low growth and productivity characteristics. The two typical cell lines could be used for most of the studies with the outliers included for studies that aim to confirm significant conclusions. The high growth outlier cell lines are also a good test on potential nutrient limitations since greater growth could lead to faster depletion while the low outlier cell line could indicate potential inhibitory effects and ensure that the selected media do not cause significant negative responses. In addition to growth and productivity, the performance indicators should also include lactate and ammonia profiles, since excessive lactate or ammonia synthesis could indicate deficient or excessive concentrations of certain nutrients in the media. Furthermore, these waste products can potentially affect culture performance and/or product quality, particularly when a scale-up exercise results in differences in the culture environment and influence metabolic behavior.

The feeding strategy that is developed as part of the platform should be relatively simple, manufacture-friendly, and easily transferred across multiple sites either within the company or to a contract manufacturing organization. On-line or continuous feeding strategies that are widely used in academia have not yet gained favor in industrial cell culture processes due to these constraints as well as the cost and complexity of automation and validation efforts. Usually, a predefined volume of the feed media is fed at one or more times during the course of the fed-batch culture. The feed volume can be determined based on the nutritional demands of the cell as well as the concentration of the feed media. The feed volume in the platform process is also determined based on investigations with multiple representative cell lines. Feeding is usually initiated approximately three days after batch inoculation. Feed initiation should occur after a significant fraction of nutrients initially present in the batch media are near depletion. Since the concentrations of amino acids and vitamins are not routinely measured during manufacturing, a proxy variable such as glucose or glutamine concentration could be used to initiate the first feed. Alternately, the feed initiation could also be defined by culture time. It is essential that such a process be extremely robust in order to operate with such a simplified criterion.

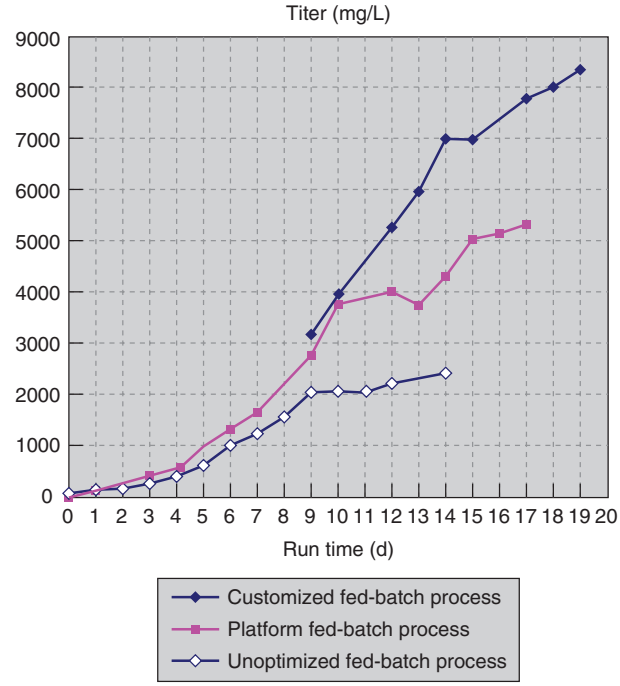

Figure 26.5. Experiments were conducted in 2-L controlled bioreactors. Titer profiles are shown for fed-batch cultures of a specific cell line, which used the same basal medium but different feed media (unoptimized, platform, and customized feed). While the platform feed led to significant improvement over the unoptimized feed, customization of the process to this specific cell line led to even higher titers. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Due to increased market demand or manufacturing capacity constraints, processes for specific therapeutic products might require extensive optimization. Under these conditions, the specific characteristics of the cell line need to be considered to customize the feed medium to achieve high titers. Figure 26.5 shows the product titer profiles for the same cell line in the unoptimized fed-batch process, the developed platform fed-batch process, and in the fed-batch process customized for this specific cell line. While unoptimized process led to a titer of 2.4 g/L, use of the platform process led to a titer of approximately 4 g/L. Intensive optimization of the platform process led to a final titer of approximately 8 g/L. It is to be noted that such high volumetric productivity was achieved in serum and peptone-free chemically defined media. Among the strategies that might be considered for such customized optimization are feed composition optimization based on nutritional demands of the specific cell line, sophisticated feeding strategies, and the option of using multiple feeds to deliver different nutrients or to account

for varying nutritional demands during different phases of cell culture. Recently, titers higher than 10 g/L have been reported (135).

26.7.2 Liquid Media Stability and Scalability

Other important considerations that need to be tested are the stability of the liquid medium formulation and scalability of the process developed using the medium. The shelf life of developed liquid formulations may be limited to as little as two weeks due to precipitation of specific amino acids such as cystine and tyrosine. While short shelf life is less of a concern in manufacturing where the medium is used immediately after preparation, longer shelf of at least a month at 4°C is usually desired in process development to allow for experiment schedule flexibility. The most problematic medium components with regard to solubility include cysteine and/or cystine, tyrosine and iron (if added in the chelated forms). Forms of cysteine or cystine are more soluble in acid, whereas tyrosine is most soluble at high pH (above pH 10.5). It is often difficult to supply both in adequate concentrations, even in the basal medium. Combining them together in a single, concentrated nutrient feed is particularly more challenging. In most media formulations, tyrosine is the limiting factor due to its low solubility (2.5 m*M*). For this reason, tyrosine is typically added as a separate component late in the feed preparation, and it is added as the free base dissolved in sodium hydroxide or as the disodium salt. At very high concentrations, the disodium salt dissolves readily in water. Cystine, being less soluble, may be added from an acidic stock solution. Alternatively, the cystine–disodium–monohydrate form is more soluble and may be dissolved directly in the medium. Since cysteine is more soluble, it is usually preferred over cystine. However, cysteine in the media readily converts mostly to cystine during medium preparation and could eventually precipitate. The media need to be formulated such that these components do not precipitate over the required shelf life. Various strategies to extend shelf life could include testing lower concentrations or alternate forms of the amino acids in question, changing the final pH of the media or changing storage conditions.

Even though media are developed for eventual use in large-scale bioreactors, it might not be cost-effective or necessary to test prototype media in early stages of development in such large scales. However, the developed media should at least be tested in pilot scale to ensure that the newly developed media can be solubilized and sterilely filtered without problems in the larger scale equipment and to ensure comparability of data to lab-scale. When a medium is used in manufacturing scale reactors, it may be subjected to high temperature treatment for short times (HTST) to ensure viral inactivation (17). Newly formulated media should be subjected to such treatment at pilot scale to ensure that there is no loss of productivity after such treatment. If such heat treatment leads to adverse effects on productivity, the specific medium constituent(s) that are susceptible to this treatment should be identified. These constituent(s) should either be supplied at increased concentrations or added to the medium after the heat treatment step.

26.8 CONCLUDING REMARKS

In just over two decades recombinant protein titers have increased from about 50 mg/L to over 10 g/L. Today cell culture is a mature technology capable of synthesizing tons of recombinant biopharmaceutical products, in the process meeting market demand for life saving drugs. Alongside advances in cell line engineering, medium optimization provides the greatest tool in cell culture technology to optimize productivity, modulate product quality, and improve robustness of the cell culture process. Development of robust and productive cell culture media is at the crossroads of fundamental understanding of animal cell metabolism, empirical experimentation, and business needs. We have shown that through systematic and rational media development, it is possible to achieve high volumetric productivities, using peptone-free, serum-free chemically defined media in fed-batch cell culture processes. The focus for future research areas could include greater fundamental understanding of the cell culture process, specifically on factors in the media that affect metabolite and product quality profiles. While considerable progress has been made in achieving high titers with specific cell lines, clonal variations in productivity and metabolite profiles continue to exist, even for clones derived from the same parental host. Future research could also focus on influencing the behavior of these cell lines that display inherently undesirable phenotypic behavior, namely high lactate or ammonia synthesis rates and inherently low productivity.

ANIMAL CELL CULTURE, EFFECTS OF OSMOLALITY AND TEMPERATURE

JAMES C. WARREN AND SHYAMSUNDAR SUBRAMANIAN
Department of Fermentation and Cell Culture, Merck & Co. Inc., West Point, Pennsylvania

27.1 EFFECT OF OSMOLALITY OF THE CELLULAR MICROENVIRONMENT

27.1.1 Introduction

The osmolality of the extracellular environment is critical to the maintenance of cellular hydration and biovolumes at levels which promote optimal cellular functions (1,2). Most tissues in the human body are protected from fluctuations in osmotic pressures due to the essential functions of the kidney, and as a result these cells are primarily exposed to the osmolality levels of serum, of which the normal range is 285–295 mOsm. In order to simulate physiologically optimal conditions, animal cells in culture are typically propagated under isotonic conditions defined by culture media osmolalities between 280 and 320 mOsm (3). Exposure of cells to anisotonic (4) conditions results in a variety of physiological responses, including volume-regulatory responses, cytoskeletal reorganization, cellular signaling responses, regulation of gene expression, and metabolic changes. This chapter will proceed to describe the various physiological responses of cells to anisotonic conditions and focus on the impact and applications to industrial bioprocess systems.

27.1.2 Cellular Responses to Osmolality Perturbations

27.1.2.1 Volume-Regulatory Responses. Depending on the osmolality of the extracellular environment, animal cells are subject to regular exchanges of water in either direction due to the high water permeability of their membranes. Exposure of cells to hyperosmotic conditions drives water out, resulting in cell shrinkage, while exposure to hypoosmotic conditions causes cells to swell due to water influx. These changes in cellular volume are usually transient and can be corrected by various volume-regulatory responses which are triggered by cell shrinking or swelling. Regulatory volume decrease (RVD) mechanisms are triggered by exposure to hypoosmotic conditions, while regulatory volume increase (RVI) mechanisms are triggered under hyperosmotic conditions (2). Both RVI and RVD are primarily mediated by various ion channels, cotransporters, exchangers, and symporters, which actively and passively regulate the intracellular concentrations of ions (Na^+, Ca^{2+}, K^+, Cl^-, others) or organic osmolytes in order to return the osmosis-driven cellular hydration level to optimum levels. Osmolytes are organic molecules synthesized by the cell which serve little metabolic function other than maintaining intracellular osmolality (5). Some common cellular osmolytes include sorbitol, glycerophosphorylcholine (GPC), inositol, taurine, and betaine. Specific cellular responses vary among cell types and species.

Under hypoosmotic conditions, RVD is mediated by the activity of at least three main classes of channels: voltage-gated Cl^- channels (CLC2, sCLC3), voltage sensitive organic osmolyte and anion channels [volume-sensitive osmolyte and anion channel (VSOAC)], and "maxi" volume-sensitive anion channels (6). These channels are all triggered by cell swelling and mediate the efflux of Cl^- (and other anions), organic osmolytes,

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

acetate, and bicarbonate, respectively. Under hypoosmotic conditions, cells excrete organic osmolytes which are at relatively high concentrations relative to their metabolic activity (7). Incubation at 230 mOsm stimulated the release of the organic osmolyte taurine from human neuroblastoma cells and this release was regulated by VSOAC (7).

Whereas low osmolality conditions stimulate cell swelling and subsequent RVD via anion and osmolyte efflux, high osmolality stimulates cell shrinking and subsequent RVI via ion and osmolyte influx. RVI is mediated primarily by the uptake of ions and osmolytes by the activity of the following systems: $K^+/Na^+/2Cl^-$ symport, Na^+/H^+ and Cl^-/HCO_3^- antiports, Na^+ and K^+ channels, Cl^- channel inhibition, and various osmolyte transport systems (8). The ability of a cell to increase volume through RVI mechanisms may mean the difference between life and death, as cell volume increase is necessary for mitosis, while reduction in cell volume is often the hallmark of apoptosis (9).

27.1.2.2 Cytoskeletal Reorganization. In addition to cell volume changes, exposure of cells to hyperosmotic or hypoosmotic conditions lead to specific rearrangements of the actin cytoskeleton which accompanies both RVD and RVI (10). Cell swelling in response to hypoosmotic conditions causes a breakdown in actin stress fibers, disruption of filamentous actin at the cell periphery, and formation of peripheral F-actin patches (11–15). Efficient RVD requires an intact actin cytoskeleton, as actin depolymerization agents inhibit the activation of ion or osmolyte channels which typically mediate the RVD response (11,15,16). Recent evidence has demonstrated direct interactions between filamentous actin and the voltage-gated Cl^- channel sCLC3, which are necessary for efficient RVD response (17).

Alterations in the actin cytoskeleton has also been associated with cell shrinking and RVI following exposure of cells to hyperosmotic conditions, although the results are more subtle than those associated with RVD (18). In contrast to the distinct swelling-induced actin depolymerization which is associated with RVD, hyperosmotic conditions induce rearrangement of the actin cytoskeleton, such as depolymerization of cortical networks and redistribution and polymerization to dense peripheral actin networks (19). The RVI response is tightly linked to the organization of the actin cytoskeleton, as actin polymer stabilization agents inhibit RVI, whereas actin depolymerization agents enhance the RVI response (19,20).

27.1.2.3 Cellular Signaling. Exposure to changes in osmotic pressure induces a variety of cellular signaling responses which allow cells to appropriately compensate to changing environments through coordinated networks of molecular regulation. Volume-regulatory responses and the associated cytoskeletal reorganization responses are dependent upon specific osmosensory signaling molecules which are activated in response to sudden changes in osmolality and/or cell size. Among other signaling molecules, the functional relationship between osmotic regulatory responses and activation of the mitogen-activated protein (MAP) kinases has been extensively reported (19,21–25).

All three groups of signaling molecules within the MAP kinase family, ERKs, and p38 have been connected with RVD and/or RVI responses. Hypoosmotic stress and cell swelling activates ERK1, ERK2, p38, and JNK and the inhibition of these signaling molecules perturbs the RVD response (21,24,26,27). The swelling-activated MAP kinase responses are dependent upon upstream activation of MEK, protein tyrosine kinase, or protein kinase C (PKC) (28). Raf-1 has recently been identified as a stretch-induced signaling molecule (29), confirming the essential role of the Raf/MEK/ERK pathway in the RVD response.

The MAP kinase p38, and to a lesser extent ERK and JNK are also associated with the cell shrinking response to hyperosmotic conditions (19,30,31). Hyperosmotic stress-induced cell shrinkage increases intracellular levels of the signaling molecule PIP2, which is dependent upon a specific PIP kinase PIP5Kiβ and acts upstream of the cell shrinkage response (32). Hyperosmotic stress also stimulates the expression of serum- and glucocorticoid-inducible protein kinase (Sgk) by a p38-dependent mechanism (33).

27.1.3 Effect of Osmotic Stress on Cultured Mammalian Cells: Bioprocess Applications

As the demand for mammalian cell culture-derived monoclonal antibodies and therapeutic proteins continues to increase (34), there is continued interest in enhancing the volumetric productivity of cell culture systems while preserving the product quality profile. Traditional approaches to enhancing productivity of cell culture systems have focused on optimizing feeding strategies to replace depleted nutrient levels and/or remove inhibitory metabolic by-products, resulting in increased maximum cell density, maintenance of high cell viability and prolonged periods of high antibody production (35). As a result of the extensive research that has been performed over the last 20 years toward these fundamental goals, the biotechnology industry has successfully implemented various batch-feed, fed-batch, and perfusion-based methodologies to supply the market with what is now a long list of cell culture-based therapeutic proteins and antibodies (34,36).

27.1.3.1 Effect of Culture Media Osmolality on Protein Productivity. Besides increasing cell density and prolonging culture longevity, various approaches to increasing cell-specific productivity have been employed.

Specifically, the positive effect on cell-specific protein production following exposure to hyperosmolar culture conditions (350–425 mOsm) has been demonstrated repeatedly (37–42). In general, hyperosmolar culture conditions enhance specific protein productivity in a variety of host cell systems, in some cases by twofold or more, but high osmolarity typically has negative impact on cell health and growth rates. As a result of the negative impact of hyperosmolar conditions on cell viability and diminished cell growth, the osmolarity-induced increase in specific protein productivity does not always result in substantial volumetric increases in antibody productivity (43,44). This section addresses the degree to which changes in culture osmolality affects cell-specific and volumetric protein productivity, what mitigating factors have been applied to address negative impacts of hyperosmolar conditions, and how this varies among the most commonly utilized cell types.

Ozturk and Palsson (37) reported the observation that specific protein productivity of a murine hybridoma cell line increased proportionally with culture osmolality between 290 and 435 mOsm (37). In these studies, exposure of cells to 435 mOsm resulted in greater than twofold increase in cell-specific antibody production, although this was coupled with approximately threefold increase in cell death rate in hyperosmolar relative to isotonic conditions. Although the increase in osmolality in this case was generated by increasing levels of NaCl in the culture medium, similar increased antibody productivity was reported with hybridoma cells grown in hyperosmolar conditions generated by elevated sugar levels (45). As suboptimal pH conditions had also been associated with reports of enhanced specific antibody production (46), a causality developed linking stressful culture environmental factors and subsequent suppression of cell growth to increased cell-specific protein production.

The effects of growth-suppressing conditions on specific antibody production were further exploited in studies where hyperosmolar conditions (350 mOsm) and treatment with 0.1 m*M* sodium butyrate were combined (47). Butyrate is a known suppressor of cell growth, although it has recently shown to have more specific impacts to cellular protein processing, including histone modification, chaperone activity, and lipid metabolism (48). The combination of exposures to high osmolarity and moderate levels of butyrate resulted in greater than twofold increase in volumetric antibody production relative to control conditions. In these experiments, hyperosmolar/butyrate conditions reduced maximum cell concentrations by approximately 30% relative to controls, but the combination of enhanced specific productivity and prolonged culture duration in the high osmolarity/butyrate conditions ultimately resulted in increased volumetric protein production.

Although the positive effect of hyperosmotic conditions on specific protein or antibody production has been observed across multiple cell lines, this effect has been cell line specific and variable (49). For example, whereas S3H5/γ2bA2 hybridomas exhibit greater than 200% increase in specific antibody production at ~400 mOsm relative to the specific production observed at 280 mOsm, DB9G8 hybridomas exhibit only a 10% increase in specific antibody production under the same hyperosmolar conditions relative to control.

27.1.3.2 Use of Osmoprotective Compounds to Mitigate Inhibitory Effects. Within 2–3 years following the first report of enhanced specific productivity resulting from exposure to hyperosmolar conditions (45), it became clear that for most cell lines the enhanced antibody productivity was coupled with a substantial suppression in cell growth. The inhibitory effect on cell growth occurred in a dose-dependent fashion with increasing osmolality levels above 330 mOsm, and the effect was independent of the raw material used to induce the hyperosmolar conditions (50). Hybridoma cell growth ceased when media osmolality levels reached approximately 435 mOsm through the addition of either NaCl, KCl, or sucrose (50). Subsequent research was directed toward identifying ways to maintain high cell concentration and longevity under hyperosmolar conditions.

As previously described, mammalian cell membranes are unable to selectively maintain substantial differentials in osmotic pressure relative to their surroundings, so intercellular osmolality is usually equivalent to that of the extracellular environment. The function of mammalian kidneys maintains isosmotic balance, and as a result most tissues are protected from exposure to extreme osmolality levels. Exception to this rule includes tissues such as those in mammalian excretory systems which are regularly exposed to high salt conditions. Renal cells are able to avoid the damaging effects of cell volume fluctuations by synthesizing organic osmolytes which help to maintain cellular water balance during exposure to high or fluctuating osmolality conditions (51). Examples of osmolytes typically synthesized in renal tissues to counteract the damaging effects of high osmolality include betaine, myoinositol, amino acids, sorbitol and GPC. In response to exposure to high osmolality, these osmolytes accumulate in the cell by either enhancing the transfer rate from the extracellular space, increased intracellular synthesis, or decreased intracellular breakdown (51). Previously, these osmolytes were also found to accumulate in the brains of salt-loaded rats (52).

With the knowledge that the protective effects of organic osmolytes could be achieved by cellular uptake of these compounds from the extracellular environment, a variety of osmoprotective osmolytes were added to culture media and evaluated for their ability to counteract the

inhibitory effect of hyperosmolar conditions in bioprocess systems. A variety of amino acids and methyl amines were identified as having a positive effect on cell growth when coupled with addition of high salt or sucrose (50). Among these, asparagine, proline, glycine, sarcosine, dimethylglycine, and glycine betaine were found to have the highest osmoprotective activity on hybridoma cells propagated under hyperosmolar conditions. Interestingly, with glycine compounds the degree of osmoprotection increased with increasing *N*-linked methlyation (50). Glycine betaine (trimethylglycine) provided the highest osmoprotection, followed by dimethylglycine, with glycine and sarcosine (methylglycine) providing comparatively moderate osmoprotection.

It is now known that glycine betaine provides superior protection against the inhibitory effects of hyperosmolar conditions on cells in bioprocess systems (41,50,53). In hybridoma cells exposed to extreme osmolality levels (465, 525 mOsm/kg), glycine betaine addition (15 m*M*) restored cell growth rates to a level at or near that observed with isosmotic conditions (50). As expected, cell-specific antibody production doubled under high osmolality conditions relative to isosmotic conditions. The net effect of culturing hybridoma cells at high osmolality (465–525 mOsm) in the presence of 15 m*M* glycine betaine was approximately twofold increase in volumetric antibody production (50).

The positive effect of incorporating glycine betaine in culture media under conditions of high osmolality has also been confirmed with CHO cells for the production of therapeutic proteins (53). A two to threefold increase in volumetric production of erythropoietin (EPO) from CHO cells was observed by combining hyperosmotic shock with supplementation of 15 m*M* glycine betaine (53). In a follow-up study, CHO cells grown in hyperosmolar conditions (435 mOsm) grew at half the rate relative to cells grown under isosmotic conditions, and glycine betaine (25 m*M*) mitigated this inhibition, restoring cell growth to control levels (41). In this case, however, high osmolality resulted in decreased cell-specific protein production. It is not clear whether this negative effect is related to the fact that, in this case, high osmolality was coupled with extreme carbon dioxide saturation in the liquid phase (195 mmHg).

27.1.3.3 Effect of Culture Medium Osmolality on Hybridoma Cell Size. As discussed previously, the typical cellular volume-regulatory response to a hyperosmolar shock is a transient shrinking event due to water loss, followed by a recovery phase in which intracellular ion and osmolyte levels accumulate, water is regained, and cell size is recovered. Ion and osmolyte accumulation results in increased water influx, which over time may result in an overall increase in cell size. Consistent with this principle, hybridoma cells exposed to hyperosmotic stress are up to 50% larger than cells grown in isosmotic conditions (37,39,47,54). The mechanisms responsible for this osmolality-induced increase in cellular volume have not been characterized, although increased intracellular ion, amino acid, protein, or nucleic acid concentrations have been implicated (47). Cell size increases with progression through the cell cycle, from smallest to largest in G0/G1, S, and G2/M, respectively (54). As exposure of cells to environmentally unfavorable conditions is known to decrease cell growth rate and presumably decrease the mitotic index, these conditions may lead to an overall increase in the relative proportions of cells locked in S- or G2-phase, resulting in an increase in average cell size.

27.1.3.4 Effect of Culture Medium Osmolality on Protein Posttranslational Modification. Although cell-specific and volumetric protein productivity is of utmost concern in a bioprocess production system, the maintenance of proper posttranslational modifications for these proteins is of utmost concern to the product quality profile. Among other posttranslational modifications, the addition of glycans to polypeptide chains, or glycosylation, has received a great deal of attention due to the link between glycosylation patterns and bioactivity. Most therapeutic glycoproteins undergo a complex series of oligosaccharide linking and processing in the endoplasmic reticulum and golgi (55) which have a substantial impact on protein stability, immunogenicity, biological activity, and binding specificity. Due to the critical need to maintain and promote proper glycosylation in therapeutic protein and antibody production processes, the effects of metabolic biproducts and stressful culture conditions on protein glycosylation has been studied extensively (56–58). These studies have shown overall that increased environmental stress on cells in culture leads to an increase in the variability of glycosylation patterns.

The composition and charge of glycan structures are critical to the potency and pharmacokinetics of therapeutic proteins. Addition of multiple sialic acid residues increase the net negative charge of glycoproteins which has a significant impact on the activity and efficacy of some therapeutic proteins (59,60). The polysialylation (PSA) of neural cell adhesion molecule (NCAM) is particularly sensitive to stressful culture conditions (56) and was used as a model system to understand how hyperosmotic conditions effects glycoprotein production profile. CHO cells were exposed to a series of increasingly high osmolality levels, and levels of NCAM PSA decreased as a function of increased osmolality. At approximately 500 mOsm/kg, NCAM PSA levels were 75%–80% lower than levels observed when cells were grown under isosmotic conditions (61). Addition of the osmoprotectant glycine betaine only marginally mitigated

this dramatic decrease in protein sialylation induced by hyperosmotic conditions.

Another way of characterizing general changes in posttranslational modification is to track the generation of degradation products, under the assumption that deficiencies in modifications such as *N*-linked glycosylation will generate degraded or misfolded protein products. *N*-linked glycosylation is necessary to mediate interactions with chaperones in the ER and ensure proper protein folding (62). When hybridoma cell growth and IgG production were compared in control conditions (290 mOsm/kg) and hyperosmotic conditions (400 mOsm/kg), the cell-specific antibody production rate increased by 60%, while the cell growth rate decreased accordingly (54). To determine whether posttranslational modifications were rate-limiting to the specific antibody production rate, pulse-chase labeling experiments were performed to quantify degradation in immunoglobulin light chain (LC) and heavy chain (HC) (54). No change in degradation profiles were observed between cultures propagated under control and hyperosmotic conditions, indicating that rates of posttranslational modifications increased with enhanced rates of antibody production.

27.1.3.5 Effect of Hypoosmotic Conditions on Specific Protein Productivity. Although particular attention has been devoted to understanding the positive effects of hyperosmotic conditions on specific protein or antibody productivity, a much fewer number of cases have been reported describing the positive effects of hypoosmotic conditions on specific protein productivity. CHO cells exposed to hypoosmotic conditions (150 mOsm/kg) exhibited approximately 70% lower cell growth rates relative to cells cultured under control conditions (300 mOsm/kg) (63). Exposure to these hypoosmotic conditions resulted in a dramatic increase in specific antibody production rate, greater than twofold relative to control conditions (63). This trend was confirmed in another CHO cell line, engineered for the production of EPO. Cells propagated under conditions of low osmolality (210 mOsm/kg) exhibited a twofold increase in specific protein production rates relative to control (310 mOsm/kg) conditions (64). When multiple stressful conditions were applied to this cell line, including low osmolality (210 mOsm/kg), low temperature (32°C), and sodium butyrate addition (1 m*M*), specific protein production rate increased by fivefold relative to control conditions. These observations put into question the precise mechanism responsible for osmolality-induced enhancements to cellular-specific protein productivity. In particular, these observations suggest an overall nonspecific mechanism by which the exposure of cells to environmentally unfavorable conditions may result in enhanced product production or secretion. This topic is explored in greater detail in the following section.

27.1.4 Potential Mechanisms Responsible for Osmotic Stress-Induced Enhancement of Recombinant Protein Production

In order to understand the mechanisms responsible for osmolality-induced increases in cell-specific protein production which have been observed as previously described herein, it is necessary to understand how changes in extracellular osmolality affects rates of gene expression (i.e. levels of immunoglobulin (Ig) mRNA), translation (i.e. Ig synthesis rates), and protein secretion.

27.1.4.1 Effect of Hypermolar Stress on Immunoglobulin mRNA Levels and Transcription Rates. Exposure of cells to hyperosmolar conditions results in a substantial increase in total cytoplasmic RNA, including preferentially higher levels of Ig mRNA (39,42,65). Hybridoma cells propagated at elevated osmolality levels (425 mOsm/kg) exhibited greater than 50% more total RNA per cell relative to cells grown under isosmotic conditions (285 mOsm/kg) (39). When this analysis was extended to quantify the levels of Ig heavy chain (HC) and light chain (LC) mRNA, it was found that cells exposed to high osmolality conditions produced greater than threefold higher Ig (both HC and LC) mRNA levels relative to cells maintained under control conditions. Overall, this data reflects that hyperosmolar conditions result in nearly a fivefold increase in Ig HC and LC transcription rates (39). In a subsequent study, approximately 10–60 h after shifting the osmolality from 290 to 400 mOsm/kg, an enhancement (~30%) of Ig-specific fractions of total RNA levels (both LC and HC) were observed relative to control conditions (54).

These results were confirmed in another commonly used antibody-producing cell line, GS-NS0 (42). Out of approximately 7000 GS-NS0 genes analyzed, approximately 550 genes were upregulated by twofold or more when cells were cultured under hyperosmolar conditions (450 mOsm/kg) relative to cells grown at isosmotic conditions (290 mOsm/kg). The hyperosmolality-induced upregulation was observed among all classes of NS0 genes, including those genes associated with cell proliferation, physiology, signaling, transport, and metabolism. Most notably, the category in which the highest number of upregulated genes were observed was transcriptional regulation. In this category, 41 individual genes were upregulated in response to hyperosmotic stress (42). Most recent data has confirmed that hyperosmotic stress induces the upregulation of approximately 20 genes involved in regulation of transcription in hybridoma cells (65). Within 4 h post hyperosmotic shock, these genes are present in two to fourfold higher levels relative to those seen in

control cells, and the enhanced levels are maintained for greater than 12 h (65).

It is possible that exposure of mammalian cells to hyperosmotic shock induces chromatin remodeling, thereby stimulating the engagement of osmoresponsive promoter elements and enhancing gene expression. In yeast, hyperosmotic conditions trigger the HOG1 pathway (analogous to mammalian cell mitogen-activated protein kinases [MAPK]) which recruits a histone deacetylase to remodel chromatin structure, thereby facilitating the expression of osmoresponsive genes (66).

Despite multiple observations of higher total RNA and Ig mRNA levels in hyperosmotic stressed cells, it is unlikely that mRNA levels are rate limiting, and there does not seem to be a direct relationship between increased mRNA production and increased antibody production. Because the kinetics of mRNA production is distinct from antibody production kinetics, there is yet no clear correlation between elevated levels of Ig mRNA levels and increased mAb production (54,67).

27.1.4.2 Effect of Hyperosmolar Stress on Immunoglobulin mRNA Translation Rates. In further support of the claim that Ig mRNA levels do not represent rate-limiting steps toward increasing protein productivity, studies have shown that >fourfold increases in Ig mRNA transcription rates lead to only approximately twofold increase in Ig mRNA specific translation rates (39). In these experiments, a biosynthetic labeling approach was used to quantify the amount of LC and HC polypeptides synthesized over a 30 minute pulse time. Hybridoma cells exposed to hyperosmolar stress exhibited increases in levels of HC and LC polypeptide levels of 1.7- and 2.4-fold (respectively) when compared to the same measurements in cells maintained at isosmotic conditions (39). Sun *et al*. observed similar levels of protein synthesis increase in response to hyperosmotic stress, with an approximately 1.6-fold increase in total protein synthesis relative to controls (54). In these experiments, there was no preferential increase in Ig-specific protein synthesis above the 1.6-fold increase which was attributed to the nonspecific enhancement in total protein levels.

In contrast to observations in transcription-specific genes, hyperosmotic stress does not induce upregulation of a large number translation-specific genes. Whereas two genes associated with regulation of translation were found to be upregulated (approximately 1.5–2.5-fold) following exposure of cells to hyperosmotic conditions, two others in this category were significantly downregulated (65). At least one hyperosmotic stress-regulated promoter element has been identified, a GC-rich sequence which binds a p38-responsive transcription factor, resulting in stimulation of Sgk production through a well-characterized stress-response pathway (33).

Overall, the existing data suggests that Ig mRNA translation and protein synthesis rates, not Ig mRNA transcription rates, are rate-limiting with respect to cell-specific antibody production. While hyperosmotic stress may induce four to fivefold increases in Ig-specific transcription rates, the subsequent increase in Ig-specific translation rates of approximately twofold relative to control are consistent with the expected increases in specific antibody productivity. This trend is supported by recent findings that NS0 cells which exhibit higher specific antibody productivity have significantly higher levels of ER chaperone, non–ER chaperone, cytoskeletal, cell signaling, metabolic, and mitochondrial protein levels per cell relative to those with lower specific antibody productivity (68). In short, increased antibody productivity requires increases in the protein machinery required for the modulation of cell physiology, signaling, and protein synthesis.

27.1.4.3 Effect of Hyperosmolar Stress on Antibody Secretion Rates. Antibody transport from the ER through the Golgi Apparatus and secretion into the extracellular space has been modeled to account for the nongrowth associated kinetics displayed by hybridoma cells in batch culture (69). Nongrowth associated antibody secretion kinetics predicts that antibody secretion rates are inversely proportional to cell growth rates, and as such maximum secretion rates are obtained when cell growth rate approaches zero, as in batch culture stationary phase (70). To date, most experimental evidence supports the claim that factors which enhance Ig-specific translation and protein synthesis result in corresponding increases in antibody secretion rates (39,54). In other words, once the Ig LC and HC peptides are synthesized, assembled, and processed, the extracellular transport of antibodies is not a rate-limiting step. In hybridoma cells, antibody secretion rates were maintained at high levels throughout the batch culture when cells were exposed to hyperosmotic conditions (54). These antibody secretion rates were approximately 50%–60% higher than those observed under control conditions, where levels steadily declined throughout the course of the batch. This increase in antibody secretion was in direct accord with the percentage increase in LC and HC protein synthesis described previously (54). In this way, antibody secretion rates are responsive to increased protein synthesis, not specifically to changes in extracellular osmolality.

27.1.5 Effect of Hyperosmolality on Virus Expression Systems

Virus expression systems are frequently used in industry in the production of recombinant proteins, gene therapy vectors, and vaccines. The effect of culture medium osmolality on virus expression systems have been described by two

distinct observations: (i) enhancement of recombinant protein synthesis, or (ii) the enhancement in virus productivity and infectivity.

27.1.5.1 Baculovirus Expression Vector System. The baculovirus expression vector system (BEVS) is widely used in industry as a platform for the production of recombinant proteins in insect cells (71). In contrast to mammalian cell lines, insect cells have a relatively high tolerance for hyperosmolar conditions (72,73). After a 24 h adaptation period, the growth rate of Tn-5 cells was not inhibited when exposed to a range of osmolality (350–500 mOsm/kg) which would clearly be inhibitory in mammalian cells (73). In these studies, exposure to hyperosmolar conditions resulted in enhanced cellular metabolism as indicated by almost threefold increase in specific glucose uptake rate at 500 mOsm/kg compared to those propagated at 350 mOsm/kg. Only moderate increase in recombinant protein production has been associated with baculovirus-infected insect cell exposure to hyperosmolar conditions. When nutrient limitations were mitigated by feeding or media replacement, cells exposed to 500 mOsm/kg exhibited 30%–40% higher recombinant protein production relative to the production in cells exposed to lower osmolality (350 mOsm/kg) (73).

27.1.5.2 Sensitivity of Animal Virus Replication to Osmotic Conditions. Consistent with observations previously described of enhanced protein production under hyperosmolar conditions, hyperosmolar conditions have also been described to result in enhanced virus production in cultured animal cells. Bovine rotavirus production and infectivity was enhanced by 2 logs when 100 m*M* NaCl was added to the MEM virus maintenance media (74). Productivity of duck hepatitis B virus (DHBV) in primary cultured duck hepatocytes was inhibited by 50% under hypoosmotic conditions (277 mOsm/kg) and enhanced by fourfold when cultured under hyperosmotic conditions (addition of 46 m*M* NaCl, 421 mOsm/kg) (4).

Cell-specific production of a retroviral gene therapy vector has been enhanced by exposure of a continuous human cell line (TE Fly A7) to hyperosmolar conditions (75), although this effect was not observed with salt addition alone. While NaCl had an inhibitory effect on Moloney murine leukemia virus (MoMLV) production, increased osmolality up to 500 mOsm/kg by the addition of sorbitol or sugars enhanced the cell-specific production of retroviral vectors by three- to fourfold (75). Hyperosmolar conditions also resulted in approximately twofold increases in cell volume, consistent with results described for hybridoma cells previously cited in this chapter.

A thorough investigation of the effect of medium osmolality on adenovirus production in 293 human embryonic kidney cells has revealed that exposure of cells to hyperosmolar conditions did not impact cell-specific virus productivity (76). Adenovirus productivity remained relatively unchanged relative to control throughout a range of 300–430 mOsm/kg. Previous studies have shown that exposure of 293 cells to hyperosmolar conditions result in enhanced production of recombinant proteins (77). This highlights the likelihood that mechanisms responsible for osmotic shock-induced enhancements to protein production may not directly apply to virus production systems.

27.2 EFFECTS OF TEMPERATURE PERTURBATIONS ON CELLULAR PHYSIOLOGY AND PERFORMANCE IN BIOPROCESS SYSTEMS

27.2.1 Introduction

Temperature is a critical process variable to be controlled for animal/mammalian cell culture. Mammalian cells are typically cultured at a temperature slightly (0.5°C) below the optimum physiological temperature of 37°C (3). This is due to the fact that deviations below set point are tolerated better than deviations above. Temperature variations may occur due to tolerance in control schemes or failures in these control schemes. Overall impact of temperature excursions above 37°C is quite different from the impact of excursions below 37°C, and highly variable effects on cell growth, physiology, and protein productivity have been observed. While the effects of temperature on mammalian cell growth (78,79) and protein production (80) have been demonstrated previously, this section will mainly focus on current understanding of temperature effects in industrially relevant cell culture systems on the production of therapeutic proteins, viral vaccines, and gene therapy vectors.

27.2.2 Cell Culture Responses to Temperature Perturbations: Hyperthermia

27.2.2.1 Heat-Shock Response. Exposure of animal cells to temperature greater than 37°C induces a cascade of events termed *the heat-shock response*, characterized by the expression a family of proteins called heat-shock proteins (HSPs) (81,82). The response does vary based on the temperature, time of exposure, and, perhaps, the rate at which the temperature changes. Exposure to temperature greater than 39°C results in a mild heat-shock response, while exposure to temperature greater than 42°C leads to a full blown response with induction of cell death (83). Changes in membrane fluidity, permeability, DNA, RNA, and protein synthesis, and cytoskeletal rearrangements have been reported (83,84). Broad changes in signaling, specifically with MAP kinases (MAPK) and protein kinase B (PKB/Akt), have also been documented (85). These changes were observed to precede the induction of HSPs

and contributed either to counteracting the effects of heat or directing the cell to programmed cell death.

27.2.2.2 Cell Growth, Metabolism, and Physiology. The optimal temperature for mammalian cell growth (specific growth rate) is typically close to mammalian 37°C, if not precisely at that temperature. Increase in temperature up to 39°C resulted in specific growth rates similar to (86) or lower than (87) the specific growth rate observed at 37°C. However, cell growth has been observed to cease with increased cell death rates at temperatures greater than 39°C. In some cases cell growth ceases even at 39°C (88), but even if this does not occur maximum cell density obtained in batch culture at ≥39°C was always lower than that obtained at 37°C (86,87), presumably due to activation of cell death pathways. The specific glucose consumption has been reported to increase up to 39°C (86,87,89), with concomitant increase in specific lactate production. While many of these observations are from hybridomas, this effect is also generalizable to other cell types such as CHO.

27.2.2.3 Recombinant Protein Production: Quantity and Quality. With hybridomas, specific productivity of antibodies was maintained (86,88) or increased (87) with higher temperature of cultivation (upto 38–39°C), but final yield is at best comparable (88) and typically lower than at 37°C due to lower cell density (86,87). Specific productivity of EPO-Fc in CHO cells was maintained up to 38°C and then decreased (specific productivity decreases by 20%) when temperature was increased to 39°C (90). Heat-shocking CHO cells (91) or hybridomas (92) at temperatures ≥42°C did not demonstrate a negative impact on cellular health and protein productivity (EPO from CHO cells), but this data is limited and only explores brief exposure to these high temperatures. EPO glycosylation patterns were not apparently affected after a 1-hr heat-shock at 42°C (91). The only positive data reported for the use of temperature greater than 37°C comes from Jenkins and Hovey (93,94), who generated a temperature sensitive (ts) CHO cell line and demonstrated that alternating between 39°C (nonpremissive for the ts mutant) and 34°C resulted in a 35% improvement in volumetric productivity of tissue inhibitor of metalloproteinases (TIMP), compared to control cultures maintained constant at 34°C. Cultures were arrested at the G0/G1 cell cycle phase and also showed reduced metabolism under this mode of cultivation. The use of a heat-responsive promoter and altered heat-shock profiles led to even better improvements in TIMP production with this ts cell line (94).

27.2.2.4 Viral Vector Production: Quantity and Quality. Viruses also do not show higher production at temperatures beyond the optimum temperature for the cells they are adapted to grow in, since they rely heavily on the cell machinery for their replication. It is well known that enveloped viruses such as retroviruses are heat-labile (95–97), but it is interesting to note that even stable nonenveloped viruses such as adenovirus replicated efficiently with highest virus titers at a cultivation temperature of 35°C postinfection, especially when cells were cultured at 37°C preinfection in HEK293 cells (98,99) and PER.C6 cells (100). Interestingly, if PER.C6 cells were cultured at lower temperatures prior to infection (33°C), the optimal temperature for infection changed to 37°C (100) with peak titer obtained faster. Information of changes to quality of viruses upon production at temperatures ≥37°C is not available.

27.2.3 Effect of High Temperature: Potential Mechanisms

The mechanism behind changes in protein and virus productivity is less clear than the effects on cell growth and metabolism. At least in a small range around the optimal temperature, the kinetics of enzymatic and other cellular processes can be expected to respond to changes in temperature as per Arrhenius models. Therefore, slight increases in temperature resulting in increases in growth rate and metabolism can be rationalized. When these temperature excursions from optimal are sustained or if the excursions are large, other processes induced as part of the heat-shock response (protein aggregation, induction of apoptosis) can be expected to play a bigger role (101–103). Heat-shock for short duration and cultivation at lower temperature both curtail growth and could lead to synchronization of mammalian cells with respect to the cell cycle. Therefore we can speculate that certain effects seen, as with PER.C6 cells grown at 33°C producing adenovirus at 37°C, may be as a result of infection under synchronized conditions. Higher adenovirus productivity with culture synchronized with respect to the cell cycle has indeed been reported (104). However, cell cycle synchronization was not reported and so other mechanisms cannot be ruled out.

27.2.4 Cell Culture Responses to Temperature Perturbations: Hypothermia

27.2.4.1 Cold-Shock Response. Recent work has revealed that mammalian cells have an orchestrated response to hypothermia with the induction of ~20 proteins (105). Notable among the induced proteins were cold-inducible Ribonucleic acid-binding protein (CIRP) (106,107) and RNA binding motif 3 (RBM3) (108,109). Enhancement of protein synthesis could be due to increases in cap-independent translation via internal ribosome entry sites (110) or mediated through interaction with microRNA (111). These hypotheses have been demonstrated in at least one system, but await further studies to generalize.

27.2.4.2 Cell Growth, Metabolism, and Physiology. A reduction in temperature from 37°C generally leads to a reduction in the growth rate of mammalian cells, with cell cycle arrest observed at ~30°C incubation temperature, while viability was maintained for longer periods (88,90,101,112–117). Apoptosis was also generally reduced in mammalian cell cultures at reduced cultivation temperature (101,102,118,119), while exceptions to this rule have been reported (120). Oxygen consumption rates decreased with cultivation at lower temperatures (101,121) and were described using a simple Arrhenius model within the 6–37°C range (122). The decreased oxygen consumption rate is an important factor to consider when growing cells at high cell concentrations such as in perfusion cultures (123). The specific uptake rate for nutrients such as glucose, glutamine, and amino acids and the specific production rate for metabolites such as lactate decreased in general, while the lactate production to glucose utilization ratios remained constant (87,89,124), increased (90) or decreased (123). The changes in metabolism are more substantial at temperatures much lower than 37°C (<35°C). Downregulation of CIRP increased mammalian cell growth rate in mouse fibroblasts (107) but the manipulation of CIRP levels in CHO cells did not alter growth rates (125,126). In the temperature range of 28–39°C, shear sensitivity of BHK-21 cells increased with temperature (127). While shear sensitivity to temperature variation has not been reported in other cell lines, this finding may be important to consider.

27.2.4.3 Recombinant Protein Production: Quantity and Quality. Hybridomas were the first cell lines subjected to temperature optimization studies for industrial production of antibodies. None of the hybridomas studied showed significant improvements in specific productivity upon cultivation at temperatures lower than 37°C (86–88,116,128).

Research has demonstrated that there is some benefit to cultivating NS0 myeloma cells engineered for antibody production at temperatures below 37°C. In one study, slightly higher antibody yields were obtained with continuous cultivation at lower temperature (34°C) due to a combination of comparable specific productivity and higher average viable cell density (119). In another study, lower antibody yields were obtained when cells were initially grown at 37°C before switching to 37°C or 32°C (117). In the latter case, the viable cell density was lower at 32°C in comparison to 37°C, while specific productivity was similar despite increases in levels of heavy chain and light chain mRNA at the lower temperature. Reduction of temperature to 27°C resulted in poor antibody yields (117), as did continuous cultivation at 22°C (119), due to negative effects on both cell growth and specific productivity.

BHK-21 production of human antithrombin III (AT III) was not affected with a reduction in temperature to 30–33°C (129), while growth rate and metabolism (glucose consumption and lactate production) decreased, the peak cell densities obtained were similar at 33°C and 37°C. The volumetric productivity was similar with an increase in cycle time at 33°C. Chuppa *et al*. (123) used hamster cells (presumably BHK-21 or CHO) and demonstrated that reduced temperature cultivation (34, 35.5°C) in perfusion culture enabled a higher cell density to be supported (due to reduced specific oxygen/nutrient consumption). In addition, an increase in specific productivity was realized under these conditions, resulting in higher recombinant protein yield with comparable glycosylation and increased product stability.

CHO cell-based expression of recombinant proteins for therapeutic use is by far the predominant method used industrially, and accordingly has the most number of published studies (a subset is captured in Table 27.1). Production of several recombinant proteins such as EPO (64,130–132), interferon-γ (133,134,134), GM-CSF (124), antibodies and fragments (116,135–138) utilized a temperature shift down (to 30–34°C) and observed improved process productivity since the production phase could be extended (due to reduction in cell death, etc.) with similar or higher specific productivity. Even lower temperatures are used for the production of certain complex proteins such as Factor VIII, where cultivation at a temperature of 27°C and a reduced residence time in perfusion mode bioreactors increases productivity tremendously (up to sixfold) in COS-7 or CHO cells (139). Decreased aggregation and potential reduction in proteolysis were hypothesized to be partially responsible.

The improvement in recombinant protein production at low temperature is not universal, and in one study clonal variation of response to temperature shift was observed in CHO cells expressing an antibody during different stages of dihydrofolate reductase (DHFR) amplification (136). Adaptation of cell lines to enhance growth at lower temperature did not result in anticipated productivity improvements with a negative correlation observed between growth rate and specific productivity for EPO and FSH (146). Since volumetric productivity and product yield depend on both the viable cell density and specific productivity, a temperature shift strategy where cells are grown up to a desired high cell density at around 37°C following which the temperature is reduced to the desired temperature set point for production has worked effectively (112,132,133). This was also borne in direct comparisons where both single temperature (89,124) and dual temperature (141,144) strategies for growth/production have been applied. The optimal temperature shift down in single temperature cultivation (35°C) (89) may not be the same as the optimal temperature shift down for dual temperature cultivation (37°C/32°C) (141). Transient expression of proteins in CHO cells also show

TABLE 27.1. Summary of Temperature-Induced Changes to Protein Productivity Observed in Mammalian Cell Culture Bioprocess Systems

Cell Line	Protein	Temperature (°C) Growth	Temperature (°C) Production	Fold-change Specific Productivity	Fold-change Volumetric Productivity	Fold-change Yield*	Quality Comments	Quality	References
CHO	SEAP	37°C	30°C	1.7	2.3	3.4	T-flask Batch; Serum present	Sialylation ↑	112,113

enhanced productivity when low cultivation temperatures are used (149–151).

The effect of temperature on specific productivity also depends on other operating conditions such as pH, osmolality, presence of sodium butyrate and or serum in the media (64,131,135). For instance at pH 7.0, incubation at 32.5°C resulted in 1.5 fold improvement in specific productivity of EPO, while at pH <7.0 or >7.4, the specific productivity was lower at 32.5°C than at 37°C (131). The use of serum-free media instead of serum containing media resulted in greater enhancement of maximal Fab fragment yields (135). So, optimization of temperature should be considered along with other process variables using design of experiments (DOE) methodology, rather than individually.

Glycosylation is a critical quality attribute for therapeutic proteins (152–154) that affects protein function and pharmacokinetics and it has been clearly established that process conditions can have significant impact on glycosylation (147,155,156). In terms of product quality, the effects are mixed with depression in production temperature leading to detrimental (148), beneficial (112,113), or no (123,124,144) observable effects on glycosylation. Reduced temperature (<30°C) decreased fraction of protein with tetra-antennary structures and the degree of sialylation of EPO (148), while increased sialylation was seen with secreted alkaline phosphatase (112,113). Other process conditions can alleviate or exacerbate the changes to product quality attributes like glycosylation. For instance, lower pH increased the degree of sialylation when the cultivation temperature is low (90). Combining osmolality, sodium butyrate and low temperature treatments resulted in detrimental effects on quality of EPO (64).

27.2.4.4 Viral Vector Production: Quantity and Quality. The dual temperature mode of operation with physiological temperature for cell growth and a lower temperature during virus propagation is very common in virus production systems (157). This is mainly due to the fact that viruses used as vaccines are typically passaged at low temperature for attenuation and so cultivation at physiological temperature is considered risky in terms of reversing attenuation (157). The other reason is the labile nature of enveloped viruses such as retroviruses where stability at physiological temperature (37°C) is a concern (95). Increased productivity of several enveloped viruses (retrovirus, lentivirus, rabies virus, herpesviruses and reovirus) are reported at cultivation temperatures lower than 37°C (96,97,158–163). In most cases, increased stability of synthesized virus may be the reason, but improved cell physiology at lower temperature may also contribute. There are recent studies that point out that retrovirus prepared at low temperature were less stable than retrovirus prepared at 37°C (164), which was related to the presence of higher levels of cholesterol. These authors also did not see improvements in productivity at lower temperature. There are many other studies that do demonstrate higher titers at lower cultivation temperatures (96,97,158,160–162).

27.2.5 Effect of Low Temperature: Potential Mechanisms

Induction of a few proteins such as CIRP and RBM3 have been reported under hypothermic conditions (107,108). It is plausible that altered regulation at low temperature may happen at the mRNA level and there is some support from literature. Increases in mRNA levels for interferon γ were observed for instance, when temperature was reduced to 32°C from 37°C during cultivation of CHO cells (134) and similar increases in EPO mRNA levels were seen at 30–33°C (130). Increased levels for HC and/or LC mRNA does not guarantee higher antibody productivity in CHO or NS0 cells (117). It is also conceivable that product stability improvements contribute to increased productivity at low temperature for entities that are unstable such as Factor VIII (139) or retrovirus (95,96). There is less cell lysis and reduced levels of proteases released at lower cultivation temperatures (89,123). However, there are other publications that argue this is not always true (143).

Shotgun approaches to measure changes in mRNA, protein, and miRNA are being applied to determine if there are other hypothermia markers (119,165–169). These studies are in a preliminary stage and have not resulted in new hypotheses. However, it is not clear that these proteins alone are the effectors for any benefit seen in protein/virus production.

It is interesting to note that new data is revealing growth at low temperature (134,149) rather than the lack of growth (i.e. cell cycle arrest) (88) is more associated with increased productivity. However, as previously mentioned, cell-type and product differences probably play a role in these apparently contradictory observations.

27.3 CONCLUSIONS

Temperature reduction (30–34°C) has an overall positive effect on recombinant protein and virus production, especially when applied to the production phase for CHO and other cell types. While the mechanism is not completely understood, a combination of extended culture viability, reduced proteolysis/increased stability of product, increased mRNA expression seem to be responsible for these effects. However, the reader should view these results in the context of culture systems (batch vs fed-batch vs perfusion), operation set points for environmental variables (pH, DO) and media used (for e.g. presence of serum) and their potential interactions with temperature. Furthermore, these effects are variable between cell lines and even within clones of

the same cell line and therefore not necessarily predictable. Temperature greater than 37°C is generally not beneficial for cell growth and/or production of recombinant proteins or viruses.

ANIMAL CELL STABILITY

Martin S. Sinacore, Timothy S. Charlebois, Denis Drapeau, Mark Leonard, Scott Harrison, and S. Robert Adamson
Genetics Institute, Andover, Massachusetts

The genotypic and phenotypic stability of animal cells in culture are of great interest to cell and molecular biologists conducting basic biological investigations and to those in the biopharmaceutical sector engaged in the applied aspects of cell-culture-based process development. The genotypic and phenotypic status of animal cells is under constant assault by both intrinsic and extrinsic factors that conspire to invoke change in the nature of animal cell in culture. Since change is one of few certainties in nature, it is the context in which changes manifest that define their impact. The cell transformation process profoundly changes the genotype and phenotype of animal cells. In the context of a living organism, this can have significant negative effects while, in another context, it can enable cells to grow perpetually *in vitro* to the benefit of basic biological investigations. The focus of this chapter will be to review and discuss the mechanisms by which the genotypes and phenotypes of transformed animal cells change and, once established, the means by which genotypes and phenotypes can be stably maintained in continuous culture.

The starting place for the discussion of animal cell stability is to review factors that affect genomic stability of endogenous genes at the molecular level. This discussion is centered on the incompletely understood mechanisms and manifestations of genetic and phenotypic instability associated with oncogenic transformation of cells in culture. This is by no means a comprehensive review of the field of cell transformation but rather is focused on several key aspects of the transformation process that have been shown to directly impact genetic and phenotypic stability of animal cells during continuous culture.

Cell transformation is a profound alteration in the genotypic and phenotypic attributes of animal cells and represents a critical turning point in the molecular decision making process that signals continued proliferation of cells, cellular senescence, or activation of apoptotic pathways. The balance between the activation of proto-oncogenes and the inactivation of tumor suppressor genes is at the center of the transformation process. Just as important are processes by which the genetic integrity of animal cells is protected and preserved through the action of DNA repair systems activated by errors generated during DNA replication or in response to DNA damage inflicted by radiation or chemical assaults to cells.

With some understanding of the molecular processes that preserve the stability of endogenous genes, we then move on to consider the factors that affect the stability of heterologous genes in recombinant cells and factors that influence maintenance of stable phenotypes during continuous culture. These subjects are of particular interest to scientists focused on the development of biological systems that rely upon the stable expression of heterologous genes in continuously cultured animal cells. Frequently in these systems, the level of foreign protein expression is maximized through gene amplification strategies that create additional challenges with respect to genetic stability that arises from the dispersion of gene integrants throughout the cell genome. Flexibility or adaptability of animal cell phenotypes within the context of cell biology and biopharmaceutical process development offers the opportunity to shape animal cells to fit a particular experimental system or cell-culture process paradigm.

However, once the appropriate genotypes and phenotypes are established through cell line adaptation strategies or by direct genetic manipulation, further change (instability) of those attributes is not welcome. Herein lies the paradox of animal cell technologists—practitioners depend and rely on the pliability of cell genotypes and phenotypes in developing for instance, large-scale cell culture processes to produce recombinant proteins, yet once established, strive to make those attributes stable to provide assurance of process and recombinant product consistency.

For the cell and molecular biologists set upon the task of developing cell-culture-based manufacturing processes, the possible linkage between genetic (and phenotypic) stability and recombinant product quality has historically been the subject of discussion and investigation. The consequence of genotypic and phenotypic instability on recombinant protein quality is discussed by way of specific examples derived from experience in cell-line and cell-culture process development at Genetics Institute. These case studies provide a basis for arguments against a linkage between cell stability and recombinant protein quality and exemplify the nature of the challenges that are faced in developing robust cell-culture-based processes used in the manufacture of biotherapeutic proteins. Finally, approaches taken at Genetics Institute to characterize genotypes of recombinant cell lines for evaluating the genetic stability of recombinant cell lines and cell culture processes are discussed.

28.1 FACTORS THAT AFFECT GENETIC STABILITY OF ENDOGENOUS GENES

28.1.1 Oncogenic Transformation, Aneuploidy, and Genetic Stability

Genetic instability, manifested as various chromosomal aberrations such as aneuploidy, gene amplification, translocation, deletions and point mutations, is frequently observed during oncogenic transformation of cells. The cause and effect relationship between genetic instability and cell transformation has been a subject of much discussion, particularly with respect to the role of aneuploidy in these processes. Aneuploidy (an abnormal complement of chromosomes) is a massive genetic abnormality observed in nearly all of the many thousands of solid human cancers examined. This fundamental observation has led to the "aneuploidy-genetic instability" hypothesis which holds that the degree of aneuploidy is proportional to the degree of genetic instability associated with oncogenic transformation.

The aneuploidy-genetic instability hypothesis gained support over the years through the tight association between aneuploidy, genetic instability, and carcinogenesis. Recently, investigations using clones of chemically and spontaneously transformed Chinese hamster embryo cells indicated that clones were 50–100% aneuploid. Furthermore, colonies of transformed cells were highly heterogeneous with respect to chromosomal number, suggesting that aneuploidy can perpetually destabilize the karyotypes of these cells (1). Likewise, it was found that karyotypic instability was proportional to the degree of aneuploidy in cultures of continuously passaged clonal Chinese hamster embryo transformants (2). Furthermore, the quasidiploid karyotype of wild-type and a variety of mutant Chinese hamster ovary (CHO) cells were shown to be relatively stable after being cultured for extended periods of time. In contrast, quasitetraploid cells, derived spontaneously or by Sendai virus-induced fusion, were more prone to losses and gains in whole chromosomes, rearrangements of chromosomes, and the appearance of new and distinctive chromosomes (3). A model has emerged from these observations in which the loss of genes (or sets of genes in chromosomes) involved in mitosis perpetuates unequal segregation of chromosomes in subsequent cell divisions. Clearly, under such a model, stable maintenance of a genotype that contains an abnormal number of chromosomes would be improbable.

The notion that aneuploidy is a cause of genetic instability was challenged by data suggesting that an abnormal number of chromosomes in a cell, in and of itself, could not account for the high level of chromosomal instability found in aneuploid colorectal cancer cells (4). The authors proposed that dominant genetic defects in chromosomal segregation result in chromosomal instability, which drives aneuploidy. The basis for this assertion came from experiments in which the genetic stability of cells was not disturbed by the introduction of a single extra chromosome or by gross aneuploidy created by cell fusion techniques. Similarly, using gene amplification as an index for genetic instability, results from another study indicated that the propensity of methotrexate-resistant CHO cells to amplify endogenous dihydrofolate reductase genes was comparable in quasidiploid and quasitetraploid subclones (5). However, it was noted that genetic instability of aneuploid cells created spontaneously or by cell fusions was more pronounced when the resultant chromosomal number was nonmodal (4). Although a cause and effect relationship between aneuploidy and genetic instability has not been firmly established, it seems clear that once an aneuploid karyotype has been established in transformed animal cells, maintaining a stable karyotype in successive culture passages becomes more difficult.

28.1.2 Molecular Regulation of Genetic Stablity

28.1.2.1 Tumor Suppressor Genes and Proto-Oncogenes. A hypothesis opposing the aneuploid-genetic instability hypothesis, termed the "somatic gene mutation" hypothesis, holds that activation of proto-oncogenes and inactivation of tumor suppressor genes trigger transformation and

genetic instability. Under the somatic gene mutation hypothesis, animal cell transformation is the result of a multistage process starting with the activation of cellular proto-oncogenes and inactivation of tumor suppressor genes. These and other events arise from (or lead to) an enhanced state of genetic instability in which the genotypic (and phenotypic) diversity among clones increases. Most notably, this diversification manifests itself in changes in cell morphology and karyology among clones in a transformed cell population. The molecular mechanisms that underlie the genotypic and phenotypic instabilities associated with cell transformation are incompletely understood. However, some key molecules have been identified and their roles in regulating and maintaining genetic stability have become clearer. The following discussions focus on these key molecular factors and the mechanisms by which they influence the stability of cell genomes.

28.1.2.1.1 The p53 Tumor Suppressor Gene. Genetic alterations that involve inactivation of tumor suppressor genes are among the most thoroughly documented changes associated with animal cell transformation. In particular, mutation in the p53 tumor suppressor gene is frequently observed in human cancers.

The p53 tumor suppressor gene has been associated with critical cellular events involved in cell immortalization, growth arrest at the G1/S boundary in the cell cycle (i.e., cellular senescence), and activation of cell death by apoptosis (6,7). In these capacities, p53 has been considered a central factor of a genomic protection system in which, it has been hypothesized, accumulation of excess somatic mutations is prevented by growth arrest (presumably to facilitate DNA repair) or by the prevention of the further propagation of such DNA defects via apoptotic cell death. Because of the pivotal role of p53 in protecting cells and tissues from the generation and proliferation of genetic defects, it has been called the "guardian of the genome" (8).

Consistent with its role in maintaining genomic stability, the loss of p53 tumor suppressor functions results in genetic instability manifested by changes in chromosomal ploidy (9–14) and gene amplifications and deletions (12,13,15,16). Furthermore, in contrast to normal mouse fibroblast cells, mouse fibroblast cells that lack p53 protein display abnormal centrosomal amplification that causes unequal segregation of chromosomes (17).

The role of the p53 tumor suppressor function in genetic stability may have its basis in its proposed role in DNA repair. The human p53 protein contains both specific and non-specific DNA-binding domains that are hot spots for mutations that inactivate p53 function (6). Wild-type p53 protein can bind to damaged DNA and it has been shown that it plays a role in nucleotide excision repair in response to ionizing radiation (18–22) and bridge-breakage fusion of DNA (23), which has been implicated in gene amplification processes.

28.1.2.1.2 The Retinoblastoma Tumor Suppressor Gene. The possible role of tumor suppressor genes in genomic stability was also exemplified in studies involving the retinoblastoma tumor suppressor gene (pRb). Like p53, pRb is central in regulating cell-cycle progression and can act alone or in concert with p53 to arrest cell growth in response to DNA damage induced by gamma or UV irradiation or treatment with chemotherapeutic drugs (24,25). Linkage between pRb- and p53-mediated arrest pathways appears to come about via inhibition of pRb phosphorylation by cyclin-dependent kinases. Hypophosphorylated pRb promotes a growth-suppressive state via E2F transcription-factor-mediated repression of genes required for cell cycle progression (26). Similar to the model proposed for p53, pRb-mediated growth arrest and activation of DNA repair systems prevent replication of damaged DNA.

28.1.2.1.3 Proto-Oncogenes and Genomic Instability. The proto-oncogene *c-myc* is a key regulator of both cell growth and apoptosis and has been associated with cell immortalization and transformation (27). Gene amplification, a marker for genetic instability in mammalian cells, is often associated with *c-myc*-mediated transformation. Targets of *c-myc*-induced gene amplification include dihydrofolate reductase (28,29). Amplification of the dihydrofolate reductase gene may be associated with ongoing gene rearrangements and further genomic instabilities that lead to neoplastic transformation (30). Furthermore, it has been shown that *c-myc* has a direct role in activating telomerase by inducing the catalytic subunit, telomerase reverse transcriptase (31). As discussed in a section later in this chapter, it has been shown that telomerase is critical in maintaining genomic stability.

Likewise, expression of the human H-ras oncogene in mammalian cells results in cell transformation and DHFR gene amplification within a single cell cycle (32–34). H-ras tranformation is also associated with loss of contact inhibition of growth and the ability to form colonies in soft agar. Furthermore coexpression of the Ras-related tumor suppressor gene, *Rap1*, suppressed H-ras-induced amplification of the DHFR gene (35). Coexpression of the *Rap1* gene also caused H-ras-transformed cells to revert to a flat morphology and reestablished contact inhibition of growth and loss of the capacity to grow in soft agar. These studies demonstrated the profound influence of proto-oncogenes on cell phenotypes and genotypes.

28.1.2.1.4 Phenotypic Change Due to DNA Methylation and Gene Silencing. Enzymatic methylation of the C-5 position of cytosine residues in DNA motifs termed CpG islands may lead to inactivation of genes in a heritable

fashion (36). Hypermethylation of promoter sequences may lead to silencing of genes by inhibiting DNA transcription as a result of interference with transcription factor binding. Several tumor-suppressor genes contain CpG islands in their promoters and show evidence of methylation-based gene silencing. In addition, the majority of colorectal carcinomas with microsatellite DNA instability have hypermethylation of the promoter CpG island of the DNA mismatch repair gene MLH1 (37). Hypermethylation-induced attenuation of the DNA mismatch-repair system may, in turn, render the genome susceptible to additional genetic hits that lead to further genomic instability and oncogenic transformation. However, whether hypermethylation of DNA sequences is a cause or consequence of gene inactivation is highly disputed.

28.1.2.2 Poly(ADP-Ribose) Polymerase. Interruptions of DNA strands brought about by DNA-damaging agents (e.g., γ irradiation, alkylating reagents) elicit a rapid response that involves the mobilization of several DNA repair systems. Components of these DNA repair systems have been implicated in DNA gap repair and religation, DNA integration and recombination efficiency, and genomic stability. One such rapid response to DNA damage involves attachment of poly(ADP-ribose) polymerase (PARP) to DNA strand breaks (38,39). PARP is found in abundance tightly associated with chromatin in the nuclear compartment of eukaryotic cells. The PARP protein contains three functional domains: a DNA-binding domain, an automodification domain, and a catalytic domain. The DNA-binding domain rapidly binds to DNA strand breaks which in turn stimulates the catalytic domain. Using NAD as substrate, the catalytic domain carries out extensive ADP-ribosylation of PARP in the automodification site, as well as in a variety of nuclear target proteins, including topoisomerase and histones. PARP and other ADP-ribosylated proteins are recycled to their active state by the action of poly(ADP-ribose) glycohydrolase.

ADP-ribosylated PARP has a reduced affinity for DNA because of electrostatic repulsion, and the complex falls off the DNA strand and allows other DNA repair enzymes to dock and carry out DNA repair. Therefore, PARP functions as a "molecular nick sensor" in eukaryotes and, by way of direct interaction with nicked DNA, protects the site from the action of nucleases and other DNA-binding proteins. Furthermore PARP may be acting to home in other proteins at the damaged site, such as XRCC1, DNA ligase III, DNA polymerase β, p53 and DNA-dependent protein kinase and, in so doing, primes damaged DNA for repair.

The temporary protection of nicked DNA by PARP and the rapidity of the response have been considered indicative of the critical role of PARP in maintaining DNA integrity. Several lines of investigation have implicated its role in genomic stability (40–42) gene amplification (43), efficient retroviral infection (44), DNA transfection (45,46), and DNA base excision repair (47). Compelling evidence of the critical role of PARP in maintaining genomic stability comes from work done with PARP (−/−) knockouts. Mice that lack the gene that encodes PARP display no phenotypic abnormalities but are sensitive to γ irradiation and treatment with genotoxic agents like *N*-methyl-*N*-nitrosourea (48–50). In addition, primary cultures of PARP (−/−) cells are more prone to sister chromatid exchange that indicates a higher rate of rejoining of chromosomal breaks (41,43,48,49). Cells from PARP (−/−) animals also tend to display an increased number of micronuclei (a marker for genomic stability) after γ irradiation or treatment with mitomycin C (41,48) and exhibit a larger number of chromatid breaks and chromatid exchanges (49).

The potential interplay between PARP and other DNA-binding proteins like p53 and DNA-dependent protein kinase (discussed in the section following) has also been a subject of investigation. Agarwall *et al*. (49) observed a twofold lower basal level of p53 in PARP (−/−) cells and diminished induction of p53 in response to DNA damage that combine to reduce the induced level of p53 protein by four- to fivefold compared to normal cells. However, a decrease in the induction of p53 activity in PARP-deficient cells was not noted in these cells. In contrast, splenocytes from PARP knock-out mice exhibit normal or even elevated p53 (50). These results indicated that p53 protein induction may be regulated by a combination of PARP-dependent and-independent pathways. Finally, using PARP-specific antibody, it was shown that PARP and p53 coimmunoprecipitate in HeLa cell extracts after induction of apoptosis (51). This suggests that PARP and p53 may directly interact under these conditions.

28.1.2.3 DNA-Dependent Protein Kinase. It is thought that DNA-dependent protein kinase (DNA-PK) is critical in T-cell receptor V(D)J recombination in lymphoid cells and DNA double-strand break repair (52). The recombination process involves site-specific cleavage by recombination activating gene (RAG)1 and RAG2, that generates double-strand breaks that are specifically joined and repaired. DNA-PK binds to DNA double-strand breaks leading to activation of the protein kinase catalytic subunit. Phosphorylation of DNA-binding proteins such as transcription factors Sp1, c-Jun, and p53 takes place along with autophosphorylation of DNA-PK subunits. Localized phosphorylation of transcription factors may arrest transcription in the vicinity of the double-strand break that allows docking and assembly of DNA repair machinery.

Cells derived from animals that bear the spontaneous severe combined immunodeficiency (SCID) mutation lack DNA-PK activity and are defective in V(D)J recombination and DNA repair (53–55). The role of DNA-PK in DNA

recombination and repair has been definitively confirmed in murine DNA-PK null knockouts (56,57) and in a variety of murine and CHO cell mutants that lack DNA-PK activity (58–62).

Both DNA-PK and PARP are nuclear proteins that bind to DNA at strand breaks and may, in fact, compete for binding to DNA strand breaks induced by genotoxic agents or by normal recombination. These similarities have led some to suggest that PARP and DNA-PK can substitute for one another under different physiological circumstances (38). Because PARP mutant cells have elevated levels of spontaneous sister chromatid exchange, indicative of a higher rate of rejoining of chromosomal breaks, some have hypothesized that a PARP deficiency might permit processing and ligation of V(D)J recombination intermediates. Indeed, Morrison *et al*. (63) tested this hypothesis directly by creating SCID/PARP (−/−) double knock-out mice. These mice have a reduced survival rate, and double knock-out survivors appear to have regained, to a limited extent, the ability to carry out V(D)J recombination. These results suggest that PARP deficiency partially rescues animals from the SCID phenotype and may play a direct role in the V(D)J recombination process. In this context, PARP appears to be acting as an "antirecombinogenic molecule" suggesting that PARP and DNA-dependent protein kinase act cooperatively to minimize genomic damage caused by DNA strand breaks. These observations confirm the critical roles of both PARP and DNA-PK in maintaining genomic stability.

28.1.2.4 Telomeres and Telomerase. Cultures of primary human and other mammalian cells undergo a limited number of cell divisions, cease to divide thereafter, and often go on to die. This phenomenon, termed replicative senescence, has been a model for cellular aging (64). As cells age, the specialized nucleoprotein structures located at the ends of chromosome, called telomeres, become progressively shorter. Telomeres protect chromosomes from DNA degradation, end-to-end fusions, rearrangements, and chromosomal loss.

Telomeres are composed of tandem $(TTAGGG)_n$ nucleotide repeats bound to a unique family of telomere-binding proteins, including telomerase, which maintains telomeric length by synthesizing telomeric repeats (65,66). Telomerase is an enzyme that consists of an RNA-protein complex containing a reverse transcriptase component and an RNA template. The small proportion of cells that become immortalized and emerge from a growth crisis associated with cellular senescence were correlated with the presence of telomerase activity whereas precrisis cells were not (67,68). Therefore, continued maintenance of telomeres by the action of telomerase is considered a critical event responsible for preventing cellular senescence and for continued growth of transformed cells. Indeed, direct demonstration of the role of telomerase activity in overcoming senescence was obtained by overexpressing telomerase in cells (68–70) and the observation that immortal HeLa cells can be forced to crisis when telomerase activity is inhibited by expression of the antisense transcript to the RNA component of telomerase (71).

A critical role of telomerase function in maintaining genomic stability was observed in mice in which the gene that encodes the telomerase RNA component was knocked out (72). As these telomerase-deficient mice aged, an increased frequency of chromosomal fusions and a twofold increase in aneuploidy were observed. A model emerged from these studies in which chromosomal aberrations associated with crisis may be brought about by shortening telomeric structures into subtelomeric regions that lead to the formation of dicentric chromosomes via end-to-end fusion (73). In addition, the observed genomic instability was coincident with an increased frequency of spontaneous cancer in aged animals. All of these observations were correlated with shortening of telomeric length.

Activation of telomerase and cell immortalization has been associated with inactivation of p53 and pRb (73–75), and the telomerase gene is a direct target for activation by *c-myc* (76). The potential interplay between p53 and telomerase functions was also suggested by the observation that inhibition of telomerase activity triggered cell death (77).

28.2 GENOTYPIC AND PHENOTYPIC STABILITY OF RECOMBINANT CELL LINES

28.2.1 Stable Integration of Heterologous Genes in Animal Cell Genomes

Animal cells have been used as hosts for expressing a wide variety of heterologous proteins. Introduction of foreign DNA into animal cells by using any one of a number of transfection techniques (e.g., electroporation, lipofection and calcium phosphate coprecipitation) leads to transient expression of genes for up to several days. Stable expression of heterologous genes, however, is associated with integration into the host-cell genome. The mechanism by which foreign DNA integrates into the genome of host cells is not fully understood. Presumably, the integration process involves the normal DNA excision-repair systems, DNA ligase, and possibly eukaryotic analogs of prokaryotic integrase activities (78,79). Consistent with this model are observations in which perturbations of the eukaryotic DNA replicative and repair systems have been shown to affect the frequency of cell transformation, indicating that integration of foreign DNA (via heterologous recombination) may arise from normal DNA replication and/or double-strand break repair mechanisms (80), including PARP (81).

Isolation of transfected cells that have stably integrated and express heterologous genes can be achieved by

coexpressing selectable (and often amplifiable) marker genes that confer resistance to cytotoxic agents on recipient cells. The use of the selectable and amplifiable marker genes dihydrofolate reductase (DHFR) and glutamine synthetase (GS) has been extensively studied (82). In the former, coexpression of DHFR and another gene of interest renders recipient cells resistant to the cytotoxic folate analog, methotrexate (MTX). Further selection of drug-resistant transfected cell populations with increased concentrations of MTX results in coamplifying DHFR and the gene of interest. Drug-resistant cells cultured in the absence of the selective agent are vulnerable to the loss of amplified genes, whereas it has been shown that extended cultivation of cells under selective pressure increases the stability of amplified genes (83,84).

Once integrated, the genomic localization of amplified genes, it has been shown, influences their stability. Unstable amplified genes tend to be found in acentric double minute chromosomes that do not segregate properly during mitosis and are rapidly lost with each cell division. In contrast, stably amplified genes are usually found integrated into the chromosome associated with homogeneously staining regions that replicate in the early part of the S phase (85–87). Furthermore, amplified plasmid DNA was found associated at or near the ends of chromosomes or on unstable dicentric chromosomes. These observations suggested that integration and/or amplification of DNA may disrupt telomeres and facilitate formation of unstable dicentric chromosomes. Instability of amplified genes in the absence of selective pressure may also be related to the tendency of integrated genes to be arranged in a "head-to-tail" mode, that increases the frequency of homologous recombination between the integrated plasmids (87).

The distribution of amplified genes in a recombinant CHO cell line was elucidated using flourescent *in situ* hybridization (88,89). In highly amplified cells cultured under selective pressure, integrated amplification units were widely dispersed throughout the genome. Upon removing drug selection, subpopulations of recombinant CHO cells displayed genotypic instability marked by the loss of amplified genes in multiple and heterogeneous integrations dispersed throughout the genome. Continued cultivation of unstable cell lines under nonselective conditions resulted in the appearance of a dominant integration, termed the "master integration," which remained stable for up to 100 days in the absence of selective pressure.

Other examples of genomic positional effects come from work done to optimize expression of heterologous genes in cultured cells and transgenic animals. In one example of positional effects, Wurm *et al*. (90) showed that incorporation of retroviral sequences, endogenous to CHO cells, within expression plasmids significantly improved the efficiency with which high-expressing clones were obtained. The authors speculated that homologous recombination of the retroviral sequences in the expression plasmid with endogenous sequences in the CHO genome targeted the integration of foreign DNA into transcriptionally active regions of the CHO genome. In another example, the targeted insertion of a hypoxanthine phosphoribosyl transferase (HPRT) marker gene at different loci in embryonic stem cells resulted in heterogeneity in expressing stability phenotypes (91). Interestingly, loci displaying expression instability were associated with hypermethylation of the promoter which could be corrected by inserting a different promoter that contains a CpG island.

28.2.2 Phenotypic Heterogeneity and Population Dynamics

Recombinant CHO cells, in which amplified coexpression of DHFR and a heterologous gene of interest has been achieved, generally display good correlation between gene copy number, RNA transcription levels, and heterologous protein expression (92–94). Although this relationship is generally true, there are examples in which divergence in these parameters has been noted. Gene silencing by hypermethylation may play a role in creating phenotypic divergences within cell populations. However, phenotypic divergences can come about through alternate mechanisms as well. For example, it has been shown that expression levels of recombinant hepatitis B surface antigen in CHO cells became uncoupled from gene copy number because of decreased secretion efficiencies and increased intracellular degradation of recombinant protein (92). In another study, population analysis of recombinant CHO cells after extended culture in the presence of methotrexate indicated an increase in heterogeneity among subclones with respect to their cellular productivity phenotypes. In contrast, the recombinant CHO cell population became more homogeneous with respect to expression of DHFR (95). These results indicate that coexpression of DHFR and heterologous proteins can diverge post-transcriptionally at the level of protein translation, post-translational modifications, or protein secretion.

Instability of amplified genes in recombinant CHO cell populations may result from phenotypic changes caused by the amplification process itself or by the large increase in heterologous gene copy number in the host-cell genome. Results from several investigations have suggested that increased gene copy number may impose a metabolic burden on recombinant cells that manifests in a decrease in cellular growth rates (92,96). The model emerging from these observations would be one in which the population is overcome by faster growing, low-producing subpopulations. This model also has precedent in populations of hybridoma cells in which increased monoclonal antibody secretion rates can be associated with decreased growth rates (97,98) and expression instability associated with the

appearance of fast-growing, nonproducing subpopulations (99,100). However, other investigations point to a mechanism of population instability in which no increase in nonproducers was noted, but rather a general decline in heterologous protein secretion rates was observed (95,101). Furthermore, the growth rates of clones isolated from a population of recombinant CHO cells went unchanged despite a decrease in cellular productivity after extended culture in the absence of selective pressure (94).

In general, a positive correlation between cell growth rates and cellular productivity of heterologous proteins has been observed in triphasic batch cultures that experience an initial lag phase followed by a logarithmic growth phase and a plateau phase in which cell growth ceases (102–105). However, it has been shown that an increase in cellular productivity was obtained in growth-arrested recombinant CHO cells (106–108) and hybridoma cells (97). The promoter/enhancer systems used to drive expression of heterologous genes (109) and possibly the chromosomal location/environment into which the genes are integrated, are likely to play roles in the degree to which cellular growth rates and cellular productivity phenotypes are coupled.

28.2.3 Genetic and Epigenetic Manipulation of Cell Phenotypes

Cell phenotypes can, and have been, altered, by genetic modifications in which, for example, cells can be made resistant to cytotoxic drugs by introducing the appropriate drug-resistance marker genes. Furthermore, fundamental phenotypic attributes of animal cells such as the proliferative requirement for attachment strata (anchorage-dependency) and dependence on serum or exogenous growth factors, can be genetically manipulated. Renner *et al*. (110) showed that the anchorage-dependence of Chinese hamster ovary cells was eliminated by expression of cyclin E. Similarly, a loss in the anchorage-dependency of fibroblasts was associated with overexpression of cyclin A (111). In another series of experiments, the robust growth of hybridoma and CHO cells under a variety of culture stresses was enhanced by overexpression of antiapoptotic genes such as *bcl*-2 (112).

Cellular phenotypes can also be shaped in response to environmental conditions imposed upon them during cell culture. Examples of this phenomenon come from successful laboratory attempts to alter a variety of phenotypes through strategies that involve cell line adaptation. Much of the impetus for intentionally reshaping cellular phenotypes comes from the desire to eliminate the serum- and anchorage-dependency of animal cells used in producing protein biopharmaceuticals (113).

Without the use of adaptation procedures, the growth of CHO and BHK cells tends to be both anchorage-dependent and serum-dependent. In addition, once a serum-free suspension-adapted lineage is established, the volumetric productivity of the cell culture process can be optimized by adaptation strategies that lead to significant improvements in the final cell densities of cultures (113). Although the mechanism by which animal cells adapt to high cell-density conditions is unclear, one means is by developing tolerance to growth-inhibiting substances released by the cells, such as lactic acid and ammonia (114–118).

The adaptation to serum-free suspension or high cell-density conditions is generally performed using cell lineages that have already been engineered to express the desired protein biotherapeutic through recombinant technologies or methods based on cell fusion (102,119–124). However, reports have been made of CHO (125–127), murine myeloma (128,129), and Namalwa (130) cell lineages that were adapted to growth in serum-free suspension culture before serving as host cells. This approach greatly reduces or eliminates the need for further adaptation once expression of the desired protein is achieved in these preadapted mammalian-cell host lineages.

The transition to high cell-density, serum-free suspension culture can lead to changes in the growth performance phenotypes of cells and the structural characteristics of secreted proteins. Some decline in growth performance (i.e., decreased growth rate or cell viability) following serum withdrawal and/or removal of cell attachment substrata was reported (126,131). This response to changes in culture conditions is potentially due to a perturbation of events associated with cell-cycle progression and entry into the S phase (132). In the most severe case, recovery from such perturbations may be prevented by activating apoptotic pathways (133,134). Furthermore, significant differences in the carbohydrate structures of secreted proteins were documented (135–140). Finally, cell populations that undergo a "growth crisis" (i.e., a significant decline in growth rate and cell viability) during the adaptation process may be vulnerable to outgrowth of nonrepresentative or undesirable subpopulations of cells that may not have optimum performance characteristics (126,141).

Cell growth and expression phenotypes can also be significantly influenced by cell-culture parameters such as temperature, medium pH, and dissolved oxygen levels. For instance, lowering the temperature of cell cultures can decrease cell growth rates, increase protein expression rates, and alter nutrient metabolism (106,142). These results suggest that culture temperature is a variable with the potential for improving the performance of cell-culture processes, such as fed-batch and perfusion-based processes, in which static growth and prolongation of relatively high protein-expression rates are desired outcomes.

In addition to the effects of temperature, cell phenotypes can be reshaped by the action of agents that alter gene expression patterns. The most widely studied of these agents is sodium butyrate. Butyrate inhibits cell growth

and alters gene expression of butyrate-responsive elements (positively or negatively) by increasing acetylation of nucleosomal histone proteins via inhibition of histone deacetylase (143). Sodium butyrate administration alone or in combination with a temperature shift has been shown to improve the expression of recombinant proteins (143,144).

28.3 CONSEQUENCES OF GENETIC INSTABILITY ON RECOMBINANT PROTEIN QUALITY

The genetic stability of recombinant cell lines and its impact on the quality and consistency of protein biopharmaceuticals continues to be a topic of great interest to process scientists and regulatory agencies. Many different technologies have been used in constructing expression vectors and expression systems, as well as manufacturing processes. The genetic stability of recombinant cells, defined within the limits of a particular cell-culture manufacturing process, has historically been a surrogate marker for biopharmaceutical protein consistency. However, the link between genetic stability and recombinant protein quality and consistency has not been absolutely established or may be of reduced importance in view of improved analytical methods for protein product characterization.

Two key phenotypic markers thought to be relevant to protein synthesis have been emphasized when assessing the stability of recombinant cell lines and cell-culture processes: specific growth rate (hours^{-1}) and cellular productivity (units of product produced per cell per unit time). To date, where possible, cell lines have generally been selected and manufacturing processes designed so that the product was made during a period when growth rate and cellular productivity are essentially constant. This approach can be restrictive at times, adds significant time and resources to the development process (e.g., when a number of candidate cell lines need to be evaluated to select a stable production cell line), or disallows flexibility in a manufacturing process (e.g., when a process has to be limited in duration to ensure that the product is made during a period of stable growth rate and cellular productivity).

The challenges of establishing the stable performance of cell-culture processes used in manufacturing recombinant biotherapeutic proteins are complex because of the variations inherent in biological systems and the metrics used to monitor their performance. An example of this can be seen when one examines cellular productivity data from a recombinant CHO (rCHO)-cell-based process developed and used by Genetics Institute to manufacture recombinant human antihemophiliac factor (rAHF, Recombinate). rAHF is a highly complex glycoprotein used therapeutically in treating hemophilia A (145). Efficient expression of rAHF by CHO cells is greatly facilitated by coexpressing von Willebrand factor (vWF) which binds to and stabilizes the rAHF molecule. In constructing the rCHO cell line used in the commercial production of rAHF, amplified coexpression of rAHF and vWF was driven by separate selectable/amplifiable markers: DHFR and adenosine deaminase, respectively (82). Therefore, complete evaluation of the expression phenotype of rAHF-producing rCHO cells required evaluating both rAHF and vWF cellular productivities. Based on this analysis, a rCHO cell line was identified and used to develop a rAHF commercial manufacturing process.

A conventional two-tiered cell banking system was used in which a Master Cell Bank (MCB) and Working Cell Bank (WCB) were prepared. The batch-refeed cell-culture process developed and used in the large-scale manufacturing of rAHF starts when cells are inoculated into a production bioreactor (2500 L) after expansion from the frozen WCB. After inoculation, WCB cells are grown for three days (which constitutes a single batch), by which time they have reached maximum cell density (just before the onset of the stationary phase). At this point, approximately 80% of the cell suspension is removed from the bioreactor for cell separation and purification and is replaced with an equivalent volume of fresh medium. The remaining 20% of the cell suspension acts as the inoculum for the next cycle. This process continues up to a maximum number of batches which is established for an individual cell line based on cell-culture performance characteristics and product characterization. Throughout this process, cells are cultured in the absence of selective pressure.

The perspective that genetic stability served as a surrogate marker for recombinant protein quality and consistency led to establishing operational limits for the rAHF cell-culture process within which rAHF expression was relatively stable. To establish process limits, the rAHF cell-culture process was operated at full scale for an extended period in which the number of cumulative population doublings (CPD) allowed for the WCB cell population was extended to more than 120. The rAHF and vWF cellular productivity data were acquired and analyzed for trends. Figure 28.1a shows the rAHF and vWF cellular productivity data obtained during the operation of the extended process. Upon extended culture of the WCB cell line to greater than 70 CPD, both rAHF and vWF productivity gradually declined. Southern blot and Northern blot analysis of in-process samples indicated that qualitative changes in the genes or RNA transcripts that encode either protein could not be detected (data not shown). The results also indicated that a significant change in rAHF gene copy number or RNA transcript level was not observed over the course of the extended cell culture (approximately 127 CPD from the WCB). However, a reduction in vWF gene copy number and transcript level was observed after 110 CPD of continuous culture (data not shown). Consistent

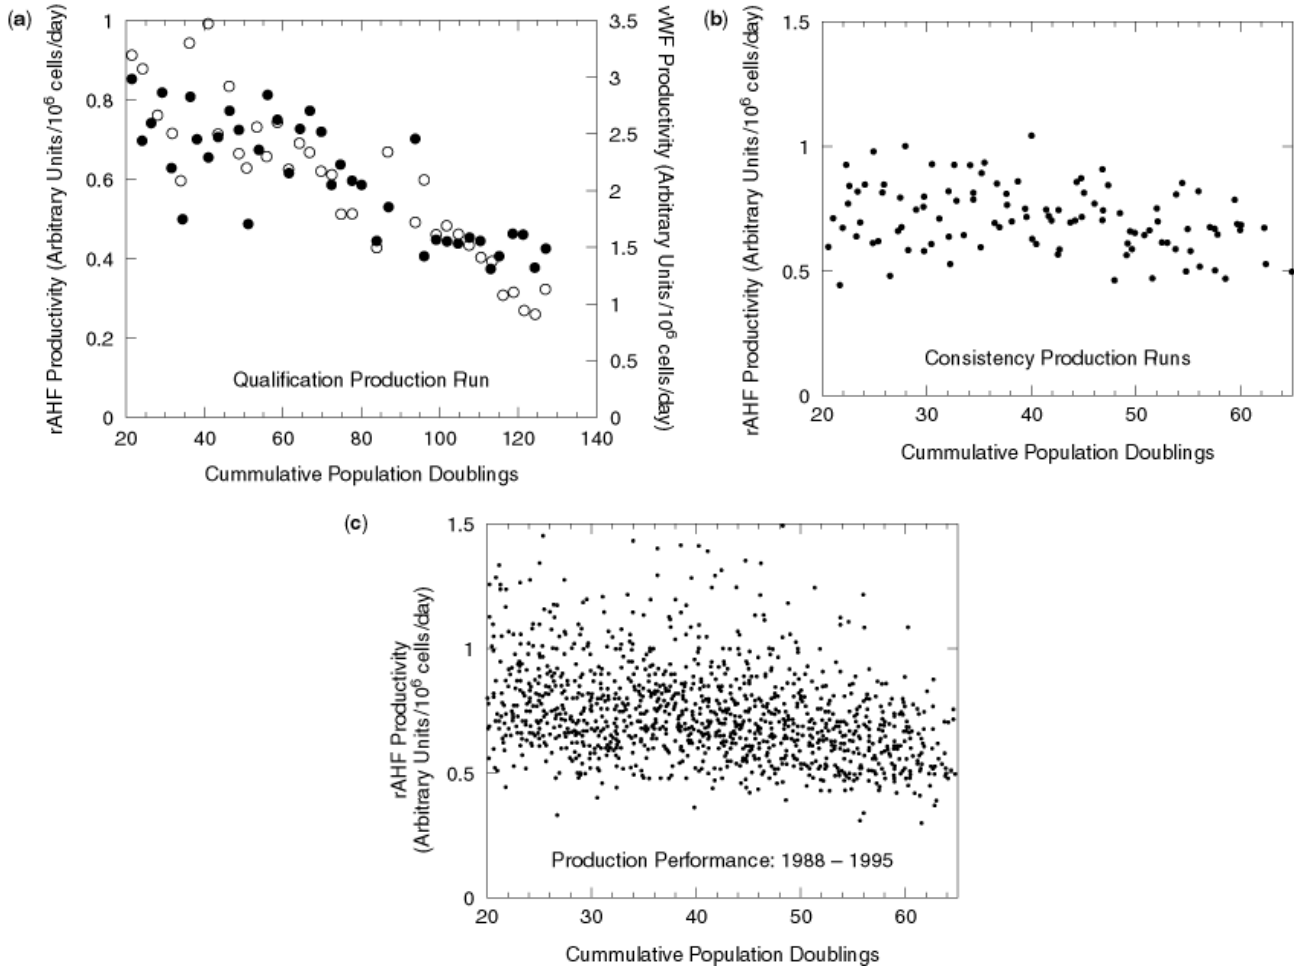

Figure 28.1. Performance of the rAHF cell-culture manufacturing process. The rAHF cell-culture process was operated, as described in the text, for an extended period of time or for periods restricted to 65 total CPD. Expression of rAHF (closed circles) and vWF protein (panel A, open circles) in conditioned medium was determined by using an activity assay and by ELISA, respectively, and the cellular productivities were calculated.

with the physiological role of vWF in stabilizing rAHF protein and because a detectable change in rAHF gene copy number or transcript level was not found, we interpreted these results to mean that the decline in rAHF productivity was driven by vWF expression instability after 70 CPD of continuous culture. With this information in hand, the duration of the cell-culture process was restricted to 65 CPD to ensure consistent process performance.

To validate the consistency of the manufacturing process operationally restricted to 65 CPD, two additional production runs were performed to establish a database for process consistency. The results obtained from the process consistency runs indicated that the cellular productivity phenotype of WCB cells was relatively stable when operationally restricted to 65 CPD (Fig. 28.1b). However, when cellular productivity data obtained from commercial production runs carried out from 1989 through 1995 are plotted, a slight negative trend (representing a decline of approximately 30%) was observed in the data (Fig. 28.1c). Therefore, the phenotypic stability of the production cell line and cell-culture process may be difficult to evaluate fully in the absence of a suitably large performance database. Thorough biochemical characterization of the rAHF produced during this period indicated that a detectable qualitative change in the product did not occur, challenging the notion that cellular productivity is an appropriate surrogate marker for recombinant protein quality.

To further investigate whether a correlation exists between changes in the cellular productivity (and growth rate) phenotypes of rCHO cells and recombinant product quality, a series of studies was performed at both bench and production scale, and the effect of variations in both phenotypic markers on product characteristics, with emphasis on N-linked glycan, were examined. The focus on

protein glycosylation was based on an expectation that this complex, energy-requiring post-translational modification might well be influenced by changes in global phenotypic markers such as growth rate and cellular productivity. In all cases, a host/expression vector system was employed which uses CHO cells genetically engineered to contain multiple genomic copies of the product gene by using DHFR as the selectable/amplifiable marker.

In one such study, a rCHO cell line that produced a thrombolytic protein was cultured using a generic serum-free, suspension-culture-based, batch-refeed cell-culture process. Figure 28.2 shows the cellular productivity of a rCHO cell line as a function of generations from the WCB in a 2500-L batch-refeed process. Cellular productivity dropped by approximately 50% from the beginning to the end of the process. It was of interest to establish whether the progressive drop in cellular productivity caused a progressive change in the product profile. Accordingly, product derived from sequential batches was characterized by using a number of biochemical and biophysical analyses, including peptide mapping and specific activity (potency) determination. A significant change in product characteristics was not evident from batch to batch. This qualitative similarity is illustrated in Figure 28.3, which shows that high pH anion-exchange chromatographic (HPAEC) carbohydrate fingerprints (147,148) of complex type, N-linked glycan released from product produced from batches early (26 generations) and late in the process (76 generations) are indistinguishable. This case again illustrates that a substantial change in cellular productivity can take place within a population of continuously cultured cells without causing detectable changes in product characteristics.

Another study involved a large-scale production process employing a rCHO cell line that produced a glycosylated lymphokine. Figure 28.4 shows a profile of cell growth during a serum-free, suspension-culture-based, batch-refeed process similar to that described before. Population doubling time (inversely proportional to growth rate), calculated as an average over each three-day growth period, increased from an initial value of approximately 22 h in the first batch to approximately 32 h in batch 3 (B3) and then declined in batches 4, 5, and 6. The improved growth rate resulted in significantly higher cell densities in batches 5 and 6. Subsequent product characterization revealed that the observed fluctuations in growth rate and maximum cell density did not cause any detectable change in the product (characterization included peptide mapping and specific activity determination, among others). Consistent with this conclusion, HPAEC-carbohydrate fingerprints of complex type, N-linked glycan from batches 2 to 6 were indistinguishable (Fig. 28.5). This study illustrates that substantial changes in growth rate can take place under the production conditions described without causing significant changes in product characteristics.

The final study involved a large-scale production process employing a rCHO cell line that produced a glycosylated cytokine in a serum-free, suspension-culture-based, batch-refeed system similar to that described before. Figure 28.6 shows the growth rate and cellular productivity (in arbitrary units) of the production cell line as a function of generations from the WCB. The growth rate increased as a function of generations from the WCB from approximately 0.025 h^{-1} (28 hour doubling time) at around 20 generations to approximately 0.033 h^{-1} (21 hour doubling time) at around 70 generations. In the same time frame, the cellular productivity declined by approximately 40%. It was of interest to establish whether this coordinate change in growth rate and cellular productivity caused any change in the product profile.

Subsequent product characterization, which included peptide mapping and specific activity determination, showed that the observed concurrent increase in growth rate and decline in cellular productivity had no effect on the product profile from batch to batch. HPAEC-carbohydrate

Reprinted from Ref. 146 with permission.

fingerprint analysis was carried out in this case on the high-mannose glycan released from product that was purified at five different points in the production process. Figure 28.7 shows that glycan fingerprints were comparable from generation 28 to 66. This case study illustrates that significant changes can take place simultaneously in growth rate and cellular productivity without causing significant changes in product characteristics. The results from these studies clearly demonstrate that significant changes in growth rate and cellular productivity, under the conditions described, do not necessarily predict changes in product quality. Similar observations (with respect to cellular productivity) were made by others working with rCHO production systems (149).

These studies, at both small scale and manufacturing scale, illustrate a key principle pertaining to the development, implementation, and long-term success of a cell-culture-based biopharmaceutical manufacturing process. Manufacturers should not assume that absolute consistency of process performance is necessary to ensure that qualitatively consistent product is produced. In particular, for biopharmaceutical products whose active substance can be characterized in great detail using modern analytical methods, it is possible to determine with a high degree of confidence that variations in process parameters such as growth rate and cellular productivity do not lead to significant variations in the quality of the active substance produced. Therefore the emerging paradigm for "well-characterized" (150) or specified biotechnology products (151) is one that makes it possible for a manufacturer to rely on analytical characterization of an active substance to determine which measures of process performance are important for ensuring consistent product quality.

28.4 GENOTYPIC CHARACTERIZATION AND VALIDATION OF GENETIC STABILITY

Genotypic instability has the potential to impact the quality of heterologous proteins expressed by a recombinant cell line. Obviously, changes in the DNA sequence via point mutations (which can occur spontaneously at a frequency of $\geq 10^{-6}$), deletions, or gene rearrangements can alter the structure of the gene product. Accordingly, extensive genotypic characterization of recombinant cell lines needs to be carried out as part of a package that provides assurance of recombinant protein quality. A general practice for characterizing the expression construct is outlined here. Emphasis is placed on characterizing the MCB cells and the transcripts derived from them, so that a comprehensive understanding of the structure of integrated and amplified genes is established at the starting point of the manufacturing process. Once the manufacturing process has been established, end-of-production (EOP) cells taken from a representative run are analyzed in a manner similar to

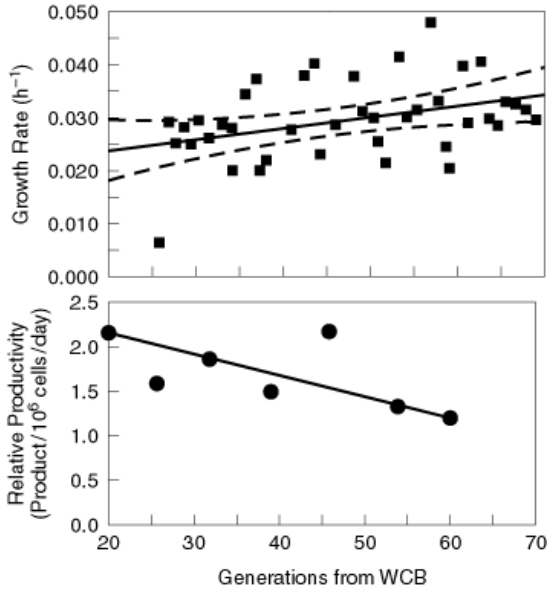

Figure 28.6. Characteristics of a large-scale rCHO production process in which changes in growth rate and cellular productivity were observed. Growth rate and relative productivity are indicated as a function of increasing generations. Reprinted from Ref. 146 with permission.

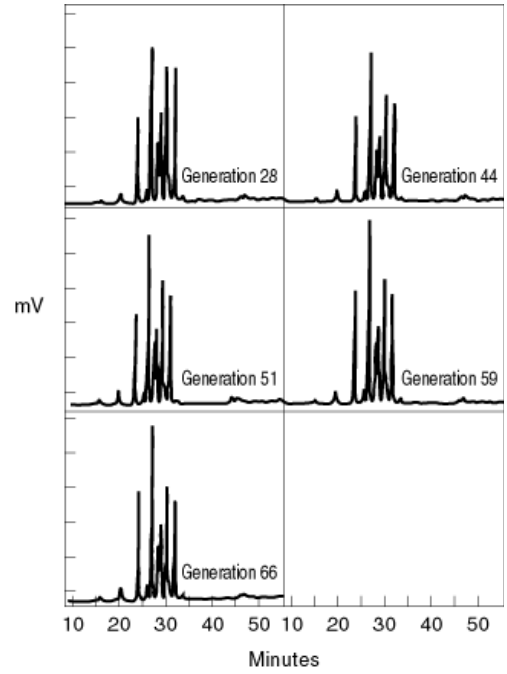

Figure 28.7. HPAEC carbohydrate fingerprint analysis of high-mannose glycan. HPAEC carbohydrate fingerprint analysis was performed on samples released from product produced at five different points in a large-scale rCHO production process. Reprinted from Ref. 146 with permission.

the MCB, to ensure that significant changes in the product genes or closely flanking sequences do not occur during the production process.

28.4.1 Gross Structural Evaluation of Genes and Transcripts

The evaluation of the expression construct includes an analysis of the integrity of the RNA transcripts that encode the protein(s) representing the active substance. This analysis employs standard molecular techniques (such as Northern blot hybridization) to establish that the predicted transcript(s) is produced by the production cell line and that significant qualitative changes in transcript structure do not occur over the course of production.

Similarly, the copy number of the expression construct is evaluated by using standard techniques. This analysis is undertaken not because the exact number of integrated and amplified copies is considered critical (it requires a very substantial effort to credibly obtain even a reasonably precise estimate of gene copy number). Rather, this estimate is useful as part of the general description of the way the cell line was established and how suitable expression levels were achieved. What is much more relevant to establish is that the correct coding sequence of the product has been incorporated into the host-cell genome and is maintained during culture to the end of production. Methods which can be employed to provide this assurance are illustrated here with several examples.

The gross structural integrity of integrated and amplified genes is evaluated by digesting genomic DNA at restriction sites that immediately flank the coding regions, followed by Southern blot analysis to establish the presence of the appropriately sized fragment in genomic DNA (usually compared directly to expression plasmid digested with the same restriction enzymes). Detection of fragments other than those predicted indicate the presence of rearranged or aberrant copies of these genes. By loading various amounts of control (expression plasmid) DNA in adjacent lanes, it is possible to estimate the sensitivity of this method for detecting variant sequences. In our experience, if aberrant fragments are electrophoretically distinguishable, they are detectable at a level of 1–5% of the intact genes.

The second level of characterization is directed toward a more detailed understanding of the initial expression plasmid integrants that are represented in the amplified DNA of the cell line. In particular, we seek to determine if one or more plasmid molecule is integrated into host CHO cell DNA (often in tandem at a single chromosomal site). This question is approached by using genomic Southern blot analysis, taking advantage of the known restriction map of the expression plasmid to permit identifying restriction fragments in which one site is contributed by host-cell genomic DNA flanking the expression plasmid. Such chimeric fragments are generally distinct in size for each of the original integrations. Thus, the number of

distinct fragments identified can be used to determine the number of unique sites of integration and potentially, the number of plasmid molecules that were integrated upon transfection and before amplification. This information is valuable in planning a rational DNA cloning and sequencing strategy (discussed in more detail following).

Our approach to integration unit characterization is illustrated by considering the example of a rCHO cell line that produces recombinant human interleukin-12 (IL-12), a novel immunomodulator (152). The IL-12 molecule is a heterodimer of molecular weight 75 kDa, consisting of 35-kDa (p35) and 40-kDa (p40) subunits. IL-12-producing rCHO cells were generated by introducing p35 and p40 cDNAs into independent DHFR expression plasmids and subsequently amplifying DHFR/IL-12 genes with increasing levels of methotrexate. The approach by which we characterized the integration units of both p35 and p40 genes is illustrated in Figure 28.8, which depicts the integrated linearized expression plasmids for both genes flanked by host-cell genomic DNA.

DNA derived from the MCB was digested with restriction enzymes for which recognition sites are present in the expression plasmid on only one side of the gene of interest. This is illustrated for the p40 gene in Figure 28.8 (right-hand panel), where a single *Bgl* II site is present within the p40 expression plasmid, just 5′ of the p40 cDNA (indicated by the dotted arrow below the expression plasmid). The next downstream *Bgl* II recognition site cannot come from this same expression plasmid, but instead must derive from DNA that flanks the integrated plasmid. Therefore, visualization of a single p40-positive *Bgl* II fragment on genomic Southern analysis argues that the 3′ DNA segment that flanks all copies of the integrated p40 plasmid is the same (i.e., contains a *Bgl* II site at the same position relative to the 3′ end of the integrated plasmid). This suggests that a single p40 expression plasmid integrated into the host-cell genome (with a *Bgl* II site just

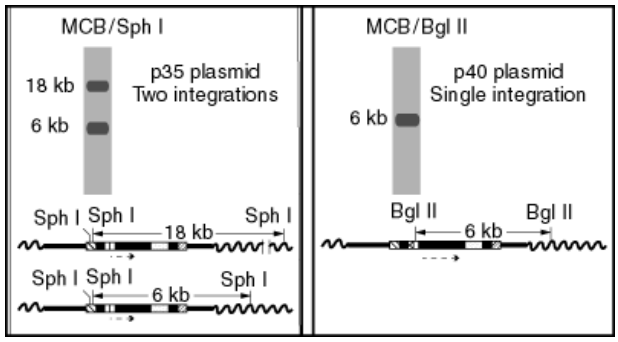

Figure 28.8. Evaluation of plasmid integration units in a recombinant human IL-12 cell line. The position and orientation of the p35 and p45 cDNA inserts are indicated by dotted arrows. Genomic Southern blots are shown from a representative digest for both p35 and p40. Reprinted from Ref. 146 with permission.

downstream) and that the configuration of the gene and local flanking DNA was maintained upon gene amplification. In contrast, the presence of two fragments in the p35 (*Sph* I-digested) Southern blot (Fig. 28.8, left-hand panel) argues that at least two distinct copies of the p35 plasmid (with *Sph* I sites at unique distances from the 3′ ends of the integrated plasmids) were integrated and amplified in the cell line. In each case, the results shown are representative of a number of experiments using different restriction enzymes which, taken together, allow conclusions to be drawn regarding the number of initial plasmid integrations that are represented in the amplified DNA of the cell line.

The insertion sites described before should not be confused with chromosomal sites that contain multiple copies of amplified genes, observed on cytogenetic analysis and designated as homogeneously staining regions (84–86), or smaller chromosomally amplified sequences detected by fluorescent *in situ* hybridization (88). The insertion sites described before are likely to reflect integrations which took place on transfection of the cells. As discussed previously, subsequent gene amplification and extended serial propagation of the cell line under methotrexate selection is normally accompanied by translocation of the original plasmid inserts and flanking DNA to different sites in the genome. The average size of such amplicons (including flanking host-cell DNA) has been observed to be on the order of 1 megabase, significantly larger than the fragments evaluated by the Southern blot method. Nevertheless, the value of establishing the number of original sites of integration for a particular gene is that this information directs our strategy in the next step in the genotypic characterization process, gene cloning, and DNA sequence analysis.

28.4.2 Sequence Analysis of Genes and Transcripts Encoding the Product

In the IL-12 p40 gene, cloning and DNA sequence were analyed on genomic DNA prepared from the MCB. Subsequent DNA sequence analysis of the cloned p40 gene was used to establish that the sequence completely agreed with that present in the expression plasmid. This indicated that the initial plasmid integrant represented in all the amplified copies of the p40 gene contained a completely intact coding region at the DNA sequence level. However, because we detected two independent plasmid integrants represented in the amplified p35 genes, it was necessary to carry out an additional investigation to demonstrate that both copies integrated with complete fidelity. Accordingly, the two Sph I fragments shown in Figure 28.8 (p35 plasmid) were isolated, cloned, and sequenced. DNA sequences from both fragments completely agreed with the p35 coding sequence in the original expression plasmid. Thus the DNA sequencing approach described allowed us to conclude that both p40 and p35 expression plasmids were integrated into

the CHO genome with complete fidelity. However, this DNA sequencing strategy does not allow us to ascertain the fidelity of all, or even the majority of multicopy amplified genes or the RNA transcripts derived from these originally integrated plasmid molecules. For this reason, a complementary approach needs to be applied to address the bulk population of transcripts present in the cell line.

Recent regulatory guidance (153) has called for DNA sequencing approaches such as DNA sequence analysis of bulk cDNA derived from reverse transcriptase polymerase chain reaction (RT-PCR) treatment of total RNA. Althought it does not set a required sensitivity limit for such methods, the guidance document requested that the sensitivity of methods employed to detect variant sequences be estimated. Accordingly, DNA sequencing was performed on cDNA clones derived from product genes expressed in a rCHO MCB and end-of-production (EOP) cells (see also Genetic Stability discussion following). Emphasis in these experiments was placed on establishing limits of detection of aberrant sequences.

Total RNA was isolated from the MCB or EOP cells, reverse transcribed into cDNA, and the entire coding region of the recombinant protein was amplified by high-fidelity PCR. The expression plasmid used in constructing the MCB lineage was subjected to the same PCR procedure as a control. Pairs of PCR primers were designed to permit amplification of the coding region in four overlapping fragments. Only fragments of the predicted size were observed upon agarose gel analysis of the RT-PCR products, and these were indistinguishable from the expression plasmid control PCR fragments, further confirming the integrity of the coding region of expressed genes in MCB cells.

The products of each PCR reaction were cloned and sequenced. Similarly, PCR-products from expression plasmids that encode defined structure-function mutants of the product gene were cloned. The cloned mutant PCR-products were used to evaluate the ability of the DNA sequencing methodology to detect sequence variants by spiking the wild-type DNA preparations with known quantities of the mutant DNA preparations. The DNA sequencing of these samples indicated that mutations could be quantitatively detected to a level of about 20% (Table 28.1).

Population sequencing provides a convenient and sensitive method for evaluating the protein coding sequence in a large and statistically significant number of independently derived cDNA clones. The results confirm that the predominant sequence at each position is correct, but the method cannot demonstrate that the actual sequence of any one clone is correct in its entirety. For this reason, these data are complemented by sequencing individual product genes cloned from MCB genomic DNA, as described before. In conjunction with Northern and Southern blot data (not shown), the sequencing results confirm that expression plasmids with the expected product coding sequence are stably maintained in the genome of these cells during inoculum buildup and full-scale production.

28.4.3 Genetic Stability

The purpose of analyzing the expression construct is to establish that the correct coding sequence for the product has been incorporated into the host cell and is maintained over the course of production. Our approach, which is consistent with current regulatory guidance (150), is to comprehensively analyze the expression construct at least

TABLE 28.1. Evaluation of the Ability to Detect DNA Sequence Variants

Sample	Mutation 1[a]	Mutation 2[a]	Mutation 3[a]	Mutation 4[a]

once at the end of production. The analysis of EOP cells covers all of the major characteristics of the expression construct that are also analyzed in MCB cells: gross structural integrity of genes and transcripts that encode the product, gene organization and copy number, and DNA sequencing. For this analysis, EOP cells at the "limit of *in vitro* age used for production" are characterized, so that the data can be used to establish that no significant change occurs in the product-encoding genes during production. Over the course of several years of commercial production at Genetics Institute, analysis of EOP cells has not revealed any detectable genetic instability in rCHO cells.

ANIMAL CELL TYPES, HYBRIDOMAS

K. Heilmann and B. Micheel
Institute of Biochemistry and Biology, University of Potsdam, Germany

29.1 INTRODUCTION

29.1.1 Biotechnological Production of Proteins for Biomedical Use

Large-scale production methods offer new possibilities for the diagnostic and therapeutic application of many proteins which were identified in basic biomedical sciences as regulators of important metabolic processes. Several of these proteins are now established as medical drugs for the treatment of different diseases. The overall requirements, for example, of insulin for the treatment of diabetes mellitus in the industrial countries are now estimated to come to 5 to 6 tons per year. These amounts cannot be realized without recombinant techniques (1). Further examples are several growth factor proteins, such as granulocyte colony stimulating factor (G-CSF) which is applied after chemotherapy for the treatment of cancer (2) or nerve growth factor (NGF) with application in Parkinson's or Alzheimer's disease (3). Other proteins widely used in biomedicine and therefore produced in very vast amounts are antibodies. Antibodies are applied for diagnostic purposes in pregnancy tests, for blood typing, or for the detection of inflammatory markers or tumor markers (4). More than 10 monoclonal antibodies (in most cases modified by recombinant methods) are already approved in many countries for the treatment of cancer, infectious diseases, and immunological disorders, and many more antibodies are in the progress of clinical testing (5) (Table 29.1). To provide the extremely large quantities of antibodies for therapeutic application is a great challenge for the biotechnological industry.

29.1.2 Animal Cell Types Used for Industrial Protein Expression (Insect Cells, Mammalian Cells)

Relatively simple proteins can easily be produced by recombinant methods in bacteria. But for the production of more complicated molecules other cell types have to be employed. Unfortunately, antibodies belong to a structurally complicated family of proteins. For the production of antibodies or antibody fragments several expression systems were used, including bacteria, yeast, plants, insect cells, or mammalian cells in addition to hybridoma cells. Since bacteria and yeasts can so far only be used exclusively (or almost exclusively) for the production of antibody fragments and plant cell, cultures do not directly offer an alternative for the production of intact antibody molecules (which is possible in plants growing in the fields which might be some day a real alternative); only hybridoma cells and other animal cells will be dealt with here. The expression of proteins in insect cells is characterized by simple handling and minor costs in cultivation. The expressed proteins get folded correctly and many modifications like disulfide bond formation or acetylation are performed as good as in mammalian cells (7). Moreover the proteins are able to form tertiary and quaternary structures. The infection of insect cells with recombinant baculoviruses is carried out with commercially available shuttle vectors. These vectors have a promoter for virus proteins, mostly the polyhedrin- or p10-promoter, which induces a strong transcription of DNA sequences behind. The coding DNA sequence is the desired one for the recombinant protein. Vectors with both

Alemtuzumab	Treatment of B cell chronic lymphocytic leukemia	Humanized mAb	2001	Millenium Pharmaceuticals Inc.ILEX Oncology Inc.

[Modified after Van Dijk et al. 2001] (6).

promoters are used to express protein complexes from two subunits. The selection of positive viruses is performed by plaque assays with a combined blue-white screening. These viruses will be used to infect insect cells. The maximum protein expression is normally achieved after 30 to 60 h of infection and a high expression rate of nearly 50% can be obtained. But for every virus the expression conditions have to be tested to reach the optimum. Disadvantages could be a possible aggregation of proteins and a different glycosylation pattern. For protein expression in stable cell clones, blasticidin or hygromycin resistant vectors are used to infect Sf, High Five®, or S2 cells. Sf cells are ovary cells from *Spodoptera frugiperda* and High Five cells are alternative derivative ovary cells from *Trichoplusia ni* and S2 cells are originated from *Drosophila melanogaster*. The vectors are generated with an ampicillin resistence and a pUC-origin for selection and replication in *E.coli*. But the yield of recombinant proteins with this method is diminished if compared to the baculovirus system (7). Insect cells have also been used to produce recombinant antibodies, but so far mammalian cells are preferred which might be because of higher concentrations of the recombinant protein.

Protein expression in mammalian cells is common and several vector systems are offered for this purpose. Mostly, immortal cells with high transfection efficiencies are used; for example, Chinese hamster ovary (CHO) cells, human embryonic kidney cells-293 (HEK-293) or CV-1 cells transformed by origin-defective mutant of SV40 cells (COS 1/7). For better yields of recombinant proteins cells growing in suspension are favored. Mostly, lipofectamine, electroporation, or $CaCl_2$ methods are used for transfection. The vectors often have a hygromycin or geneticin resistence. Viral associated vector systems are applied if the transfection efficiency is too low, but actually these vector systems are out of biological safety and have very stringent safety conditions (8).

29.1.3 Cultivation Methods

For efficient protein expression in mammalian cells the used cultivation conditions or supplementals are extremely important for high yields. There exist several favorite strategies for different cell lines. Hybridoma cells are often cultivated in complete media with fetal bovine serum, glutamine, and mercaptoethanol. But recent data has shown that the supplemental coating of tissue culture polystyrene with components of the extracellular matrix such as fibronectin, laminin, or collagen I is inducing a significant higher synthesis of antibodies (9). These results are different for every hybridoma because of the malignant properties, but in summary the yield of monoclonal antibodies can be increased by nearly 20% to 50%. Other

strategies are the cultivation under serum-free conditions in order to minimize the interactions with animal proteins and to avoid contaminations of the antibody products. The disadvantage of serum-free conditions is an extremely long adaptation phase for mammalian cells, especially for fresh transfected cells, but if the recombinant proteins are needed for therapeutic approaches this step is absolutely necessary to avoid strong side effects. For large-scale production of recombinant proteins, different strategies for cell cultivation are pursued to increase the yields and the lifetime of the cells. The cultivation takes place in bioreactors, mainly hollow fiber reactors or huge stirring bioreactors, in which the cells are grown within macroporous carriers to reduce the extent of toxic metabolites in long-term culture. Additionally, different feeding procedures based on mathematical equations related to the kinetics of cell metabolism were adapted to the cell culture process. Mostly, these strategies are not published because of the competitiveness of the related pharma companies.

29.2 ANTIBODY PRODUCTION BY ANIMAL CELLS *IN VITRO*

29.2.1 Introduction

The mammalian immune system is principally characterized by two ways of immune defense (10) (Fig. 29.1). The first step in eliminating pathogens is known as *innate host defense*. This means a rather common immune response characterized by physical barriers such as skin, the acidic environment in the stomach, or different proteins, for example, lysozyme in tear fluid or saliva. Moreover, a very important function in the first line of defense is the complement system, which causes the degradation of infected or exogenous cells by induction of terminal cytolytic complexes in the cell membrane. The cellular response to pathogens is performed by phagocytes. These cells are specialized to eliminate infected or exogenous cells by endocytotic mechanisms. The recognition is principally initiated by toll-like receptors, which bind exogenous surface markers like lipopolysaccharides or virus-related peptides like CpG. There are different cell populations such as monocytes, macrophages, neutrophilic granulocytes, and dendritic cells, which are able to phagocytose. But, moreover, macrophages and dendritic cells are antigen-presenting cells (APC), which process exogenous proteins and present them at the cell surface to B and T lymphocytes. Therefore, these cell populations are defined as mediators between innate and adaptive immune response (11). Dendritic cells represent the most potent and efficient APC in mammalians (10). It is known that very small numbers of dendritic cells are able to induce strong T cell responses. Only one dendritic cell may stimulate 100 to 3000 T cells, so that the amplification accomplished by dendritic cells leads to very potent immune responses (12). The presentation of antigens is carried out by major histocompatibility complexes (MHC) on the cell surface of APC. The peptides are recognized by T-cell receptor complexes and this leads to an activation and differentiation in T helper cells or cytotoxic T cells. T helper cells are necessary to activate B lymphocytes and to induce antibody responses. B lymphocytes indeed are able to recognize antigens by themselves but need further cytokine signals to start the secretion of antibodies. The

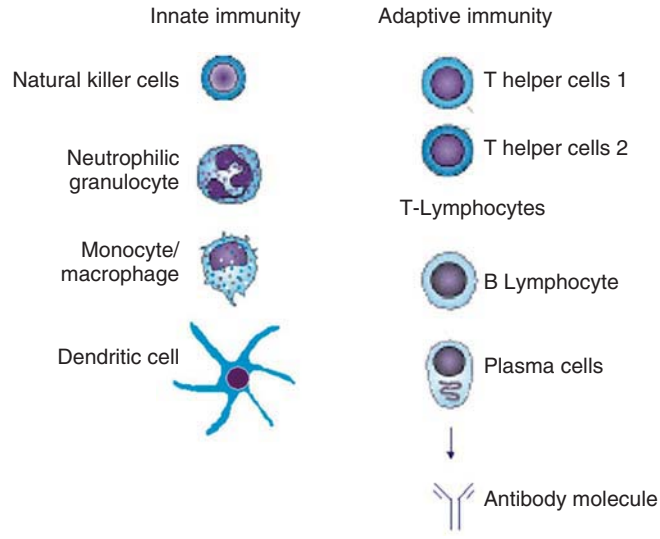

Figure 29.1. Cell Types of the immune system. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

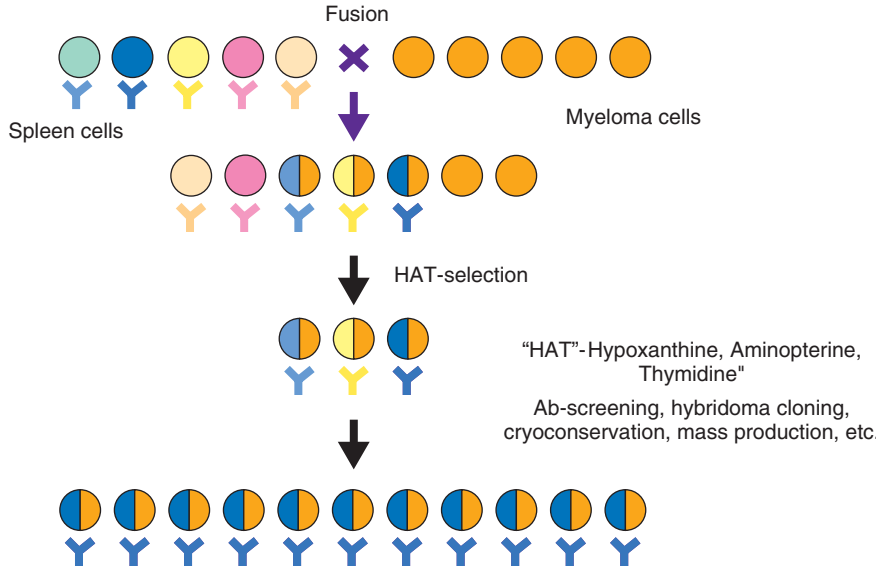

Figure 29.2. Schematic description of the hybridoma technology. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

adaptive immune response is highly specific and directed to single types of pathogens. Furthermore, this response leads to the establishment of an immunological memory for faster and more effective immune responses by later infections with the same pathogen. The antibody response is called *humoral immune response* because antibodies are secreted into the surrounding body fluid and are therefore able to find the pathogen also if the induction takes place far away from the site of infection (11).

29.2.2 Antibody Production by Hybridoma Technique

29.2.2.1 Induction of Antibody Responses. To initiate an immune reaction by artificial immunization, an intraperitoneal injection with purified antigen and adjuvant is performed. Only after this step the generation of antibodies takes place and antibody molecules can be detected in the serum. The generation of monoclonal antibodies is based on the hybridoma technology developed by Köhler and Milstein in 1975 (13) (Fig. 29.2). The basic principle is the fusion of antibody-producing B lymphocytes with immortal myeloma cells to get immortal antibody-producing cells (14). The lifetime of B lymphocytes in vivo is restricted to approximately 7 days, so that gaining immortality constitutes the most important feature of the technique. The used myeloma cell lines are modified and are not able to generate immunoglobulins by themselves. Therefore, fused cells have the two attributes from the parental cells: immortality from the myeloma cells and antibody secretion from the B lymphocytes. So, it is possible to generate biochemically defined and uniform antibody molecules in huge amounts. The selection of hybridomas is performed by utilization of a hypoxanthin-guanin-phosphoribosyl-transferase (HGPRT)-deficiency of myeloma cells (15). This enzyme is necessary for using the alternative way (salvage pathway) for purine synthesis. The culture media additionally contains azaserine or aminopterine, which is blocking the main pathway (the *de novo* pathway) for purine synthesis. Myeloma cells do not survive the selection process because they are unable to use one of the pathways for nucleotide synthesis and B lymphocytes are restricted because of their shortened lifetime in culture. That means, only hybridomas are able to survive and grow under these conditions. At regular intervals hybridoma cells are expanded by limited dilution to obtain a homogeneous cell clone tested for the wanted antibody secretion. Making them immortal the hybrid cells can be stored in liquid nitrogen. The screening processes are extremely time consuming and could not be automated till now because of the necessity of sterile conditions. The hybridoma technique is a scientific standard for over 20 years now and there are several established fusion protocols and myeloma cell lines used for this purpose. In the following sections these strategies are described in more detail.

29.2.2.2 Cell Fusion Strategies to Produce Hybridoma. In the last decades a few myeloma cell lines were established as fusion cell lines, the most common ones till now are X63-Ag 8.653 (16) and Sp2/0-Ag 14 (17) from a Balb/c mouse strain. Table 29.2 shows the most important myeloma cell lines used to generate hybridomas. In the beginning of hybridoma technique myeloma tumor cells were used which synthesized or secreted immunoglobulin chains by themselves. This was a much undesired fact and

TABLE 29.2. Mouse Myeloma Cell Lines Used for Hybridoma Generation

Mouse Strain	Cell Line	Ig Chains Produced/ Expressed	References
Balb/c	X63-Ag 8.653	—	16
Balb/c	Sp2/0-Ag 14	—	17
Balb/c	P3X63-Ag 8 (P3)	$\gamma 1 + \kappa$ chain	13
Balb/c	P3/NS-1/1-Ag4-1	κ chain	13
Balb/c	F0	—	17
C57BL6	EL4BU	NA	Salk Institute

by now these cell lines are replaced by sublines which do not produce any heavy or light chains. Moreover, these myeloma cells are very stable, so that emerging hybridomas survive the selection process.

Cell fusion is mostly facilitated by polyethylene glycol (PEG), a polywax that promotes cell adherence and the exchange of nuclei. PEG has become the agent of choice because it is relatively nontoxic and highly effective. For successful fusions the optimal concentration, molecular weight, and exposure time seem to be crucial (18). In our laboratory, we prefer PEG with a molecular weight of 8000. Myeloma cells and splenocytes are mixed in a ratio of 1:4 and fused by electroporation according to a modified protocol of Stoicheva and Hui (19). The mixed cell population is aligned by exposure to a low-level nonuniform electric field and because of emerging dipoles the cells are oriented. Through a brief pulse of high voltage, microscopic pores are created in the membrane that allow a physical fusion of both cell types after cultivation under normal conditions without any stress. Other fusion strategies are related to virus induced cell fusions. But this approach is not really useful for hybridoma technique. Therefore, fusion with PEG and electroporation has established a technical standard (19).

There are other strategies to fuse human B lymphocytes with Epstein-Barr virus (EBV) to get immortal antibody-producing cells (20). The fused cells are termed *lymphoblastoid cell lines* (LCL) and were provided as a source of human monoclonal antibodies, but they also have serious deficiencies. They possess a poor stability and a low Ig secretion rate, which is limiting the properties of the approach. Further, the application of EBV immortalized cells needs a higher protection stage than working with myeloma cells alone and for therapeutic approaches it is difficult to get an approval for the treatment of human diseases by applying antibodies which are originated from an EBV-induced cell culture.

29.2.2.3 Large-Scale Production of Hybridoma Antibodies. The generation of monoclonal antibodies is one of the most important discoveries in the biomedical field because these molecules are highly specific for their target and show a long-term stability. Hence, it is not surprising that monoclonal antibodies are produced in large amounts in industry. The material mostly applied to cultivate hybridoma cells *in vitro* is tissue culture polystyrene (21). Bioreactor technology for mass production of monoclonal antibodies is based on large-scale stirring bioreactors, and hollow fibers or flat-sheet membranes to cultivate hybridoma cells (22) (Fig. 29.3). The most frequently used membranes in these systems are hydrophilic ones, such as cellulose acetate or polymethylmethacrylate (23). The specific cutoffs of these membranes between 10

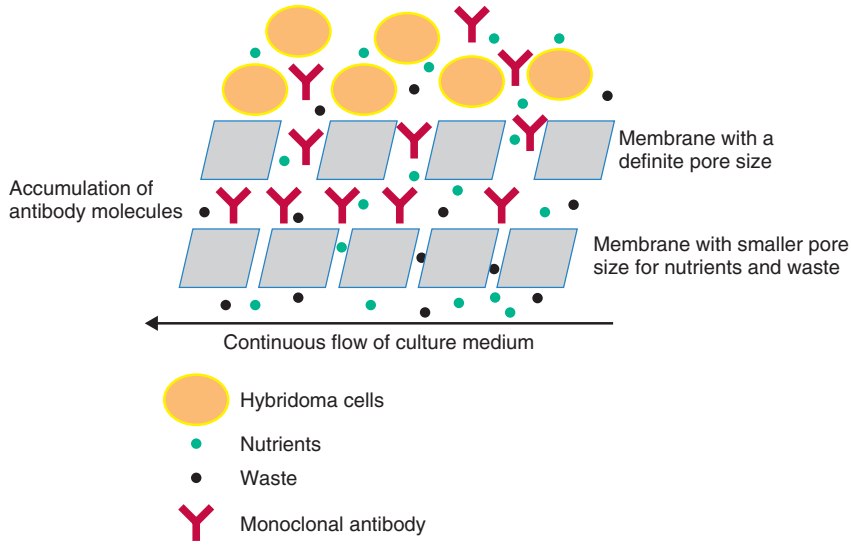

Figure 29.3. Bioreactor technology for mass scale production of monoclonal antibodies. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

and 15 kDa allow a continuous influx of essential components, for example, amino acids, vitamins, and so on and an effective removal of toxic metabolites like ammonia or lactate (24). Secreted antibodies cannot pass the membrane because of their higher molecular weight. They are enriched in the "cellular" compartment of the bioreactor and large quantities of monoclonal antibodies can be accumulated. The quantities achieved in these systems vary between 1 and 4 mg/mL, while the yield of monoclonal antibodies is limited to 10–100 μg/mL in the conventional tissue culture technology (24,25). Bioreactor technology has been optimized so far for supply of nutrients and oxygen and removal of waste materials. Advantages of these systems are a warranted purity and a product, generally free of contaminants or fragmented or denatured antibodies in high concentrations. Big pharma companies dispose of huge 2000 L fermenters in which the production of recombinant proteins is performed. With a protein concentration of approximately 4 mg/mL, it means, a yield of up to 8 kg recombinant protein is produced by one fermenter.

29.2.3 Production of Human Antibodies

An overview is shown in Fig. 29.4.

29.2.3.1 Chimeric and Humanized Antibodies. For therapeutic purposes, human or human-like antibodies have to be applied to avoid an immune reaction against the injected protein. One aspect in this area is the chimerization and humanization of mouse-generated antibodies (26). The murine variable parts of the antibody molecule are fused to human originated constant domains, which reduce the murine part to approximately 35% (chimeric antibodies). A second possibility was established in which only the complimentarity-determined regions (CDRs) are of murine origin and that is reducing the murine part to 5%–10% (humanized antibodies) (27). For these purposes, the mRNA of the antibody-producing hybridoma has to be isolated, translated into cDNA, and cloned in vectors for chimerization or humanization, based on genomic sequences for the human constant domains and cloning cassettes for the insertion of murine cDNA. The expression is performed by transformation of mammalian cells, cultivation under serum-free conditions, and secreted chimerized or humanized antibodies are purified from the culture supernatant via protein A or affinity chromatography. The experimental design is extensive, cost-intensive, and associated with current problems regarding molecular cloning and transformation

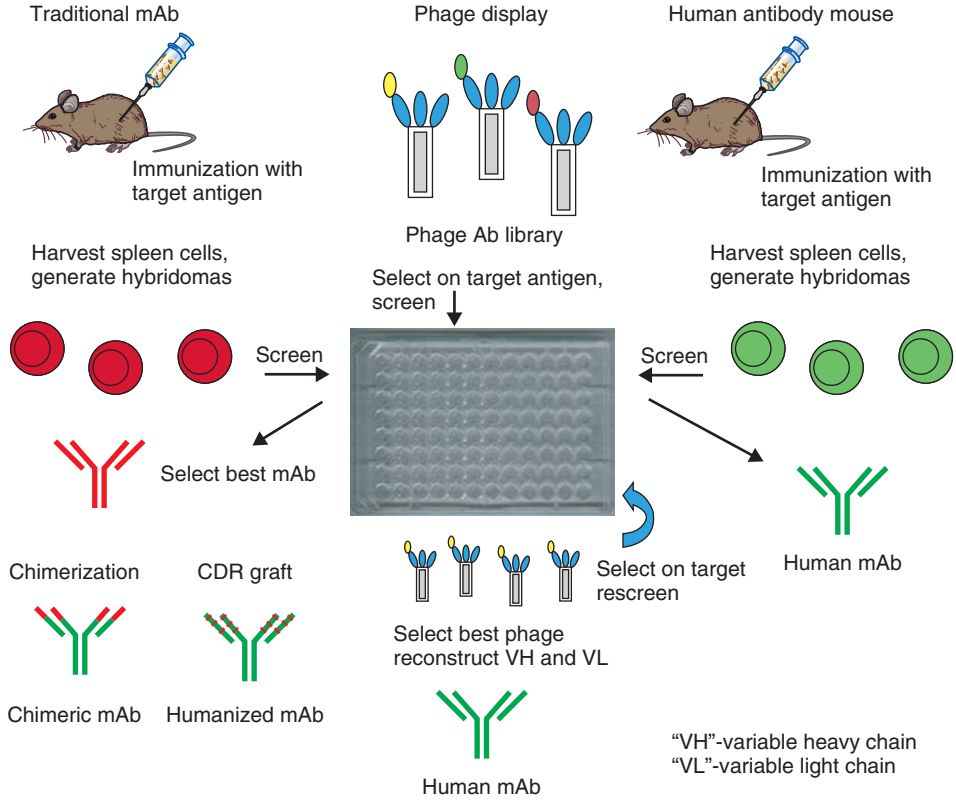

Figure 29.4. Overview of antibody technologies for chimerization and humanization of murine antibodies. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

of mammalian cells. Frequently, the substitution of amino acid residues by back-mutations or affinity maturation leads to drops in affinity relative to the original mouse antibody.

29.2.3.2 Human Antibodies Obtained From Phage Antibody Libraries. Another promising technique in generating immunmodulating molecules is the creation of single chain antibodies of human origin (28). These very small molecules are joined variable segments consisting of the variable light and heavy chains of an antibody. The linker between the variable segments allows the flexible orientation of antigen-binding sites toward the target as in natural antibodies. These single chain fragments are usually expressed on bacteriophage outer coat proteins. Hence, the generation takes place by a technique called *phage display*. For this purpose, DNA from nonimmunized donors is used to generate large antibody libraries of variable light and heavy chains. The target cDNA is cloned into phagemid-vectors containing the major coat protein pIII of the bacteriophage M13. The major coat protein is responsible for the introduction of the single chain molecule into the envelope of the phage. After cotransfection with a M13 helper phage the genetic information for heavy and light chain is incorporated into a phage particle containing the phagemid. Thereby, recombinant phages are designed with single chain fragments in their envelopes and the genetic information inside comparable to B lymphocytes in mammalian organisms. The screening for target structures is called *biopanning* in which relevant antibody genes can be isolated and used to reconstruct a fully humanized antibody. This method is very useful to generate antibodies against self-antigens and allow the successful production of therapeutic antibodies. Continuative strategies combine single chain molecules against tumor markers with toxic ligands to eliminate the target cell. In cases where complete intact antibodies are needed the human single chain antibody fragments can be combined by DNA technology with human constant antibody parts as in antibody chimerization. Such fully human antibodies can then be propagated by large-scale techniques such as phage display as *in vitro* selection system (29). By now recombinant antibodies represent nearly 30% of all biopharmaceuticals being in clinical trials. That, in fact shows the great potential in biotechnology and biomedicine as useful strategy in controlling human diseases more effectively.

29.2.3.3 Human Antibodies From Human Hybridomas and Hybridomas From Humanized Mice. The technique to create human hybridomas is not as well developed as the production of murine hybridomas. Therefore, only very few human antibodies are available going back to B cells of human origin. To generate completely human originated antibody molecules, immunodeficient mice (30) or xenomice (31) are used currently. Human stem cells were transferred into severe combined immunodeficient (SCID) mice (SCID mice) which then develop a temporary human immune system. After challenging these mice with antigen the antibody-producing cells can be isolated by standardized hybridoma technology but for fusion a human immortal cell line is required. For this purpose, heterohybridomas from mouse and human origin as HF2x653 (human WI-L2-729-FF2, mouse P3X63/Ag.8.653) or K6H6/B5 (human nodular lymphoma cells from a patient with non-Hodgkin's lymphoma, mouse NS-1-Ag4) were used. The animal husbandry for immunodeficient mice is strongly regulated. The mice need a completely sterile environment because of their established immune deficiency. Further limitation for this system is the dependence of appropriate donors and the generation of antibodies against unknown targets is not possible because of the immunological tolerance. This makes it very difficult and not common to produce human antibodies in higher amounts.

The next "evolutionary" step in creating fully human antibodies is a genetically engineered mouse, a so-called *xenomouse*. These mice have inactivated murine antibody genes, and therefore, cannot produce murine antibodies (32). But by gene transfer, human gene segments for heavy and light chains were introduced successfully into the mouse genome. The segments were incorporated completely and fully functional so that these mice can produce human antibodies against every target, also of human origin, and are able to initiate affinity maturation and isotype switching. Difficulties can appear regarding compatible glycosylation patterns of antibody molecules generated with mouse hybridomas but this should be avoided by using heterohybridomas or fully human-related fusion cell lines. Another recently presented technology is the transgenic rabbit technology which implies the use of transgenic rabbits for the production of human antibodies after immunization with therapeutic targets (33). The advantage of using transgenic rabbits is the higher immune competence (compared to mice) to create antibodies against different targets which could not be achieved by common technologies as described earlier.

29.3 NEW METHODS FOR HUMAN ANTIBODY PRODUCTION (*IN VITRO* IMMUNIZATION, ARTIFICIAL LYMPH NODE SYSTEMS)

By now the development of promising alternatives and new tools for generating human antibodies are unfortunately in its infancy. There are some interesting experimental designs like *in vitro* immunization or the development of artificial lymph node systems. Several approaches have been tried to achieve an *in vitro* immunization but the definition of the term is interpreted differently by different authors.

Borrebaeck *et al*. (34) described the production of human monoclonal antibodies by an *in vitro* immunization of peripheral blood lymphocytes. In other studies, the activation of dendritic cells with selected antigens was carried out to generate cytotoxic T lymphocytes and this procedure was also named as *in vitro immunization* (35). In spite of some positive results there is no established routine method, currently, combining the most important *in vivo* components for an *in vitro* immunization. For long-term studies the accomplishment of an immune response *in vitro* requires the cooperation of the important populations of immune cells involved normally *in vivo* together with a lymph node–like surface as biomimetic support. This would result in an experimental design with possibilities to generate human antibodies and could be a basis to obtain a defined activation status to nearly every antigen so that the production of specific antibodies against these antigens could be accomplished. Problems which need to be solved in this technology is first the shortened lifetime of B and T-lymphocytes and second the constant requisition of new cell populations which can be activated against specific antigen. These problems could be prevented by fusion with adequate cell lines or by special biomimetic cultivation supports related to an extracellular matrix as seen in the paracortical area of lymph nodes. By now, several bioreactor systems are in progress in which the permanent cultivation and activation of dendritic cells is possible. These systems are supported by an alginate layer that allows the self-assembly of human lymphatic tissue due to proper emulation of human architecture and homeostasis (36). The development of extracorporeal human lymphatic organs would be a highly specific application to study matrix organization, cell-matrix interactions, and immunological tolerance processes which could broaden the knowledge of human immune responses in a superior manner. But all these new and advanced experimental tools are possible only due to one brilliant invention in 1975—the hybridoma technology from Köhler and Milstein—and there could be no better proof that the nobel prize was awarded right for this part of scientific history.

29.4 ALTERNATIVES TO ANTIBODIES FOR USE IN HUMAN BEINGS

Antibodies are the most successful binding molecules in science since nearly 20 years, but for all that there are disadvantages based on their complicated molecular composition. Immunoglobulins show a large and multidomain structure with specific glycosylation patterns and disulfide bonds, both essential for assembly and function. Hence, the manufacturing process is very expensive and some of the immune effector functions of the constant domains seem to be undesirably in many therapeutic approaches. The generation of antibody fragments like Fab fragments or single chain antibodies was the next step to avoid effector functions but this resulted in a lack of stability. Further, it was difficult to tag them for detection. For this reason, alternative binding proteins other than antibody molecules were needed to handle with the upcoming problems. Such alternative binding molecules were invented in nonvertebrate animal groups as defense molecules and so it was logical to try the usefulness of such protein molecules as universal binding molecules, too. Alternative binding molecules are entering the field of classical antibody application stepwise and are currently being evaluated. Examples for alternatives are affibodies, lipocalins, designed ankyrin repeat protein (DARPins), and nanobodies (37,38). Affibodies are small protein domains that are derived from a bacterial surface receptor like the immunoglobulin-binding domain from *Staphylococcus aureus* protein A (39). The selected protein domains are folded individually, no disulfide bonds are necessary, and they show a high proteolytic and thermic stability. Affibodies were selected by phage display technology from a protein library and some have entered the diagnostic and therapeutic market, for example, affibody-alexa fluor conjugates for the semiquantitative imaging of HER2 expressing cells *in vivo* (40). Lipocalins are a broadly distributed protein family consisting of β-barrel structures with an internal ligand binding site that are present in nearly all organisms (41). The natural function of these proteins is the transport of small hydrophobic proteins such as retinoids, lipids, or steroids. These properties are currently used for genetic engineering to modify the binding sites. The generated molecules are then called *anticalins*. The application of recombinant neutrophil gelatinase-associated lipocalin (NGAL) to mice with acute kidney injury has recently attracted great attention as this resulted in marked preservation of kidney function and structure (42). DARPins are designed ankyrin-repeat proteins with consecutive copies of small structural units (20–40 amino acid residues) that stack together to form elongated repeat domains displaying variable and modular target-binding surfaces (43). Because of the repeat domains the molecule can be adapted to every target size and they are characterized by a high affinity, high thermodynamic stability, and reverse folding behavior. Further, the generation seems to be beneficial because the expression in *E. coli* is extremely high and accompanied by low aggregation tendencies. Recent data showed that ankyrin-repeat domains are also useful for therapeutic approaches. Schweizer *et al*. (44) designed a novel type HIV entry inhibitor based on the DARPin technology. The proteins were highly specific for CD4 and potently inhibit infection of genetically divergent HIV isolates. They seem to be therefore promising candidates for the use in human beings. Nanobodies or single domain antibodies are derived from camelids and are functional antibodies

devoid of light chains but fully capable of antigen binding (38). These properties cause some interesting features like an improved solubility and stability. Further the molecules are characterized by a more simple expression in microorganisms comparing to the expression of complex antibody molecules in mammalian cells and the suitability to construct larger molecules and selection techniques such as phage, yeast, and ribosome display. Nanobodies are offering new therapeutic strategies, especially for an oral immunization because of the resistance in the extremes of pH and the property to bind their target. so in high concentration of chaotropic agents. Till now, several therapeutic approaches could be realized with nanobodies like the treatment of diarrhea, sepsis, or rheumatoid arthritis.

29.5 OUTLOOK

The hybridoma technology developed from Köhler and Milstein over 20 years ago is currently the scientific standard in generating monoclonal antibodies and demonstrates a hallmark in biotechnology and biomedicine. This basic method and all arising technologies opened up a new field for experimental designs and innovative results in understanding and clarifying courses in diseases. The possible application of antibodies in research leads to well-defined characterizations of cell types, cell–cell and cell–matrix interactions, and correlation of signaling cascades. An outstanding example is the identification of nearly over 300 cluster of differentiation (CD) antigens (14). With this knowledge it is possible to understand intracellular processes and last but not least, to develop new and highly effective strategies in controlling diseases. The hybridoma technology has provided scientists and clinicians with invaluable tools for research and diagnostic. Several genome projects with mammalian genomes identified thousands of functional genes, which have to be identified, characterized, and investigated regarding protein expression and regulation processes. These perspectives indicate a continuous requirement and therefore have a huge global demand for antibody molecules, related detection markers, and biomedical tools. In the course of this development, a multitude of new techniques is necessary and will be designed in future to simplify the generation of human therapeutic antibodies, which, in fact, seems to be a highly effective tool in the treatment of malignant or autoimmune diseases.

ANTIBODY PRODUCTION, HUMAN RECOMBINANT

STEFAN DÜBEL

Technische Universität Braunschweig, Institute of Biochemistry and Biotechnology, Spielmannstr, Braunschweig, Germany

30.1 INTRODUCTION

The main function of antibodies in nature is the specific labeling of pathogen determinants for their subsequent recognition by the immune system. A very large collection of antibodies with different binding specificities can be produced by our body for this purpose. However, it would be far too inefficient to store individual genes for each of the approximated $>10^8$ different antibodies present in the human organism, and the amount of DNA required would exceed the size of the entire human genome itself. The solution to this problem depends instead on the principle of genetic recombination. The final antibody gene is individually assembled in every B cell from a limited number of different gene fragments. In addition to the recombination of gene fragments, further coincidental mechanisms introduce new, short sequences at one of the fusion points of the different gene fragments. The diversity of possible structures is further increased through the combination of two different protein chains (*light* and *heavy* antibody chains).

The generation of binding diversities, while maintaining constant functions of the effector mechanisms of the immune system is made possible through the modular construction of the antibody. A typical immunoglobulin polypeptide chain is constituted from two or more very similar protein units (“regions”)having the same folding structure (“immunglobulin superfamily fold”). Two or more of these polypeptide chains are then assembled to the complete immunglobulin. Antigen binding is achieved by the aminoterminal folded units, named the variable regions, which contain the *hypervariable regions*. Structurally, these form the complementary determining regions (CDRs) because they form a structure which is complementary to the antigen. Six of these hypervariable regions in total (three in the light chains and three in the heavy chains) are organized throughout the rest of the sequence (the so-called framework regions) so that they come together with the top end of the T or Y forming structure of the molecule (Fig. 30.1 and Fig. 30.2). This structure, made up of the CDRs and the framework regions, forms the V domain (variable domain) of the antibody.

The constant domains mediate the effector function; different constant domains can therefore mediate a large range of different biological effects. Among these effects are the activation of complement, a protease cascade finally leading to the lysis of target cells, or antibody dependent cellular cytotoxicity (ADCC), where the antibody targets effector cells to the antigen. Further, the type of constant domains determine the strength of these effects as well as the half-life in the blood plasma. Immediately evident when looking at an immunoglobulin is its modular structure, as the individual domains are all of the same fold, and many variations can be achieved by adding more or less domains. For example, the number of constant domains varies, and immunoglobulin forms with 2–10 binding sites are made in our body, based on combination of a variable number of IgG-like modules.

The selection of the B lymphocyte (B cell) which produces a corresponding antigen-binding antibody occurs after contact with the antigen through selective reproduction of this B cell (a process called *clonal selection*). This selection was previously achieved using the immune system of animals (mainly mice or rabbits).

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

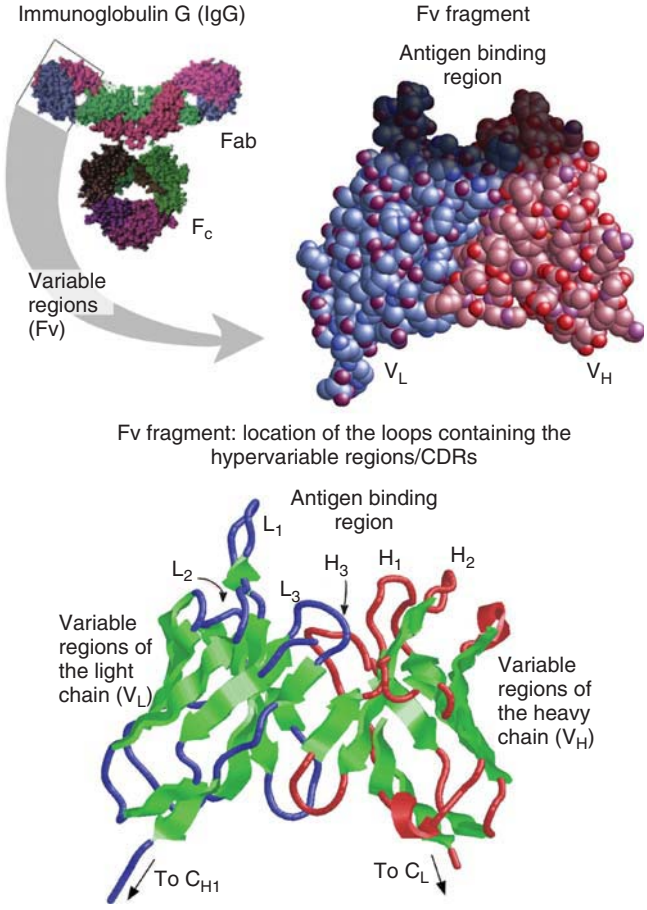

Figure 30.1. Structure of immunoglobin and the antigen-binding fragment (Fv). Below: The structure of the immunoglobin domains are defined by the sheet region (green) of the framework, whereas the antigen-binding sites are formed from six loops (H1–H3, L1–L3). The carboxyl-terminal of both variable polypeptide chains of an Fv fragment (C) lies on the antigen-binding site at opposite ends of the molecules, therefore it is the preferred site for protein fusion. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

In this way either antisera (polyclonal antibodies) or B lymphocytes, which after immortalization produce monoclonal antibodies, were obtained (refer to section on *hybridoma technology monoclonal antibodies*). In each case, however, it was necessary to first immunize an animal. In the late 1980s, a third method of manufacturing antibody fragments, based on gene technology, became available. Using this method, the antibodies are no longer made in research animals (or in humans) but instead they are produced *in vitro* in bacteria or cultured cells. Further, it was realized at the beginning of the 1990s that the selection of specific antigen-binding sequences could be carried out completely *in vitro*. The methods that were developed in this way are explained in the following sections.

30.2 WHY RECOMBINANT ANTIBODY SELECTION AND PRODUCTION?

30.2.1 Human Monospecific Antibodies

In the late nineteenth century, the German army doctor Emil von Behring (1854–1917), later first Nobel laureate for medicine, pioneered the therapeutic application of antibodies. It took an entire century, however, to develop methods allowing the development of monospecific antibodies for the therapy of human diseases. Why? Behring used blood serum for the treatment of tetanus and diphtheria ("Blutserumtherapie"). Following the underlying principle of this approach, today there is still a significant number of blood products based on the effect of naturally occurring immunoglobulins. These agents are used mainly for passive vaccination. If they are made in animals, an immune response against the foreign protein can be expected, prohibiting repeated use of these agents. Human blood products are used as well, but bear the risks of virus contamination arising from any pool of donor blood preparation. Further, a continuous quality is difficult to achieve, since it depends on a mixture of individual and quite limited sources of donor blood. So, there is no way to utilize these blood derived antibodies for the treatment of chronic diseases, like cancer or autoimmune diseases. Also, human monoclonal antibodies are rarely used for two main reasons. First, an immunization for the production of antibodies in humans is only possible in exceptional cases. Second, the hybridoma generation with human cells has proven to be very difficult, and many of the few existing human monoclonal antibodies are derived from cells immortalized by other methods, for example, Epstein–Barr Virus (EBV) infection—a method not really preferable for the generation of drugs for human use due to the inherent risk of EBV contamination.

These restrictions explain why the clinical use of monoclonal antibodies only flourished starting a 100 years after the first human serum therapy by Behring. It was necessary to develop novel methods for the generation and production of human antibodies.

Nowadays, human antibodies for *in vivo* use (such as therapy and diagnosis) can be obtained from recombinant methods such that the antibodies are not recognized as *foreign* by the human immune system, resulting in a lower immune response by the patient against the antibody. This minimizes the risk of a patient's response which neutralizes the therapeutic antibody. Even further, human antibodies can be generated completely *outside* of a vertebrate organism. Some methods even allow the adjustment of antibody features since the biochemical properties for the binding can be precisely controlled during *in vitro* selection. For this reason antibodies are available that could never be produced in animals, for example, antibodies against transient conformation of a molecule

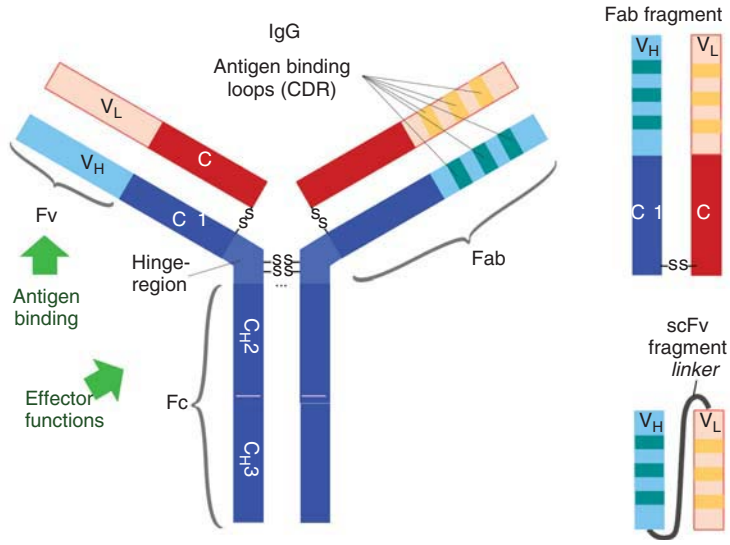

Figure 30.2. Schematic diagram of IgG and recombinant antibody fragments derived from it which can be produced in bacteria. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

after cofactor binding. Cross reactivities can be suppressed by the addition of a respective competitor during selection. Antibodies against antigens with which an immunization is not possible can also be obtained, for example, antibodies against highly toxic substances, lethal pathogens, or evolutionary conserved molecules. Thus, only recombinant antibody technology made the manufacture of *human* antibody therapeutics possible in a systematic manner (Fig. 30.3).

30.2.2 Antibodies with Improved Functions and Properties can be Created

Once a recombinant antibody clone is obtained, it can be manipulated using the entire arsenal of modern genetic engineering. By strategies ranging from employing *in vitro* evolution (mutation and reselection) to computer aided molecular design, almost all biochemical properties of an antibody nowadays can be adjusted, from net surface charge, molecular mass and valency to affinity, stability, serum half-life, and immunogenicity.

This is perfectly illustrated by the antibody variants made to block the Tumor Necrosis Factor (TNF)/Tumor Necrosis Factor Receptor (TNFR) interaction to down-regulate overshooting inflammations (Fig. 30.4). Starting with a clinically failed mouse hybridoma antibody, the next steps were chimeric and then humanized antibodies. A completely human antibody and a human soluble receptor-Fc fusion were the next clinically tested and approved iterations of the idea. Recently, a humanised Fab fragment fused to polyethylene glycol (PEG) to improve pharmacokinetics marks the sixth generation of TNF antagonist antibody constructs. Already, the list includes two examples of novel designs based on antibody fragments, but not anymore resembling a molecule present in nature. Recombinant antibody technology may even reach its limits here, and a seventh generation TNF antagonist could well be a novel synthetic binder of nonantibody structure ("alternative scaffold").

Many promising new concepts for the treatment of a huge variety of different diseases could now be envisaged. For example, the antibody genes can be coupled to a gene of interest, so that both genes are fused together and produced as a single protein. The antigen-binding site and the carboxyl-terminal of the V domain are on opposite sides of the molecule. Therefore, through the introduction of heterologous proteins to the carboxyl-terminal of a V domain it is possible to provide the antigen-binding site of the antibody with new biochemical functions, which would not occur naturally. For example, an enzyme can be specifically directed to a tumor with the help of an antibody fragment—such *bifunctional antibodies* can lead to new cancer therapies.

The connection of two different antigen binding sites to form a *bispecific antibody* is also possible. Recombinantly produced genetic fusions offer the advantage, that the coupling product and the stoichiometry of both partners are exactly defined.

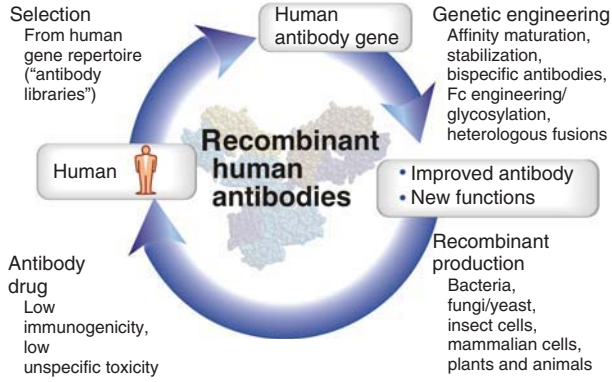

Figure 30.3. The idealized production cycle of human recombinant antibodies. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

30.3 MAKING HYBRIDOMA-DERIVED ANTIBODIES MORE HUMAN

After the discovery of human anti-mouse antibody (HAMA) responses in patients treated with hybridoma-derived monoclonals, various attempts have been followed to make animal derived immunoglobulin molecules looking more human. Two of these strategies led to success in form of several approved therapeutics. In the late 1980s, the molecular details of epitope specificities in T-lymphocyte responses to foreign proteins were barely known. The transformation from mouse to human-like protein sequences was therefore attempted by exchanging parts of the immunoglobulin polypeptide with homologous human sequences. So, this strategy was based on the assumption that human sequences, when given as a drug, may cause less adverse reactions due to the lack of specific T-cells in the patients. When looking on the immune responses observed in clinical application of these antibodies, it is evident that this concept not only worked, but was the

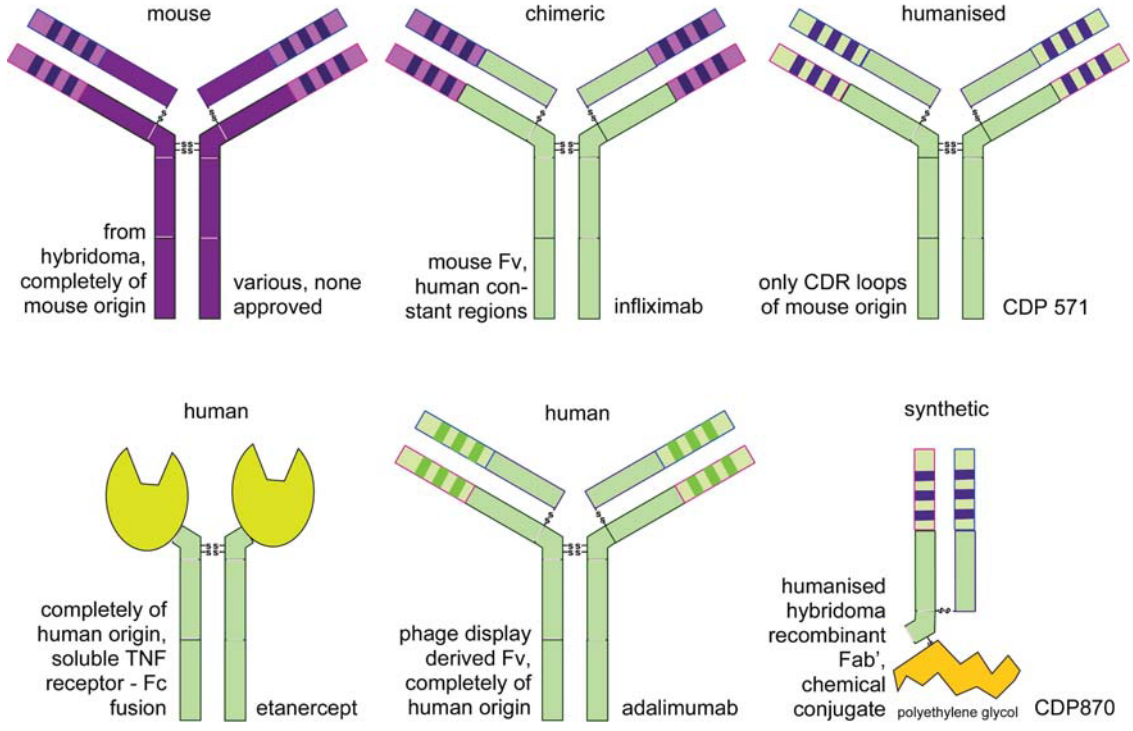

Figure 30.4. Development steps of antibody-derived TNF antagonists for the therapy of overshooting immune responses. Approval dates given in Table 30.2. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

spark to ignite an entirely new industry for the generation of these recombinant antibodies (see approved antibody therapeutics in Table 30.1). However, it became evident finally with the approval of completely human antibody sequences (like in Humira) that the absence on nonhuman polypeptide sequences does not guarantee a complete lack of immune response against the therapeutic protein. This can be explained by three factors: first allelic variations are not studied yet to an extent allowing broad conclusions on the differences between individual patients. Second, the fact that the antigen-binding domains of every antibody contain randomly rearranged amino acid compositions, even with newly synthesized sequences in CDR3H, suggest that individual patients will have different tolerance patterns to these parts of the antibody molecule. No humanization strategy known so far, however, can completely eliminate this potential source of immunogenicity since it would effect antigen specificity and affinity as well. Third, most approved antibodies are produced in hamster cell cultures, which may lead to different post-translational modifications when compared to human plasma cells, where immunoglobulins are naturally made. These modifications, in particular those of the glycosylation pattern, may effect immunogenicity as well. In addition, carefully adjusted galenics can lower immunogenicity, for example, by avoiding aggregation.

30.3.1 Chimerization

The first approach to lower the fraction of animal derived protein sequence from hybridoma antibodies was the genetic fusion of the original mouse antigenic binding domain to human constant domains. The resulting *chimeric antibody* (Fig. 30.4) gene was then introduced to CHO (Chinese hamster ovary) cells for recombinant production. The advantage of this method is that the structural integrity of the variable domains of heavy and light chain remains untouched, thus increasing the chances that a chimerized antibody retains the antigen-binding properties of the original hybridoma antibody. However, two domains out of the 12 forming an IgG molecule are encoded by mouse sequences, and consequently HAMA antibodies can be found in patients treated with chimeric antibodies.

30.3.2 Humanization

A large number of different approaches has been conceived to eliminate as much as possible the mouse-derived sequences from the IgG molecule. Based on the structural knowledge of the antigen-binding site, many of these strategies aim to transfer the six peptide loops contacting the antigen to a human framework ("CDR grafting"). When following this approach, it soon became evident that in almost all cases where a one-to-one transfer of mouse CDRs to even highly homologous human framework parts led to a dramatical loss in affinity or even specificity. Other variants created this way were difficult to being produced in cell culture. So, the approved antibodies required several "back"-mutations, reintroducing mouse-specific amino acid side chains into the human framework, to cure these deficiencies. Consequently, the nomenclature "humanized" does not mean that the resulting antibody is consisting only of human sequences.

Other humanization strategies rely on changing just the outside of the antibody which is exposed to the blood, but leaving the structural core of the antibodies V regions in their original mouse-derived organization. A more radical method uses the successive exchange of the two V domains by human domains, either in *guided selection* or *chain shuffling* approaches.

In many cases, the primary sequence of different mouse antibodies, when analyzed, shows individual differences forcing to combine two different humanization methods. So, every humanization approach should start with a thorough analysis of the real differences between the mouse gene and its nearest human homolog. It has been proposed that the use of genomic sequences instead of sequences of somatically mutated IgG lowers the risk for immunogenicity, but despite all these attempts, also humanized antibodies induce responses in patients, because of the reasons mentioned above.

30.3.3 *In silico* Humanization

The experimental assessment of the immunogenicity of a protein in man is still not satisfactory. *In vitro* studies relying on activation of T-lymphocyte preparations can give a hint, but a negative result in these assays does not allow the conclusion that this will be mirrored in a living human body. With the advent of increasing knowledge on the molecular mechanisms of antigenic peptide processing and presentation on the major histocompatibility complex (MHC) molecules, methods were developed to predict the "immunogenicity" of polypeptide sequences by bioinformatic algorithms (*"in silico"*). Various approaches were followed here and it developed into an industry standard to check potential immunogenicity of antibodies before the start of a clinical study. Unfortunately, it is very difficult to judge the success rate of the various algorithms, since negative controls (without *in silico* humanization/deimmunization) are usually not available.

30.4 OBTAINING HUMAN RECOMBINANT ANTIBODIES

The lengthy procedures and limited success of humanization strategies inspired the development of completely new methods to obtain human antibody sequences from the start.

TABLE 30.1. Production Systems for Recombinant Antibodies[a]

Host Prokaryotes	Antibody Format	Production System	Maximal Yield
Gram-negative bacteria			
Escherichia coli	$F(ab')_2$	Fermentor	2.5 g/L
	V_{HH}	100 L shake flask	10 mg/L
	Fab	10 L fermentor	1–2 g/L
	VL single domain	1.5 L fermentor	35–65 mg/L
	scFv	3 L fermentor	1.2 g/L
	IgG	10 L fermentor	130–150 mg/L
	Fv	Fermentor	450 mg/L
Proteus mirabilis	scFv	50 mL shake flask	~12 mg/L
Gram-positive bacteria			
Bacillus brevis	Fab	2 L shake flask	100 mg/L
Bacillus megaterium	scFv	400 mL shake flask	0.41 mg/L
Bacillus subtilis	scFv	N.d	12 mg/L
Lactobacillus paracasei	V_{HH}	N.d.	~1 mg/L
Streptomyces lividans	Fv	N.d.	~1 mg/L
Eukaryotes			
Yeast			
Pichia pastoris	V_{HH}	Baffle flask	10–15 mg/L
	scFv	Baffle flask	60–250 mg/L
	Fab	5 L fermentor	458 mg/L
	scFv-Fc	5 L fermentor	10–30 mg/L
	scFv-$(G_2S_2)_2$-GS-C_{1-3}	4 L fermentor	60 mg/L
	Tetravalent scFvs	20–30% tetramers	15–20 mg/L
Saccharomyces cerevisiae	V_{HH}	100 mL shake flask	Up to 100 mg/L
	Fab	N.d.	100–200 μg/L
	IgG	N.d.	50–80 μg/L/
Filamentous fungi			
Aspergillus niger var. *awamori*	IgG1	50 mL shake flask	0.9 g/L
	Fab	50 mL shake flask	1.2 g/L
	scFv	N.d.	10 mg/L[b]
	V_{HH}	Shake flask	7.5 mg/L
Trichoderma reesei	Fab	15 L fermentor	1 mg/L
Insect cells			
Drosophila melanogaster, DS2	scFv	25-cm^2 flasks	25 mg/L
Spodoptera frugiperda, Sf9	scFv	6 L bioreactor	32 mg/L
	Several IgGs	T75 flasks	6–18 mg/L
	IgG1	N.d.	10 mg/L
Trichoplusia ni	IgG2a	150 mL shake flasks	N.d.
Mammalian cells			
Transient			
HEK293T	IgG and scFv-Fc	lipofectamine (LP), HEKfectin, tissue culture plates	1–20 mg/L
HEK293E	IgG	Polyethylenimine (PEI), 10 L shake bottle	80 mg/L
CHO-K1	IgG	LF, 1 L spinner flask	20 mg/L
CHO-K1-S	IgG4	PEI, 10 L, shake flask	39 mg/L
Stable			
CHO	Fv	Roller bottle	4 mg/L
GS-NS0	cIgG4	Fermentor, fed-batch, airlift	560 mg/L
NS0	scFv-CH3	N.d.	60 mg/L
SP2/0	IgG	Serum free	300 mg/L
GS-NS0	IgG	Fermentor, fed-batch	2.7 g/L
CHO-S	IgG	Fermentor	4.7 g/L
Transgenic plants			
Arabidopsis thaliana	Fab	Leaves	1.3, 3–6% total soluble protein
Medicago sativa	IgG	Leaves	0.1–1% total soluble protein
Nicotiana tabacum	V_{HH}	Leaves	28–136 mg/kg
	scFv	Leaves	1% soluble protein
	Fab	Leaves	0.044% total soluble protein

TABLE 30.1. *(Continued)*

Host Prokaryotes	Antibody Format	Production System	Maximal Yield
	IgG	Leaves	1.3% total protein
	IgG	Leaves	0.04–0.16% total protein, 1.56 mg/kg
	IgG	Suspension culture	37.6 mg/kg
Oryza sativa	scFv	Leaves	1.5–29 mg/kg
Petunia hybrida	scFv	Leaves	1% total soluble protein
Triticium aestivum	scFv	Leaves	50–900 μg/kg
Transgenic animals			
Mouse	IgA	Milk	5–6 g/L
	IgG-RNase	Milk	0.8 g/L
	IgG	Milk	0.5 g/L

[a]Based on data collected by Schirrmann T, *et al*. Production systems for recombinant antibodies. Front Biosci 2008;13:4576–4594.
[b]Five times higher yield was obtained after fusion to glucoamylase.

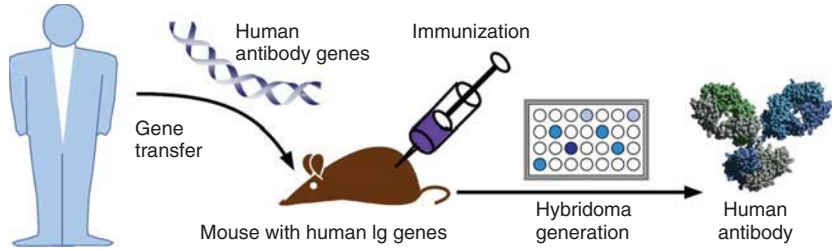

Figure 30.5. Human antibodies can be generated by obtaining hybridoma cell lines from immunized mice carrying the human Ig gene locus. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Two major methods were conceived. First, transgenic mice have been made to yield hybridomas secreting antibodies with human sequence. Second, a couple of methods allows the selection of antibodies completely *in vitro*, that is, outside of any immune system.

30.4.1 Transgenic Mice

With the help of genetic methods, individual genes can be specifically inactivated (*knockout*) and foreign genes can be introduced in mice (*knockin*). Therefore mice are bred whose immunoglobin gene locus has been inactivated and replaced by homologous stretches of the human immunoglobin genes. Human antibody genes rearrange in the same way as mouse genes; they can undergo class switching and somatic hypermutation. After immunization, these transgenic mice produce human antibodies in mouse cells, which (as apposed to human hybridoma cells) can easily be used to generate mouse hybridomas (Fig. 30.5). This serves as a system for the production of human antibodies, which methodically resorts to the large experience with mouse hybridoma technology avoiding the problems with the generation of human hybridomas. However, this system is based on the conventional method of immunization. This prevents the production of antibodies against substances with low immunogenicity, toxins, or lethal pathogens. Affinity maturation occurs analogous to the human immune system, so that high affinity antibodies can also be obtained. These methods have already been introduced successfully for the production of a few therapeutically relevant human antibodies.

30.4.2 Selection of Human Antibodies *In Vitro*

There are three major elements needed to select a specific antibody. For the *in vitro* generation, these three basic elements have to be realized independent of the mammalian immune response:

1. the construction of the gene collection encoding the multitude of antibody genes (in the form of recombinant gene libraries);
2. the effective selection of the correct gene from this initial repertoire (typically with the help of a surface expression vector);
3. the improvement of affinity and specificity of a selected antibody fragment (through *in vitro* mutagenesis and re-selection using (2)).

For the ease of genetic manipulation and their fast growth, microorganisms are the most convenient hosts

to perform *in vitro* antibody selections. However, it is not too simple since antibody folding requires a complex molecular helper apparatus and an oxidative biochemical environment for the production of the disulfide bonds. Consequently, in bacteria, a production of functional antibody domains is first of all acquired through a fusion of the antibodies to a bacteria signal sequence, which leads to the secretion into the periplasmatic space (PS). This PS lies between the two cell membranes of gram-negative bacteria and contains a biochemical environment that, unlike the cytoplasm, allows the correct folding of the antibody and the correct formation of disulfide bonds.

30.4.2.1 Recombinant Antibody Gene Repertoires ("Antibody Libraries"). In transgenic mice used for making human antibodies, the human recombinant gene repertoire is present within the B lymphocyte population of the mouse (Fig. 30.5). In contrast, for all *in vitro* methods, this antibody gene repertoire has first to be generated. It is estimated that in humans more than 10^8 different antibody genes are available through the random combination of gene fragments. This genetic diversity can be extracted from B lymphocyte mRNA through polymerase chain reaction (PCR) with the help of oligonucleotide primer sets which bind to conserved sequences at the ends of the antibody gene. These PCR primers contain restriction sites, so that the antibody genes can be assembled in expression vectors. The PCR has to be performed for both the variable fragment of the heavy and the light chain to provide both the polypeptides of a functional antigen-binding site. A typical flow chart for the generation of an antibody library is given in Fig. 30.6. Antibody libraries can also be assembled from the complete set of human genomic sequences taken from our respective gene locus. Here, the native combinatorial assembly of V, D, and J domains could be repeated *in vitro*.

There is also a plethora of methods for the generation of an additional variety through the introduction of synthetic sequences. These mostly include randomized sequences, which largely increase the diversity in the region of the antigen contact site. Completely synthetic gene libraries have been generated using randomized CDR regions, but much care has to be taken to avoid that the possible sequence space (i.e. the total number of possible sequence combinations) does exceed the maximum number of clones which can physically be generated. This limitation results from the observation that many random sequences impede antibody production or folding, or do not provide sufficient rigidity to structurally maintain a high affinity binding site. Even when avoiding cysteins while creating randomized CDR variants, the 19 remaining amino acids provide about 10^9 different sequences if only seven positions are randomized. When randomizing more positions, it is obvious that the transformation efficiency of microorganisms becomes a limiting factor. Consequently, after initial failures, libraries using careful and limited randomization have proven to be useful.

30.4.2.2 Selection Systems for Recombinant Antibodies. After a recombinant repertoire of antibody genes has been created, the next step requires the selection of a single antibody out of these huge gene libraries. Conventional selection systems, requiring individual characterization of every clone to identify a hit, are not anymore applicable for the library sizes of "universal" antibody gene repertoires. Despite selection from blots obtained from arrays of gridded clones have been used to select binders from smaller repertoires (with less than a million members), all larger libraries require another selection principle. They are done in *Escherichia coli* or completely *in vitro*, and rely on physical linkage of the protein to its encoding gene. The *in vitro* selection systems, in contrast to transgenic mice, do not require a complete immunoglobin, but instead use the antigen-binding fragment, generally either in the form of a single chain Fv fragment (scFv) or in the form of a Fab fragment (given below and in Fig. 30.2).

30.4.2.2.1 Cellular Display. The underlying principle of the *in vitro* selection systems is to imitate our immune system by physically coupling function (antigen-binding domain) and genetic information (antibody coding nucleic acids) into one particle (Fig. 30.7)—very much like the immune system does with the IgM-presenting B cells. For *in vitro* selections, such particles can be bacteria or yeast cells, with the antibody fragments anchored to the cell surface, while the encoding gene is carried on a plasmid inside. Selection can be achieved by affinity enrichment of the cells on antigen, or in a Fluorescence Activated Cell Sorter (FACS), after labeling with fluorescently labeled antigen.

30.4.2.2.2 Ribosomal/Molecular Display. The most complex libraries, however, to date use the expression of antibody fragments on much smaller particles: either the surface of filamentous phage (M13) or directly linked to their mRNA.

Ribosomal/molecular display utilizes *in vitro* transcription/translation systems for the generation of antibody fragments from PCR amplified gene fragments. These antibody fragments, after completing their synthesis, keep being linked to their encoding mRNA. This is achieved by either the lack of a stop codon preventing the ribosome from leaving the mRNA/antibody complex and thus keeping them together, or a chemical linker (puromycin) between the mRNA and the freshly synthesized polypeptide chain of the antibody fragment. The advantage that library size is not limited by transfection efficiency of bacteria is however, countered by the low efficiency of antibody folding in the cytoplasmic extracts

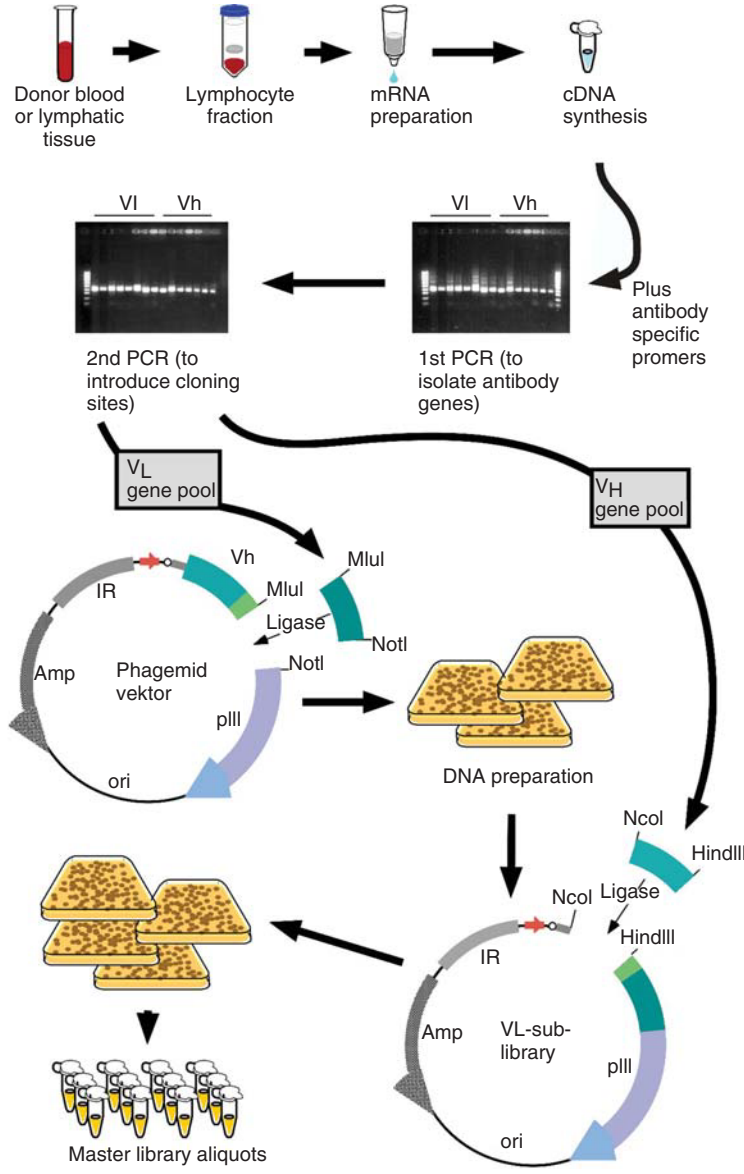

Figure 30.6. Experimental flowchart for the production of an antibody genetic library for phage display. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

used for *in vitro* transcription/translation. For this reason, antibody selections from large "universal" libraries by ribosomal/molecular display remain difficult.

30.4.2.2.3 Phage Display. Phage display has developed into the most robust and thus most widely employed *in vitro* antibody selection system in the past 18 years. Through the combination of the peptide display principle demonstrated by George P. Smith in 1985 with the possibility of production of antibody fragments in the PS of *E. coli*, a method was created for the *in vitro* selection of antibody fragments by their binding characteristics (Fig. 30.8).

Phage display is based on the fusion of scFv or Fab fragments with a surface protein, normally pIII (minor coat protein, gene III product, g3p) of the filamentous phage M13. Fusions with pVIII have not really proven to be practical. As a result of this fusion, the antibody fragment is exposed on the outside of the virion. In a step similar to affinity chromatography, called "*panning*," specific antibody gene-containing particles are selected from a mixture of more than 10^9 different phages by their binding capability under biochemical conditions that can be completely controlled. After elution from the antigen, the enriched

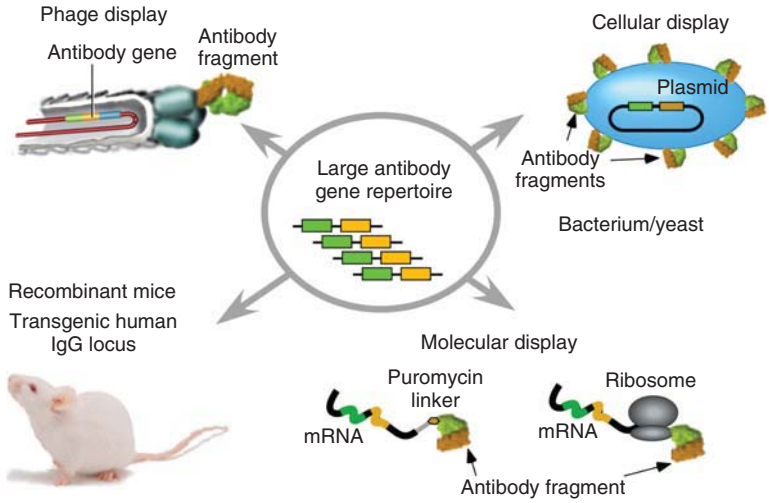

Figure 30.7. Recombinant selection systems for antibodies from gene repertoires. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

phage is used to re-infect *E. coli* cells and thus can be multiplied and propagated, leading to an immortal monoclonal cell line producing the encoded antibody fragment. It is important to the understanding of the potential, but also the possible experimental problems of phage display, to realize that here the molecular interactions of single, individual protein molecules are utilized for selection. Therefore, it is of paramount importance to decrease the unspecific binding to avoid unspecific enrichment. Further, it has been observed that the affinity of the best isolated antibody is proportional to the diversity of the initial library. Phage display has matured to a method nowadays that allows us to obtain human antibody fragments for virtually any antigen.

Furthermore, phage display can be employed for humanizing monoclonal mouse antibodies. For this purpose the genes of a Fv or Fab fragment to be humanized are cloned in a phage selection vector and expressed as a fusion protein on the phage surface. The gene fragment of the light and heavy chains, respectively, are then sequentially substituted by a library of human antibody genes (chain shuffling, see above), followed by re-selection on the antigen. Through the introduction of mutations into CDRs or the entire variable regions, followed by reselection using phage display, the affinity of an antibody fragment for an antigen can be increased by orders of magnitude (affinity maturation).

30.5 PRODUCTION OF RECOMBINANT ANTIBODIES

Recombinant antibodies, mainly in the form of antigen-binding fragments are usually initially selected and characterized in *E. coli* (see above). *E. coli*, however, only has a limited suitability for the production of recombinant antibodies. Small functional fragments of immunoglobins can easily be produced in *E. coli*, whereas production of complete IgG molecules has only been achieved in rare cases. The reason for this is the complexity of the molecule (four chains, many intra-/ intermolecular disulfide bridges) and the folding pathway involved, which is available in mammalian cells, but not in *E. coli*. A secretion into the periplasm is therefore essential for domain folding. This limits the overall yield to only a small fraction of the cytoplasmic synthesis capacity of the bacterium. *In vitro* re-folding methods have been tried, but they suffer from low yields of functional molecules.

Due to the presence of an outer membrane, the production of antibodies in gram-negative bacteria requires a laborious processing by partial lysis, in order to obtain the periplasmatic extracts.

The optimal conditions for folding and glycosylation are only provided by the cells of the mammalian immune system, which are responsible for antibody production in our bodies. For example, in order for the antibody to bind the complementary component C1q or the cell surface receptor Fc receptor (FcR), a correct glycosylation of Asn297 of the CH2 region is necessary. If however only the antigen binding without Fc effector functions is required, it is easier to produce the scFv, dsFv (disulphide-stabilized Fv), or Fab fragments in yeast or bacteria. The production in transgenic animals is only then recommended if a large number of correctly glycosylated antibodies are required. Table 30.1 describes production systems for recombinant antibodies and their fragments.

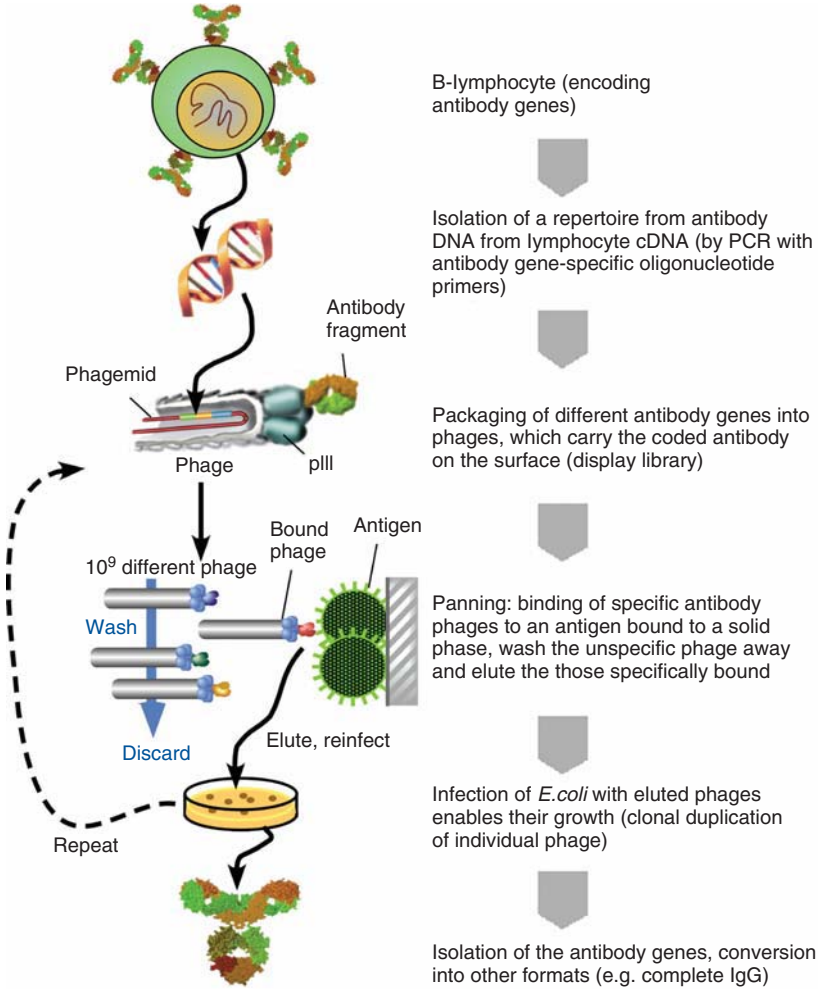

Figure 30.8. Experimental flowchart of the selection of an antibody fragment using phage display. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

30.6 RECOMBINANT ANTIBODY VARIANTS

Numerous modifications of the constant domains of complete IgG molecules have been carried out. By changing the isotype (exchange of the C domains) the type of interaction with the immune system is affected. After identification of binding sites on the Fc fragment cellular receptors, it is possible to modulate the binding characteristics of IgG antibodies via specific mutations of amino acids that code for different receptors. This can lead to improved pharmacokinetic characteristics. Particular influence on therapeutic efficacy is attributed to the glycosylation pattern of the antibodies. Here, by using either selected cell lines with improved glycosylation or recombinant cells carrying a genetically changed repertoire of sugar processing enzymes, glycosylation can be optimized upon production, and nowadays even achieved in non-mammalian cells, like yeast.

Many modifications, however, are done on the antigen-binding site, leading to a multitude of different variants with very different biochemical and pharmacokinetic properties, which are described in the following section.

Even if the antigen-binding characteristics of a monoclonal antibody in relation to its specificity and affinity appear ideal, its therapeutic use can be limited by its isotype. The different isotypes are defined through the structure of the constant domain and affect the type of the effector molecule, which is activated after antigen binding. Many stem cells exhibit receptors for the Fc fraction of an immunoglobin and therefore induce an antigen-independent background binding.

In applications which require the infiltration of an antibody in specific cells or the localization of an antigen, for example, tumor imaging, it can be an advantage to reduce the size of an antibody through removing domains from or even completely deleting the Fc fragment, respectively.

Antibodies too small to be retained by the filtration limit of the kidney (approximately 60 kDa), suffer a very rapid clearance from the plasma. This only may be of advantage if rapid clearance is beneficial, for example, in case of some radionuclide labeled antibodies used for imaging.

30.6.1 Fab Fragments

In contrast to the normal (bivalent) IgG, Fab fragments are monovalent molecules. This results in a reduction in their apparent binding affinity compared with the complete antibody if the antigen is present in several copies close to each other. Fab fragments no longer have the ability to form a precipitate with antigens. In solution they are as stable as the complete IgG molecule, since their protein chains are linked via a disulphide bridge. When produced in *E. coli*, the necessity for the synthesis of two different chains and their association in the periplasm means that the yield is decreased in comparison to single proteins.

30.6.2 Single Chain Antibody Fragments (scFv)

The Fv fragment of an antibody consists of the variable domains of the heavy (V_H) and light (V_L) chain. It constitutes the smallest entity of a human immunoglobin, which includes a complete antigen-binding site. Due to the often relatively low affinities of their variable domains to each other, Fv fragments are rarely successfully produced in *E. coli*. Additional stabilization elements are necessary in order to prevent the dissociation of both subunits of the Fv fragment.

One possibility to kinetically stabilize Fv fragments is to attach their V_H and V_L domains with the help of a short peptide to create so-called scFv or sFv (Figs 30.2 and 30.6). The peptide linker has to bridge the distance from 3.2–4.3 nm in order to allow the correct steric arrangement of both domains. Therefore flexible, hydrophilic 15–20 amino acid long spacer peptides are used, typically linking the carboxyl-terminal end of V_H with the amino-terminal end of the V_L domain. The frequently used $(G_4S)_3$ linker has been especially proved through its protease resistance and its large conformational flexibility.

ScFv fragments (26 kDa) usually have an antigen-binding activity comparable to the Fab fragment (50 kDa) of the same antibody. Compared to Fv or Fab fragments, the construction of a single scFv gene strongly simplifies the production and phage display of recombinant antibodies. If the expressed protein domains exist on a polypeptide chain, the association of the V_H and V_L domains requires no further biomolecular reaction, but just an intramolecular rearrangement. Here the concentration of both domains in the previous reaction space is high, their association to the Fv module is favored, so the scFv fragments are kinetically stabilized. A disadvantage of this format, however, is that labile scFv molecules at high concentrations tend to form aggregates. A low affinity of the variable domains of a scFv module for each other leads to their temporary dissociation, after which the variable domains of a scFv fragment can associate with one of the others. This results in the formation of dimers, oligomers, and aggregates. The rate of dissociation depends on the length of the linkers as well as other external factors and the germ line origin of the V region sequence.

30.6.3 Single Chain Fab Fragments (scFab)

Recently it has been shown that the introduction of a polypeptide linker between the Fd and LC chains of an antibody can have beneficial effects for production of Fab fragments. This strategy combines the advantages of Fab (additional constant domains improve stability and provide detection by routine secondary antibody reagents in research) and scFv (better *E. coli* production). Particularly helpful to improve the yields was the elimination of the disulfide bond between Fd and V_L.

30.6.4 Disulfide-Stabilized Fv Fragments (dsFv)

An alternative approach to the stabilization of Fv fragments lies in the introduction of mutations in the scaffolding regions of both variable domains, which lead to the formation of a covalent linkage between the two contact surfaces. Structural analysis has identified pairs of amino acids in the complementary framework regions of the V_H and V_L domains, which, when mutated to cysteine, are positioned at exactly the right distance from each other for the formation of disulfide bridges. These dsFv fragments usually exhibit similar, antigen-binding activity than their homologous scFv fragments. They show improved stability against heat, denaturing agents and proteases. Due to the direct covalent linkage between the contact surfaces of their variable regions they also tend not to aggregate at high concentrations. Some dsFv fragments have been reported to more stable in blood serum than their homologous scFv fragments, which seems however not to be a general advantage, since other scFv fragments with already extremely good stability have been described as well.

30.6.5 V_H and Camel Antibodies

Many experiments have been carried out to minimize further the antigen-binding region of an immunoglobin. It has been attempted to separately express the V_H domains as the smallest functional entity of an antibody. However, this caused a lack of interaction with the corresponding V_L domain and therefore the exposure of the hydrophobic contact surfaces, which in turn lead to reduced solubility and stability. A loophole appeared here for the expression of

V_H domains of immunoglobins from camels and their relatives, since a fraction of their immunoglobulins are naturally formed from the heavy chains only. The improved solubility of these antibodies arise from substitution of amino acids on the surfaces which would normally be masked by the variable region of a light chain. Through the absence of the V_L domains, the complexity of this antibody repertoire is reduced. This is compensated with a CDR3 region longer and more heterologous than in human antibodies. So-called *single domain* V_H antibodies are typically isolated from immunized camels and llamas. S*ingle domain* V_H antibody gene libraries derived from human genes are successfully used as well, utilizing the lessons learned from camels.

30.6.6 Antibodies with New Functions

For many therapeutic *in vivo* applications, especially, for example, against tumor associated antigens, the antibody binding alone is often not sufficient to achieve a therapeutic effect. After the antigen binding, further steps are necessary for a successful destruction of the tumor tissue. For this reason, many hopes are aimed at the development of antibodies carrying an additional effector element. The antibody fragment mediates the specific binding to the target cell, whereas the heterologous part assumes the desired effector function. For example, for immune scintigraphy, antibody-bound radio nuclides are used. Through their decay, nuclides reveal the exact position of the tumor-bound antibody. The fusion of an antibody fragment with a toxin results in a specifically binding cell toxin. Cytokines, growth factors such as interleukin-2 (IL-2), interleukin-12(IL-12), and granulocyte/macrophage colony-stimulating factor (GM-CSF) as well as liposomes, viruses, or finally entire effector cells (T bodies) have been implemented as further fusion partners. Alternatively, an enzyme fused to the antibody can turn a nontoxic precursor molecule into a toxic substance, thus killing the adjacent tumor cell. This concept is named antibody-directed enzyme prodrug therapy (ADEPT).

30.6.7 Oligovalent and Bispecific Antibodies

Natural immunoglobins, especially the *ten-armed* IgM antibody have a significantly higher apparent affinity to antigens available in several copies close to each other comparison to the respective monovalent Fab fragments. This is essentially a result of reduced dissociation of the antibody, where multiple interactions with two or more antigens, for example, from the cell surface, allow the re-binding of an initially dissociated Fv module, without the entire molecule leaving the surface. This effect is called *avidity*. For recombinant antibody variants, an analogous increase of avidity can be achieved when Fab or scFv fragments are combined to form dimers, trimers, or large complexes.

The production of bivalent recombinant $F(ab')_2$ fragments was initially done by oxidation of the reduced cysteine of their *hinge* region. In addition, monovalent Fab fragments were expressed in *E. coli*, purified and subsequently combined to homodimers by oxidation. Meanwhile, the direct production of functional bivalent $F(ab')_2$ fragments in bacteria was also successful. Unpaired cysteine residues were found to be useful for the dimerization of Fv or scFv fragments *in vitro* or *in vivo*.

An elegant method for the production of multivalent antibody fragments is the reduction of the linker length between the variable domains of a scFv fragment, which significantly influences the molecular architecture of the resulting construct. If this peptide bond is reduced to less than 8–12 amino acids, for sterical reasons both of the variable domains of a scFc polypeptide chain are no longer able to associate to an Fv fragment. Instead, the complementary domains of two scFv molecules come together and form a homodimer, a so-called *diabody* (50 kDa) with two antigen-binding sites. If the peptide linker is decreased even further in length, to less than three amino acids, or if the variable regions are fused directly together, the scFv fragments usually associate as *triabodies* (75 kDa) or also *tetrabodies* (100 kDa). As well as the length and the composition of the linker, the primary structure and orientation of the variable domains of the scFv molecule influence the exact molecular architecture of the scFv construct.

A second antibody with a different specificity can also serve as an antibody fusion partner. In the last few years such bispecific antibodies have gained particular importance in the diagnostics and therapy of malignant tumors, as they have the ability to effectively bring two molecules or cells together. This concept is now proven by the recent approval of the first bispecific antibody for clinical use (catumaxomab for the treatment ascites). Here, cells from the immune system are introduced into the tumor, compensating the lack of recognition of a tumor cell by the immune system.

Typically, tumor-specific antibodies are bound to a second antibody fragment, which can activate the immune system. At the same time, surface molecules such as CD3 or CD28 are used as target molecules for cytotoxic T cells, CD16 for natural killer (NK) cells, or CD64 for macrophage. In addition, bispecific antibodies have been described which can introduce viruses into tumor cells for gene therapy; here, one of the antibodies binds to the virus and the other to a receptor on the surface of the target cell. An alternative use of bispecific antibodies is the simultaneous binding of two different, but adjacent, surface epitopes of the same target molecule. These constructs have a significant advantage of avidity and specificity over monospecific antibodies.

In order to produce bispecific antibodies, two IgG molecules were initially joined together via a simple chemical coupling. However, such complexes, at around 300 kDa, are too large to ensure effective tumor penetration. Their connected Fc parts can also bind to other somatic cells with the corresponding receptors and induce a relatively high background effect. The production of bispecific immunoglobins via the fusion, two different hybridomal cell lines that leads to hybrid–hybridoma (or quadroma) cells has also been attempted. However, through the random combination of different heavy and light immunoglobin chains, 90% of the immunoglobin variants are wrongly assembled immunoglobins, which are difficult to remove in subsequent purification. To avoid this, different bispecific recombinant antibody constructs with molecular masses of between 60 and 120 kDa have been developed, that on the one hand are small enough to enable the rapid penetration of a tumor, and on the other hand they are large enough to prevent their filtration through the kidneys, and finally they accumulate effectively and specifically in the target tissue. In contrast to immunoglobins produced with hybridoma technology, recombinant antibodies can be modified and combined with other genes or gene fragments with little effort. The recombinant production of bispecific antibodies also avoids the non-functional by-products of quadromas.

A large range of recombinant coupling strategies have been developed, that are usually either based on the introduction of a dimerizing domain at the end of the C-terminal of two antibody fragments or on the direct fusion of the genes of both partners. One of these such methods for the production of bispecific antibodies is the direct fusion of two scFv fragments forming so-called tandem antibodies.

The diabody design was also employed for the construction of bispecific antibody fragments. The genetic fusion of the variable domains of two antibodies A and B via the formation of two crossover polypeptide chains (V_HA-V_LB and V_HB-V_LA) results in a significant number of the desired bispecific molecules in addition to homodimers. The fraction of functional heterodimers compared to the inactive homodimers is increased significantly via the introduction of *knob-into-hole* mutations at the V_H/V_L contact surfaces. Diabodies have already been described, which couple colon carcinoma cells to serum immunoglobins, whereby inducing phagocytosis, the complement cascade as well as a T-cell response to tumor cells.

As a further example, C1q targeted bispecific diabodies activate the complement cascade against the target cell. In addition, bispecific antibodies have been produced against surface proteins of immune effector cells, such as CD3 for T cells, and different surface molecules, which are overexpressed in specific tumor cells, such as CEA, Ep-CAM, Her-2, or CD19.

A constructional dependent disadvantage of the diabody format is that the contact surfaces of the variable domains are not covalently linked. The lack of constant domains can result in the typical dissociation of scFv fragments' variable domains with subsequent formation of aggregates. This problem of stability has been partially solved through the expression of single chain diabodies (sc diabodies), tetravalent tandem diabodies, knob-into-hole diabodies, and also through the formation of disulfide stabilized diabodies (ds diabodies).

In an alternative approach to the production of bivalent and bispecific molecules, the interaction of constant domains of the immunoglobins is exploited. For example, bivalent *minibodies* are generated by the fusion of a scFv fragment with the C_H3 domain of an IgG, which serves as a dimerization domain. The production of bivalent antibodies is also achieved through the fusion of a scFv fragment with the constant domains of an IgG heavy chain. These strategies are admittedly not very suitable for producing bispecific heterodimers due to the symmetrical formation of the product. Nevertheless, the dimerization of bispecific single chain diabodies through their fusion with the C_H3 domain or the entire Fc part of an antibody has been successful. Bispecific minibodies have been produced through the fusion of a scFv fragment with the constant domain of the light chain, as well as the fusion of the other scFv fragment with the constant C_H1 domain of the heavy chain. The association of both of the different constant domains then resulted in the *in vivo* formation of bispecific heterodimers. In the previously described cases, the antigen bound Fv fragments, analogous to native IgGs, were always fused with the N-terminal of the constant domains. Alternatively, scFv fragments can also be fused with the C-terminal of C_H1-, C_L-, C_H3-domains or with hinge regions, to generate such Fab scFv or Fab $(scFv)_2$ constructs with two or three antigen-binding sites. Fusion with bispecific $(scFv)_4-IgG$ molecules, $(Fab\ scFv)_2$ or $IgG-(scFv)_2$ fusion proteins generate constructs with four antigen-binding sites.

Another set of designs rely on the use of heterologous peptides or proteins as oligomerization domains. The short leucine zipper motif of the two transcription factors *fos* and *jun* are useful here. These oligopeptide motifs from transcription factors form secondary structures which tend to dimerize by the formation of *coiled coils*. This type of peptide could be used for the production of bivalent and bispecific antibodies. Other helical structures have been used as tetramerization domains for the formation of tetravalent antibody molecules according to the same principle. Following formation of four-helix bundles, they dimerize and are used for the production of bivalent and bispecific scFv antibody constructs with two or four antibody-binding sites, respectively. Larger multivalent multimer scFv fusion proteins have been obtained through the use of protein domains such as Streptavidin, the tetramerization domain of the p53

protein, or the octamerization domain of the C4 binding protein.

30.7 APPLICATIONS OF RECOMBINANT ANTIBODIES

At present, about 24 antibodies are approved for clinical use, on a fast growing list. Over 500 antibody-based products are presently being developed. Because about a decade is needed to develop and approve therapeutics, the antibodies approved today reflect the state of the art of *antibody engineering* from 10 years ago. From 1988 until the middle of the 1990s, recombinant humanization or chimerization was used as the method of choice, while by now, recombinantly produced complete human antibodies from transgenic mice and phage display enter development in increasing numbers. An overview of approved antibody products is given in Table 30.2.

The next generation of antibody therapeutics will include more examples using the possibilities of the bifunctionality/bispecificity approach or fusion proteins when compared to the currently approved therapeutics, most of which consist of IgG molecules made in CHO cells.

The methods developed for the *in vitro* generation of human antibodies have also opened up new opportunities for areas where a human origin is not essential, but which benefit from the advantage of the recombinant process. Despite commercial contractors of recombinant antibody production are usually focused on obtaining therapeutic antibodies, a growing number of academic initiatives now employ *in vitro* antibody selection to create the large numbers of antibodies needed for future proteomic and systems biology approaches. Three cases where these recombinant technologies are of particular advantage, or even offer the only way to succeed, are described below.

30.7.1 Recombinant Antibodies can be Selected to Avoid Cross Reactivity

The advantage of recombinant production of antibodies is that it allows to select binders to toxic substances or with specificities, which cannot be achieved with immunization. For example, highly specific antibodies against the heroin metabolite 6-mono-acetyl-morphine (6-MAM) could be obtained from a phage display library, which in contrast to the previously available mouse antibodies, can distinguish between this indicator of drug abuse and other morphines (e.g. those contained in cough syrup). This was achieved by adding the unwanted antigens as competitors during panning. The use of very complex mixtures (even whole cell extracts) as competitors has been successfully demonstrated, for example, to avoid the selection of antibodies to host cell proteins on the surface of membranous virus particles.

TABLE 30.2. Clinically Approved Antibody Products (In Chronological Order of Approval as of 2009)

Name (Product/Antibody)	Origin/Type	Indication	Year of Approval
Orthoclone®(Muromonab-CD3)	Mouse hybridoma	Graft rejection	1986
ReoPro® (Abciximab)	Chimeric, Fab	Platelet aggregation	1994/-1997
Humaspect® (Votumumab)	Human, radiolabelled	Colon cancer *in vivo* diagnostics	1996
Rituxan® (Rituximab)	Chimeric	Non-Hodgkin's lymphoma	1997
Zenapax® (Daclizumab)	Humanized	Graft rejection	1997
Simulect® (Basiliximab)	Chimeric	Graft rejection	1998
Synagis® (Palivizumab)	Humanized	Respiratory syncytial virus	1998
Remicade® (Infliximab)	Chimeric	Rheumatoid Arthritis, Morbus Crohn	1998/–1999
Herceptin® (Trastuzumab)	Humanized	Breast cancer	1998
Mylotarg™(Gemtuzumab ozogamicin)	Humanized immunotoxin	Leukemia	2000
Campath® (Alemtuzumab)	Humanized	Leukemia	2001
Humira® (Adalimumab)	Human	Rheumatoide arthritis	2002
Xolair® (Omalizumab)	Humanized	Asthma	2003
Bexxar®(Tositumomab-I131)	Maus, radioactives conjugate	Non-Hodgkin lymphoma	2003
Raptiva® (Efalizumab)	Humanized	Psoriasis	2003
Erbitux® (Cetuximab)	Chimeric	Colon cancer	2004
Avastin® (Bevacizumab)	Humanized	Colon cancer	2004
Tysabri® (Natalizumab)	Humanized	Multiple sclerosis	2004
Lucentis® (Ranibizumab)	Humanized, fab	Macular degeneration	2006
Vectibix® (Panitumumab)	Human	Colon cancer	2006
Soliris® (Eculizumab)	Humanized	Paroxysmal nocturnal hämoglobinurie (PNH)	2007
Cimzia® (Certolizumab pegol)	PEGylated humanized fab	Morbus Crohn, Rheumatoid Arthritis	2008
Simponi® (Golimumab)	Human	Rheumatoid arthritis	2009
Removab® (Catumaxomab)	Mouse/rat bispecific	Ascites	2009

30.7.2 Intracellular Antibodies

In many cases, the deactivation of the antigens inside the cell has been attempted by the expression of antibody fragments in the cytoplasm. This has frequently failed due to the inadequate folding of the antibody (intracellular antibody, intrabody) in the reduced environment of the cytoplasm. Success could be achieved if the natural intracellular IgG production pathway was used. Antibodies with signal sequences as well as retention signals for the endoplasmic reticulum (peptide sequence: KDEL) have been shown to knock down molecules form the secretory/membrane pathway. This offers a novel approach for functional genomics, in particular, since potentially useful antibodies are provided by research initiatives in increasing numbers. Here, a knock down phenotype of an unknown open reading frame can be observed requiring just one subcloning of the selected scFv into a respective eukaryotic vector and transfection to a suitable system.

30.7.3 Recombinant Antibodies for Proteomics and Interactomics

After sequencing of the human genome, there is an enormous demand for binding molecules for the further functional analysis of the new genes. Here, antibodies are the tools of choice for the biochemical and cell biological characterization of the gene products and their functions (immunoblots, immunohistology, FACS, purification, pull-downs, etc.). The use of hundreds of different antibodies in a *protein microarray* (proteome chip) is already being intensively evaluated. Many proteins have splice form polymers or complexes. The availability of binders able to discriminate between these different forms is essential for the understanding of gene function, and can only be assessed on the post-translational/protein level. To systematically study the interactions of proteins (*interactomics*), antibodies are the agents of choice for the enrichment of complexes from various cells and tissues prior to the proteomic analysis by 2D-gels or mass spectrometry. Therefore, the demand for antibodies is rapidly increasing beyond the supposed number of human 22,000 genes. Without recombinant technology the production of these antibodies would require around one million animals! The effort of producing an antibody against every gene product and their relevant variants can therefore be best accomplished with a highly parallel *in vitro* selection approach, such as phage display.

30.8 OUTLOOK

Despite all of the recent success stories of recombinant human antibodies, they do not mark the end of the development, but just the start. As we understand more and more of the complex molecular interactions between immune cells or in cancer tissues, and in expectation of a significant speed-up of knowledge gain from the "-omics" and systems biology approaches, we can endeavor to expand the design limits of a future antibody drug. Fascinating concepts are under evaluation in hundreds of labs. There are so many ideas—and so many parameters affecting therapeutic efficiency to be learned about—that the development of recombinant human antibody therapeutics will not reach saturation for any foreseeable time. Further, major technology patents which blocked some developments in the past are expired or close to do so. Given that only the first generation of antibody drugs just has been approved in significant numbers, given the availability of recombinant human antibodies and the vast number of targets in the developer's pipelines plus the advent of completely novel therapeutic strategies using antibody fusion proteins, therapeutic antibodies look forward to a golden future.

ANTIFOAMS AND PLURONIC POLYOLS, CELL PROTECTION

David W. Murhammer
University of Iowa, Iowa City, Iowa

31.1 INTRODUCTION

Animal cell cultures are widely used in the production of some products (e.g. complex recombinant DNA proteins) because of the inability of other expression systems (e.g. bacteria) to properly perform posttranslational modifications (e.g. glycosylation and proper folding). Unfortunately, animal cells lack a protective cell wall and thus are subject to damage from sparging and other environmental stresses. In large-scale bioreactors, however, aerating the cultures through direct sparging is the most practical method of supplying oxygen to the culture medium. Therefore, in order to realize the full potential of using animal cells to produce recombinant DNA proteins on an industrial scale, there is a critical need for large-scale sparged bioreactors capable of supporting animal cell growth. Currently, the generally accepted approach to solving this problem is to supplement the medium with a protective agent, such as the commercially available surfactant Pluronic F-68.

31.2 PROPERTIES OF PLURONIC POLYOLS

A wide range of Pluronic polyols are available that are capable of protecting animal cells in suspension cultures from the adverse effects of sparging. Of these, Pluronic F-68 is by far the most widely used. Properties of Pluronic polyols that are relevant to the selection of a protective agent are discussed in this section.

31.2.1 Synthesis and Structure

Pluronic polyols, commercially available from the BASF Corporation (Wyandotte, Mich.), are block copolymer nonionic surfactants consisting of a center block of poly(oxypropylene) (hydrophobe) and end blocks of poly(oxyethylene) (hydrophile). They are synthesized by the two-step process shown in Fig. 31.1 (1). In the first step, a poly(oxypropylene) block is synthesized by the addition of propylene oxide to propylene glycol. The poly(oxyethylene) blocks are then added to both ends by reacting the resulting poly(oxypropylene) with ethylene oxide. The oxyalkylation steps are carried out in the presence of an alkaline catalyst (e.g. potassium hydroxide) that is subsequently neutralized and removed from the final product. The properties of the Pluronic polyols are altered by varying the relative sizes of the poly(oxypropylene) and poly(oxyethylene) blocks (note that the sizes of the two poly(oxyethylene) blocks are statistically identical). The properties of a variety of Pluronic polyols are given in Table 31.1.

31.2.2 Nomenclature

The letters L, P, and F in the Pluronic polyol nomenclauture represent liquid, paste, and flake, respectively (Table 31.1) (1). The first two digits of the three-digit polyol number or the first digit of a two-digit polyol number are indicative of the hydrophobe [poly(oxypropylene)] molecular weight; for example, 6, 8, and 12 represent average hydrophobe

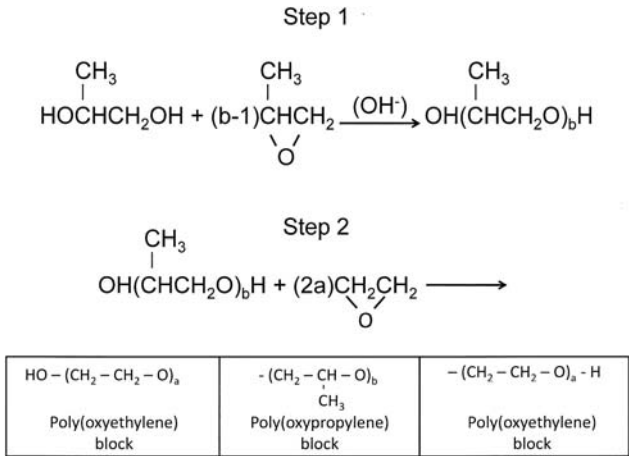

Figure 31.1. Pluronic polyol synthesis.

molecular weights of 1750, 2250, and 4000, respectively. The last digit in the polyol number represents approximately 1/10th the percentage of hydrophile [poly(oxyethylene)] in the molecule. For example, Pluronic F-68, a flake (i.e. a white powder), has a hydrophobe molecular weight of approximately 1750, and contains approximately 80% hydrophile.

31.2.3 Impurities

Commercial-grade Pluronic polyols have been demonstrated to contain low molecular weight impurities, including aldehydes, formic acid, and acetic acid (3,4). In addition, peroxide derivatives of the Pluronic polyols can be formed during steam sterilization. The formation of the peroxide derivatives can be prevented by filter sterilizing the Pluronic polyol solutions instead of using steam sterilization. The low molecular weight impurities can be removed from aqueous solutions of Pluronic polyols by silicagel column absorption (3).

31.2.4 Hydrophilic–Lipophilic Balance

The hydrophilic–lipophilic balance (HLB) is an empirical measure of the emulsifying capabilities of surfactant molecules (5). Lower values of the HLB are representative of molecules with a higher degree of hydrophobicity. In general, molecules with high HLBs tend to be water soluble, and those with low HLBs tend to be oil soluble. The HLBs given in Table 31.1 are given in terms of ranges to indicate that the effective HLB of the Pluronic polyols varies with the emulsion system (6). From the results given in Table 31.1, it is clear that Pluronic polyols with low HLBs are unsuitable for use as protective agents because medium supplemented with 0.2% (w/v) of these Pluronic polyols either lysed *Spodoptera frugiperda* Sf-9 cells or significantly inhibited their growth in the absence of sparging, specifically in 50-mL spinner flasks oxygenation by surface diffusion (2). It was further demonstrated that at higher HLB values, Sf-9 cell growth was not inhibited in the absence of sparging and that protection from the adverse effects of sparging was provided in airlift bioreactor studies. Thus, the key to finding a Pluronic polyol that served as a protective agent for the Sf-9 cells in a sparged environment corresponded to finding one that did not inhibit cell growth in the absence of sparging. It should be noted that the results may be different with other cell lines.

31.2.5 Foaming Characteristics

Excessive foaming is generally undesirable in animal cell cultures. Therefore, if Pluronic polyols that exhibit

unacceptable levels of foaming are used, either an antifoam should be added to the medium (2) or an alternative Pluronic polyol should be used (6). Of the Pluronic polyols given in Table 31.1, F-68, P-105, and P-65 are the most active foam generators (6) and other Pluronic polyols could be used if foaming is problematic (e.g. L-35 or F-127).

31.2.6 Surface Tension

Because the Pluronic polyols are surfactants, it would be expected that they would reduce the air–water static surface tension. Indeed, according to BASF literature (6), the addition of 0.1% (w/v) Pluronic polyols to aqueous solutions reduces the static surface tension from 72 dyne/cm for pure water to a range of 22 (L-121) to 52 dyne/cm (F-38). In addition, the static surface tension of a 0.1% (w/v) aqueous solution of Pluronic F-68 is 50 dyne/cm. Michaels *et al*. (7), however, have given a convincing argument that the dynamic surface tension is a more suitable measure for sparged systems since interfacial properties are sensitive to the physical state of the interface. They found that the reduced dynamic surface tension afforded by Pluronic F-68 addition correlated well with reduced cell–bubble interactions and thereby provided cell protection.

31.2.7 Oxygen Transport

Zhang *et al*. (8) found that the addition of Pluronic F-68 to growth medium had minimal effect on K_La values for large bubbles (~5 mm diameter), but significantly enhanced K_La for intermediate (~1 mm diameter) and micron-sized (~100 μm diameter) bubbles. It is generally accepted that surfactants can affect oxygen transport from bubbles in two different ways: affecting the diffusional resistance and affecting the interfacial area, K_L and a, respectively. The addition of surfactants usually results in decreased K_L (9) and in increased a (10). Consistent with this expected behavior, Zhang *et al*. (8) found that there was a significant reduction in the Sauter mean bubble size for the intermediate and micron-sized bubbles, thereby resulting in an increased a. Pluronic F-68 addition, however, had minimal effect on the size of the large bubbles. No measurements directly related to the K_L term were taken in this study, although the results clearly demonstrate that the presence of the Pluronic F-68 resulted in a greater increase in a than decrease in K_L. Recently, Lee and Kim (11) found that K_La increased with increasing Pluronic F-68 concentration up to 0.1% (w/v) and then remained essentially constant as the Pluronic F-68 concentration was increased from 0.1% to 1.0% (w/v). Although no data were provided regarding the effect of Pluronic F-68 concentration on bubble size, previous results from other researchers suggest that a increased (due to decreased bubble size) faster than K_L, with decreasing Pluronic F-68 concentration up to 0.1% (w/v), and that the effect on a and K_L were balanced at higher Pluronic F-68 concentrations.

31.3 PROTECTIVE EFFECTS OF PLURONIC POLYOLS

It has been clearly demonstrated that Pluronic polyols can protect insect and mammalian cells from the adverse effects of sparging. Evidence supporting this protective effect, as well as protection (or lack thereof) from shear and agitation damage, is discussed in this section. Furthermore, the corresponding mechanisms are discussed.

31.3.1 Sparging Damage

In 1968, Kilburn and Webb (12) were the first to report the use of Pluronic polyols to protect animal cells from sparging. Specifically, they found that supplementing the medium with 0.02% (w/v) Pluronic F-68 protected mouse LS cells from the adverse effects of sparging in short-term studies. They did not, however, show any results from long-term tests, such as an entire bioreactor run. No comprehensive studies regarding the use of Pluronic polyols to protect animal cells from the adverse effects of sparging were conducted until the late 1980s, when Handa-Corrigan *et al*. (13,14) and Murhammer and Goochee (2,15,16) demonstrated the ability of Pluronic F-68 to protect mammalian and insect cells. Handa-Corrigan *et al*. (13,14) demonstrated that the survival of a variety of mammalian cells (hybridomas, mouse myeloma [NS1] cells, baby hamster kidney [BHK-21] cells, and human lymphoblastoid [RAJI]) cells in the presence of sparging depends on cell type and bubble size and frequency (i.e. small bubbles and high flow rates are more detrimental). They further demonstrated that the protective effect of Pluronic F-68 was concentration dependent, with 0.1% (w/v) being sufficient to protect cells under the most severe conditions reported. Murhammer and Goochee (15) investigated the protective effect of Pluronic F-68 in both airlift and sparged agitated bioreactors. It was found that supplementing the medium with 0.1% (w/v) Pluronic F-68 resulted in a major protective effect and that 0.2% (w/v) provided full protection for Sf-9 cells grown in both types of bioreactors. It was also demonstrated that recombinant protein synthesis (produced after infection of the cells with a recombinant baculovirus) in the airlift bioreactor significantly decreased compared to the unsparged control even after increasing the Pluronic F-68 concentration to 0.5% (w/v). This was hypothesized to result from the increased susceptibility of virally infected cells to lysis in a sparged environment. This decrease in productivity was not due to an inhibitory effect of Pluronic

F-68 since it was found that recombinant protein production was not affected by Pluronic F-68 in the absence of sparging (15). This is in contrast to the results of Palomares *et al*. (17), who found that Pluronic F-68 significantly affects the recombinant protein and baculovirus production of baculovirus-infected insect cells in the absence of sparging.

After the development of conclusive evidence regarding the ability of Pluronic F-68 to protect mammalian and insect cell cultures from the adverse effects of sparging, the research focus in this field shifted to the mechanisms of this protective effect and of cell damage in the absence of protective agents. In regard to bubbles in sparged bioreactors, there are three regions in which cell damage could potentially occur: (i) the bubble formation region at the gas distributor; (ii) the rising bubble region between the gas distributor and medium surface; and (iii) the bursting bubble region at the medium surface. The results of Handa-Corrigan *et al*. (14) and Tramper *et al*. (18) clearly demonstrated that the primary source of cell damage is not in the region of rising bubbles in their bioreactor systems. Specifically, they demonstrated that cell damage decreased as the height of the bioreactors increased. In addition, Michaels *et al*. (19) demonstrated that cell-to-bubble interactions in the bulk of the bioreactor are not responsible for cell damage in studies, in which the headspace above the medium where bubbles can burst was eliminated. Murhammer and Goochee (16) demonstrated that it is possible to have cell damage in the sparger region and that this damage correlates with a high pressure drop across the sparger. In most practical applications (i.e. when the sparger is properly designed), however, significant cell damage occurs only at the medium surface in the bursting bubble region, as first proposed by Handa *et al*. (13). It has also been demonstrated that cells tend to adhere to air–medium interfaces and that fatal damage occurs to these attached cells as the bubbles burst at the medium surface; that is, the energy released by the bursting bubbles results in extensive cell lysis (20–23). Additional details of the mechanisms involved with cell damage in sparged bioreactors are discussed in a review chapter by Wu (24).

Michaels *et al*. (25) suggested that the protective effect of Pluronic polyols could result either from a biological mechanism (i.e. through changes in the cells' ability to resist shear) or from a physical mechanism (i.e. through changes in the medium properties that affect the level of frequency of forces experienced by cells). They concluded that the protective effect of Pluronic F-68 in sparged bioreactors is caused by a physical effect. Consistent with this hypothesis, it was later demonstrated that the protective effect of Pluronic F-68 resulted from its ability to cover the medium–bubble surface and thereby prevent cell adhesion to the bubbles (23,26). Thus, cells are not in the immediate vicinity of bursting bubbles at the medium surface.

It has also been demonstrated that Vero cells grown on microcarriers are damaged in sparged bioreactors (27). It was suggested that the addition of Pluronic F-68 to the medium may be able to protect cells grown on microcarriers from the adverse effects of sparging. It has subsequently been demonstrated, however, that the addition of Pluronic F-68 does not protect animal cells from spaaging damage in microcarrier cultures (28).

Although Pluronic F-68 has become the predominantly used additive to protect insect and mammalian cells from sparging damage, other additives have also demonstrated effectiveness. For example, Murhammer and Goochee (2) demonstrated that many other Pluronic polyols could serve as protective agents (Table 31.1). Furthermore, Chattopadhyay *et al*. (23) and Wu *et al*. (29) have shown that other substances that lower liquid–vapor interfacial tension at a sufficiently rapid rate can protect cells from sparging.

31.3.2 Agitation Damage

Although a few studies have reported that supplementing the medium with Pluronic F-68 can protect attachment-independent cells growing in suspension from agitation damage (30), this is generally not a relevant issue because insect (16) and mammalian (19) cells are commonly tolerant to relatively high agitation rates. For example, it was found that Sf-9 cell damage did not occur unless the agitation rate was high enough to induce bubble incorporation via cavitation or vortexing (16). Furthermore, supplementing the medium with Pluronic F-68 protected the cells from damage caused by bubble incorporation by either of these mechanisms. It is assumed that the corresponding mechanisms of cell damage without Pluronic F-68 and protection by Pluronic F-68 are similar to those reported above for sparged bioreactors.

In spite of the lack of evidence demonstrating that Pluronic F-68 can protect cells from agitation damage, there is some evidence that Pluronic F-68 can make cells more resistant to shear damage. For example, Goldblum *et al*. (31) demonstrated that the addition of Pluronic F-68 (0.2% and 0.3% [w/v]) to the medium protected Sf-9 and *Trichoplusia ni* Tn-368 insect cells from shear damage in viscometer studies in a concentration-dependent manner. In contrast to these results, Michaels *et al*. (25) found that Pluronic F-68 did not make hybridoma (CRL-8018) cells more shear tolerant. These results suggest that the ability of Pluronic F-68 to increase a cell's shear tolerance may be cell line dependent. Direct interaction with the cell (e.g. incorporation of the hydrophobic portion of Pluronic F-68 with the cell membrane) is a possible mechanism through which Pluronic F-68 may increase the shear tolerance of cells. Several lines of evidence are consistent with an interaction of Pluronic F-68 with the cell membrane. First, Pluronic polyols of low HLB values

lyse cells (Table 31.1). Secondly, Pluronic F-68 inhibits the uptake of trypan blue dye that would normally be taken up in the absence of Pluronic F-68 (15). Thirdly, treating sickled erythrocytes with Pluronic F-68 decreases their rigidity (32). Finally, Pluronic F-68 increases the fluidity of hybridoma membranes, which correlates with increased resistance to shear (33).

31.4 APPLICATION

If attachment-independent insect or mammalian cells are to be grown in sparged bioreactors, then it is recommended that the medium be supplemented with a Pluronic polyol. Many commercially available serum-free media already contain Pluronic F-68; therefore, additional supplementation may not be necessary. If supplementation is necessary, then a 10% (w/v) aqueous solution of Pluronic F-68 (obtained from BASF Corp.) can be prepared and filter sterilized. This solution can then be used to supplement the medium at 0.1–0.2% (w/v) Pluronic F-68. Ready-made solutions of Pluronic F-68 are also commercially available (e.g. Invitrogen, Carlsbad, CA; Mediatech, Inc., Herndon, VA; Sigma–Aldrich Company, St. Louis, MO). The resulting medium should first be tested in the absence of sparging (e.g. in spinner or shaker flasks) to detect any potential inhibitory effects. Note that purification of the Pluronic F-68 (as mentioned above) may be necessary to remove inhibitory impurities. The next step is to test the ability of the medium to protect cells in small-scale sparged bioreactors. Success in protecting the cells at this scale is a good indicator of similar success in large-scale sparged bioreactors. The use of Pluronic F-68 allows sparging with micron-sized bubbles that significantly enhance culture oxygenation. If Pluronic F-68 is not successful, then many other Pluronic polyols are available for testing (Table 31.1). Another concern is that Pluronic polyols may interact with the protein of interest and interfere with downstream purification (34). Winzerling *et al*. (35) have demonstrated, however, that recombinant insect transferrin can be purified from Sf-9 cell supernatant containing 0.1% (w/v) Pluronic F-68 by using high metal ion capacity gel chromatography. Finally, it should be noted that surfactants (e.g. Pluronic F-68) in the medium may clog chromatography columns and thus it may be desirable to remove the Pluronic F-68 from the medium, which can be accomplished through dialysis, prior to introducing to the column (36).

BIOMINIATURIZATION OF BIOREACTORS

Michael A. Hanson
Bio-Manufacturing Sciences Group, Pfizer, New York
Govind Rao
Center for Advanced Sensor Technology, University of Maryland Baltimore County, Baltimore, Maryland

32.1 INTRODUCTION

For centuries, microorganisms have played an essential role in producing everyday commodities, such as alcoholic beverages and bread, as well as specialty items like medicines and enzymes. Throughout this time, submerged culturing of cells has emerged as the primary mode of cultivation. As demand for products has increased, so has the size of the vessels in which cells are grown, up to hundreds of thousands of liters (1). It is extremely expensive to execute these large-scale reactions due to the cost of supplies, energy, and equipment. Total costs can be minimized, in part, by making processes as efficient as possible. This is done by carrying out developmental experiments with the following objectives: (i) selection and genetic engineering of production strains, (ii) formulation of appropriate growth media, and (iii) optimization of bioreactor parameters and cultivation strategy (i.e. fed-batch vs perfusion). To achieve these goals, hundreds of development experiments must be carried out. Due to the reasons stated above, it is fairly obvious that experiments cannot be carried out at production scale. Also, since the length of the development timeline is inversely proportional to the number of experiments that can be carried out simultaneously, it is common practice to carry them out at a small scale in a high throughput and highly parallel manner.

Traditionally, strain selection and media development have taken place in flasks on the scale of 50–6000 mL (2). There are several related drawbacks to using standard shake flasks for these purposes. The first is the inability to monitor environmental conditions, most importantly pH and dissolved oxygen (DO) concentration, within flasks. Favorable behavior exhibited by production strains in flasks may not be displayed at production scale because of differences in environmental conditions, resulting in a process hampered by an inefficient, poorly chosen strain (3). Environmental monitoring would ensure strain selection under conditions comparable to the production scale. Similarly, during media development the importance of a specific media component may not be discernable if the productivity of the culture is being impeded by an unsuitable environmental condition, such as oxygen limitation. Without knowing the environmental state in the flask, these outcomes cannot be avoided. Related to these, is that without the ability to monitor environmental conditions, it is impossible to accurately control them. In addition to these monitoring-related shortcomings of flasks, higher throughput can be achieved with the reduced culture volumes afforded by other platforms, such as multiwell plates.

As mentioned previously, the third objective in upstream bioprocess development is to choose a cultivation strategy and optimize bioreactor parameters. Historically, this has occurred in lab scale bioreactors with volumes of up to tens of liters as opposed to smaller scale vessels. This is due to, again, the inability to monitor and control important process parameters in the latter. Lab-scale bioreactors are relatively low throughput in comparison to plates and flasks due to space requirements and various tasks that accompany their

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

use, such as reactor sterilization, calibration of electrodes, and aseptic processing of fluids. Low throughput results in slow process develop-breakment. Ultimately, regardless of the platform used for bioreactor development, it must be able to provide a process solution that can be implemented at production scale.

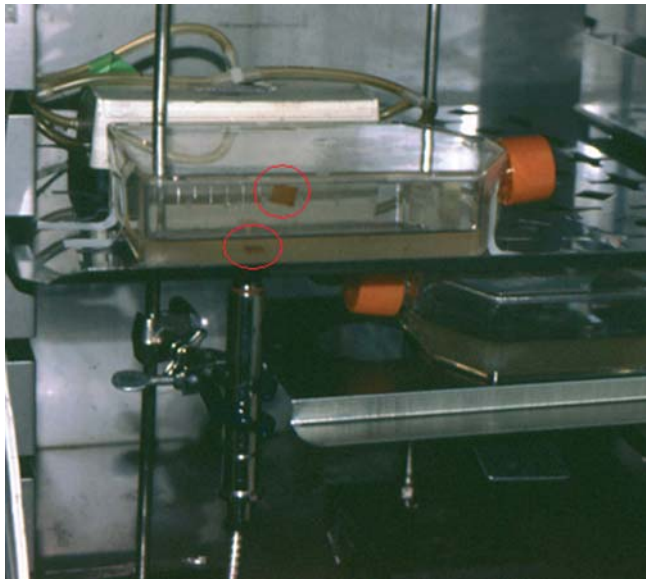
Based on the proceeding discussion on shortcomings in traditional upstream development, it follows that the ideal culturing platform is one where (i) culture volume is small, (ii) the necessary information to compare scales is accessible, (iii) samples should be large enough to enable off-line assaying where needed, and (iv) development scale is able to provide a culture solution that is applicable at the production scale. These industrial needs have resulted in a sudden increase of research in the field of bioreactor miniaturization. Here it must be qualified as to what is meant by *bioreactor*: a culturing vessel that is equipped with sensors to monitor any number of critical process parameters. By definition, standard shake flasks and multiwell plates are excluded unless they have been equipped with monitoring capabilities.

Two key reviews of this field have been carried out recently by Betts and Baganz (4) and Kumar *et al*. (5). The previous review gave an overview of many small-scale technologies and some examples of their usage. The latter emphasized the engineering design and characterization of small-scale bioreactors and the future directions of the field. The current review will describe in detail the practical usage of many small-scale systems. In many situations, data will be presented where small-scale systems were compared to larger traditional systems. The reviewed systems were chosen based on the capabilities to monitor at the small scale or if they were particularly innovative and had at least some engineering characterization carried out. As in the other reviews, a method of mixing was used to organize the miniature bioreactor systems. Here we have used the following groups: static, shaken, stirred, bubble column, and convective flow.

32.2 BIOREACTOR MONITORING TOOLS

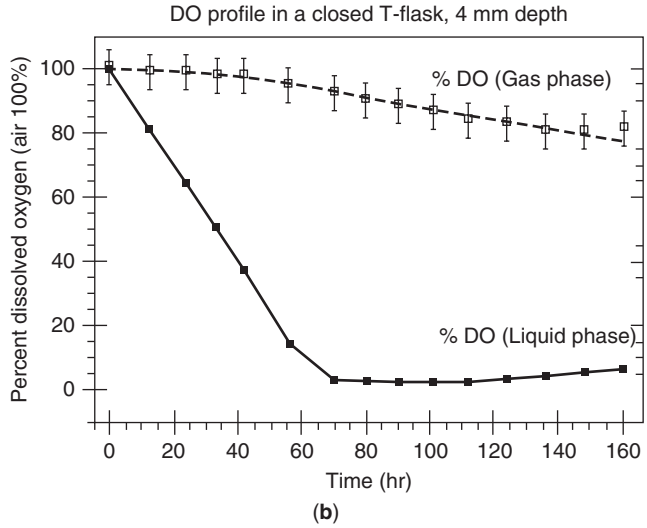
Over the years bioreactors have been equipped with a variety of tools for the on-line monitoring of environmental conditions and assessing the physiological state of cells. For industrial processes electrochemical probes are the standard means to observe culture broth conditions, while off-gas analyzers are used for gas exiting the reactor headspace. In general, these technologies have not been utilized at a small scale due to the size constraints imposed by such small volumes. Although microelectrodes have been developed and are commercially available (6), other problems still exist. For example, electrodes have stability issues due to the strain shaking imposes on wire-based connections.

For decades culture fluorescence has been used to assess the physiological state of cells, for instance, by determining their internal redox potential (7). More recently, the need for small-scale process monitoring has been a driving force for the development of optical sensors utilizing analyte specific fluorophores. In general, optical sensing in this way requires the following three steps: the fluorophores are (i) brought into physical contact with the material which contains their analyte; (ii) excited by light sources of characteristic wavelengths; and (iii) properties of the resulting emission are measured (8). Application of this technology has varied by changing the way in which fluorophores are exposed to analytes and how excitation and fluorescence detection is carried out. Different approaches will be described for many of the miniature bioreactor platforms presented here. For a more detailed look into fluorescence spectroscopy and its application, see *Principles of Fluorescence Spectroscopy* (8).



32.3 STATIC BIOREACTOR SYSTEMS

32.3.1 Tissue Culture Flasks (T Flasks)



T-flasks are a common platform for small-scale mammalian cell culture. They are generally used for the expansion of selected clones, in industrial seed trains to generate inocula for spinner flasks and bioreactors, or just as simple vessels for which to carry out cell culture related experiments in. They are often coated with proteins, such as collagen or fibronectin, which make them ideal for the growth of adherent cells. Their skinny boxlike shape results in a large headspace aeration area to liquid volume ratio (A_S/V), enhances the diffusional mass transfer of gaseous species in and out of the media. Without convective mixing, diffusion is the sole mode of transport. Therefore, during culture a DO concentration gradient forms from saturation at the air-liquid interface to some lower percentage at the flask bottom.

The Clark-type electrode has been the standard method for measuring DO tension in bioreactors. However, based on several factors, it is not a feasible option for measuring DO concentration in T-flasks. First, the Clark-type electrode consumes oxygen to make its measurement. At low DO concentrations this is undesirable and can impact the accuracy of the reading. Also, based on its design and that of the T-flask's opening, the electrode is not suitable for making measurements in culture broth that is only several millimeters in height. Lastly, also based on design, the maintenance of sterility would be difficult.

Randers-Eichhorn *et al*. characterized the mass transfer of oxygen during the culture of mouse hybridoma cells by

(a)

(b)

Figure 32.1. (a) T-flask with DO sensor patches on the wall in the gas phase and on the bottom in the liquid phase. Located below the flask is the fiber optic used for fluorophore excitation and emission detection of the liquid-phase patch. (b) Liquid and gas-phase DO profiles obtained using optical sensors during the culture of hybridoma mouse cells (9). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

fitting a standard T-flask with optical sensors in both the gas and liquid phases (9). Here an oxygen sensitive fluorophore was immobilized in sensor patches that were affixed to the inside sidewall and bottom of the T-flask (Fig. 32.1a). An external fiber-optic optrode was used to both excite the fluorophore and detect its emission. The DO profiles in Fig. 32.1b show DO concentrations near 0% air saturation at the bottom of the flask, and a gas-phase concentration of greater than 80% throughout the experiment justifies closing the T-flask lids completely.

32.4 MICROFABRICATED REACTORS

Since 2004, researchers at MIT have developed several versions of microfabricated microbioreactors with working volumes as low as 5 μL (10). A membrane aerated version, shown in Fig. 32.2, constructed out of poly(dimethylsiloxane) (PDMS) and glass was equipped with optical sensors for pH, DO, and optical density (OD). The top layer of PDMS served as the aeration membrane through which oxygen diffused into the reactor. Zanzotto *et al*. compared 5–50 μL *E. coli* fermentations carried out in this reactor and in 500 ml SixFors bioreactors (SixFors to be discussed in the Stirred Bioreactor Systems section). Run conditions in the larger reactors were configured to match the k_La of the smaller vessels. Fig. 32.3 shows the pH, DO, and OD profiles for this comparison. Samples for high performance liquid chromatography (HPLC) analysis of organic acids (data not shown) were obtained by sacrificing entire microbioreactors. In another experiment, the same bioreactor system and DNA microarrays were used to determine how gene expression changes upon switching from the complex to defined media (11).

The scale of bioreactors has been decreased even further to the realm of nanoliters using two-level soft lithography (12). The 4 cm^2 64-unit array and a 3-nL individual reactor are shown in Fig. 32.4. The C-shaped reactors were designed so that the opening was smaller than the cell size, trapping the cells within, and microfluidic controlled media flows in the rings surrounding the reactors, allowing the nutrients to diffuse through the opening. The array is not equipped with any sensors, but its transparency allowed for visualization after fluorescent staining. Lee *et*

al. demonstrated the utility of the system by observing the serum response of HeLa human cancer cells.

32.5 SHAKEN BIOREACTOR SYSTEMS

The goal during development is to expose cultures to a variety of conditions with the objective of finding ones where productivity (or some end goal) is maximized. Shaken systems are still the most high throughput approach we have for process development, enabling many conditions to be tested simultaneously. However, control over conditions is fairly limited in traditional shaken systems given the restricted number of variables we have to alter, and whether changing them affects individual bioreactors or groups. For instance, to investigate the impact of increased DO tension, the rotational rate of the shaker can be increased to raise the k_La. However, no differences would be observed amongst units on a single shaking platform since mass transfer in all the bioreactors would improve. In order to influence only a subset of reactors, their culture volume must be reduced, thus improving the transfer area to volume ratio. The flask closures could also be changed to ones with less transfer resistance.

Instead of only qualitatively controlling the reactor environment as described above, it is more empowering to have a quantitative measurement of to what extent conditions are changing. Sensors allow for this. This following section will describe how various sensors and apparatus have enabled the characterization and monitoring of cultures in shaken bioreactor systems.

32.5.1 Shake Flasks

The design of shake flasks is slightly more conducive to measurements with electrochemical probes as they can be fixed in a stopper at the top or inserted into specially made ports on the flask wall as shown in Fig. 32.5a (13). Hodson

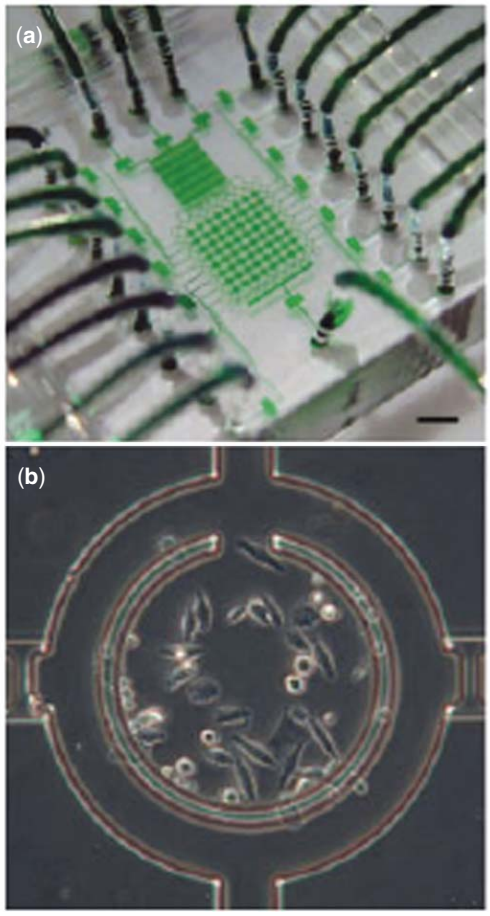

Figure 32.4. Nanoliter scale bioreactor for quantitative cell biology: (a) the 4 cm^2 64-unit array; (b) an individual 3-nL reactor (12). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

used that system to monitor gas and liquid-phase oxygen concentrations (Fig. 32.5b) during the cultivation of *Bacillus subtillis*. An air purge device ensured that there was air saturation in the gas phase which was confirmed with the gas-phase sensor. Even in the early days of industrial biotechnology, the prevalence of oxygen limitation during microbial cultivation in large-scale fermentors was well know. As shake flasks were (and are) the primary tool for development, pioneering engineers wanted to know how much DO flasks could provide to growing cultures under defined (agitation speed, culture volume, liquid viscosity, etc.) conditions. There are various techniques to characterize the mass transfer in bioreactors, such as the gassing out, water evaporation, and sulfite oxidation methods. Change in flask mass due to water evaporation can be used to analyze gas transfer through shake flask enclosures (14). The sulfite oxidation method has drawbacks,for instance sampling at regular intervals (15). This technique and improvements of it will be described in the next section on *Multiwell Plates*.

The gassing-out method requires carrying out a mass balance over the liquid and/or gas phases within the flask. This requires one or more oxygen sensors depending on the analysis being carried out and the associated assumptions. For instance by tracking the oxygen concentration in a liquid-less flask during the gassing-out method, the resistance being measured is only that of the plug. Schultz carried this out finding that the density and dimensions of the plug impact its resistance to the oxygen flow (16). Tribe *et al*. warned of the large errors that are introduced into the mass transfer coefficient by the gassing-out method if the response time of the electrode is not taken into consideration (17). This caution was observed by Nikakhtari and Hill who developed and incorporated models for mass transfer into the growth and substrate utilization models of *Pseudomonas putida* fermentation in shake flasks while taking both the air-liquid interface and a variety of flask closures into consideration (18).

However, during the shake flask development many experiments are carried out simultaneously. Thus it becomes cumbersome to calibrate and sterilize each Clark-type electrode beforehand and maintain sterility during sampling throughout the experiment. All the wires running from the flasks to the data acquisition system could pose a logistical problem as well. Recently Vasala *et al*. developed a shake flask (Fig. 32.6) equipped with steam sterilizable "wireless" DO and pH electrochemical sensors (19). The flask has ports for the probes, which are connected to a small transmitter that is strapped to the flask. The transmitter broadcasts a signal to the receiver which is connected to the computer responsible for logging the data.

Another problem of using a liquid-phase DO electrode is that it becomes a baffle, confounding the mass transfer characteristics it is measuring. Anderlei *et al*. developed an oxygen transfer rate (OTR) measuring device, where OTR is defined as the rate at which a species is moving from gas to liquid phase (20). The specially made flask instead uses a gas-phase oxygen sensor in cooperation with computer controlled gas in- and out-let valves where the inlet was hooked up to a gas mixing system. By introducing defined concentrations of gas, and opening and closing the valves in a time defined manner, the phases shown in Fig. 32.7 are carried out, OTR can be determined during fermentation. This device is the basis for an advanced instrument, named the respiration activity monitoring system (RAMOS), capable of also measuring the carbon dioxide transfer rate (CTR) and thus the respiratory quotient (RQ) of cultures. The instrument is commercially available through AC Biotec GmbH (Jülich, Germany) (21). Freyer *et al*. used a prototype of the system to demonstrate the utility of using OTR as a scaling factor between scales (22) while Losen *et al*. used OTR via RAMOS to identify critical growth parameters, such as deficiencies in media components and

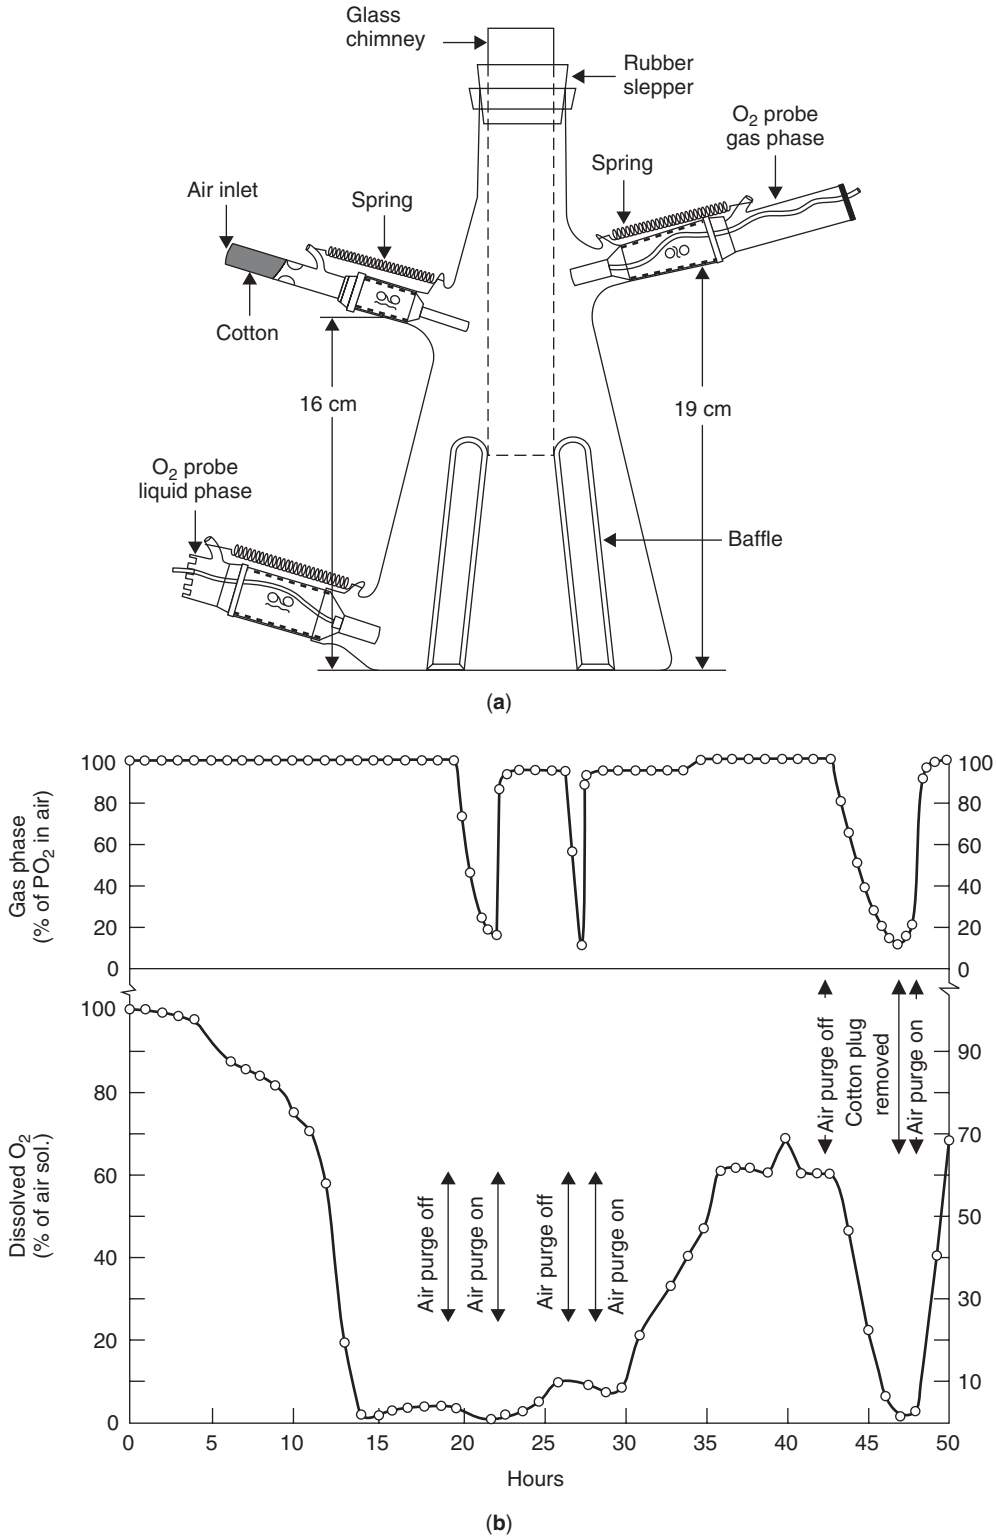

Figure 32.5. (a) A specially made shake flask with ports for gas and liquid-phase electrochemical oxygen probes and an air purge system to supply fresh air; (b) gas and liquid-phase oxygen concentrations during a 2-L shake flask cultivation of the *Bacillus subtilis* (13).

Figure 32.6. A wireless system for measuring pH and DO in shake flasks. The system is composed of a specially designed flask, electrochemical pH and DO electrodes, a transmitter (shown strapped to the flask and in the picture to the right), and a receiver which interfaces to a computer for data storage and analysis (19). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

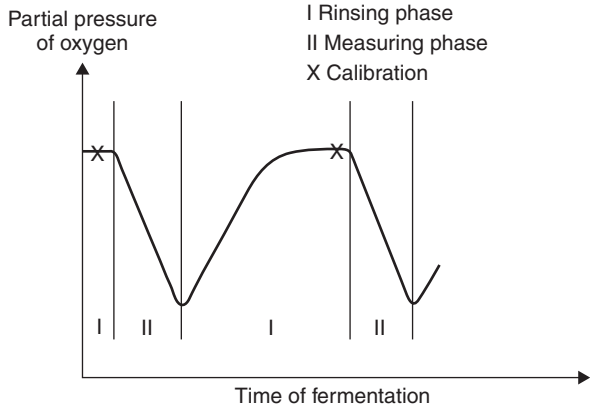

Figure 32.7. The sequence of phases during OTR determination using a sterile on-line device (20).

oxygen limitation (23). Short of actual culture broth DO data, OTR is a great solution to understanding the oxygen consumption during culture.

Optical sensors have provided a more manageable solution to monitoring in DO tension in shake flasks. Tolosa *et al*. demonstrated their first use in shake flask fermentations of *E. coli* and *S. cerevisiae* (24). The optical sensing setup is shown in Fig. 32.8. The oxygen sensing patch was affixed to the inside bottom of the shake flask. Both the flask and the coaster, which housed the optical instrumentation, were shaken. The system is designed to be modular enabling easy hookup to laptops or any available computer. Gupta and Rao used the same setup to characterize the combined resistance across the flask enclosure and the air-liquid interface (25). Fig. 32.9 shows the impact of enclosure type and addition of baffles on DO profiles during *E. coli* fermentation. The results comparing a shake flask fermentation to one carried out in a 1-L fermentor are shown in Fig. 32.10. The similarities in on-line DO, and offline OD and product expression via green fluorescent protein (GFP) fluorescence support scaling is based on k_La where enclosure is accounted for.

A complementary study of mass transfer in shake flasks with optical DO sensors manufactured by a different supplier was performed by Wittmann *et al*. (26). There k_La was quantified over several liquid volumes and agitation speeds and utilized in the fermentation of *Corynebacterium glutamicum*. A 45-s pause in shaking was necessary for the offline sampling of the culture. During this time a 20% drop in DO tension occurred which, if extrapolated on, would predict that all residual oxygen in the media would be consumed in about 2 min if the nonshaking persisted. This type of information is incredibly valuable when designing protocols to carry out screening experiments, and would not be available without monitoring on a small scale.

The pH monitoring in shake flasks has less attention than that of DO. This may be due to the fact that growth media is often buffered, leading researchers to believe that pH is not changing significantly. Also, in the case of cell culture media, a pH indicator, such as phenol red, is sometimes included in the media, enabling a rough estimate of culture pH. However, this is surprising given the pH sensitivity of microbial (27) and especially mammalian (28) cells. For use in shake flasks, electrochemical pH probes have many of the disadvantages already described for DO electrodes.

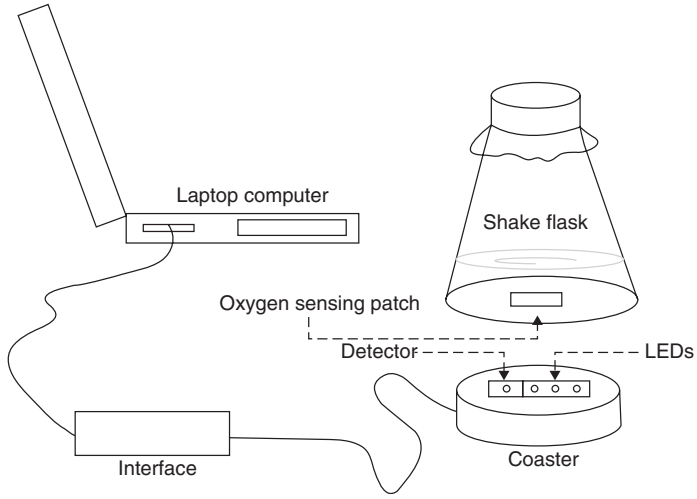

Figure 32.8. The setup for optical DO sensing in shake flasks. The system consists of a flask with an immobilized sensor patch on the bottom, a coaster that houses the optical instrumentation, and an interface which converts the data for storage and analysis in the laptop (24).

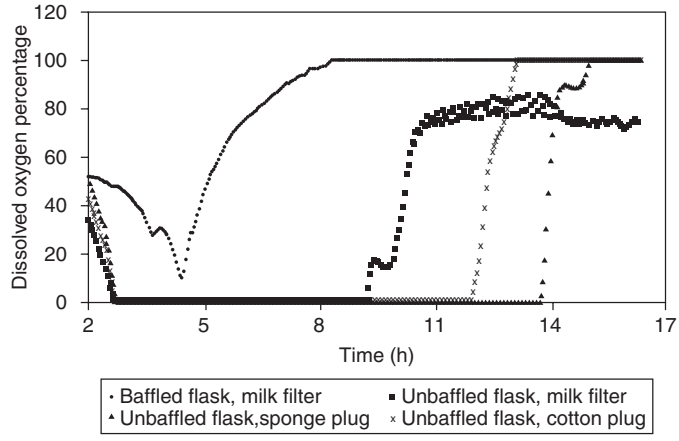

Figure 32.9. Use of the optical DO sensing platform is shown in Fig. 32.8 to measure the impact of flask baffling and various enclosures on DO profiles during *E. coli* fermentations (25).

For the same reasons, optical pH sensors have been developed. Optical monitoring of pH was first demonstrated in a shake flask by Kermis *et al*. during fermentation of *E. coli* (29). A setup similar to that for DO in Fig. 32.8 was employed where the pH sensing patch used here is shown in Fig. 32.11a. A comparison of the on- and off-line pH values are shown in Fig. 32.11b.

The pH monitoring and control was demonstrated by Weuster-Botz *et al*. in the fed-batch parallel shake flask system pictured in Fig. 32.12 that is commercially available from DASGIP AG (Jülich, Germany) (30,31). The pH was monitored during *E*. coli cultivation using pH electrodes inserted in ports of flasks made specially for the system and controlled starting at 4.5 h into the experiment (Fig. 32.12b). Differences between on- and off-line pH measurements were not accounted for.

Another parallel flask shaking system, shown in Fig. 32.13a, developed by Akgun *et al*. was designed for continuous culture (32). The specially made flasks used in their system were fully characterized based on filling volume, substrate feed rate, outlet height, shaking diameter, aeration rate, and shaking frequency. Fig. 32.13b shows that the same dilution rate in a continuous culture comparison between this system and a 1-L bioreactor resulted in the same steady-state biomass and substrate concentrations, as well as ethanol produced.

In designing a screening system, the goal is to make as many parameters as similar to the production scale as possible. Thus far, tools for quantifying transport and process monitoring have been discussed. However, there are other parameters of interest. Buchs *et al*. designed a device to measure power consumption (per unit volume) in culture

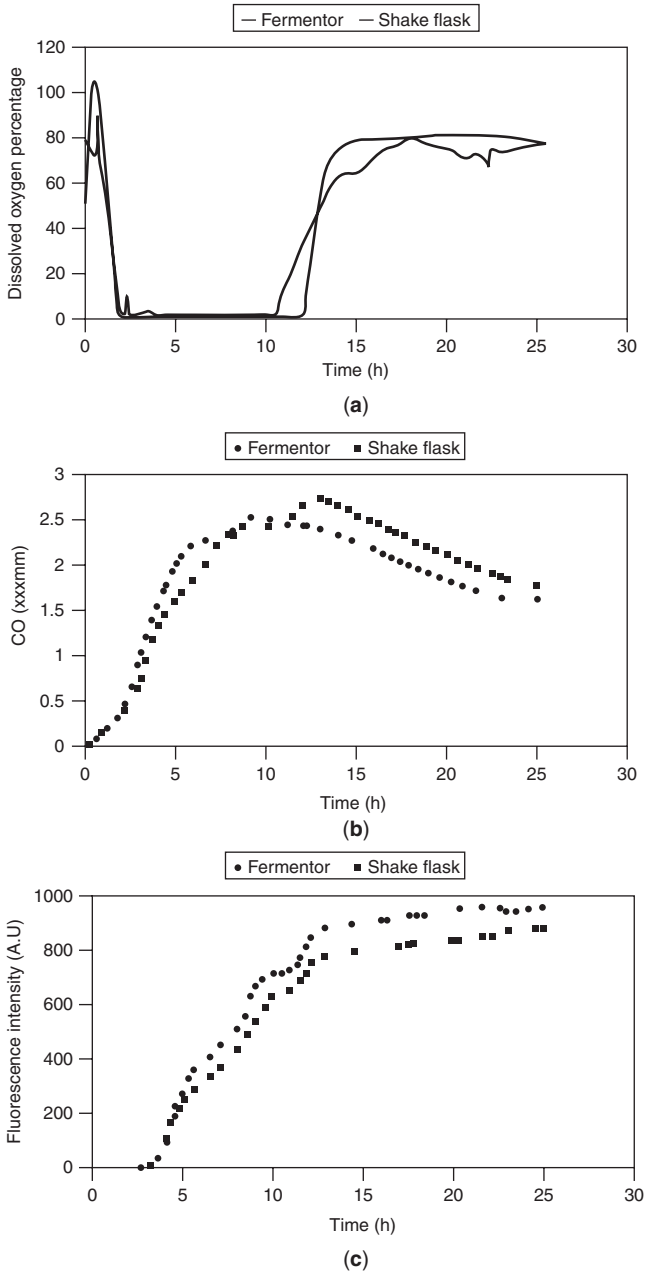

Figure 32.10. A comparison of *E. coli* fermentations carried out in a shake flask and a 1-L fermentor. (a) On-line DO, (b) offline OD, and (c) GFP expression are shown for the two systems (25).

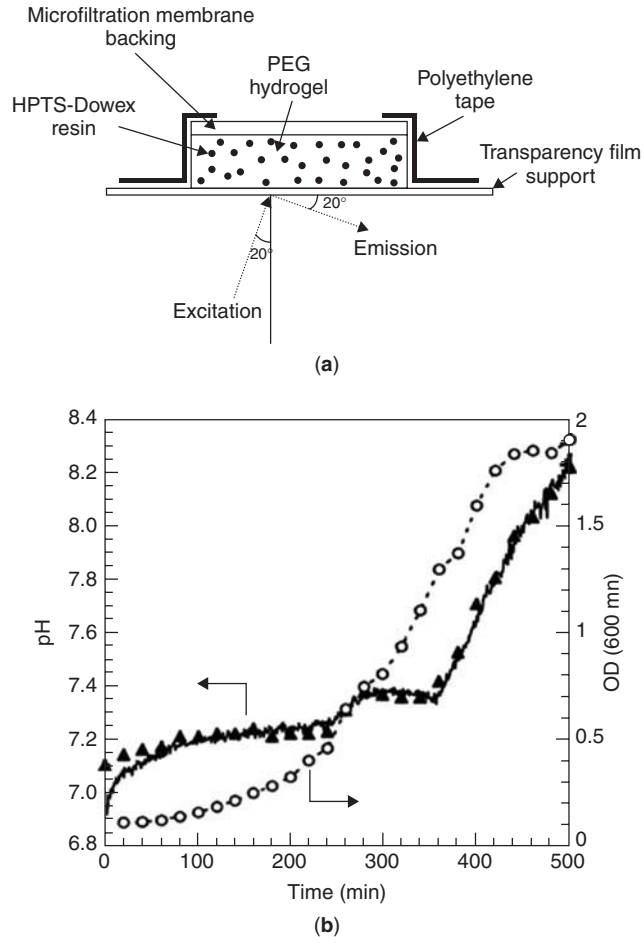
broth, which plays an essential role in the fermentation of microbes and is regarded as one of the critical values for characterizing and upscaling cultures (33). Another parameter of importance is the extent of hydromechanical stress imposed on cells. Peter *et al*. measured this via energy dissipation rate (EDR) (34). EDR was correlated with a maximum stable drop size in a coalescence inhibited liquid/liquid dispersion.



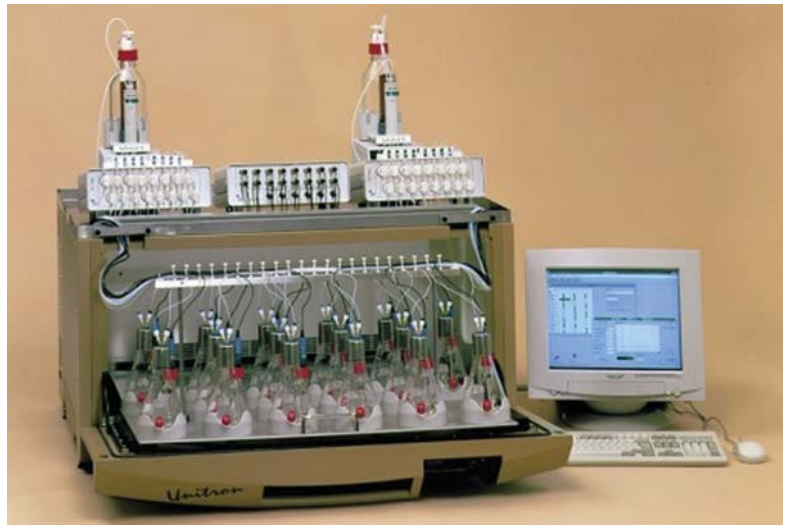


Figure 32.11. (a) An optical sensing patch for pH. The fluorophore encapsulated patch is affixed to the inside of a transparent reaction vessel. (b) Comparison of on-line optical (–) pH measurements with those made off-line (▲) during cultivation of *E. coli* in a shake flask (29).

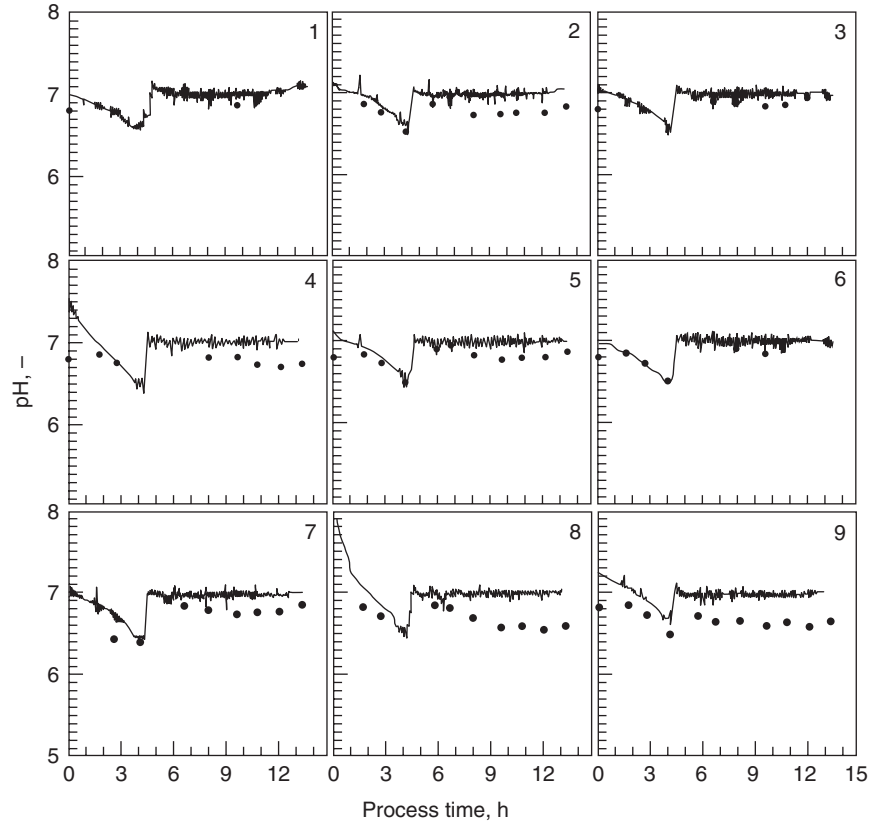

32.5.2 Multi-Well Plates

Since very little culture volume is needed for small-scale operations in upstream bioprocessing, such as screening and cloning, multiwell plates are well-suited to perform these functions. However, at such small volumes, fluid handling and well-to-well reproducibility are often difficult to control. Duetz *et al*. developed a system capable of reproducibly accessing 96 different frozen glycerol stocks, a plate each on agar, and ultimately inoculate 96 wells in a new plate with the agar cultures (35). The 40-mm deep well plate system was also able to shake and rotate at a variety of speeds and angles (Fig. 32.14), respectively, in order to maximize OTR as determined by the sulfite oxidation method utilizing a gas-phase electrode.

Two methods for measuring OTR were improved upon for use in multiwell plates by Hermann *et al*. as a result of incorporating a gas-phase oxygen sensor and an LCD

camera (36). The gas-phase sensor was sealed to the top of a single well in a plate and used to monitor the parti al pressure of oxygen over time. This accepted technique was used to validate the proposed sulfite oxidation LCD camera-based method. When using the sulfite oxidation method to measure OTR, a characteristic drop in pH occurs upon completion of the sulfite oxidation reaction, signaling oxygen depletion. By adding bromophenol blue, the change in pH was accompanied by a solution color change. The camera was used to visualize the time taken to achieve the color change, thus a reaction rate could be calculated based on the amount of oxygen necessary to stoichiometrically react with the starting quantity of sulfite. Hermann *et al*. went on to use the camera-based method for characterizing 96-well plates, for example by correlating OTR_{max} and shaking frequency at different shaking diameters, as shown in Fig. 32.15 (37). The 48-well plates were characterized in three different ways by Kensy *et al*. by utilizing the camera-based method above, replacing the gas-phase sensor with a modified RAMOS device, and verifying both biologically using a *Hansenula polymorpha* cultivation (38).

Optical sensing for bioprocessing was first demonstrated in multiwell plates by Li *et al*. who used GFP to study the galactose-inducible *GAL1* promoter in *Saccharomyces cerevisiae* (39). Comparable *GAL1*-controlled GFP profiles were observed in shake flasks and in the 96-well plate format. Girard *et al*. used fluorescence from a GFP-expressing Chinese hamster ovary (CHO) cell line as a surrogate indicator of cell density in 12-well plates (40). The culture pH was quantitatively monitored as well by phenol red absorbance. DO concentration was first monitored optically in multiwell plates by John *et al*. during the culture of *Corynebacterium glutamicum* in 96-well plates (41). DO sensor spots were immobilized and optical instrumentation was positioned as shown in Fig. 32.16a. DO profiles are shown in Fig. 32.16b.

Optical fluorescent sensing of pH was first used in multiwell plates to study mixing (42). Weiss *et al*. utilized two different pH sensitive fluorophores: 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS) dissolved in buffer solution and fluorescein immobilized in a sensor

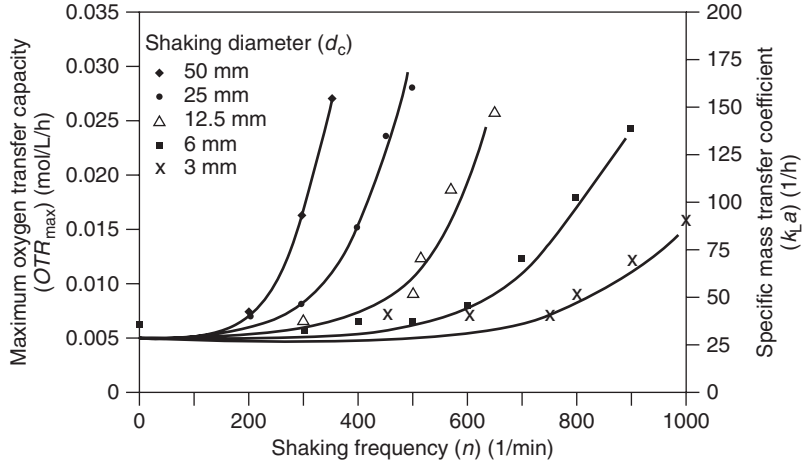

Figure 32.15. The OTR and k_La as a function of shaking diameter and frequency in 48-well multiwell plates (37).

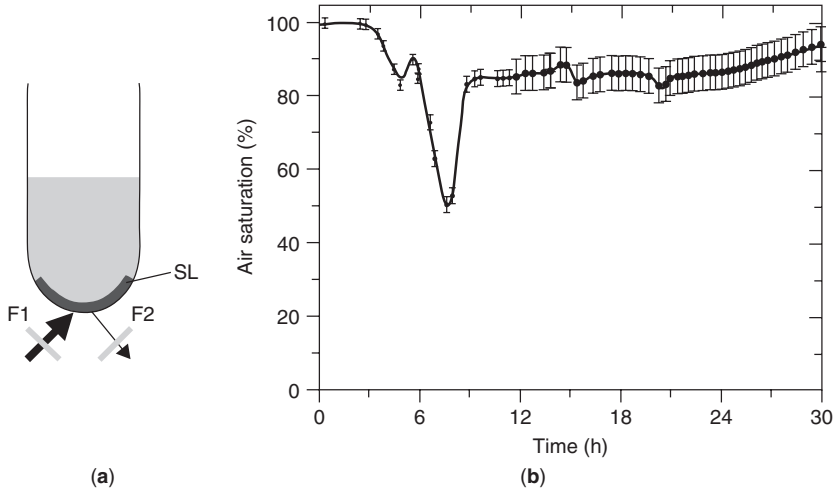

Figure 32.16. (a) A schematic of a single well of a multiwell plate with optical monitoring of DO. A DO-sensitive fluorophore encapsulated sensor spot is affixed to the inside bottom of the well with an excitation source (F1) and detector (F2) located underneath.(b) The DO profile obtained with optical sensing during fermentation of *Corynebacterium glutamicum* in 96-well plates (41).

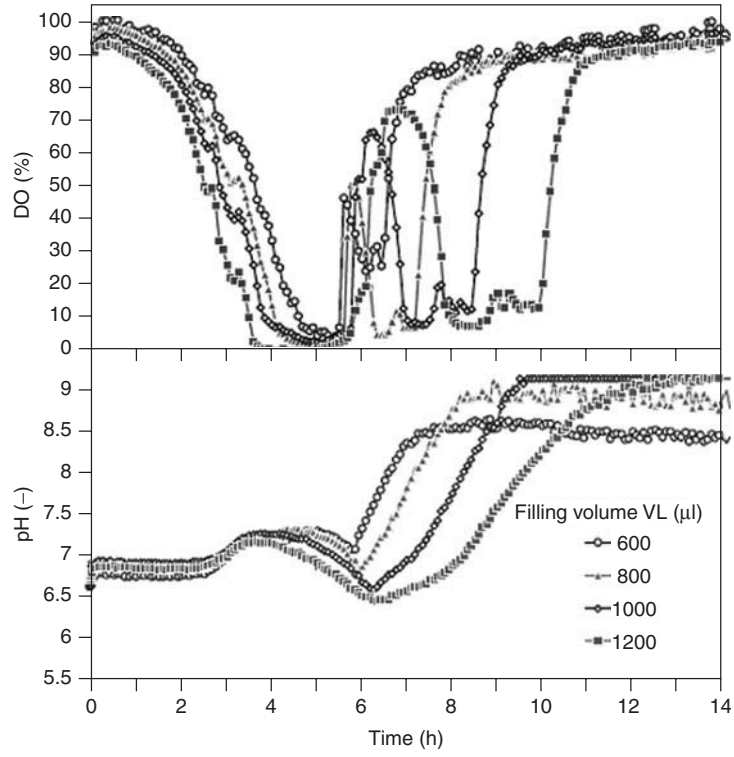

Figure 32.17. Optical pH and DO profiles during the fermentation of *E. coli* in 24-well plates. Only one of the parameters per culture could be monitored in the plates, therefore the other parameter was observed in a second, replicate culture (43).

spot that was affixed to the inside bottom of the well. Results from the fluorescent experiments were compared to visualization experiments where a camera recorded the color change of a pH indicator, thymolphthalein. Controlled drops of alkali addition were responsible for pH changes.

The DO concentration and pH were both optically monitored by Kensy *et al*. in experiments carried out in 24-well

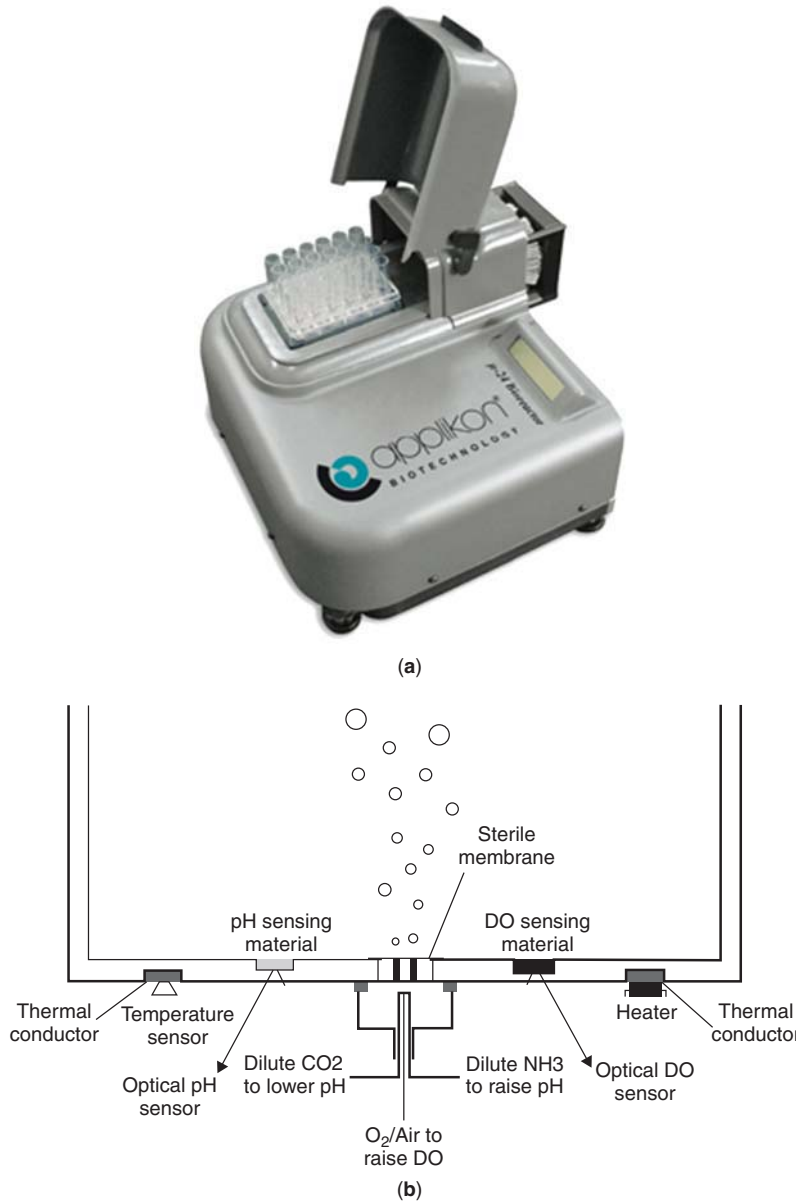

Figure 32.18. (a) The Applikon μ-24 bioreactor: a 24 deep-well plate with sensors and control for temperature, DO, and pH. (b) A schematic of a single well in the μ-24 system. Located underneath each well in the plate are a temperature sensor, a heater, optical DO and pH sensors, a sterile membrane for aeration, and a mixing chamber for CO_2, O_2, air, and NH_3 gases (45). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

plates (43). Similar to Weiss *et al*., sensor spots were immobilized on well bottoms. Although pH and DO were both monitored, they weren't done in the same experiment. The experimental setup only allowed for one of the two parameters to be measured per plate. Therefore, the other parameter was monitored in a subsequent replicate plate. Figure 32.17 shows how changes in culture volume affect the pH and DO profiles of the *E. coli* cultures.

The simultaneous monitoring of DO and pH in shaken multiwell plates was first achieved by Tang *et al*. using a prototype of a commercially available system, Fig. 32.18a, from Applikon (Shiedam, Netherlands) (44,45). Each individual reactor, shown in Fig. 32.18b, consists of a deep well that is equipped with optical sensors for DO and pH, a temperature sensor, a heater, gas lines for aeration and pH control, and a sterile gas membrane. On-line temperature,

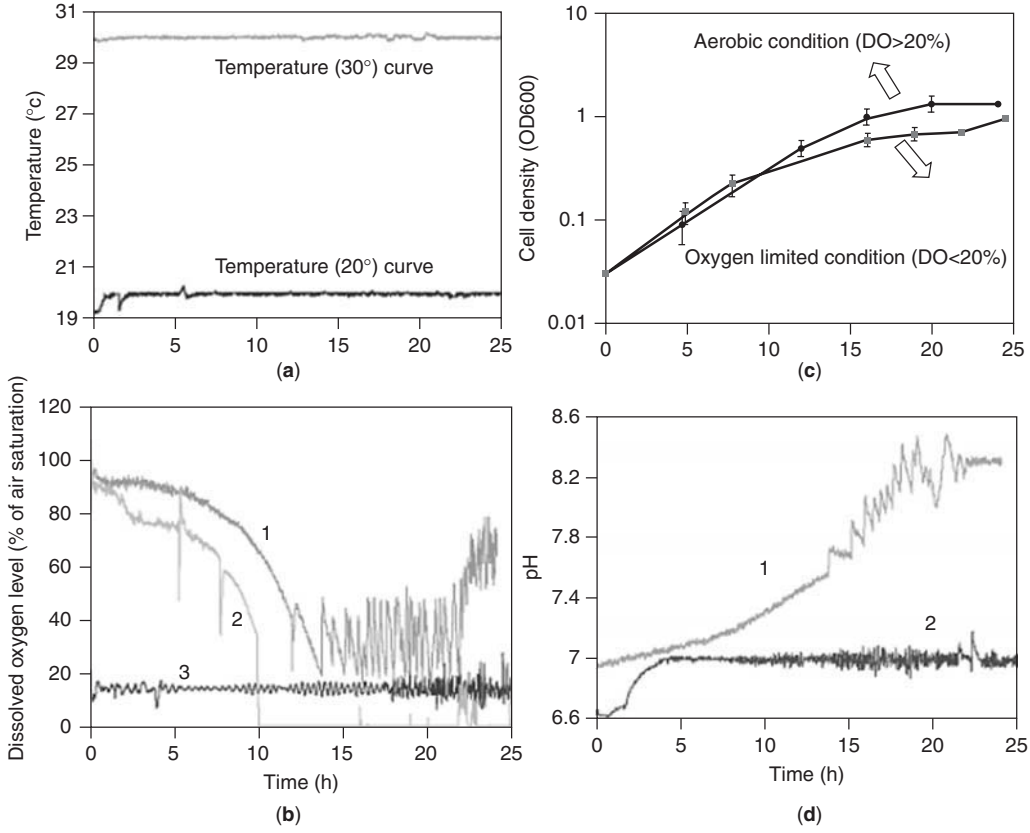

Figure 32.19. The demonstration of control of MR-1 growth conditions in individual wells. (a) Controlling and monitoring temperature at 30 and 20°C. (b) Dissolved oxygen control. (1) Dissolved oxygen was controlled above 20%; (2) dissolved oxygen control was off; (3) dissolved oxygen was controlled at 15%.; (c) MR-1 growth curves under aerobic (◇) and oxygen-limited (■) conditions at 30°C; (d) Control of pH (at 7.0) during growth on 60 m*M* sodium lactate using CO_2: (1) no pH control, incubation at 30°C; (2) pH control (45).

DO, and pH profiles, as well as offline OD are shown for the fermentation of *Shewanella oneidensis* in Fig. 32.19. The same system has also been used to cultivate *S. cerevisiae*, *E. coli*, *Pichia pastoris* and CHO cell lines (46,47). However, in the latter, the standard pH and DO control strategies had to be modified to resolve foaming and pH control issues, thus more work is needed for cell culture applications.

For many shaken plate systems, a pause in shaking is necessary in order to perform the optical measurement. This pause can disrupt the culture in terms of OTR, cell settling, and so on Samorski *et al*. developed a system which enabled the optical monitoring with uninterrupted shaking (48). The plate-optics configuration, shown in Fig. 32.20a, is capable of monitoring scattered light and culture fluorescence. Comparisons were made between this 96-well system and 250 ml shake flasks equipped with the RAMOS device discussed previously. An increase in OTR and offline OD correlated with on-line scattered light and NADH fluorescence (Fig. 32.20b and c).

Maharbiz *et al*. constructed a parallel microbioreactor array from two 8-well strips (49). Each of the 250 μL wells continuously reports OD, temperature, and oxygen input. Oxygen is individually controlled and supplied to each reactor by electrolytic generation in the lower strip. Temperature is individually monitored and controlled by film thermistors and heaters under each well. The impact of different oxygen input rates on OD profiles is shown in Fig. 32.21a. Because of the printed circuit board framework, additional sensors can be added. To demonstrate this modularity, a solid-state pH sensor chip was added to the 8th well of the strip for an *E. coli* fermentation. A pH profile from this additional sensor and the corresponding OD profile are shown in Fig. 32.21b.

32.5.3 Tubes

In an effort to make cell culture simultaneously high-throughput and simple, De Jesus *et al*. developed the TubeSpin cell culture centrifuge tubes (50). The tubes,

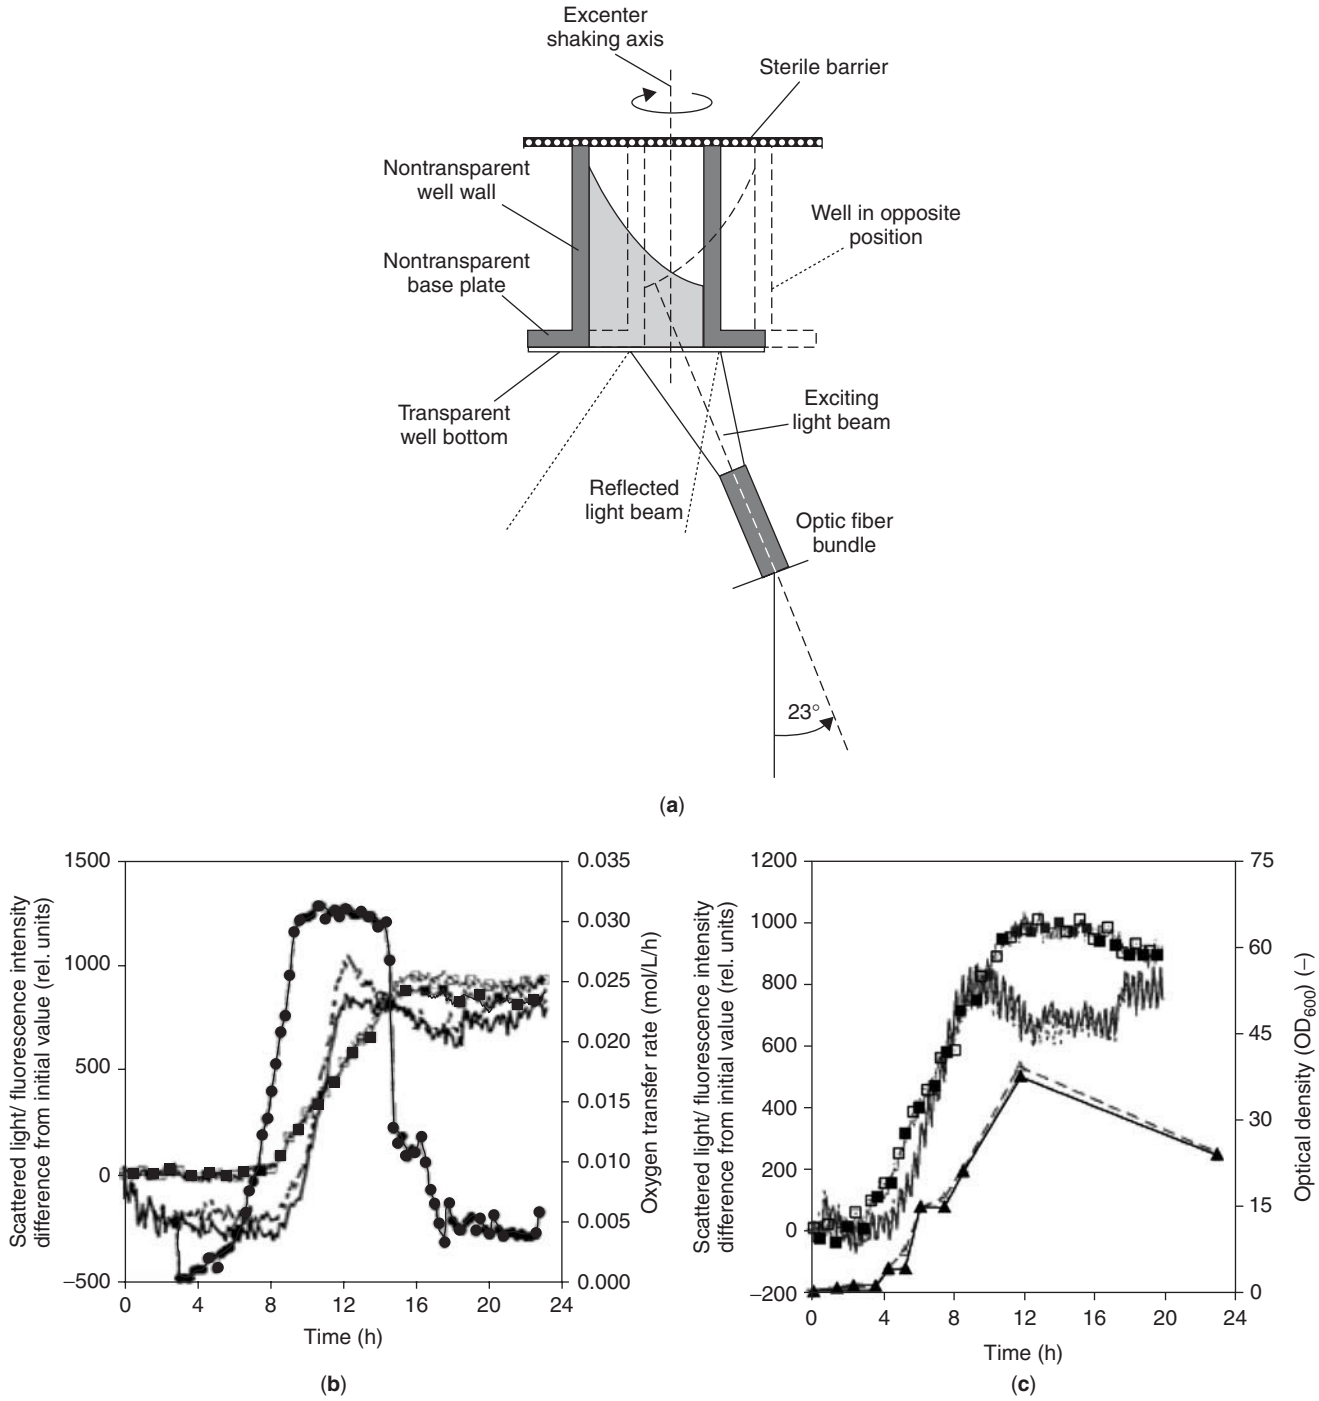

Figure 32.20. (a) A 96-well plate system capable of monitoring scattered light and fluorescence without stopping shaking. (b) Scattered light (—, –) and NADH fluorescence (■, □) intensities of two wells of a microtiter plate in comparison to the oxygen transfer rate of a simultaneously shaken Erlenmeyer flasks culture (•) all during fermentation of *E. coli* JM 109. Scattered light and NADH fluorescence are shown in duplicates. (c) Scattered light (—, –) and NADH fluorescence (■, □) intensities of two wells of a microtiter plate in comparison to off-line measured optical density at 600 nm of simultaneously conducted normal shaken 250 mL Erlenmeyer flasks cultures (▲, Δ) of *E. coli* JM 109. All measurements are shown in duplicates (48).

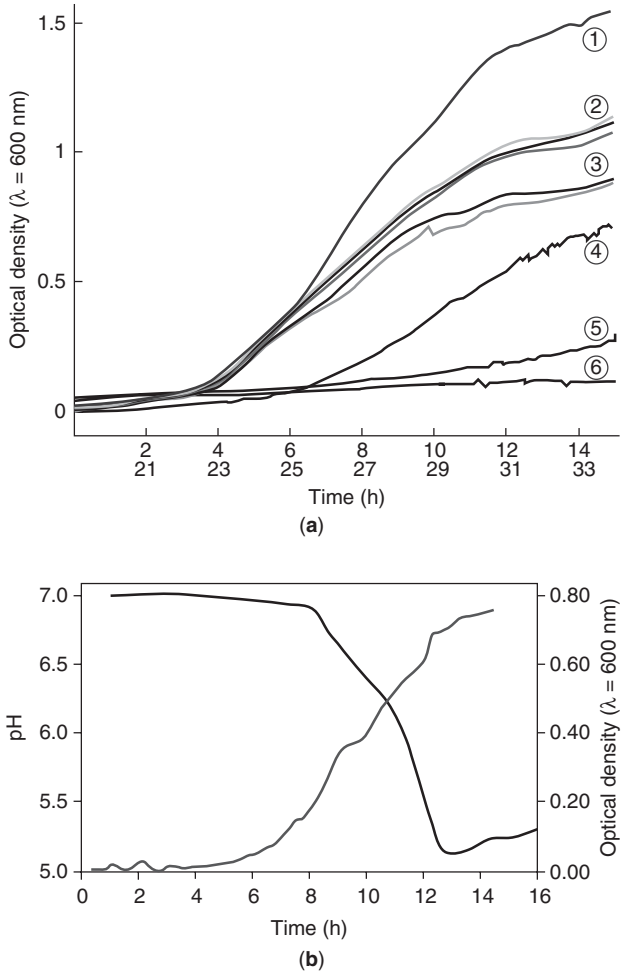

Figure 32.21. (a) *E. coli* growth as a function of oxygen generation. Oxygen supplied: (1) 10 mmol O_2/h, (2) 6 mmol O_2/h, (3) 3 mmol O_2/h, (4) 0 mmol O_2/h, (5) 6 mmol O_2/h (lower time axis), (6) 0 mmol O_2/h. Multiple curves are shown for curves (2) and (3) to illustrate reproducibility. Cultures 1–4 were grown in LB medium. Cultures 5–6 were grown in M9 minimal medium with 1% glycerol (lower time axis). (b) An ISFET chip from Sentron Europe (E2310000, 0.5–1.5 mm) and reference electrode were assembled into the eighth well of a microreactor array. Using the ISFET, pH was monitored during the course of a 16-h *E. coli* fermentation. OD600 is also plotted (49).

commercially available through Techno Plastic Products (Trasadingen, Switzerland), have specially made caps with holes allowing for aeration. Racks and large incubators allow for many experiments to be carried out concurrently. Other than incubator temperature and shaker speed, no sensors or controls exist for the platform.

32.5.4 Roller Bottles

Roller bottles are used for both small-scale culture and commercial manufacturing of therapeutic proteins, primarily for adherent cells. The cylindrical vessels rotate around their axis allowing cells to attach over the entire inner surface area. A thin layer of liquid results when rolling, allowing for an adequate oxygen mass transfer to the cells. Although, no on-line monitoring or control exists beyond rotational speed and temperature, in depth characterization of flow patterns and particle settling has been carried out (51,52). The addition of a recirculation loop by Berson *et al*. enabled a threefold increase in cell density over standard roller bottles due to enhanced liquid mixing and oxygen transfer (53).

32.6 STIRRED BIOREACTOR SYSTEMS

The majority of upstream commercial bioprocesses, regardless of size, utilize bioreactors of the stirred-tank variety. This fact is the biggest motivation to carry out small-scale developmental studies in stirred bioreactor systems. Similarity in the reactor geometry and a means of agitation can aid in scale-up, allowing for comparable behavior across all scales of production.

32.6.1 Spinner Flasks

Spinner flasks are most commonly used for the culturing of mammalian cells in volumes greater than can be achieved in T-flasks but less than in bench-top bioreactors. Incubator temperature and gaseous CO_2 concentration are generally controlled along with a magnetically controlled impeller agitation speed.

Optical monitoring in spinner flasks was first carried out by Bambot *et al*. during the fermentation of *E. coli* (54). The spinner flask was equipped with both an optical DO sensor and a Clark-type electrode. The offline OD and on-line DO concentrations from both sensors are shown in Fig. 32.22. Chang *et al*. optically monitored dissolved

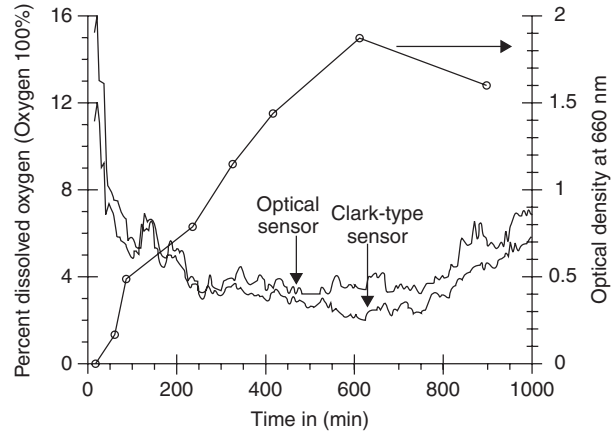

Figure 32.22. The monitoring of DO simultaneously with an optical sensor and an electrochemical probe during spinner flask culture of *E. coli*. OD is also plotted (54).

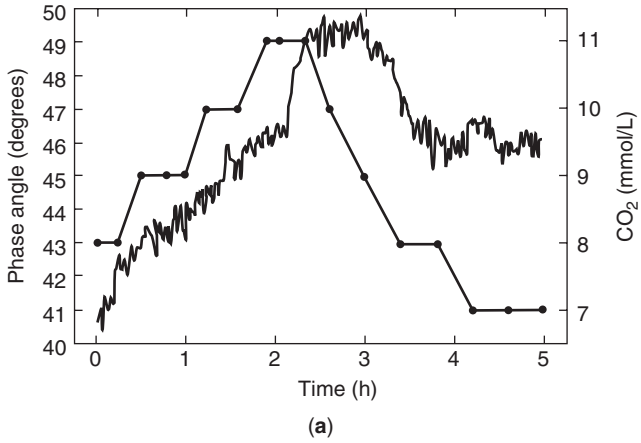

Figure 32.23. On- (–) and off-line (·) measurements of dissolved CO_2 during spinner flask fermentation of *E. coli* (55).

the CO_2 in spinner flask fermentations of *E. coli* by circulating culture broth from a spinner flask through a sensor equipped cuvette and back (55). In Fig. 32.23 the on- and off-line measurements are compared.

32.6.2 Cuvette

A proof-of-concept 2-mL bioreactor was constructed by Kostov *et al*. out of a standard cuvette (56). A schematic of the reactor, shown in Fig. 32.24, was capable of optical on-line monitoring of OD, pH, and DO concentration, stirred with a magnetic stir bar, and was aerated by sparging. Using k_La as a scaling factor, fermentations of *E. coli* in the cuvette reactor and a 1-L fermentor were compared (Fig. 32.25). The Gaden Award-winning publication was the first to demonstrate simultaneous on-line monitoring of OD, pH, and DO at such a small scale.

32.6.3 Plate Type

Based on the simple design of standard plates, their typical means of agitation is by shaking, as was highlighted above. However, plate-type platforms have also been equipped with stirring mechanisms, enabling increases in the mass transfer over shaking. Puskeiler *et al*. developed a parallel bioreactor system, shown in Fig. 32.26, capable of carrying out 48 fermentations of less than 20 ml (57). On-line DO and at-line pH monitoring was carried out optically. The pH was controlled via a liquid handling system. At-line sampling involved the automatic pipetting of culture broth from the reaction block and transferring it to a microtiter plate (MTP). The MTP was automatically transferred to a plate reader and the OD and pH were determined.

On-line optical sensing of pH and DO during *E. coli* fermentation in a 24-well plate was demonstrated by Harms *et al*. (58). The system is capable of monitoring OD, pH, DO, and GFP on-line, as the schematic shows in Fig. 32.27a. The sensing board, on which the plate sits, housing all the optical instrumentation and the sensor patch orientation in several wells are shown in Fig. 32.27b and c. Figures 32.28a and b show the DO and pH data from the *E. coli* cultivations. DO was controlled at 20% air saturation by automatically changing agitation speed, but significant oscillations resulting from the controller were present.

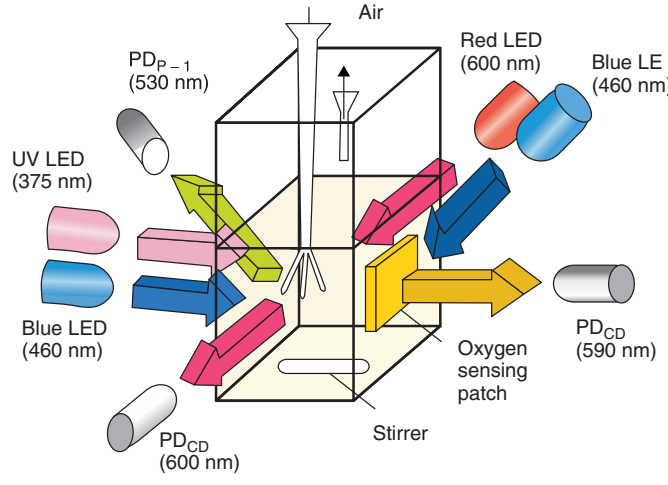

Figure 32.24. A schematic of the cuvette bioreactor equipped with optical sensing of OD, pH and DO. The pH and DO sensors consisted of sensor patches, LEDs for excitiation (blue for DO, pink and blue for pH), and photo detectors (590 nm for DO, 530 nm for pH). The optical density was measured using a 600-nm LED and a 600-nm detector. A 100-μL pipette tip was used as a sparger for aeration and a magnetic stir bar was used for stirring (56). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

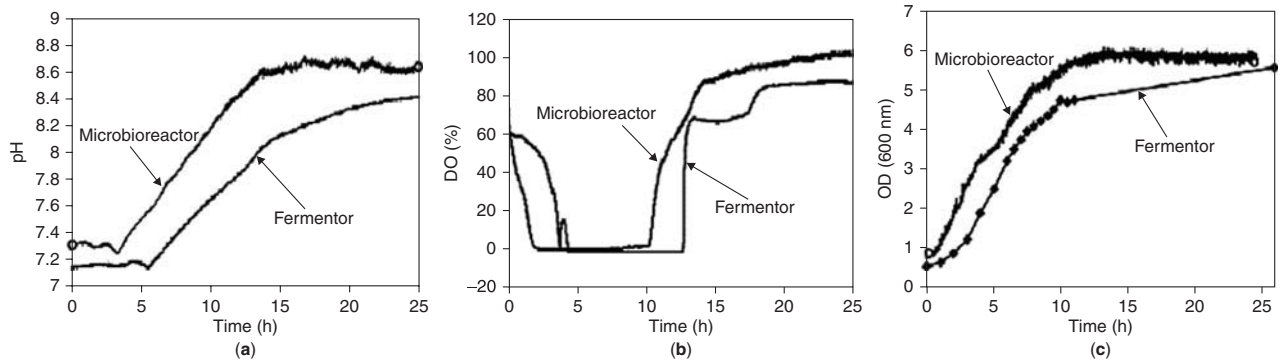

Figure 32.25. pH, DO, and OD profiles during *E. coli* fermentations carried out in the cuvette bioreactor and a 1-L fermentor. Conditions in the two reactor systems were scaled on the basis of $k_L a$ (56).

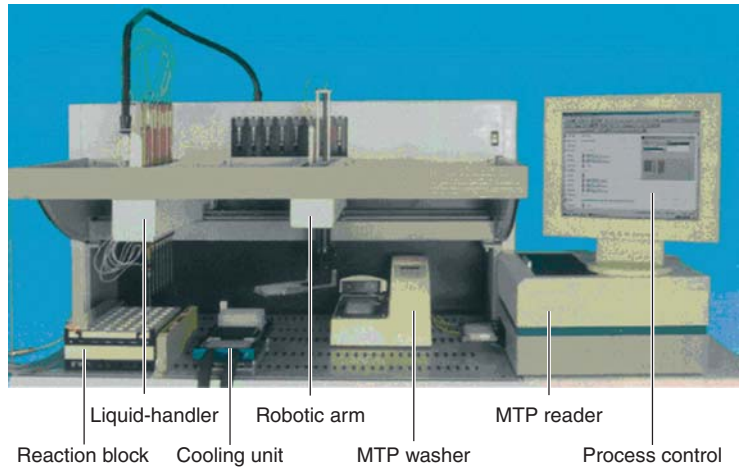

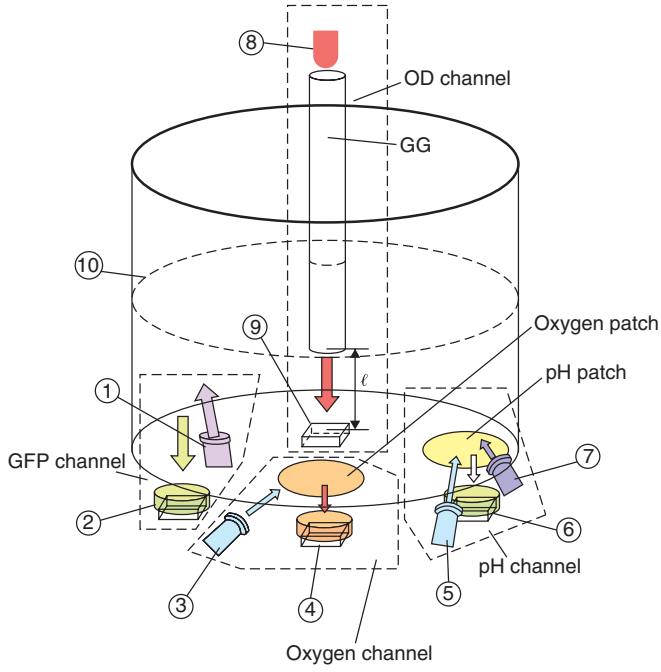

Figure 32.26. The automation concept consisting of the reaction block with 48 parallel bioreactors integrated in a liquid-handling system. The robotic arm enables independent microtiter plate (MTP) movements to an MTP reader and MTP washer. All devices are controlled by a process control program (57). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

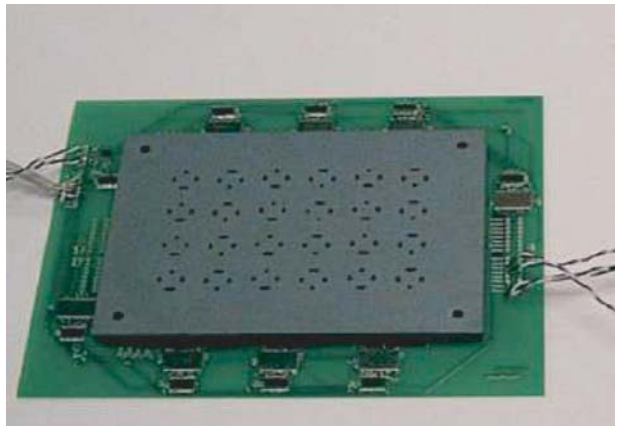

32.7 BIOREACTORS

In the early 1990s, Infors HT (Bottmingen, Switzerland) developed the first generation Sixfors parallel bioreactor system, of which a recent model is shown in Fig. 32.29 (59). The system consists of six stirred-tank bioreactors of 300–500 mL, working volume, each equipped with pH and DO monitoring using traditional electrochemical probes. The control of pH is carried out by acid or base additions while impeller speed is modulated to control DO concentration. The system was used as a basis for comparison by smaller platforms already presented in this review. Trummer *et al*. used the system for an in-depth study of the impact of pH, DO, and culture temperature on CHO growth and EPO-FC production (60). Three system runs were carried out to compare 16 different reactor conditions, the results of which are shown in Fig. 32.30. The Sixfors system enables highly parallel cultures to be carried out, however, the reactor volumes are not small enough to significantly improve throughput.

Lamping *et al*. designed a 6-mL bioreactor made of Plexiglass with the same diameter as a well in a standard 24-well plate and a height of 4.8 cm (61). The reactor, shown in Fig. 32.31 (4), has optical sensors for DO, pH, and OD, a three blade impeller, and a sparger for gas delivery. This reactor was compared to a 15-L (working volume) reactor for performance in *E. coli* fermentation (Fig. 32.32). Run conditions were not scaled to achieve comparable results. Also, the immobilized pH sensitive dye behaved erratically, therefore pH readings shown are a result of dissolving the pH sensitive dye (HPTS) directly into the culture broth. This reactor was used by Betts *et al*.

(b)

(c)

Figure 32.27. (a) Schematic of the positioning of the optical sensors around a single well in a 24-well microplate. The light source and the detectors are not drawn to scale. Interference filters are positioned in front of the LEDs and photodiodes (represented here by small disks). A pinhole is installed in front of every detector for better collection of the light (not shown). The spatial positioning is selected in such a way that the excitation light from one channel creates minimum interference to the other channels. The glass optical guide GG extends below the liquid level to achieve a constant light path length l for OD measurements. (1) excitation UV LED for the GFP channel; (2) detection photodiode for the GFP channel; (3) excitation blue LED for the oxygen channel; (4) detection photodiode for the oxygen channel; (5, 7) excitation blue and UV LEDs for the pH channel; (6) detection photodiode for the pH channel; (8) red LED for the OD channel; (9) detection photodiode for the OD channel; (10) the liquid level.(b) A measurement board which the 24-well plate sits on. All LEDs and detectors decribed in (a) are precisely positioned within the board (58). (c) 24-well plate with optical sensing patches for dissolved oxygen and pH. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

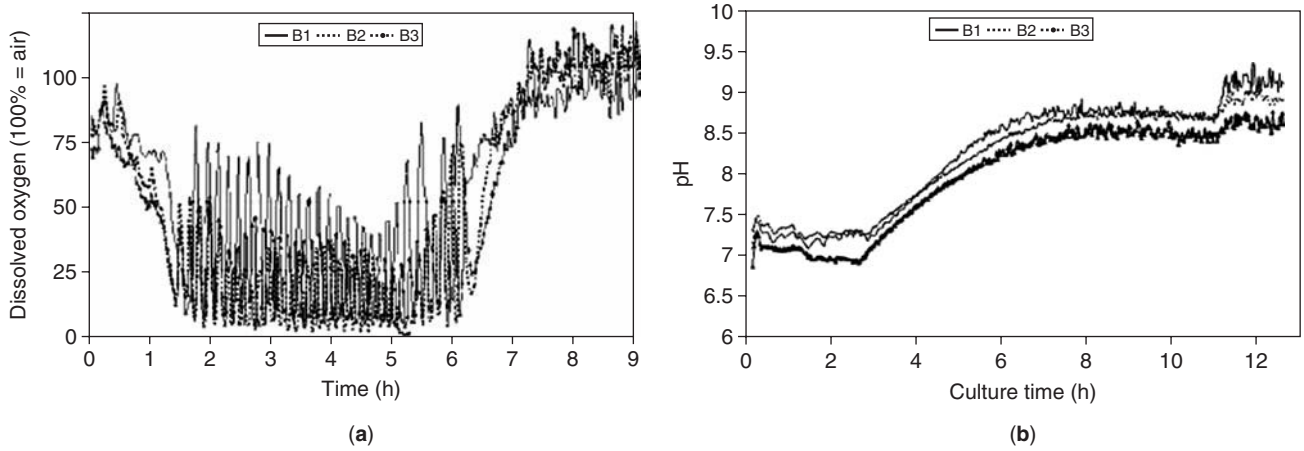

Figure 32.28. (a) The DO profiles of triplicate *E. coli* fermentations where the concentration was controlled using an on-off algorithm. (b) The pH profiles of triplicate *E. coli* fermentations (58).

Figure 32.29. The Infors HT Sixfors parallel bioreactor system. Each of the six bioreactors has a working volume of 300–500 mL, and monitoring (via electrochemical probes) and control of DO and pH (59). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

to demonstrate scale-down utilizing power input per unit volume, k_La, and mixing time as scaling parameters (62). Results from the scale-down of a 7-L bioreactor based on power input per unit volume during the oxygen-limited fermentation of *E. coli* are shown in Fig. 32.33.

The static bioreactor of Zanzotto *et al*. discussed previously suffered from an oxygen gradient from the membrane surface to the bottom of the reaction well (10). This gradient becomes more pronounced if the reactor volume is enlarged by increasing the vessel depth. Zhang *et al*. counteracted this phenomenon by adding a magnetic stirrer to a deeper welled (150 μL) version of the Zanzotto *et al*. reactor (63). When the enhanced reactor was compared to the SixFors system, test tubes, and shake flasks, comparable OD, DO (microbioreactor and SixFors only), and pH profiles were obtained as shown in Fig. 32.34. These reactors have been multiplexed to form a parallel reactor system (64).

A schematic of a 12-unit high throughput bioreactor (HTBR) system developed by Ge *et al*. is shown in Fig. 32.35a (65). The system is capable of monitoring GFP, OD, pH, and DO. The carousel, which also serves as a water bath for temperature control, holds the individual glass reactor vessels and positions them above the detector arm when optical sensing is to commence. The system's performance was evaluated during the culture of murine hybridoma cells. Offline viable cell density and viability, and on-line pH and DO profiles are shown in Fig. 32.35b and Fig. 32.35c. The DNA microarray analysis showed that light exposure for optical monitoring had no impact on the global gene expression. A similar system, shown in Fig. 32.36, with smaller, 6 ml volumes was presented by Harms *et al*. where each reactor had its own set of instrumentation for optical monitoring (58). Data from an experiment where all 24 units were utilized in fermentation of *E. coli* are shown in Fig. 32.37. These vessels were characterized by Vallejos *et al*. using a fluorescence optical mixing sensor (66). This sensor functions by measuring the size of dissipating droplet via its fluorescence as illustrated in Fig. 32.38.

32.7.1 Bubble Column Bioreactors

Bubble column reactors consist of a cylindrical vessel with a gas distributor at the bottom. Aeration is carried out by gas sparging in the form of bubbles into liquid or a liquid–solid suspension (67). Miniaturization of bubble columns faces the same hurdle as other bioreactor platforms in terms of the need for a small sensing instrumentation. Weuster-Botz *et al*. characterized bubble columns 200 ml in volume; large

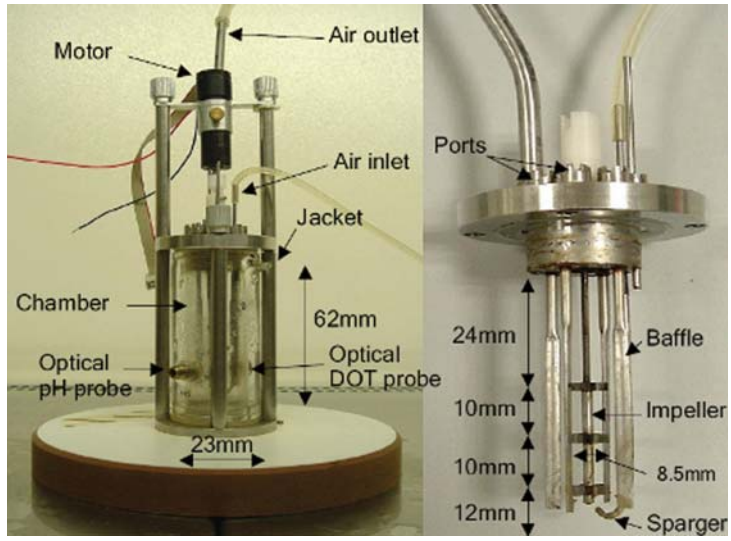

Figure 32.31. A miniature 6-mL (working volume) bioreactor made of Plexiglas. The reactor has three six-blade impellers, baffles, a sparging tube with a perforated end, and optical monitoring of OD, pH, and DO (4). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

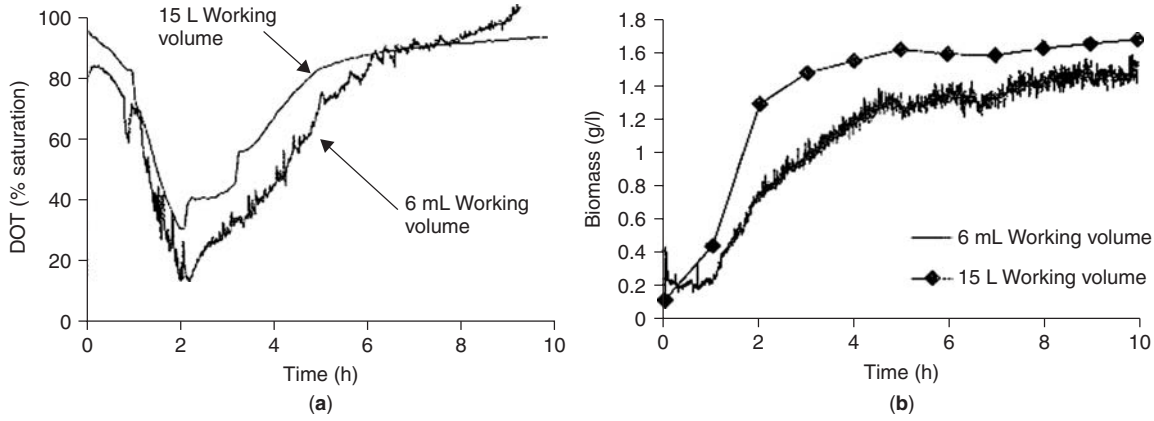

Figure 32.32. (a) DO tension in the miniature bioreactor and a 15-L (working volume) fermentor during *E. coli* fermentation. (b) Biomasses during the two fermentations: OD in the miniature bioreactor and the 15-L fermentor were measured on-line and offline, respectively (61).

enough to use standard polarographic electrodes for measuring oxygen (68). Bubble diameter, gas holdup percentage, k_La, liquid evaporation rate, and power input were correlated to distributor pore diameter, superficial gas velocity, and liquid height. It was concluded that power input per unit volume for bubble columns is an order of magnitude less than for shaking flasks and stirred bioreactors. Changes in energy dissipation into the broth can result in changes in culture biology, for instance in the expression of particular genes (69). Therefore, if power input changes significantly, so will the behavior of cells.

Significantly smaller bubble columns with volumes of 2-mL were characterized and used for fermentation of *E. coli* by Doig *et al*. (70). Rules for scale-up were determined based on volumetric power input and bubble formation characteristics. Based on two gas flow rates in the bubble column and two impeller speeds in a conventional stirred-tank reactor, two corresponding k_Las were determined and utilized for *E. coli* fermentations. Comparable cell density profiles are shown Fig. 32.39. Frachon *et al*. designed a battery of microfermentor bubble columns, shown in Fig. 32.40a, each 80 ml in working volume (71). Production of several model proteins in the microfermentor battery was compared to that in a traditional fermentor where in both cultures DO was automatically maintained at greater than 80% air saturation by mixing in pure oxygen

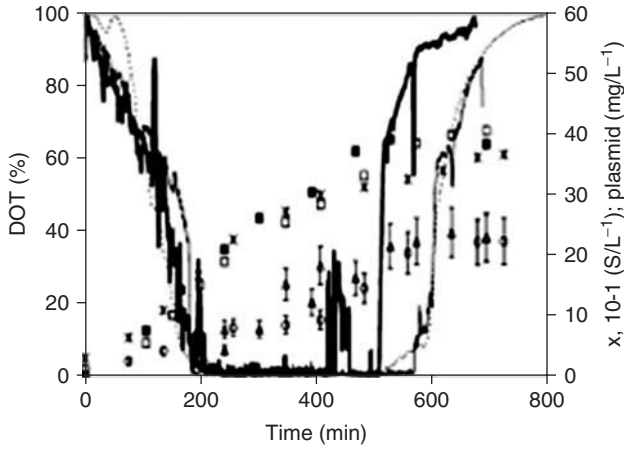

Figure 32.33. *E. coli* DH5α pSVβ fermentation profiles in the 7-L bioreactor and 10-mL MBR under oxygen limiting conditions. Key to symbols: (-) DOT 10 mL 1; (—) DOT 10 mL 2; (- - -) DOT 7 L; (■) (biomass) 10 mL 1; (□) (biomass) 10 mL 2; (∗) (biomass) 7 L; (▲) (plasmid) 10 mL 1; (Δ) (plasmid) 10 mL 2; (O) (plasmid) 7 L. Error bars for the plasmid DNA concentration data represent standard deviations from the mean of a quadruple assayed sample (62).

in the former and by increasing the agitation speed in the latter. The amount of protein recovered per ml of culture was comparable in both fermentors for all proteins tested.

A novel 4.5 mL bubble column with smooth periodic constrictions in the tube, shown in Fig. 32.41, was described by Reis *et al*. and utilized in a proof-of-concept fermentation of *S. cerevisiae* (72). No in-depth characterization of the reactor was carried out; however, data from when the system was compared to a stirred-tank bioreactor is shown in Fig. 32.42.

32.8 OTHER METHODS OF CONVECTIVE MIXING

Other reactors exist which cause the convective mixing of fluid by different means. Another microfabricated bioreactor from MIT described by Lee *et al*. used peristaltic mixing to circulate liquid within a bioreactor (73). The 100 μL (working volume) reactors were complexed to have four vessels per chip. Each reactor had optical sensing of pH, DO, and OD. This bioreactor system is set apart from others of its scale by the ability to automatically control the pH and DO by the injection of acid or base and by changing the oxygen concentration in the peristaltic mixing system.

A commercially successful system manufactured by bioprocessors called *SimCell* (Fig. 32.43) rotates bioreactors, utilizing gravity to circulate a bubble through the 1-mL reactor vessel, thus mixing the culture (74). The SimCell

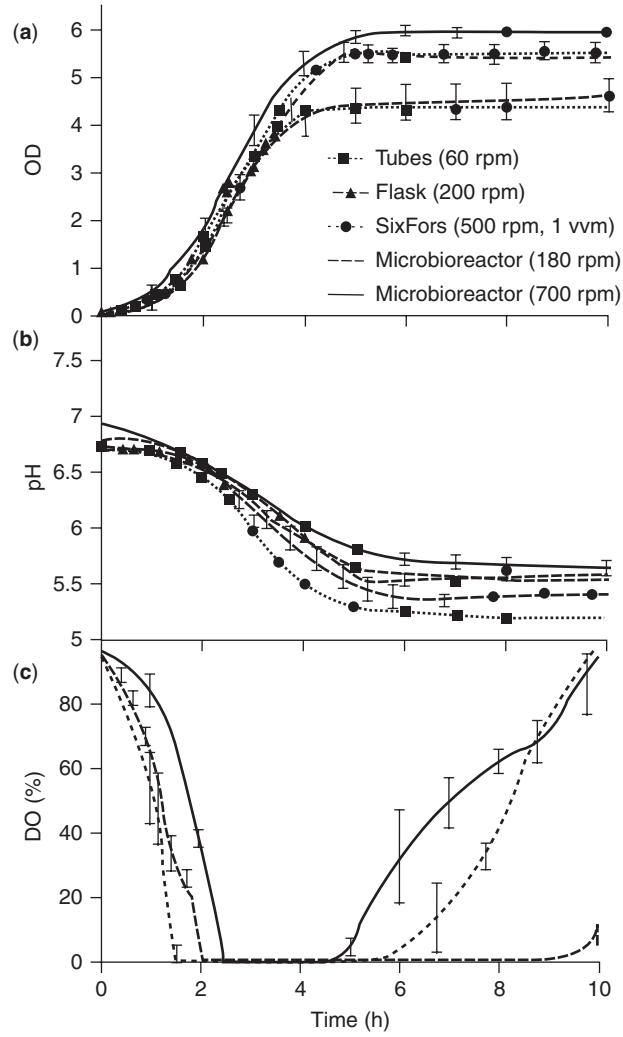

Figure 32.34. The comparison of *E. coli* FB21591 growth kinetics in an LB medium in the microbioreactor (n = 3, stirring speed at 180 and 700 rpm, respectively) with conventional bioreactors including test tubes (n = 4), shake flasks (n = 4), and Sixfors (n = 3). Each growth curve represents the average value with standard deviation from *n* replicate experiments carried out in separate bioreactors. (a) OD, (b) pH, (c) DO.

system can simultaneously carry out thousands of experiments where the pH and DO are optically monitored and controlled.

32.9 CONCLUSION

Clearly, advances in biominiaturization have moved what was once an exotic laboratory technology into the mainstream. Importantly, the technology has proven to be scalable, so data generated at a small scale is representative of larger scale operations. The consistent use of process monitoring across scales should also

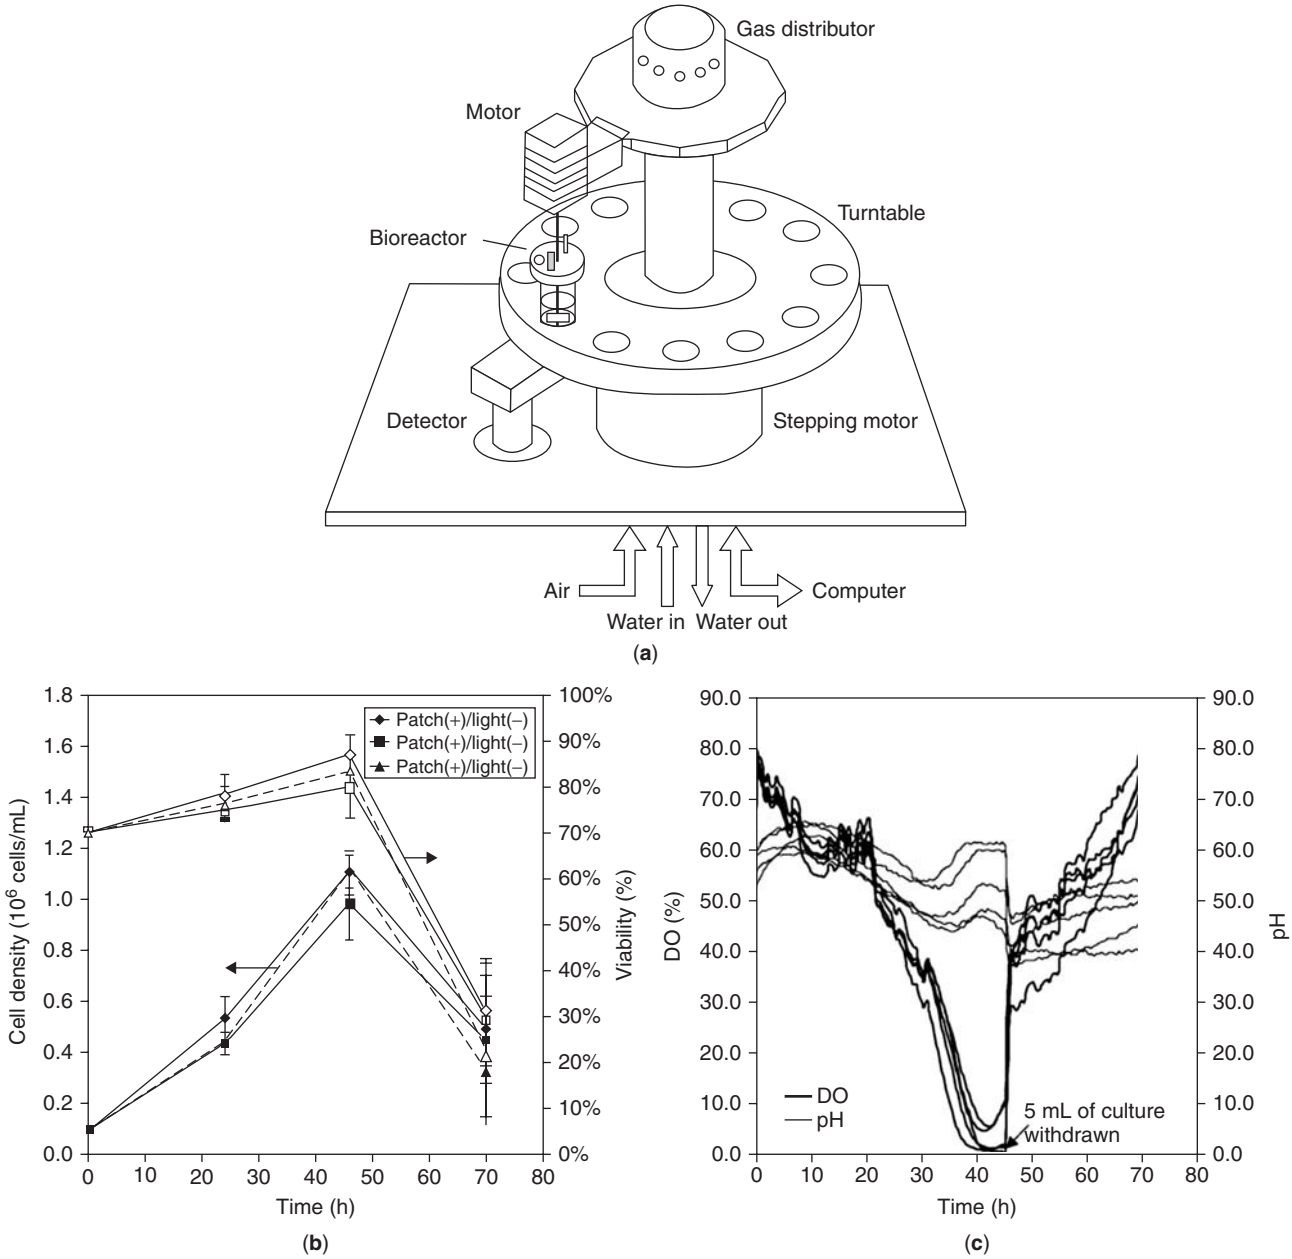

Figure 32.35. (a) The HTBR system capable of simultaneously carrying out 12 cell cultures: The reactor vessels are housed in the turntable which also serves as a water-jacket for temperature control. For DO, pH, GFP, or OD measurements, the turntable rotates placing the vessels directly above the detector arm, which houses the optical instrumentation. Each reactor also has a motor for independent control of agitation speed. (b) Viable cell densities and viabilities of hybridoma cell cultures carried out under three different optical sensing configurations: patches (+) and light (+), patches (−) and light (−), and patches (−) and light (+). (c) The pH and DO profiles obtained using optical monitoring for five replicate hybridoma cell cultures carried out in the HTBR (65).

facilitate the adoption of Process Analytical Technologies (PAT). It is now possible to conduct High Throughput bioprocess development as a statistically driven experimental paradigm. There is almost no limit to the combinatorial number of experimental conditions that can be examined. These advances should allow for much more efficient process development as well as impact other areas such as bioprospecting, where hitherto "uncultivable" species now may be grown by screening samples for growth under matrices of conditions that were previously impractical.

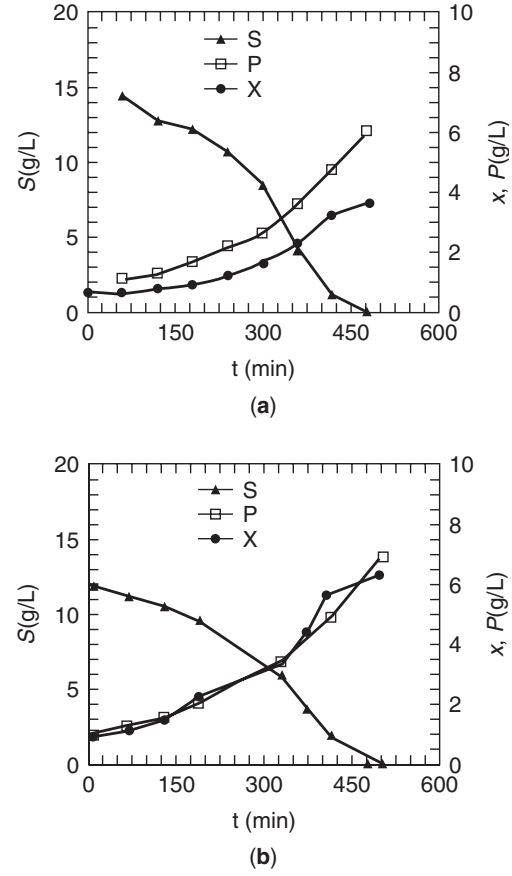

Figure 32.42. The comparison of a stirred tank and a novel bubble column bioreactor. Time coure of glucose concentration (S), cell dry weight (X), and ethanol concentration (P) in batch aerobic-growth on glucose of *S. cerevisiae*. Fermentations in a 5-L stirred-tank bioreactor (a) with an aeration rate of 1.1 vvm and in the microbioreactor (b) with an aeration rate of 0.064 vvm (72).

However, along with the developments in this technology, new challenges will be presented. Two obvious ones are the need for efficient mining of the large amounts of data that will be generated. The other will be the need to interface High Throughput analytical techniques with the miniature bioreactor systems. Fortunately, great strides have been made in both these areas and their careful integration will ultimately provide systems of the greatest value to the experimentalist.

Optical sensors that have been extensively used in the miniature systems described here are now finding their way into larger scale systems. Fluorometrix, Ocean Optics, Presense, and Polestar are some of the companies that market optical sensors that can be used in fermentation and cell culture applications at larger scales. Sartorius has just introduced its Cultibag line of disposable bag reactors that include noninvasive optical sensors, as shown in Fig. 32.44 (75). Clearly, process integration is currently under way.

Acknowledgments

We thank all of the authors who have spent years generating the advances presented here and the publishers who have allowed the use of copyrighted figures. Our own work has been generously supported by NSF, NIH, Maryland TEDCO, Dupont, Fluorometrix, Genentech, Merck, Pfizer and Sartorius over the years.

INOCULUM PREPARATION

Craig J.L. Gershater
S.B. Pharmaceuticals, Harlow, Essex, England

33.1 INTRODUCTION

Inoculum preparation is the part of the fermentation development process that secures the microbial genotype for experimental and/or production purposes by providing a viable biomass capable of high productivity. Microbial processes generally consist of two distinct elements: a biotic factor the biomass and an abiotic factor (the growth environment). Hence, in applied microbiology terms

$$\text{pheotype} = \text{genotype} + \text{environment}$$

where the phenotype represents the desired attribute (accumulation of biomass or a valuable product of that biomass), the genotype represents the collection of metabolically useful genes and associated gene products, and the environment provides a system (principally a fermenter) of control over gene expression, that is, growth and product formation. At some point in the fermentation development program, the biotic and abiotic elements must be linked; this will be defined as the supply of consistent biomass to the fermenter plus growth medium. The growth and productive phases of fermentation are, of course, the subject of intense investigatory work; much has been written about the strict control requirements of the fermenter system, including the response of the microorganism to the nutritional and environmental factors. However, the requirements for the inoculum and the influence the inoculum can have on the outcome of the fermentation has received only scant attention (in terms of literature citations). A detailed assessment of the effect of the inoculum on microbial productivity can be justified, particularly in the case of nonrecombinant microorganisms, on the basis that commercially useful microbes will be isolated directly or indirectly from an ecosystem very remote from the fermentation laboratory, where the influences on growth are unknown.

33.1.1 Microbial Ecology

The microbial metabolic attribute to be exploited has evolved as a result of environmental influences unknown to the fermentation scientist. There is a case to be made for the basic ecology of the microorganism to be understood prior to culture preservation and inoculum preparation. A simple classification of organisms isolated from soil provides a loose context against which culture maintenance and development may be defined; soil organisms may be divided into two basic categories (1,2), the attributes of which are summarized in the following:

1. Indigenous, or autochthonous species, which have lower reproductive rates and are specialized for a particular habitat or more complex/intractable substrate. These are known as K strategists and include ascomycetes, basidiomycetes, and some actinomycetes.
2. Invaders, or allochthonous species, which have high reproductive rates and tend to function as pioneer species utilizing simple soluble substrates. The zymogenous fungi within this group include the sugar-fungi *Mucor, Rhizopus, Trichoderma, Penicillium*, and *Aspergillus*; organisms such as

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

these may be activated by the presence of fresh substrate (breaking spore dormancy). These types of organisms, sometimes termed r strategists, possess good competitive abilities, which (along with some K strategists) include the ability to produce toxins (antibiotics), which is of obvious commercial interest.

Cognizance of the background ecology of the microorganism may permit a more appropriate culture storage and recovery method to be devised to maximize the chances of the organism successfully colonizing the next stage in the fermentation process.

33.1.2 Inoculum Development Conundrum

Process optimization must endeavor to replicate those factors responsible for the expression of the desired attribute in the totally artificial environment of monoculture; nutrient sufficiency (feast); and relatively stable physical parameters, such as temperature, pH, and oxygen availability. Although relatively few studies on the influence of inoculum on final stage fermentations have been made, it is certain that the inoculum preparation stage of most fermentations will affect the expression of the desired phenotype, whether qualitatively, quantitatively, or temporally. Hence, inoculum development is faced with a fundamental problem; the factors tested in seed stage or inoculum preparation investigations can only be assessed retrospectively in various high-productivity, final stage fermentations, remote from the seed stage influence. The conclusions drawn from inoculum development studies must deconvolute effects due to seed from those due to final stage fermentations. This chapter therefore seeks to explore how inoculum preparation can be incorporated into standard fermentation development programs.

33.1.3 Factors Critical to Inoculum Preparation

To adequately define the essential requirements for inoculum preparation, it is necessary to identify the elements that make up the process:

- Culture storage
- Stock culture
- Culture assessment
- Inoculum development
- Inoculation criteria

These elements will now be discussed and placed in the context of an overall inoculum strategy for fermentation development.

33.2 CULTURE STORAGE

Culture storage is only successful if the subsequent growth and productivity of the microorganism is consistent with expectations. Culture storage methodologies have been described in several authoritative texts (3–7) and are reviewed only briefly here.

33.2.1 Subculture

Depending on how cultures are received for fermentation development, some growth stage on agar will generally be required. The method of subculture relies on transferring colonies from one solid (depleted) medium to a fresh medium. This method is only suitable for short-term storage. Each transfer to fresh medium provides a comparatively nutrient replete environment, adaptation to which may select for an altered phenotypic expression. To minimize this possibility, minimal media are selected and the numbers of subcultures carried out are kept to a minimum. Minimal media agars are prepared in test tubes or screw-top Universal bottles, with the agars slanted to maximize surface area. Colonies from a master plate can be streaked onto the agar slants, allowed to grow for a minimum period, and then stored for a few weeks.

33.2.2 Desiccation

Removal or immobilization of water from the culture prevents metabolic activity, which is the key requirement of preservation. Drying methods are suitable for spore-forming fungi and streptomycetes; the principle is based on providing a solid, inert surface onto which spore suspensions can be dried. The methods differ in terms of the solid support that is used, which can include sterile soil, silica gel, dry sand, filter-paper disks, and various types of inert beads (glass, plastic, or porcelain). A suspension of spores (or possibly vegetative culture) is added to the sterile inert support, and after aseptic stoppering of the tube or vessel the mixture is allowed to dry at 25°C. This method provides a mechanism to store, typically, spore suspensions for perhaps months, but it is generally not recommended for long-term storage of process critical stock cultures.

33.2.3 Freeze-Drying (Lyophilization)

Freeze-drying removes water from a frozen culture by sublimation under a vacuum. It is suitable for the long-term preservation of many types of culture and is particularly suitable for the preservation of vegetatively grown cells. Bacteria, while frequently stored by lyophilization, may be susceptible to damage by random mutation (7,8). The benefits of freeze-drying cultures is that the lyophials are relatively easy to store, transport, and identify. The cultures

may be stable for up to 10 years. The disadvantages include the need to purchase a relatively expensive freeze-drier and the risk of mutation occurring in stored bacteria, which may be minimized by storing the lyophials in the dark at 5°C.

33.2.4 Freezing

Freezing the culture effectively deprives the cell of water and slows all metabolic and chemical activity. Intracellular water deprivation arises as a result of osmotic pressure induced at temperatures between −5°C and −15°C, the temperature at which ice forms in extracellular fluid but the intracellular space remains unfrozen (9). Under these circumstances there is solute enrichment of the extracellular fluid, and water leaves the cell by osmosis, freezes outside, and the volume fraction of the cell is thus reduced. The rate of freezing will affect the size distribution of the ice crystals and with slow cooling will tend to result in considerable water loss from the cell and large extracellular crystals; rapid freezing (−200°C/min, obtained by plunging the sample in liquid nitrogen) will result in smaller extracellular ice crystals and some intracellular ice crystal formation. It is necessary to determine the correct freezing rate for the particular cell under investigation. The properties and composition of the growth medium qualitatively affect the success of cryopreservation. Recovery from cryopreservation may also be critical due to an effect known as recrystallization, which refers to small crystals rearranging themselves into potentially more damaging larger crystals, leading to cell rupture. This may typically happen at temperatures between −100°C and −20°C. The potentially damaging effects are minimized by rapid thawing.

To minimize the general effect of ice crystal damage, high-viscosity cryopreservants are often added to the cell suspension (in the case of vegetative culture storage); these may be of two basic types, intracellular (membrane penetrating) or extracellular (nonmembrane penetrating). The intracellular agents used include dimethylsulfoxide (DMSO) and glycerol. Glycerol (added at 5–10% v/v to the final culture dispensing fluid) has the effect of reducing lesions due to osmotic shock by reducing the size of ice crystals. Extracellular cryopreservants include various carbohydrates, such as sucrose, mannitol, dextrin, and starch; 20% powdered skim milk and 12% sucrose are widely used.

The principal advantage of freezing as a method of culture storage is the relatively long duration of culture stability. The lower the temperature, the longer the duration. At −20°C it is reasonable to consider that microbial cultures will remain stable for 1 to 2 years; at −80°C, cultures should remain stable for 5 years or more, indefinite storage is obtained at temperatures of less than −80°C using liquid nitrogen. The vapor phase of liquid nitrogen is −156°C, and the liquid phase is −196°C; extreme care must be exercised when recovering culture vials from the liquid phase, because leakage of liquid nitrogen into vials may result in explosion of the sealed ampoules due to gas expansion at elevated temperatures. The main disadvantages of freezing for culture storage are the relatively high capital costs for compressor freezers (particularly those for less than −80°C) and secure purchasing and management procedures for maintaining liquid nitrogen stocks and reliability of electrical supplies. In addition, frozen ampoules are not easily transported.

Fungal culture storage may require a combination of all the methods described earlier for long-term storage, dependent on the morphological characteristics of the strain in question; for example, aconidial strains may be impossible to preserve by lyophilization (10), but may be stored on silica gel under liquid nitrogen. Methods appropriate to bacterial culture storage using both drying and liquid nitrogen have been reviewed (11).

33.3 STOCK CULTURE

A fermentation development or production process involving the culturing of commercially significant microorganisms demands that a robust system be in place for stock culture generation and maintenance. Variability of stock culture performance cannot be tolerated because culture variation masks the influence of nutritional or environmental factors within a development program.

33.3.1 What Is a Stock Culture?

The stock culture represents the current microbial investment in a fermentation program, which is manifested in both qualitative and quantitative terms. Qualitatively, the stock culture defines the current genotypic status of a commercially significant microorganism (i.e., its product formation capacity in a defined environment). Quantitatively, the stock culture is represented by a carefully controlled holding of cultivar, which will be drawn on for development and production purposes. At some critical point this holding must be replenished with equivalent stock culture or be replaced by an improved stock. Awareness of the microbial ecology of the culture may be important given that the cultivar will be required to propagate within a new environment (the ecological niche represented by fresh fermentation medium) by rapid colonization. If, for example, the culture of interest is considered to be an allochthonous species (r strategist) capable of colonizing fresh medium from spore inoculum, then the stock culture should be evaluated as a spore-based stock culture.

Management of the microbial culture resources is the most important facet of a microbiological bioprocess enterprise. Each bioprocess organization defines its own

protocols to secure the microbial investment; however, the principal objective must be to ensure that the bioprocess enterprise is never placed at risk due to stock culture mismanagement.

33.3.2 Stock Culture Generation

At various stages in a microbial development program it will be necessary to generate stock culture. The method chosen is dictated in part by the preservation protocol appropriate for the fermentation program. In my laboratory, with a relatively high turnover in new cultures for fermentation development, vegetative stock cultures are often generated and stored at −80°C. The stock generation model for cryopreservation is shown in Figure 33.1.

The model in Figure 33.1 assumes that the culture to be laid down to stock has been evaluated or in some other way nominated for long-term storage. Hence, prior to long-term culture storage, working stocks of the same culture will have been available. Working stock cultures may similarly be prepared using the model described earlier, but perhaps with far fewer vials, or they may be preserved using one of the other methods described previously.

The generation of fresh stocks may be dictated by several factors that may or may not be interrelated. As the stock culture holding is depleted, it must be replenished with fresh stocks with performance criteria as close to the existing stocks as possible. Stock culture management protocols determine at what point this should be; for critical bioprocesses (main line production) this may be initiated when 60% to 70% of the existing stock has been utilized. With less critical bioprocesses, stock culture replenishment may commence when 70% to 80% of the existing stock is depleted. Fresh stocks are also required when there is qualitative change in the culture component of the bioprocess. This may result from a deliberate attempt to improve the culture by strain improvement or culture reselection; alternatively, it may result from an inexplicable, irreversible deterioration in culture performance. If fresh stocks are to be generated from an improved strain, then the working stocks evaluated as part of the strain improvement process serve as the progenitor to the stock culture generation model previously described. If, however, the need to generate new stocks arises from severe culture deterioration, then a previous generation stock must be used for current stock culture generation. This deterioration may be accounted for by a reduction in culture viability, culture productivity performance, or microbial or viral contamination.

As new stock cultures are prepared, a family tree of related strains will be generated. To replenish stocks from an existing stock culture, a vial of the parental working stock can be used to generate a new daughter stock. Within the stock culture model each time a new generation stock culture is prepared after testing, a portion of that stock holding must be set aside for permanent retention. In my laboratory, at each stage in the stock maintenance program a portion of the existing stock is nominated as the master or "crown–jewel" stock and is held inviolable for process operations but represents a temporal marker in the history of a culture development program. To keep track of culture usage and family history, a suitable nomenclature must be devised. We use a simple decimal notation system in which the integer before the decimal point represents the current generation number and the figure after the decimal point represents the sibling stock number for the current generation.

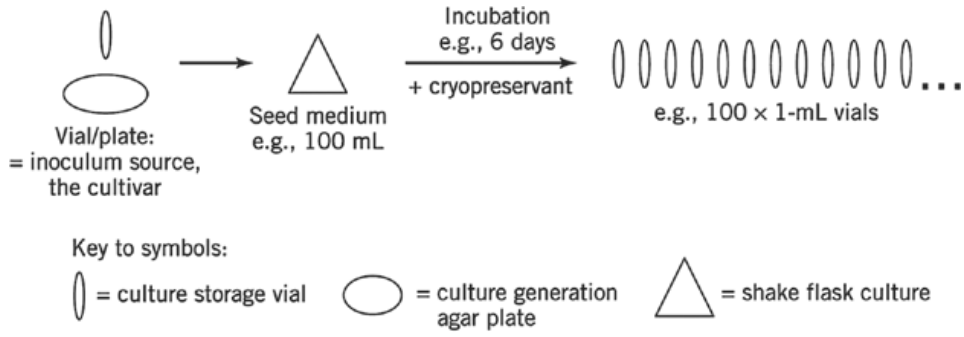

Figure 33.1. Stock culture generation models. Inoculum source for the first-stock generation is usually culture grown on agar plates; this is typically a plug (agar plugs are aseptically cut through the colony center) inoculated to liquid seed medium. The seed medium provenance, selected for vegetative growth, resides within relevant literature or, in the case of screening derived cultures, from original cultivation protocols. The incubation conditions for the culture are determined from the literature or from preexisting protocols. Dispensing of adequately grown vegetative culture to long-term culture vials is carried out under strict aseptic techniques; the number of vials dispensed to must be restricted to prevent the heterogeneous distribution of culture between first and last vials in the series.

Eventually even master or crown-jewel stocks may become depleted or obsolete, but within the active lifetime of a bioprocess, the master stock can only be drawn on in the event of a catastrophic failure of the main working stocks due to either an inexplicable loss of viability or performance or mechanical failure of the entire culture preservation system. To provide additional protection to the culture storage facility, a decision may be made to preserve split stocks not just in separate freezers but also on different sites, if possible. This type of stock culture management can be determined within an organization's disaster planning protocols.

33.4 CULTURE ASSESSMENT

The generation of new stocks imposes a profound influence on the bioprocess, and performance criteria must be reestablished at each stage in the culture maintenance program. As with any biological system, the inherent variability of the culture must be assessed prior to any development or production processes being committed to the new stock culture. The elements of culture maintenance that must be in place before an assessment of culture variability can be carried out include the following:

- Adequate numbers of culture vials (previously found to be monoculture)
- A suitable seed culture fermentation protocol
- A final or production phase fermentation protocol
- Suitable response variables to the final stage fermentation
- Validated assays for quantitatively determining the levels of the response variables
- Full supporting documentation to all of the elements mentioned

Culture variability must be addressed directly by the use of suitable statistical evaluation procedures. These procedures are largely based on a system of replication at each stage of the evaluation so as to obtain sufficient data describing the spread of variability and the contribution to total variation by each critical stage in the evaluation protocol. If the culture is being generated and evaluated as part of a good management practice (GMP) process, the stringency of these requirements may be greater. Figure 33.2 broadly defines the type of testing that may be carried out using a newly generated or existing stock.

This model permits replication sufficient to explore the contribution to the total variation of each of the stages capable of being a source of variation. This is sometimes known as a nested design, and data arising are analyzed using standard analysis of variance (ANOVA) procedures. Not only are data generated that capture the inherent variation associated with vial-to-vial variation, but the relative robustness of the remaining system can also be evaluated. Data from this kind of trial may be summarized in the form of statistical tables, but perhaps of more use would be data summarized using graphical plots. Figure 33.3 represents the actual data obtained for a reproducibility trial exploring the vial-to-vial variability of a fungal culture producing an antibiotic.

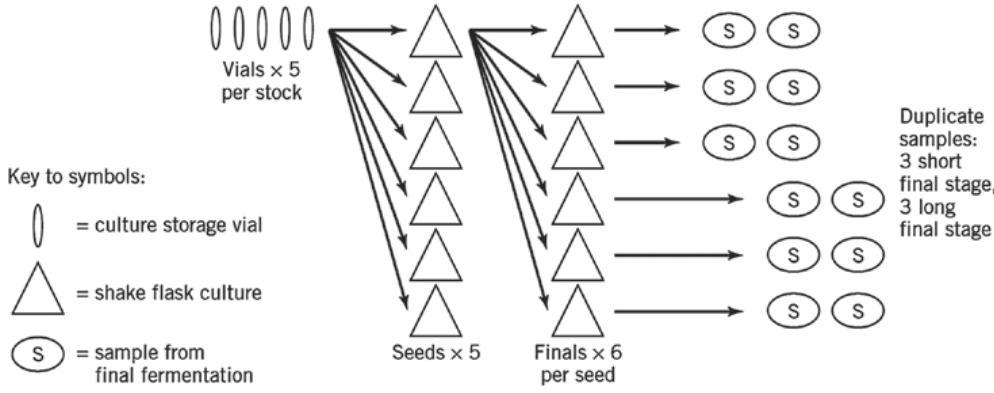

Figure 33.2. Culture variability testing model. To ensure adequate data is generated for a statistical analysis of variance to be undertaken, appropriate numbers of elements at each stage in the procedure must be selected. In this (model) case, five vials of stock culture are each used to inoculate each of five seed-media shake flasks. Each seed culture, after incubation to generate adequate biomass, is used to inoculate each of six final stage fermentations and will be assessed for reproducibility of growth. Half of the final stage shake flasks (three fermentation flasks) are incubated for a relatively short time and then duplicate sampled; the remaining half are incubated for a relatively longer time and then duplicate sampled. Each sample can be the source of duplicate or triplicate assays to enhance the analysis of variance (not shown in the model).

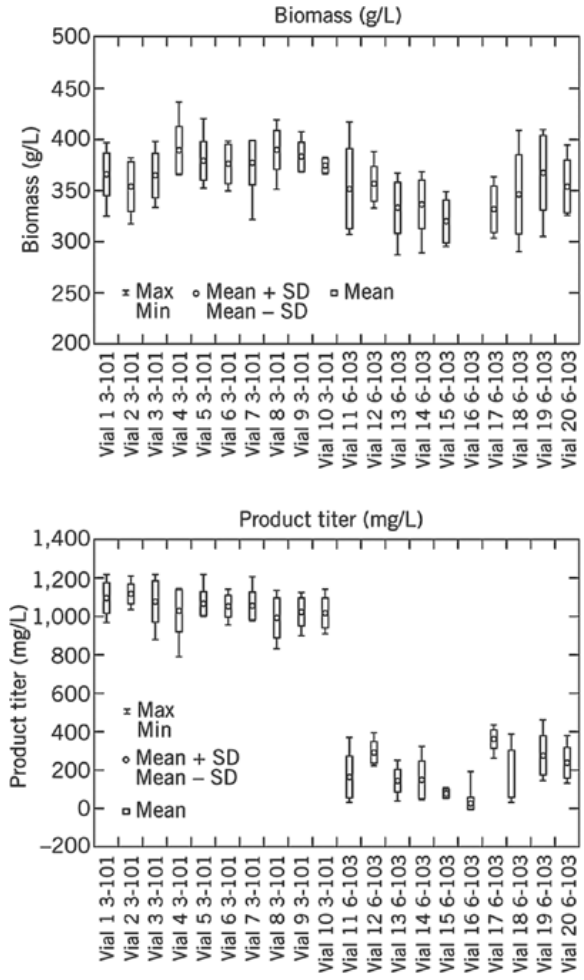

Figure 33.3. Reproducibility data from an antibiotic-producing culture. A fungal culture subject to a fermentation development program generated a number of reisolates that were tested in a reproducibility trial similar to one described in the model (Fig. 33.2). The two reisolates were called 3-101 and 6-103. Preliminary testing in single shake-flask experiments had indicated that although 3-101 was superior to 6-103, the difference was not great, therefore, working stocks of both cultures were prepared. In terms of biomass the two cultures appear very similar, although the variability of culture 6-103 was greater than that of 3–101. Biomass data was unavailable for vial 16, but this did not prevent an ANOVA of the data. In terms of product titer, 3-101 was clearly far superior to 6-103, both in terms of overall titre as well as vial-to-vial variation. The ANOVA for these experiments revealed that vial-to-vial variation was the greatest contributor to variation of 6-103 performance, and that factor tended to mask the true culture productivity.

33.5 INOCULUM DEVELOPMENT

As stated earlier, the key to successful inoculum preparation lies in the outcome in the final stage of the fermentation, hence, evaluation of seed protocols is always retrospective. The factors that can influence the inoculum and therefore the final-stage productivity are multifarious. This chapter has already identified certain key functions that may or may not influence the development of a successful seed culture, such as, microbial ecology, culture storage, and variability. In addition, some of the factors that may need to be considered in developing a inoculum preparation strategy include:

- Seed medium
- Seed incubation conditions
- Microbial growth dynamics
- Optimum transfer criteria (qualitative inoculum variable)
- Volume of inoculum on transfer (biomass concentration, quantitative inoculum variable)
- Number of seed-stage passages
- Assessing inoculum development

Several of these influences have been investigated in the past, but often in isolation from one another. The recognition that inoculum development can play a key role in fermentation development programs was recognized over 20 years ago; in a remark attributed to Hockenhull but reported by Calam (12), he stated that “once a fermentation had started it can be made worse but not better.” Despite this recognition, the bioprocess industry (high-added-value products), appears to have been very relaxed about setting resources aside to investigate the influence of inoculum on final stage fermentation productivities. This is perhaps somewhat in contrast to the fermentation food industries, where starter culture methods have been developed to provide high quality and consistent product.

In the dairy industry, factors such as correct carbon and nitrogen sources, vitamin and mineral supplements, and the addition of phage inhibitory agents, antioxidants, and neutralizers have all been considered important in defining the correct formulation for bulk starter media for lactic acid bacteria (13) in cheese production.

In the case of alcohol fermentation, relatively little work appears to have been done to investigate the influence of inoculum on alcohol yields. When reported, the studies are often limited to just one aspect of the inoculum process, for example, that inoculum levels may vary greatly with *Saccharomyces cerevisiae*, at between 0.05 and 60% (14). More recent studies with yeast fermentations have attempted to define the effect of inoculum on growth and ethanol production (15), including investigating at which point in the microbial growth curve inoculation should take place—in this case exponentially growing cells were favored. In addition, these studies were carried out while keeping factors such as medium formulation, medium sterilization, and culture growth conditions all constant, while varying inoculum size, under these circumstances inoculum levels of

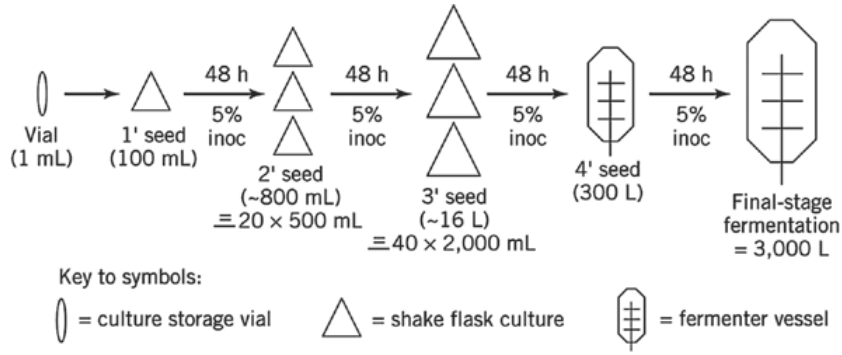

Figure 33.4. Typical multiple growth cycle fermentation seed train. The illustration indicates the logistics in preparing the inoculum for a 3,000-L final stage fermentation. In the example given, the seed train is defined by having a quaternary seed-stage inoculate the final-stage fermentation. The incubation times defined for each stage of the fermentation are designed to yield optimal inoculum to the next stage in the process. Throughout the seed train, the shock of culture transfer to nutrient feast is minimized by maintaining a relatively short residence in each seed fermentation, thus minimizing the risk of transferring from famine to feast at each stage. Inoculum transfer volumes impose logistic constraints on the seed train such that at the tertiary seed stage 40 2-L shake flasks must be inoculated. This represents a risk to the system in terms of contamination and culture heterogeneity, but small-scale fermenters can be used to overcome these problems.

10% were found to generate maximum biomass and, hence, ethanol.

Fermentations devoted to solvent formation have also been investigated to determine the influence of inoculum. The production of acetone, butanol, and ethanol by anaerobic fermentation using *Clostridium butylicum* was found to be adversely affected by repeated subculturing. This can be partly ameliorated by incorporating heat shocking and subculturing into an inoculum development program wherein the effect of heat shocking the culture to 75°C for 1.5 min may reduce the degenerative effects of subculturing (16). Again, more recent studies have confirmed the deleterious effect of repeated subculture with saccharolytic clostridia (17). Using *Clostridium acetobutylicum* it was recognized that there would be an abrupt decrease in solventogenesis after 10–12 successive transfers incorporating heat shock; further, after 25 transfers, the culture failed to form spores, and after heat shock failed to grow at all. The dramatic decrease in solventogenesis on subculture was found to be associated with deficiencies in acetate/butyrate CoA transferase and acetoacetate decarboxylase activity. The addition of exogenous acetic and butyric acids maintained solventogenesis to at least the 40th transfer.

The influence of inoculum development for fungal cultures has been investigated. The production of γ-linolenic acid (GLA) by shake flask culture of the sporulation-deficient strain of *Cunninghamella echinulta* was found to be profoundly affected by the use of fragmented mycelia, increasing biomass and GLA titre (18).

Most investigations into the influence of inoculum involving fungal and filamentous bacterial cultures have been carried out for the production of various bioactive metabolites at the high-value-added end of the bioprocess industry, some of the issues of inoculum preparation here will be now considered in more detail.

33.5.1 Multiple Growth Cycles

The generation of inoculum for large-scale bioactive metabolite production by fermentation generally necessitates a buildup of active biomass through multiple growth cycles. This is illustrated in Figure 33.4 for a typical 3,000-L pilot-plant fermentation.

In developing the multiple-growth cycle seed train, several experimental objectives must be met. The first of these is the seed medium for culture growth. There are virtually no references to seed stage medium development in the literature (19,20), however, some general principles do apply. The seed medium formulation should seek to minimize nutrient shift effects while supporting good vegetative growth over a short time scale. The overriding proviso for seed medium formulation is that high productivity is supported in the final stage medium. In the case of bioactive metabolite fermentations, the seed stage fermentation should not result in production of the metabolite of interest. Bioactive metabolites may be growth inhibitory to the producing strain (and hence are secondary metabolites), and their presence in the seed stage broth may complicate or inhibit the final stage product accretion. Sterilization control profiles for the seed stage medium, just as for the final stage medium, should ensure that Maillard reactions (browning) adversely affecting protein and glucose availability are minimized. Sterilization cycles should also be

designed such that vitamin destruction is minimized and so the formulation of the seed medium will seek to prevent trace element precipitation (e.g., phosphate and magnesium combinations and iron complexes formed on heating or pH shifts).

The overall inoculation protocol seeks to define a quality standard for the inoculum. Earlier studies had identified that larger volumes of inocula of *Trichoderma reesei* (in the range 0.5 to 5.0% v/v) ended to reduce subsequent lag phases (21). These sorts of studies were extended (22) using *Penicillium chrysogenum* for penicillin production; it had been established that the spore concentration in shake-flask seed culture was critical to growth and antibiotic production. Above 10^4–10^5 spores/mL, growth of the production cultures was good, critical enzyme levels were high, and penicillin production was good. Below 10^3 spores/mL, the fermentations were suboptimal in every respect. In further studies (23), *Penicillium* spores were seeded at different concentrations into seed medium, and samples were removed at regular intervals and examined for growth on agar for numbers of viable centers. At some critical point in the fermentation, the number of viable growth centers fell by up to 85%, presumably due to aggregation and increased branching frequency in the hyphae. These observations have been confirmed by image-analysis work (24), which demonstrates a morphology shift from dense pellet formations to more dispersed forms with inocula above 10^5 spores/mL. These data tend to confirm the notion of a quality curve for inoculum development, as illustrated in Figure 33.5.

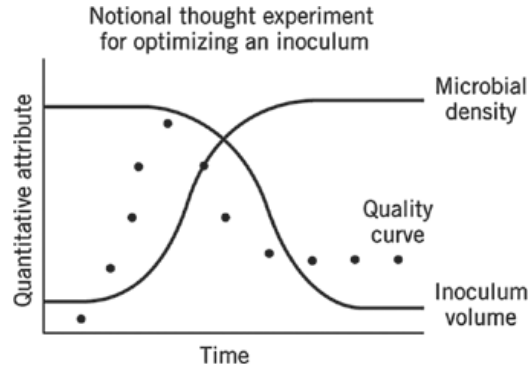

Figure 33.5. Notional quality curve for a seed stage fermentation. The thought experiment described suggests that there may be a compromise between inoculum volume and the qualitative attributes associated with the inoculum. Determining the notional quality curve requires an investigation into the optimization of the desired response variable in the subsequent fermentation stage. This may be achieved by carrying out timed transfers and measuring the physiological status of the organism at each time point.

33.6 INOCULATION/SEED TRANSFER CRITERIA

Multistage inoculum transfers and the success criteria associated with those transfers must be determined experimentally. Each stage in the process can be examined individually, but at some point the seed train protocol must be established. As already indicated, seed stage assays may be expensive in terms of numbers and time required for full analysis, and care must exercised to ensure that seed stage data correlate with final stage fermentation productivity. The use of complex media may impose additional variation on a multistage process, and wherever additional variation is suspected, greater replication in the data-gathering phase will be required.

The principal physiological markers that can be used for seed transfer criteria include:

- Biomass density or an analyte reflecting that variable (ATP)
- Gross morphology attributes (particularly for filamentous bacteria and fungi)
- Respiratory gas analysis from aerated fermenters (carbon dioxide evolution rate)
- Macromolecular titre (DNA, RNA)
- Final stage productivity

Final stage productivity can only be determined by inoculating final-stage fermentations from each seed stage and analyzing for productivity at each stage. The format for this type of experiment is shown in Figure 33.6.

33.7 INOCULUM PREPARATION STUDIES

There are very few studies reported in the literature examining the complete inoculum preparation process from initial inoculation to final stage productivity. *Streptosporangium* cultures that are capable of producing useful secondary metabolites, including chloramphenicol (25), dihydrosinefungin (26), and endothelin-converting enzyme inhibitors (27), have been investigated for various inoculum stage conditions (28). The factors examined with respect to the inoculum stage of *Streptosporangium* cultures include inoculum storage, media sources, and inoculum size on two antibiotic fermentations. Three culture preservation methods were examined: spores, slant tubes, and frozen agar plugs. When each of these sources were tested in different media and analyzed for growth, slant transfer tubes were found to be the most effective for maintaining high growth concentrations in the final stage. Examining incubation conditions with various *Streptosporangium* cultures indicated that aeration and growth phase of the inoculum may affect the time course

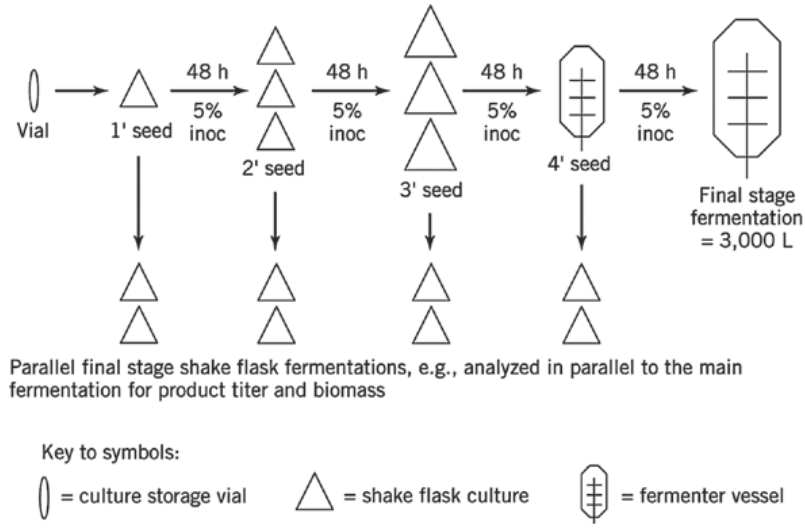

Figure 33.6. Inoculation–seed transfer experimental design. Final stage shake flask fermentations running in parallel to the main seed train, inoculated from seed stage broth generated in the inoculum train. Principal objective with this type of design is to compare productivity between each final stage fermentation to help determine if there are effects due to passage or some other seed incubation condition.

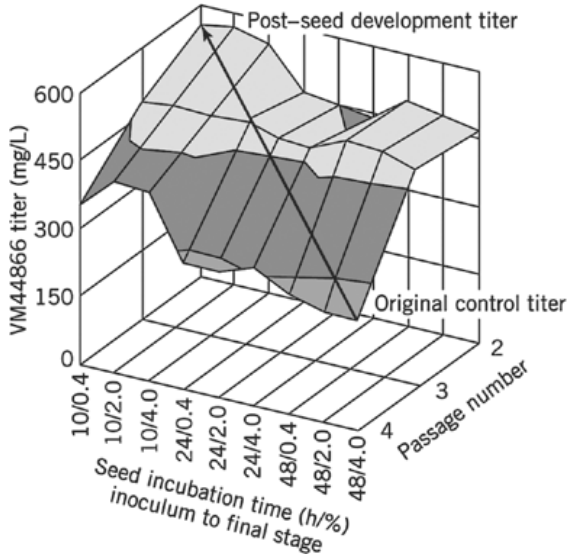

Figure 33.7. Response surface plot for milbemycin production under the influence of seed stage development factors. The response surface plot shows the final stage titers of milbemycin obtained under the seed inoculum conditions indicated by the three-dimensional plots. These data show that percentage inoculum levels into the final stages were not a key factor. However, passage number was significant, with quaternary seed stages giving rise to the lowest final stage titers. Similarly, juvenile seed was optimal for all conditions tested.

of the final stage fermentation, particularly if that fermentation stage is relatively short. These influences may be less pronounced if longer final stage fermentations are required.

The improved production of milbemycin (a macrolide with anthelminthic properties) from *Streptomyces hygroscopicus* as a result of intensive seed stage development has been reported (29). In this work an attempt was made to examine several interacting factors affecting seed stage development and subsequent final stage production of milbemycin. Time-course fermentation profiles of the seed stage revealed that a major component of the seed medium, dextrin, was not utilized, and the other major carbohydrate component, glucose, could be reduced fourfold without affecting the productivity of the final stage fermentation. Aside from medium composition, the other seed development factors investigated included:

- Age of culture at transfer
- Temperature of seed-stage incubation
- Inoculum level
- Passage number of seed stages

Inoculum age was found to have a profound influence on final stage titers, with more juvenile seeds (10 h as compared to 48 h for the control) proving beneficial to milbemycin production. Inoculum levels could be halved from 4% v/v without loss of productivity. Passage number was found to be critical in seed media containing dextrin, as these seed fermentations showed a marked decrease in final stage titers in the tertiary and quaternary seed stages. Studies investigating the combined effects of seed incubation times, percentage inoculum into each seed stage or the final stage fermentations, and passage number were undertaken. Figure 33.7 shows the response surface plot summary

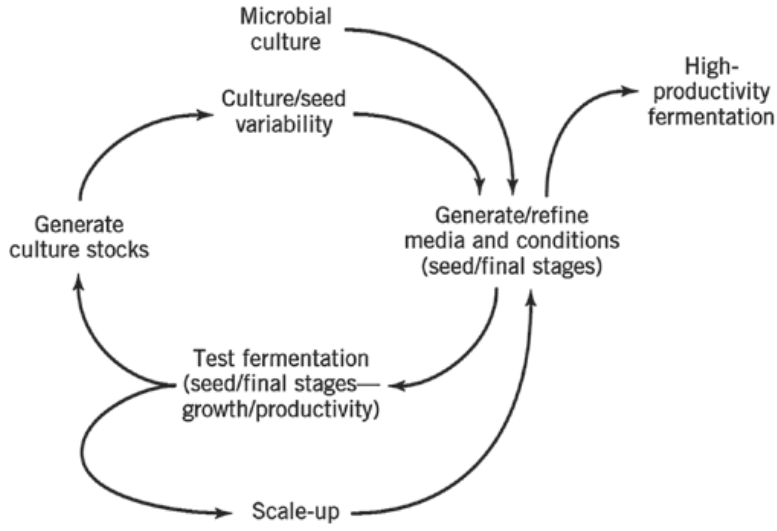

Figure 33.8. Fermentation development model incorporating seed stage investigations. The model shown assumes the process starts with receipt of the microbial culture. Seed and final stage media are identified initially. Fermentations are carried out to assess growth, and if adequate to the purpose, then culture stocks may be generated. These stocks must be tested for variability before further studies can commence. Seed and final stage fermentation conditions can then be refined with the newly generated and tested stock culture. The fermentation development process continues until performance criteria for the system are met, the process is scaled up, and if necessary further refined. Finally a high-productivity fermentation can be defined using a well-characterized and genotypically secure process.

of that work, where by examining the various seed stage factors, overall the titer of the final stage fermentation was increased fourfold.

33.8 INOCULUM DEVELOPMENT SUMMARY

This chapter has attempted to describe the various influences that may be examined when trying to define the optimal inoculum-development protocols. As indicated from the literature, this part of the fermentation process has been largely neglected, and yet the evidence indicates (from the relatively few studies undertaken) that inoculum preparation may have a profound effect on the outcome of a fermentation development process. Figure 33.8 describes how inoculum development may be incorporated into the overall fermentation development strategy for a bioprocess enterprise.

MICROCARRIER CULTURE

SUSAN T. SHARFSTEIN
Department of Chemical and Biological Engineering and Center for Biotechnology and Interdisciplinary Studies, Rensselaer Polytechnic Institute, Troy, New York

CHRISTIAN KAISERMAYER
Project Manager Cell Culture Applications & Support, GE Healthcare, Vienna, Austria

34.1 HISTORY AND DEVELOPMENT

Microcarrier development began in the 1960s when Antonius L. van Wezel first cultivated human fibroblast cells on DEAE Sephadex™ beads (1). The beads were at that time already in use as an anion exchanger in chromatography. van Wezel achieved a homogenous unit process and was thus the first to cultivate adherent cells without attachment to the vessel surface. The cultivation technique was further developed under his direction at the Laboratory for Inactivated Virus Vaccines (Bilthoven, The Netherlands). van Wezel also recognized the potential of microcarriers for large-scale culture of adherent cells and performed extensive research in the field of vaccine production (2–4). According to van Wezel, a microcarrier must have the following properties.

- The surface must allow cell adhesion.
- The diameter should be between 150 and 250 μm. This is a compromise between achieving maximum surface area and reducing adherence of the cells due to excessive curvature.
- The variation in bead size must be small to ensure that cells on all microcarriers reach confluence at the same time.
- The density of the microcarriers should be between 1.05 and 1.15 g/cm^3 to keep the carriers in suspension by relatively low stirrer speeds, thereby reducing shear forces that could hinder cell attachment and proliferation. However, the carriers should settle rapidly in the absence of stirring to allow cell separation and media change.
- The carriers should be transparent to allow microscopic observation of the cells.

For large-scale applications, handling is much easier if the carriers are autoclavable. In addition, they should be available in large batch sizes, have a good long-term stability, and have a suitable documentation (i.e. a drug master file or a regulatory support file from the manufacturer) to permit the carriers to be used for industrial purposes.

Subsequent work in the 1970s showed that the technique was scaleable for a variety of production processes (2,5). Since the yield of adherent cells depends on the surface area available for growth, it was believed that the maximum cell concentration in microcarrier cultures would increase linearly with microcarrier concentration. However, when the quantity of DEAE Sephadex A-50 exceeded 1–2 g/L, no proportional increase in cell yield was achieved, which was attributed to the toxicity of high microcarrier concentrations (2,6). This toxicity was manifested by the failure of many cell types to survive the early stages of culture, long lag phases, and limited cell concentrations at the plateau stage of culture. Explanations for this phenomenon have varied, but it was widely believed that the degree of substitution of DEAE Sephadex

A-50 was not optimal for cell growth (7–9). Horng and McLimans (8), Inooka (10), and Kuchler *et al*. (11) suggested that alterations in the ion-exchange capacity of DEAE Sephadex A-50 could lead to improvements in cell attachment and growth. The problem was overcome by the development of microcarriers with a much lower degree of substitution, yet that still fulfilled van Wezel's requirements for an optimal microcarrier. These microcarriers were the result of collaboration between van Wezel and Pharmacia Biotech AB. Instead of DEAE Sephadex A-50, a different matrix, namely, Sephadex G-50, was substituted with varying DEAE concentrations.

Cytodex™ 1 was launched in 1981. Due to the different matrix and the lower degree of DEAE substitution, the charge concentration on this carrier was only 1.5 meq/g compared to the 3.5 meq/g in the original DEAE Sephadex A-50 carrier. This new carrier avoided the toxic effects associated with the high charge concentration and was suitable for growing a wide variety of cells (12–14). Cytodex 1 was thus the first commercial product to allow the full potential of microcarrier culture to be exploited at volumes up to several hundred liters (15–17). The carrier did not show toxic effects at concentrations well above 2 g/L and cell yields increased with carrier concentration. The recommended concentration for Cytodex 1 is 3 g/L (18); however, for high cell density fermentations, it has been increased to 5 g/L and even 10 g/L (19–21) without negative effect on cell growth. Opportunities for microcarrier culture of animal cells have been further increased by the development of Cytodex 3, which consists of a dextran matrix coated with denatured porcine collagen. The collagen-coated surface of the carrier thus creates an environment similar to that encountered by the cells *in vivo*, which is important for maximizing the plating efficiency and function of cell types such as hepatocytes, fibroblasts, chondrocytes, myoblasts, and epidermal cells (22,23). Growth curves of different cell lines on Cytodex carriers are shown in Fig. 34.1.

van Wezel's requirements for microcarriers apply only to smooth or microporous carriers where cell growth takes place on the surface of the beads. Significant improvements have been made to develop microcarriers suitable for various cell types and also for different cultivation methods. Table 34.1 gives an overview of commercially available microcarriers. In addition to dextran, polystyrene, polyethylene, glass, and collagen have also been used as matrices. Carrier surfaces were modified with extracellular matrix (ECM) proteins such as collagen or fibronectin as well as with synthetic coatings like poly lactic acid, poly L-lysine, or trimethyl ammonium. A further important development was the introduction of macroporous carriers that allow cell growth inside the pores, thereby protecting

TABLE 34.1. Commercially Available Microcarriers

Name	Material	Surface Modification	Manufacturer	Diameter (μm)
Cytodex 1	Dextran	DEAE	GE Healthcare	180
Cytodex 3	Dextran	Gelatin-coated	GE Healthcare	175
Cytoline 1, 2	Polyethylene, silica		GE Healthcare	Length 1700–2500, thickness 400–1100

the cells from shear forces introduced by stirring or aeration, particularly rising gas bubbles, while at the same time increasing the available surface area to achieve higher cell concentrations (24–26).

34.2 CELL CULTIVATION

34.2.1 Cellular Adhesion Mechanisms

Cell attachment to microcarriers is influenced by a number of factors. In the beginning of microcarrier development in the 1960s, it was proposed that the charge density of positively charged surfaces was the main factor for cell attachment. Indeed, Mukopadhyay *et al*. (27) showed that adsorbed serum proteins on microcarrier surfaces, which masked the carrier charge, resulted in a lower cell-attachment rate. On Cytodex 1, cell attachment was shown to follow first-order kinetics and to rely on the electrostatic interaction between the negatively charged cell surface and positively charged amino groups on the microcarrier (18). The negative charge on the cell surface is conveyed by the glycocalyx, the carbohydrate part of glycoproteins and glycolipids embedded in the cell surface (28).

Collagen-coated surfaces are used frequently for establishing primary cultures and for growing cells that are difficult to handle or have low plating efficiency, such as hepatocytes, fibroblasts, chondrocytes, myoblasts, or epidermal cells (22,23). Collagen is almost neutrally charged and promotes cell attachment via receptor-mediated interactions (29). Cells in tissues *in vivo* are surrounded by a complex network of macromolecules to which they attach using a number of heterodimeric cell-surface adhesion receptors known as integrins (30). Integrins are noncovalently linked heterodimeric proteins that recognize proteins of the ECM or counterreceptors on adjacent cells in a cation-dependent manner. The RGD (arginine-glycine-aspartic acid) sequence is known to be the key adhesion site (31) found in many proteins of the ECM, including fibronectin, type 1 collagen, vitronectin, and laminin. Antibodies against integrin subunits block cell adhesion to vitronectin-coated surfaces (32). As cell adhesion to surfaces coated with ECM-like proteins occurs via receptor-mediated interactions, the process is slower than attachment to charged surfaces.

34.2.2 Cell Types Cultured

As Table 34.1 shows, a wide selection of microcarriers is available. Selecting the appropriate carrier for a specific cell line depends on the attachment characteristics of the cells, the process design, and whether the cultivation medium contains serum or recombinant attachment factors. In general, microporous or surface carriers will be more applicable for the cultivation of adherent cells, while the sponge-like structure of macroporous carriers is suitable for all cell types. Macroporous carriers will also facilitate the immobilization of cells that can grow in suspension. Table 34.2 shows a selection of cells that have been cultivated on microporous carriers. Examples of cells grown on macroporous carriers are given in Table 34.3. Figures 34.2–34.4 show microphotographs of cells grown on microporous and macroporous carriers.

34.2.3 Practical Aspects

The bexst results from microcarrier cultures are obtained with equipment that gives even suspension of the microcarriers with gentle stirring. Static culture can be used for initial experiments. Whenever microcarriers based on a dextran or glass matrix come into contact with glassware, the

inside of the glass vessels should be siliconized to prevent the microcarriers from sticking to the surface.

For small-scale culture, plastic bacterial petri dishes are often used for stationary cultures, while roller bottles or shake flasks are used for mixed cultures and spinner flasks for stirred cultures. Addition of microcarriers to culture bottles (tissue culture flasks or roller bottles) dramatically increases the surface area available for cell growth, thereby increasing cell yield several fold. When using shake flasks for cell cultivation on microcarriers, an orbital shaker is preferred over a reciprocal shaker as its mixing is gentler. The rate of rocking should be just sufficient to prevent sedimentation of the microcarriers. If necessary, 5–10% (w/v) Ficoll™ 400 can be added to the cultivation medium to increase its density, which facilitates microcarrier suspension.

The most suitable vessels for general purpose laboratory scale microcarrier culture are those with a stirring rod or impeller driven by a magnetic base unit. These vessels have been used for many years to cultivate suspension cells. The stirring rod or bar should never come into contact with the inside surface of the vessel since this may damage the microcarriers. Spinner vessels used under closed culture conditions are suitable for cultures ranging from about 50 mL to 5 L. The capacity of the closed culture system is limited by the gas exchange capabilities (i.e. headspace aeration) that require a minimum surface area-to-volume ratio to ensure oxygenation of the culture. For larger-scale culture, bioreactors are necessary to effectively control culture conditions. Bioreactor microcarrier cultures can be operated at very high cell densities (up to 2×10^8 cells/mL carrier in fluidized and packed beds) as well as scaled up to several thousand liters. Microcarrier cultivation can be done in very different reactor types. In addition to classical stirred-tank

reactors (STRs), microcarriers have also been used successfully in disposable bioreactors such as the Wave bioreactor (33–35). Cells can also be grown in fluidized-bed reactors using Cytoline™ carriers or packed-bed reactors with Fibracel™, Carboseed™, Cytoline, or Siran™ carriers. Cultivation in fluidized- or packed-bed mode can increase cell concentrations 15–25-fold compared to classic fed-batch culture of suspension cells, with cell concentrations of up to 2×10^8 cells/mL carrier volume. In packed beds, the cage compartment of the reactor is filled with beads or discs. In fluidized beds, microcarriers make up 10–50% of the reactor volume. Carrier concentration in homogenous stirred tanks is normally 2–3 g/L. However, especially for surface carriers, the carrier concentration can be increased to obtain higher cell concentrations. Carrier concentrations of up to 10 g/L have been reported (20,21), providing a surface area of up to 45,000 cm^2/L.

34.2.3.1 Inoculation and Attachment. It is essential to equilibrate and stabilize all culture parameters before adding the inoculum. Temperature and pH are especially important. Depending on the type of carrier, there may be an optimum pH for cell attachment. For collagen-coated surfaces, pH had no significant effect on cell attachment over a range of 7.1–8.0, while on Cytodex 1, the attachment rate varied considerably, with an optimum at pH 7.1 (36). At the time of inoculation, the cells should be in exponential growth phase to avoid lag phases in the microcarrier culture. It is also important to use single-cell suspensions for the inoculum as aggregates cause heterogeneity.

Cell attachment to microcarriers is influenced by a number of factors. For optimum attachment, the cells used for inoculation should be in a good nutritional state, preferably in late exponential phase. The harvesting procedure should result in a single-cell suspension with minimal damage to the cell-surface receptors to facilitate quick reattachment. Cell and microcarrier concentrations as well as agitation speed also play important roles. For cells with low plating efficiency, intermittent stirring (e.g. 3–5 min stirring out of every 30 min) has been reported to be beneficial (36,37). However, for large-scale culture, intermittent stirring should be avoided as the carrier settling time increases with increasing vessel height. Furthermore, microcarriers at the bottom are subject to oxygen limitation. Higher seeding densities or carrier concentrations increase the cell attachment rate because the frequency of cell-bead contacts is increased. For a given cell number, a higher carrier concentration can be simulated by reducing the vessel volume during the inoculation phase and adding more cultivation medium after the cells have attached. The initial cell concentration is not only important in terms of the attachment rate but also to ensure that every microcarrier is populated. Adherent cells can cover a surface only by growth, not by detachment and reattachment. Therefore, carriers that are unpopulated at the start of the culture remain in this state during cultivation. Mendonca *et al*. (38) showed that for Cytodex 1, a minimum initial ratio of eight cells per bead is necessary to ensure that all carriers are populated. At carrier concentrations recommended by the manufacturer (typically 2–5 g/L), surface carriers are normally inoculated with 0.5 to 2×10^5 cells/mL, which is equivalent to 0.5 to 2×10^4 cells/cm^2. Macroporous carriers are normally inoculated with a similar cell concentration. Fluidized beds are inoculated with 1 to 2×10^6 cells/mL of carrier volume. Beyond these general heuristics, the optimal inoculation density is highly dependent on cell line characteristics and media composition.

34.2.4 Optimizing Culture Conditions

34.2.4.1 Cultivation Medium. The requirements for cell growth in microcarrier culture are similar to those in other monolayer methods. The growth medium used during routine culture can therefore be used for initial experiments with microcarriers. However, several media components need to be considered if culture conditions are to be optimized. Compared to static flask or roller-bottle culture, much higher cell concentrations are reached in microcarrier culture; hence, it is important to closely follow the consumption rate of nutrients. Additionally, cell physiology often changes upon reaching confluence (39). Medium requirements during growth and maintenance phases may therefore be different. To prevent depletion, it will often be necessary to increase the concentration of glucose, amino acids, vitamins, or choline. Nutrients that are often consumed quickly include glutamine, arginine, aspartic acid, asparagine, and, when growing human, diploid cell lines, cysteine. Glucose is essential for continued cell attachment; if its concentration falls to nonphysiological levels, cells may detach from the microcarriers (40). Adding retinoids can promote the adhesion of cells (41). Choline is incorporated into membrane phospholipids and decreasing levels may result in perturbation of membrane composition, thus causing rounding of cells and decreased adhesion (42). Besides optimizing the medium for batch cultivation, the use of feeding strategies, especially for glucose and glutamine, may also be considered. Starting at a relatively low glucose concentration of 2–3 g/L and adding more after the initial cultivation phase will also help to reduce lactate formation. Alternatively, other carbon sources, for example, fructose or galactose, can be used to decrease lactate production (21).

During long-term cultivation, it is not sufficient to prevent nutrient depletion; waste products must be removed as well. This can be done by continuous or discontinuous perfusion where spent medium is removed from the reactor and fresh medium added. As microcarriers not only provide

a growth surface for the cells, but are at the same time a means of cell immobilization, they lend themselves well to perfusion culture.

34.2.4.2 Gas Supply. Supplying the correct amounts of O_2 and CO_2 is important for achieving high yields with microcarrier culture. Both gases have metabolic functions and CO_2 is also involved in controlling culture pH when using conventional bicarbonate buffers. The gas requirements for individual cells are the same whether grown in microcarrier culture or other systems; however, due to the higher cell concentrations in microcarrier cultures, special attention should be given to ensuring sufficient oxygen supply. Stirred microcarrier cultures with volumes of approximately 500 mL to 1 L are usually kept as closed systems. Provided that the liquid volume is not more than 50% of the total vessel volume, oxygen transfer should be sufficient. The gas in the headspace is renewed when taking samples or replenishing the medium. At high cell concentrations, the headspace can briefly be flushed with gas (15–20 s of 95% air and 5% CO_2) forced through a sterile filter to ensure removal of excess CO_2 generated by the culture.

For large-scale cultures in bioreactors, three aeration methods are in principal, available: surface aeration, direct sparging of gas, and bubble-free aeration through membranes. Surface aeration only works for small reactor volumes that have a sufficient liquid surface area-to-volume ratio. Bubble-free aeration using silicon or Teflon tubing has been used successfully in bioreactors (43). However, due to the large membrane area required, this approach is also limited in scale. The standard method therefore is still direct sparging of air or pure oxygen into the culture. This technique is widely used for suspension cells and can also be applied to microcarrier cultures, especially for macroporous carriers where the cells grow inside the pores and are protected from shear forces introduced by the gas bubbles. When using microcarriers in STRs, it is important to select a sparger that does not create excessively small bubbles. Small bubbles rise more slowly than large bubbles and may attach to microcarriers, transporting them into a foam layer at the surface and thereby removing carriers and cells from the fluid phase. In general, ring spargers with hole diameters of 0.5–1 mm will provide sufficient oxygenation capacity without creating a stable foam layer. For microporous carriers, the same oxygen tension can be used as for suspension cultures, usually 15–30% of air saturation. When using macroporous carriers for high cell density cultures, the oxygen tension should be raised to 40–60% of air saturation to increase the concentration gradient and facilitate diffusion into the pores. Cultures should not be excessively aerated since high oxygen tensions (above ambient) can be toxic and reduce growth rate (44). Due to the high cell concentration that is reached in macroporous carriers, several studies have been conducted to evaluate whether sufficient oxygen concentrations are maintained inside the pores. The low solubility of oxygen (6–7 mg/L) combined with a consumption rate of 2–3 $\mu g/(10^6$ cells h) for Vero cells (45) and about 9 $\mu g/$ (10^6 cells*h) for fibroblasts (46) makes it clear that oxygen is the most critical nutrient in terms of diffusional limitation. Fortunately, optimal culture performance can be obtained for a wide range of oxygen concentrations. Meuwly *et al*. (47) found that cell growth was unaffected in a concentration range of 10–80% of air saturation.

Three major effects influence oxygen concentration in a macroporous carrier: the boundary layer at the carrier surface, the diffusional limitation within the carrier, and the intraparticle convection. The thickness of the boundary layer decreases with the turbulence of the surrounding fluid. The diffusion of oxygen into pores is influenced by the shape of the pores and the presence or absence of cells. A convective flux through parts of the carrier can occur if large pore carriers are used. Fassnacht and Pörtner (48) evaluated oxygen supply in a packed-bed reactor with Siran microcarriers. The diameter of the carriers was 3–5 mm and the pore size 60–300 μm. They found that cell growth was limited due to restricted oxygen supply at 100% of air saturation. By increasing the oxygen concentration to 300% of air saturation, the nutrient consumption increased and they achieved a threefold increase in product formation. A further increase of oxygen concentration had no effect. While Taylor *et al*. (44) found a toxic effect of hyperoxic conditions on cells cultivated in a packed-bed reactor, Pörtner and Fassnacht found no such effect. They also calculated the maximum penetration depth of oxygen into the microcarrier pores. This parameter is dependent on the cell concentration and on the dissolved oxygen concentration. At a cell concentration of 2×10^8 cells/mL carrier and a dissolved oxygen concentration of 400% of air saturation, they found a maximum penetration depth of 1 mm. When the dissolved oxygen concentration was lowered to 100% of air saturation, the maximum penetration depth was reduced to 500 μm. This is in good agreement with the results of Preissmann *et al*. (46) who found a maximum penetration depth of 300 μm at 40% air saturation.

To ensure a sufficient oxygen supply, three parameters can be varied. First, the turbulence at the carrier surface should be kept high to reduce the thickness of the boundary layer. Second, the carrier diameter should be constrained to stay within the maximum oxygen penetration depth. Finally, large pore sizes facilitate a convective flow and thereby improve oxygen supply.

34.2.4.3 Culture pH. Since pH influences cell survival, attachment, growth, and function, maintaining the correct pH is vital to achieving optimal cell growth and high yields. Cell attachment to carriers with a charged surface is highly

dependent on the correct pH and has been shown to be optimal at pH 7.1 for Vero cells and Cytodex 1 (36). When initiating small-scale cultures, the cultivation medium is often exposed to the atmosphere for prolonged periods. This causes the pH to rise if bicarbonate buffer systems are used. To achieve high plating efficiency, it is important to equilibrate the cultivation vessel before inoculation to achieve a pH that is near neutral. Most cultivation media use a bicarbonate buffer system, but its capacity is often not sufficient to prevent a pH decrease toward the end of the culture cycle. HEPES (10–20 m*M*) can be used as an alternative if the buffering capacity needs to be increased (49).

34.2.4.4 Mixing and Shear. Mixing is used to provide a homogenous concentration of nutrients, to keep carriers in suspension, and to prevent the formation of pH or pO_2 gradients. The type of impeller and the stirring speed influence mixing time and oxygen transfer capacity. For cultivating animal cells, only stirrers creating low shear forces, mainly marine impellers, are used. Minimizing shear forces is especially important when cultivating cells on microporous carriers. Gregoriades *et al*. (50) have shown that cells attached to such carriers are much more susceptible than suspension cells to damage by shear forces. In similar experiments, Venkat *et al*. (51) estimated the dissipation of local energy in a turbulent spinner vessel and reported cell damage above 150 rpm. It is thus important to select a stirring rate that ensures suspension of the microcarriers but still creates low shear forces. Depending on the stirrer configuration, normal stirring speeds are 50–100 rpm. While mixing time is usually not a problem in small-scale vessels and bioreactors, mixing time at equivalent tip speeds can increase by an order of magnitude when comparing a 10- and a 10,000-L bioreactor (52). An important consequence of long mixing times is that the concentration of sodium hydroxide used for pH control must be lowered to minimize cell damage caused by elevated local concentrations of extended duration.

All animal cells are susceptible to damage from shear forces in any type of agitated culture. A number of studies have suggested that cells grown on microcarriers may be particularly sensitive due to increased energy dissipation at the microcarrier–liquid interface, adherence of microcarrier beads to gas–liquid interfaces, and the inability of the cells to rotate freely in the culture medium. In particular, Croughan *et al*. evaluated the effects of different agitation rates on FS-4 human fibroblasts grown on Cytodex 1 microcarriers in spinner flasks (53). They observed an optimum agitation rate of 60 rpm, with significantly decreased growth at higher rates. The extent of growth showed a sigmoidal dependence on integrated shear factor as shown in Fig. 34.5, with 20 s^{-1} being the transition to reduction

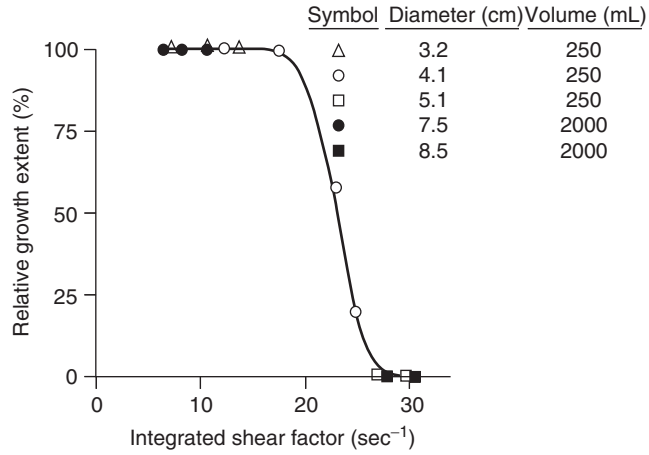

Figure 34.5. Relative growth extent of FS-4 human fibroblasts grown on Cytodex 1 microcarriers as a function of integrated shear factor. Reprinted with permission of Wiley-Liss, Inc, a subsidiary of John Wiley & Sons, Inc, from Croughan *et al*. Biotechnol Bioeng 29:132, Copyright © 1987, John Wiley & Sons.

in growth. The relative growth extent depends on Kolmogorov eddy length with no growth seen at length scales less than 100 μm and full growth seen at length scales greater than 150 μm. Results from Jeff Chalmers laboratory (50,54) confirmed that cell damage occurred at much lower energy dissipation levels for cells grown on microcarriers than cells grown in suspension [10^4 vs 10^8 ergs/(cm^3 s)]. However, their experiments, which were conducted in a novel extensional flow device with no turbulence, showed that the eddy-length explanation was apparently incorrect. Other studies from this group examined the attachment of microcarriers to gas–liquid interfaces (55). They found that microcarriers, with or without cells, tended to attach much more readily to rising bubbles than cells in suspension, and to become entrapped in a foam layer. Cell death was caused not by bubble rupture, but rather by cells being stripped off the microcarriers. In a more biological study, Mufti and Shuler observed that HepG2 human hepatoma cells cultured on microcarriers exhibited increased cytochrome P-4501A1 (CYP1A1, a marker for cellular stress) activity in an agitation rate-dependent manner (Fig. 34.6) (56).

34.2.5 Sampling

34.2.5.1 Visualization of Cells. If cells are grown on transparent microporous carriers, microscopic observation can be used routinely to obtain information about cell morphology, distribution of the cells on the microcarriers, degree of confluence, and the formation of aggregates. The microcarriers can be viewed without further preparation in an inverted microscope. For microphotography, it may be desirable to stain the cells for improved contrast. The most suitable routine procedures for staining microcarrier

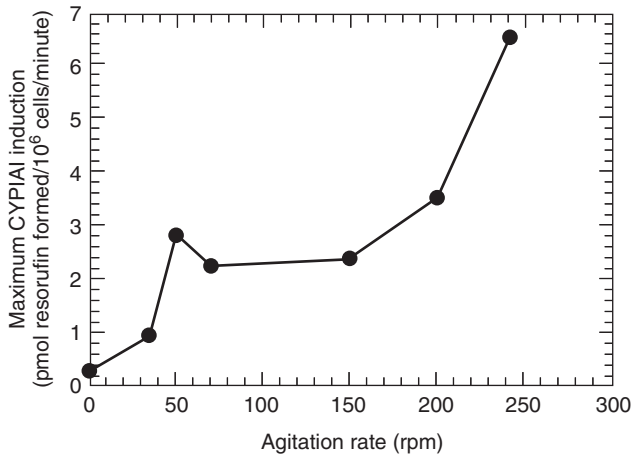

Figure 34.6. Effect of agitation intensity on the maximum induction of CYPlAl in Hep G2 cells in a 50-mL spinner flask. Reprinted with permission from Mufti, NA, Shuler, ML. Biotechnology Progress 11 : 551, Copyright © 1995, American Chemical Society and American Institute of Chemical Engineers.

cultures are Giemsa stain or Harris' hematoxylin. The latter can be used when better nuclear detail is required. Both staining methods are described in Ref. 18. Many other, more specific, staining procedures are also possible. However, it should be noted that some carbohydrate or protein-specific staining procedures may give high backgrounds due to interaction with the carrier matrix. Cells on macroporous carriers are best viewed using laser confocal microscopy after staining with acridine orange.

34.2.5.2 Cell Quantification. Cell concentration in microcarrier cultures can be determined by several direct and indirect methods. Direct methods include cell enumeration by counting whole cells after trypsinization from the carrier or determining the concentration of released nuclei. In the latter method, modified by van Wezel (6), cells growing on microcarriers are incubated in a hypotonic solution. The released nuclei are then counted using a Coulter counter or counted manually after staining with crystal violet (57). Counting released nuclei is also the preferred method for cultures grown on macroporous carriers since trypsinization will not result in complete cell release.

Cell viability is more difficult to quantify. This parameter is often determined by trypan blue or erythrosin staining after detaching the cells with trypsin. However, depending on the cell line, trypsinization may influence the result. An alternative is the MTT colorimetric method (58) that is also a good choice for cultures on macroporous carriers. Cell viability can also be assessed by staining methods. Two fluorescent dyes (fluorescein diacetate for living cells and ethidium bromide for dead cells) can be used to estimate cell viability in three-dimensional structures (59,60).

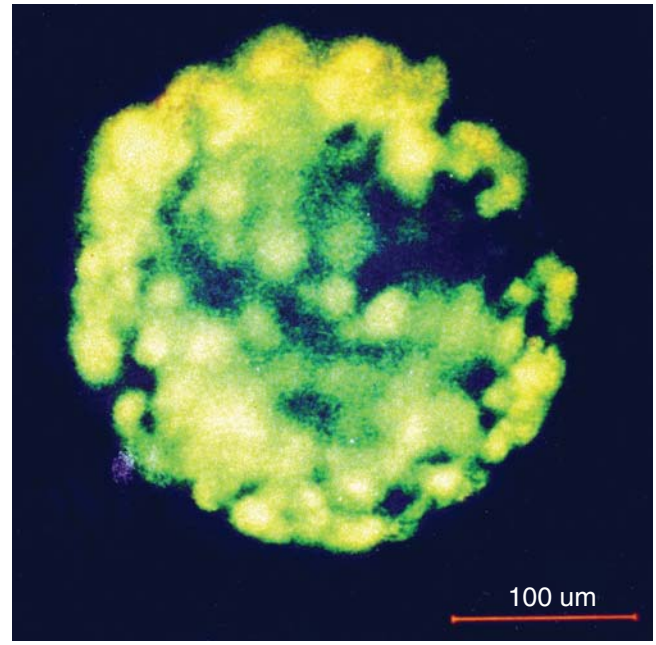

Figure 34.7. Confocal laser-scanning microscope photograph of fluorescein diacetate-stained CHO cells covering a Cytopore bead. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Fluorescein diacetate-stained Chinese hamster ovary (CHO) cells on a Cytopore™ carrier can be seen in Fig. 34.7.

Indirect methods often measure metabolic activities such as glucose or oxygen consumption, lactic or pyruvic acid production, or CO_2 production. All these methods must be calibrated using direct cell counting methods. The resulting cell-specific consumption and production rates are unique for every cell line and cultivation medium. In addition, metabolic rates will be different during the exponential growth and plateau phases of the culture. However, when a standardized process is run, these methods often provide a good estimation of the viable cell number.

In large-scale culture, it is often desirable to have on-line measurement of cell concentration. One possibility to achieving this is to continuously measure the oxygen consumption. This method is highly dependent on cell line and culture conditions, so it is only useful if the monitored process is run in exactly the same way each time. A relatively new technique is to measure capacitance and thereby determine the viable cell volume (61). Capacitance measurement has been used for cells grown in suspension, on microporous and macroporous carriers, in stirred tanks, as well as fluidized and packed beds (62,63). Sterilizable and GMP-compliant probes for this application are available from Aber Instruments (http://www.aber-instruments.co.uk/).

The main source of error for direct cell quantification of suspension cultures is aggregate formation. This can

often be circumvented by using image analysis that can distinguish the single cells up to a certain aggregate size, for example, Cedex automated cell culture analyzers (http://www.innovatis.com). Alternatively, the total cell number can be easily determined by counting the nuclei after cell lysis. This is also the recommended analysis method for microcarrier cultures. However, depending on the type of bioreactor and microcarrier used, obtaining a homogenous sample might be more difficult than in suspension culture. In packed-bed reactors, normally no removal of microcarriers is possible. The cell number in such cultures must be determined by indirect methods as described above. Fluidized-bed reactors are by definition an inhomogeneous cultivation system as the carrier compartment is separated from the rest of the vessel. However, carrier removal during the cultivation process is possible. Cell quantification can therefore be done using direct methods, for example, nuclei counting, correlating the measured cell concentration to the number of microcarriers and then calculating the cell number per milliliter of microcarriers. If digital image analysis is used for cell enumeration on macroporous carriers, staining procedures are usually necessary. However, cell loss may occur during the accompanying washing steps.

34.2.6 Cell Harvesting and Scale-Up

Culture scale-up is a key task when growing adherent cells on microcarriers. Adherent cells are unable to detach and reattach to fresh microcarriers during continuous stirring. The simple addition of fresh microcarriers will not alone achieve scale-up as the cells are in general unable to populate them. In the case of microporous carriers, there is limited data available on scale-up by adding of microcarriers and the use of special stirring regimes. Wang and Ouyang (37) expanded a culture of Vero cells on Cytodex 3 carriers without actively detaching the cells. In the study, the cells did not migrate between the carriers during continuous stirring, but this problem was solved by intermittent stirring. Microscopic observation showed that cell transfer occurred by bridging when bare beads came into contact with confluent ones. A similar approach was used by Pohlscheidt *et al*. (64). They describe the direct cell expansion of adherent bovine kidney cells by migration between Cytodex 3 microcarriers during a period of alternated stirring. To shorten the time for cell transfer and adapt the procedure to large-scale requirements, cells are usually actively detached from the beads so that they can subsequently reattach to freshly added microcarriers. Various methods can be used for cell removal, and it is important to choose procedures that minimize damage.

The optimal harvesting procedure can usually be deduced from that normally used to detach a particular cell type in monolayer culture. The aim of this step should be to have an inoculum consisting of a suspension of highly viable, single cells that were in exponential growth phase prior to harvesting. The main task is to break the cell–surface and cell–cell interactions. If the cells secrete copious amounts of ECM, it will be easier to harvest them before they are fully confluent. As cell binding is dependent on divalent ions, the carriers must be washed with citric acid or EDTA (0.2% w/v) containing buffers to help detach the cells. The methods for cell harvesting are primarily enzymatic ones using trypsin, collagenase, Pronase™ (Calbiochem), Dispase™ (Worthington Biochemical Corp.), or Accutase™ (PAA laboratories). Trypsin is the most commonly used general protease, although Pronase has advantages when harvesting cells from primary cultures. Dispase as well as Accutase can be used for cells that are sensitive to trypsin.

If the medium contains serum, alpha-1-anti-trypsin, a trypsin-blocking protein abundant in serum must also be washed out. Porous carriers require more extensive washing than solid ones, normally two washings with 10–20% of the original suspension volume. The substrate concentration for proteolytic enzymes increases drastically when they are applied to sedimented beads as compared to ordinary monolayer cultures. Normally, this means increasing trypsin concentration (e.g. to 0.25%) to perform cell detachment in a suitable volume, typically about 10% of the original volume of the culture. Cell detachment from the microcarriers is greatly enhanced if some shear force is applied by gentle stirring. However, the stirring must be brief as the carrier concentration is very high, and the cells may be damaged by bead-to-bead collisions.

After detachment, the cells can be separated from the microcarriers by a variety of methods. The simplest way is differential sedimentation, which can be used for routine harvesting, or subcultivation when maximum recovery is not required. After harvesting, the culture medium is added and the microcarriers are allowed to settle for about 5 min. The supernatant, which contains the majority of the cells and is essentially microcarrier-free, can then be removed. Better recovery can be achieved if the microcarriers are washed a second time. Pooled supernatants can then be used directly to inoculate the next culture. Filtration devices can be used when it is important to obtain very high recoveries of the harvested cells without contamination by microcarriers. Any sterilizable filter with a mesh size of approximately 100 μm is suitable. A convenient filter for small-scale work is the "Cellector" supplied by Bellco Glass Inc. (Vineland, New Jersey, USA). Alternatively, a suitable stainless steel mesh can be obtained from Spörl KG (Sigmaringendorf, Germany).

For large-scale applications, fluidized-bed separation systems have also been developed. The best reactor design in this case is a conical shape (Fig. 34.8). The fluid stream comes from the bottom and harvest occurs at the top. A

Figure 34.8. A fluidized bed for carrier/cell separation. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

top filter with a mesh size of around 100 μm reduces the risk of losing microcarriers from the system. It is also possible to detach the cells and then transfer the whole mixture of used beads and cells to the new reactor. In this case, the split ratio should be as high as possible because the cells tend to preferentially reattach to the used beads, which can lead to inhomogeneous culture conditions.

When the cells have been harvested using enzymatic methods, the detachment reagents need to be inactivated or sufficiently diluted to allow reattachment. In chemically defined, protein-free media, trypsin can be inactivated with soybean trypsin inhibitor; Pronase is inhibited by EDTA. For other enzymes a specific cell culture compatible inhibitor is not always available. In that case, sufficient dilution, that is, a high split ratio, can help.

In addition to proteolytic enzymes, other methods can also be applied to detach cells from microcarriers. Incubation in hypotonic solution can be used for harvesting cells that do not have strong adhesion properties. Lai *et al*. (65) used this method to harvest CHO cells from Cytodex 1. Chelating agents such as EDTA can be used to remove certain epithelial and transformed cells. In general, these chemicals are not very efficient in cell detachment, but they have the advantage that they leave the cells part of their ECM, and they do not harm cell-surface receptors. Some cells are extremely difficult to remove from culture surfaces, for example, macrophages. To improve recovery rate, Lignocaine (30 m*M* in PBS, pH 6.7) at 22°C can be used for detachment (66).

Once the detached cells have been transferred to the new cultivation vessel and the detachment reagent is inactivated, it is important to find a suitable stirring regimen and cultivation medium to support efficient reattachment and rapid cell spreading. During the initial time after transfer, the cells are rounded and therefore only have a limited contact area with the carrier surface. It is important to select a cultivation medium that minimizes this time period and facilitates cell spreading, as rounded cells are more sensitive to shear forces.

Scale-up generally involves a substantial amount of process development. Simulation of the vessel's fluid dynamics must be performed to ensure that the larger vessel is similar to the small-scale reactor and that it will not negatively influence growth behavior or productivity. It is also important to test cell line stability beyond the planned duration of the production process. An essential part of scale-up is the cellular multiplication at each step. It is important to work with a split ratio as high as possible to minimize the number of subcultivation steps and thereby bioreactors and other equipment. If it is possible to inoculate at a low cell density, for example, 2 to 5×10^4 cells/mL, and the process then reaches high yields of about 5×10^6 cells/mL, the multiplication factor is 100-fold. Such a scale-up factor has been reported for Vero cells by Lindner *et al*. (67). It would thus be possible to inoculate a 100-L fermentor from a 1-L spinner flask. Scaling up microcarrier cultures can be done by increasing the size of the vessel or by increasing the microcarrier concentration. Production units up to 6000 L (Fig. 34.9) have been achieved by increasing the size. Important factors that influence this strategy are the reactor configuration and the power input of mixing. Larger impellers at lower speeds generate less shear force, and marine impellers are usually preferred over pitched blade impellers. Desirable features of a stirred microcarrier reactor include the absence of baffles, curved bottom for better mixing, double jacket for heating and cooling, top driven stirrer, and a smooth surface finish (electropolished).

Scale-up by increasing microcarrier concentration requires perfusion to ensure nutrient supply at the resulting high cell concentrations. It is necessary to retain carriers in the reactor, which can be achieved by settling zones or filtration devices. The limiting factor for higher cell concentrations is usually oxygen supply. It is difficult to use microspargers in carrier cultures grown in conventional stirred tanks as the carriers may accumulate and float in the foam created. The easiest solution is to use spargers that create larger bubbles and do not cause the formation of a stable foam layer. If a higher oxygen transfer rate is required, pure oxygen can be used. The problem of

Figure 34.9. Influenza production plant (6000-L vessels for cultivating Vero cells on Cytodex). Courtesy of Baxter Biosciences. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

microcarrier entrapment in the foam can be circumvented by oxygenation via an external loop and oxygenation devices/vessels (68). It is easier to increase oxygen supply via sparging in packed or fluidized beds as the cells are protected inside the macroporous carriers and the density of the microcarriers is usually high enough to prevent entrapment in a foam layer.

34.2.7 Trouble-Shooting

The following list contains points of occasional difficulty, frequently asked questions, and the most likely solutions. It can also serve as a checklist when culturing a new cell type on microcarriers.

Medium turns acidic upon addition of the microcarriers:

Check that the microcarriers have been properly hydrated and washed.

Medium is alkaline at inoculation stage:

Gas the culture vessel and equilibrate with 95% air, 5% CO_2.

Loss of microcarriers on surface of culture vessel:

Check that the culture vessel has been properly siliconized.

Poor attachment of cells and slow initial growth:

Ensure that the culture vessel is nontoxic and well washed after siliconization.

Dilution of culture by PBS remaining after sterilization; rinse microcarriers in growth medium.

Modify initial culture conditions; increase length of static attachment period; reduce initial culture volume, or increase inoculum concentration.

Check that the inoculum consists of a viable single-cell suspension.

Eliminate vibration transmitted from stirring unit.

Change to a more enriched medium for the initial culture phase.

Check the quality of the serum supplement.

Check for contamination by mycoplasma.

Microcarriers with no cells attached:

Modify initial culture conditions; increase length of static attachment period; reduce culture volume during inoculation phase.

Check that the inoculum concentration is correct.

Ensure that all microcarriers are suspended during the stirring phase if intermittent stirring is used.

Aggregation of cells and microcarriers:

Modify initial culture conditions; reduce length of static attachment period.

Increase stirring speed during growth phase.

Reduce concentration of serum supplement as culture reaches confluence.

Reduce concentration of Ca^{2+}, Mg^{2+} in the medium..

Rounded morphology of cells and poor flattening during growth phase:

Replenish medium.

Check osmolarity and pH of culture medium.

Reduce concentration of antibiotics.

Check for contamination by mycoplasma

Rounding of cells when medium is changed:

Check temperature, pH, and osmolarity of replacement medium.

Cessation of growth during culture cycle:
- Replenish medium.
- Check that pH is optimal for cell growth.
- Re-gas culture vessel.
- Reduce stirring speed.

Difficulties controlling pH:
- Check that the buffer system is appropriate.
- Improve the supply of gas to culture vessel; lower concentration of CO_2 in headspace or increase supply of oxygen.
- Improve the supply of glutamine, supplement the medium with biotin, or use an alternative carbon source (galactose, fructose) to reduce lactate formation.

Difficulties maintaining confluent monolayers:
- Check that pH and osmolarity are optimal.
- Reduce the concentration of serum supplement.
- Improve the schedule for medium replenishment.
- Reduce the concentration of antibiotics.

Broken microcarriers:
- Ensure that dry microcarriers are handled carefully.
- Check the design of culture vessel/impeller; ensure that the mechanical seal is designed properly, that is, no gaps where microcarriers can be sheared.

Difficulty in harvesting cells:
- Ensure that the carriers have been washed extensively.
- Switch to enzymatic methods; use trypsin as a more nonspecific protease.
- Check that approximately the same amount of protease (U/cell) is used as when harvesting from T-flasks.
- Ensure that sufficient agitation is used in addition to the detachment reagent.

Microcarriers float in foam due to sparging:
- Reduce serum/protein concentration as much as possible.
- Aerate with sparger that creates larger bubbles.
- Sparge with pure oxygen to reduce gas flow rate.
- Aerate via external loop.

34.3 MICROCARRIERS IN VACCINE PRODUCTION

The majority of viral vaccines are produced in adherent cells. Table 34.4 gives an overview of the viruses that have been grown in microcarrier culture. The most important vaccines produced by this method are influenza, polio, rotavirus, Japanese encephalitis, hepatitis A, hoof, and mouth disease (69–72). Cell lines used include Vero (monkey kidney epithelial cells), human embryonic kidney (HEK) 293 cells, baby hamster kidney (BHK) cells, and Madin Darby canine kidney (MDCK) cells.

TABLE 34.4. Viruses Grown in Microcarrier Culture

Adenovirus	Marek's	Rous sarcoma
Bovine rhinotrachteritis	Papovavirus	Rubella
Endogenous C type	Parapoxvirus	Sendai
Equine rhinopneumonitis	Polio	SV40
Foot and mouth	Polyoma	Sindbis
Group B arboviruses	Pseudorabies	Small pox
HAV	Rabies	Vaccinia
Influenza	Herpes	Vesicular stomatitis
Japanese encephalitis	RSV	

Proliferation of anchorage-dependent cells occurs only after adhesion to a suitable surface. In large-scale cultivation, the microcarrier technique has proven to be more effective than cell culture on flat substrates such as culture dishes, multiple trays, or roller bottles. Microcarriers provide a suitable growth surface and at the same time allow treatment of the process as suspension culture. This enables the use of bioprocess technologies that are not feasible when cultivating cells on vessel surfaces. Large-scale production in roller bottles is possible but requires multiplication of vessels during scale-up. The drawbacks associated with cultivation in multiple vessels are a substantially higher risk of contamination and a rather poor control of process parameters in the individual vessels. Moreover, scale-up of roller-bottle processes can only be done using automatic roller stations. Such stations can handle up to 40,000 roller bottles (TTP Labtech, Cambridge, UK). The same surface area as in 40,000 roller bottles (850 cm^2) can be obtained in a 2500-L tank with a Cytodex 1 concentration of 3 g/L. Cultivation in a single vessel allows incomparably better process control and reduces the contamination risk. Due to the high cell concentration, growth on microcarriers also creates an environment that more closely mimics the *in vivo* environment.

The cost advantage of virus production in microcarrier culture has been demonstrated in a study by Isayeva *et al*. (73). Adenovirus was grown on HEK 293 cells that were cultivated on microporous microcarriers, roller bottles, and in a hollow-fiber reactor. At the same virus yield, microcarrier cultivation was 30% cheaper than the two other systems. Moreover, monitoring cell density in the hollow-fiber system could only be done by indirect methods as the cells growing in the extracapillary space were inaccessible during the process. The savings in the microcarrier process were attributed to a reduction in labor costs as well as lower expenses for disposables. In a presentation by E. Malhaise, GSK, at the National Academy of Engineering/Institute of Medicine (NAE/IOM) topical conference 2006 (Cleveland, Ohio), the consequences of

microcarrier cultivation on facility design were evaluated. In this example, microcarrier application allowed a fivefold reduction of fermentation volume due to increased cell concentration. The smaller vessel size shortened hardware engineering lead times and also resulted in an overall reduced facility footprint. The feasibility of industrial production of vaccines derived from Vero and MDCK cell lines has already been demonstrated. Kemble and Greenberg reported a production volume of 1200 L (74). Werthenstein Chemie AG, Sachen, Switzerland use a 2000-L vessel to produce recombinant adenovirus in a microcarrier-based process. Baxter AG, Orth/Donau, Austria has recently started production for clinical trials using 6000-L vessels for the cultivation of Vero cells on Cytodex carriers.

BHK cells can be in grown adherent as well as in suspension culture. For the production of rabies virus, the cells are grown on microcarriers (75,76). Geserick *et al*. (76) used microcarriers to retain BHK cells in perfusion culture. An important application for BHK cultivation in suspension is the large-scale production of vaccines against foot-and-mouth disease (FMD). Amadori *et al*. (77) have compared virus progeny from anchorage-dependent and suspension cells. They found a lower stability of FMD virus from suspension cells during the standard inactivation method. This was attributed to an altered integrin expression in suspension-adapted BHK cells compared to adherent cells. Expression of these cell-surface receptors affects the distribution of actin microfilaments, which plays a crucial role in the replication of FMD virus.

Usually, microporous carriers are used in vaccine production because the cells usually grow as a monolayer on them and are therefore easily accessible for virus infection. However, macroporous carriers have also been used successfully for virus propagation. The advantages of macroporous carriers are higher cell/bead loadings due to the increased surface area and the ability to protect cells against detrimental hydrodynamic forces generated by high agitation rates or direct sparging. Yokomizo *et al*. (78) compared the growth of rabies virus on a microporous (Cytodex 1, DEAE-dextran) and two macroporous carriers (Cytopore 1, cellulose; Cultispher™ G, gelatin). All microcarriers gave similar maximum volumetric cell densities; however, the maximum viral titers were 25% and nearly 50% higher on the Cultispher G and Cytopore carriers, respectively, than on the Cytodex microcarrier. Successful propagation on macroporous carriers was also reported for vesicular stomatitis virus (79) and hepatitis A virus (80).

The standard cultivation method in vaccine production is batch culture as the cells are usually infected with lytic viruses. However, there is also the possibility to run perfusion cultures if the cells are used to propagate nonlytic viruses that are shed into the supernatant. In this case, the microcarriers can be used for cell retention while the nutrient supply is ensured by a constant influx of cultivation medium and a removal of harvest from which the virus particles are then purified. Yokomizo *et al*. (78) performed cell cultures in semicontinuous perfusion mode with medium replacement every 48 h, while Meyer *et al*. (80) claim patent protection for the continuous production of hepatitis A virus for at least 60 days.

A number of production processes still rely on the use of serum. In these cases, the medium has to be exchanged to serum free before infection (81). As the cells are immobilized on the microcarriers, the cultivation method offers a quick possibility for medium replacement by leaving the carriers to settle.

A microcarrier application that has seen substantial growth in the last few years is the production of influenza vaccine. The worldwide production capacity in 2006 was about 350 million doses (82). The majority of these doses are still produced in embryonated hen's eggs (81). However, production in eggs is hampered by the cumbersome procedures required for egg inoculation and harvesting, as well as the extensive downstream processing to remove the egg protein that can cause allergic reactions. Additionally, virus propagation in eggs allows only limited process control, and the procurement of SPF eggs requires long lead times for production. In recent years, several continuous cell lines such as MDCK, Vero (83), the human cell line Per.C6 (84), and St. Jude porcine lung epithelial cell line (85) have been tested for the cultivation of influenza virus. Tree *et al*. (86) compared virus yields from MDCK cell cultures and hen's eggs. Although the titer from embryonated eggs was the highest (3.9×10^9 pfu/mL), MDCK cultures on microcarriers (1.3×10^9) and in roller bottles (1×10^9) produced sufficient amounts of virus. When comparing the yield from microporous and macroporous carriers, the study found that the optimum virus yield was achieved using a solid microcarrier composed of dextran with a positive charge. From the experimental results, it was concluded that the virus yield from a 1000-L bioreactor using solid microcarriers was equivalent to that from 12,000 roller bottles or 30,800 eggs. Influenza production in cell culture can be done in serum-free medium, which practically eliminates the risk of contamination with transmissible spongiform encephalitis or other viruses.

34.4 MICROCARRIERS IN RECOMBINANT PROTEIN PRODUCTION

34.4.1 Academic and Industrial Use of Microcarriers for Recombinant Protein Production

While vaccine production is the most common industrial use of microcarriers, a number of cell lines producing

recombinant therapeutic proteins have been grown on microcarriers, with approximately 10 industrial processes currently in use for therapeutic proteins. The primary interest is in the production of therapeutics other than monoclonal antibodies, particularly proteins with complex glycosylation as these often show much lower specific productivities than recombinant monoclonal antibodies. These lower productivities lead to lower titers, necessitating higher cell densities and/or perfusion processes to obtain the desired product concentrations. Both microporous and macroporous carriers have been explored using stirred tanks and fluidized-bed bioreactors with and without perfusion. Cell lines investigated include CHO, BHK, murine hybridoma cells (87,88), HeLa (cervical carcinoma) cells (89,90), COS-7 cells (91), and insect cell lines (92). Publicly available information on commercial processes using microcarriers includes the production of Aldurazyme™ on Cytopore carriers by Biomarin, recombinant human follicle-stimulating hormone (r-hFSH; INN: follitropin alfa) and recombinant human-luteinizing hormone (r-hLH; INN: lutropin alfa) on Cytodex 3 microcarriers by Seorono, Feron™ (recombinant interferon-beta) on Cytodex 1 microcarriers by Toray, and Cerezyme™, Myozyme™, and Fabrazyme™ on Cytopore microcarriers by Genzyme.

Kong *et al*. at Human Genome Sciences compared the production of recombinant human osteoblast-derived antiviral protein (OAP) for CHO cells grown on Cytoline 1 (macroporous) carriers in a fluidized-bed bioreactor and cells grown on Cytodex 1 (microporous) carriers in a STR (93). They found much higher cell densities on the macroporous carriers in the fluidized bed (3.3×10^7 cells/mL vs 2.6×10^6 cells/mL) as well as a sixfold increase in specific productivity in the fluidized-bed bioreactor. However, as the available surface area for cell growth was much higher for the macroporous carriers, the coverage was much lower (2.4×10^8 cells/m^2 on the Cytoline carriers vs 1.2×10^9 cells/m^2 on the Cytopore carriers). In a separate study, they analyzed the growth and productivity of a CHO cell line producing monocyte-colony inhibition factor (M-CIF) using 13 different microcarriers in spinner flasks and the ability of the cells to transfer autonomously between carriers (94). As shown in Table 34.5, Cytodex and Cytopore microcarriers showed the highest initial attachment, leading to the highest maximum viable cell densities. These carriers all possess a positive charge, and the more highly charged Cytodex 1 and Cytopore 2 carriers showed a faster attachment rate. Interestingly, in this study, the product titers in batch culture were similar for most of the microcarriers, indicating an inverse relationship between cell density and specific productivity.

Other proteins produced in CHO cells grown on microcarriers include prourokinase (88), urokinase-type plasminogen activator (95), and arylsulfatase B (96,97). We recently compared growth and productivity for CHO cells producing tissue plasminogen activator (t-PA) and secreted alkaline phosphatase (SEAP) for cells grown in suspension and attached to Cytodex 3 (microporous) and Cytopore 1 (macroporous) carriers (98). In static batch culture for CHO cells producing SEAP, Cytodex 3 microcarriers showed higher cell densities and product titers than suspension cells. However, in controlled, agitated, fed-batch bioreactors, suspension cultures showed higher cell densities than either Cytodex 3 or Cytopore 1 cultures for CHO cells producing either t-PA or SEAP.

TABLE 34.5. Comparison of Attachment, Growth Rate, and Productivity for a CHO Cell Line Producing Monocyte-Colony Inhibition Factor (M-CIF) using 13 Different Microcarriers in Spinner Flasks

	Attachment		Cell Growth			Batch		Media Exchanges		
Microcarrier	1 h	1 day	Maximal 10^6/mL	Batch folds	Floating Cells	HPLC mg/L	ELISA mg/L	mg/L	mg/L/day	mg/billion cells/day

The effects of culture conditions on specific productivity were cell line and/or protein product dependent as microcarrier cultures producing SEAP showed lower specific productivities than the comparable suspension cultures, while microcarrier cultures producing t-PA showed higher specific productivities than the comparable suspension cultures.

Viral infection has been used extensively for producing recombinant proteins in insect cells and more recently using vaccinia virus in HeLa cells (89,90). Viral infection provides the ability to rapidly generate recombinant proteins without the time-consuming selection and screening of other transfection methods. As HeLa cells are generally anchorage dependent and viral transfer requires cell–cell contact, a solid support was required for this system. Bleckwenn and coworkers evaluated 12 different microcarriers and found that Cytodex 3 microcarriers showed the best growth without forming multiple cell layers that might inhibit viral infection (99). They subsequently used this system to produce recombinant enhanced green fluorescent protein (EGFP) and HIV envelope coat protein, gp120 (89,90).

34.4.2 Cultivation Modes

While microcarriers can be used in batch or fed-batch modes in STRs, the greatest advantages of microcarrier use for recombinant protein production occur in perfusion or fluidized-bed cultures. Perfusion can be performed using a packed-bed reactor or a variety of separating devices, including spin filters and settlers. Voisard and coworkers have recently reviewed cell retention devices and techniques for suspension mammalian cell cultures (100). The two primary characteristics by which cells can be separated from culture media are based on differences in size or density.

For size separations, a variety of filtration modes can be used, including hollow-fiber filters and spin filters. The key challenge when using filters is preventing clogging. Microcarriers present significant advantages for filter-based retention systems as they are much larger than cells. Large pores or mesh can thus be used, thereby reducing clogging. Hu *et al*. produced urokinase-type plasminogen activator on Cytopore carriers using a spin filter to retain the cells (95). They were able to maintain perfusion for approximately 21 days before the filter clogged. They subsequently changed to batch perfusion by permitting the carriers to settle every 12 h before removing half of the culture medium. Using this technique, they were able to maintain the culture for over 100 days. Bleckwenn *et al*. used an alternating tangential flow hollow-fiber system (ATF™, Refine Technology Inc.) for production of recombinant proteins from vaccinia virus-infected HeLa cells grown on Cytodex 3 microcarriers (90). Alternating tangential flow helps prevent clogging of the hollow-fiber filter. Perfusion extended the culture duration by at least 50 h (as compared with batch culture) and increased the maximum viable cell density by nearly a factor of three, from 1.5×10^6 cells/mL to 4.4×10^6 cells /mL.

Microcarrier cultures are also advantageous for density-based separations. The specific density of a mammalian cell is only slightly greater than the density of the medium, yielding a sedimentation velocity of 0.04 cm/min. In contrast, microcarriers typically have specific densities from 1.02 to 1.04, yielding sedimentation velocities of 12–19 cm/min. Microcarriers specifically designed for fluidized-bed culture generally have significantly higher specific densities (∼1.3), resulting in sedimentation velocities of up to 220 cm/min.

As most cell lines used for recombinant protein production can be readily grown in suspension (e.g. CHO, BHK, hybridoma, and myeloma), microcarrier cultures are most commonly employed in systems that would benefit from perfusion or media exchange or require higher cell densities than can be obtained in fed-batch systems. Packed and fluidized beds are the most widely reported culture modes using microcarriers for recombinant proteins. In packed beds, carriers are either placed into a basket in an STR such as the CelliGen™ bioreactor available from New Brunswick Scientific (www.nbsc.com) or placed into a column. Packed columns provide a significant advantage of very low shear forces. However, they tend to suffer from nutrient limitations, particularly oxygen. Park and Stephanopoulos were to some extent able to overcome these limitations by inducing intraparticle convective flow (101), and McTaggart and Al-Rubeai reported retroviral vectors for gene therapy produced by the human packaging cell line LYRD18/LNChB7 grown on ImmobaSil™ G porous silicone carriers in a packed bed (102). However, unlike fluidized beds, packed beds are inherently limited in scale due to the oxygen gradients (103). Even with the convective flow described by Park and Stephanopoulos (101), a taller bed requires a faster recirculation rate to maintain adequate convection. Pressure drop, however, increases with increasing bed length and increasing fluid velocity. Additionally, packed beds have the problem of preferred flow-path formation, and it is very difficult, if not impossible, to sample carriers or cells during the run.

Fluidized beds are the most widely used culture system for porous microcarriers. In a fluidized bed, the microcarrier beads are suspended by the upward flow of medium. Recirculation can either be external as shown in Fig. 34.10 or internal as shown in Fig. 34.11. Very good mixing and oxygen mass transfer can be achieved in fluidized beds with very low shear forces. Dürrschmid and coworkers reported a comparison of fluidized-bed culture for CHO cells grown

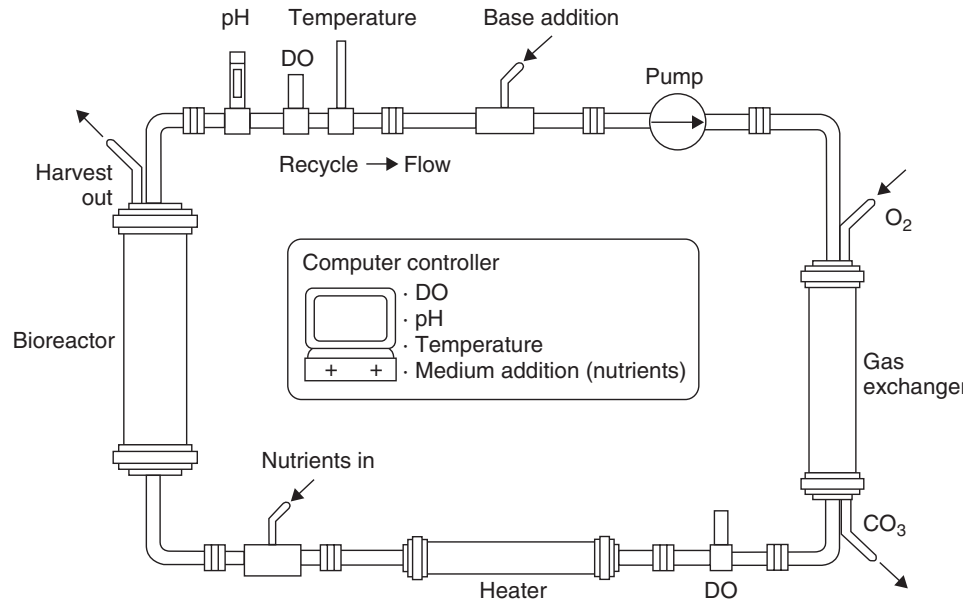

Figure 34.10. Fluidized bed with external recirculation.

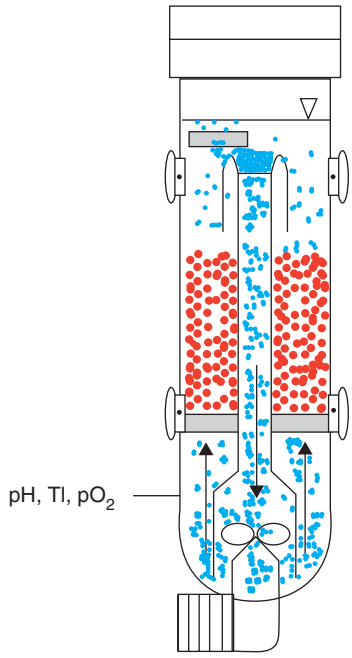

Figure 34.11. Fluidized bed with internal recirculation. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

on microcarriers and ultrasonic cell retention for suspension cultures (104). Both systems showed similar growth and productivity.

Production of a number of recombinant products in fluidized beds has been reported in research studies, including erythropoietin (105), interferon-gamma (106), and arylsulfatase B (96). In their study of CHO cells producing arylsulfatase B, Dürrschmid *et al*. found that additional non-inoculated microcarriers could be added to the fluidized bed and that these carriers would subsequently be colonized by the cells on the existing microcarriers (96).

34.4.3 Effects of Microcarrier Culture on Protein Glycosylation

A critical issue in the use of microcarrier cultures for production of recombinant proteins is the effect of microcarrier culture on glycosylation. Protein glycosylation plays critical roles in protein folding, activity, immunogenicity, and protease sensitivity *in vivo* (107). A number of studies have examined variations in glycosylation of recombinant proteins for CHO cells grown in suspension and in an adherent manner. Watson and coworkers compared the distribution of N-linked oligosaccharides in kallikrein (a serine proteinase with pharmacological potential) for CHO cells grown in suspension or attached to microcarriers (108). They noted a change in the glycosylation pattern between the kallikreins produced under the two conditions, both in the amount of branching and in the amount of sialic acid present in the oligosaccharides. Unfortunately, the culture medium used for the two sets of conditions differed slightly, adding an additional complication in the interpretation of the data.

Two studies looked specifically at fluidized beds containing microcarriers. Goldman and coworkers compared a perfused fluidized bed containing cells grown on Cytoline microcarriers with a stirred-tank, batch suspension

culture for CHO cells producing recombinant human interferon-gamma (106). They found that the perfused culture maintained a more stable glycoform distribution and a higher fraction of glycosylation than did the batch cultures. However, it is difficult to separate the effects of perfusion from the effects of microcarrier culture. Wang and coworkers investigated erythropoietin produced by CHO cells grown on microcarriers in a perfused fluidized-bed reactor, as well as suspension cultures in continuous and batch STRs and spinner and T-flasks (105). They found substantial differences in specific productivity, with the highest specific productivities occurring in spinner and T-flasks. Glycoform analysis of the fluidized-bed cultures did not show any new glycoforms, but the authors did not report whether the distribution of glycoforms was the same as observed under other culture conditions.

Spearman and coworkers recently evaluated the yield and glycosylation patterns of recombinant β-interferon produced in suspension and on Cytopore microcarriers (109). As we observed previously, there was a significant decrease in cell growth in the microcarrier cultures compared with the suspension cultures. However, they found a substantial increase in specific productivity (approximately fivefold) for the microcarrier cultures leading to a threefold increase in yield. They observed no difference in the glycosylation profile. However, they did not evaluate glycan occupancy. They also observed that microcarrier culture significantly reduced aggregation of the β-interferon, leading to a larger fraction of useful product.

A limited number of similar studies have also been performed for recombinant proteins produced in BHK cells. Gawlitzek and colleagues evaluated the changes in glycosylation for a mutant version of interleukin-2 genetically engineered to include an N-linked glycosylation site in addition to the native O-linked site (110). They compared cells grown in suspension and on Cytodex 3 microcarriers in perfusion culture in medium containing 2% fetal bovine serum and serum-free medium. In suspension culture, serum-free medium significantly increased the N-linked glycosylation and reduced the fraction of nonglycosylated protein compared to serum-containing medium. In addition, when serum-free cultures in suspension and on microcarriers were compared, the suspension cultures had a lower fraction of nonglycosylated proteins. The glycan structures were also compared for the four culture conditions. Sialylation was increased significantly in serum-free cultures both in suspension and on microcarriers. The degree of fucosylation and antennary distribution was also affected by culture conditions, with an increase in fucosylation in serum-free medium for both microcarrier and suspension cultures, and a decrease in branching in microcarrier cultures on changing from serum-containing to serum-free medium.

More recently, we evaluated the effects of two different microcarriers and suspension culture on the glycosylation of recombinant SEAP (111). As shown in Table 34.6, the net effect of growth on microcarriers was to increase the sialylation of the SEAP and decrease the fucosylation. While increased sialylation of recombinant proteins is usually beneficial (due to reduced biological clearance), the role of fucosylation is less well understood. Human IgG_1 produced in a fucosylation-deficient mutant CHO cell line (112) or produced in rat hybridoma cells and fractionated by lectin affinity chromatography for reduced fucosylation (113) exhibited up to 50-fold increased affinity to human FcγRIIIA and increased antibody-dependent cellular cytotoxicity (ADCC). Core fucosylation affects the flexibility of the antennary structures, which may be the key to lectin recognition of fucosylated glycans (114). Alterations in fucosylation also play a role in human diseases, including cancer and cystic fibrosis (115). However, beyond the effects of defucosylation of IgG, there have been no studies on the effects of fucosylation on the biological activity of recombinant proteins. Nonetheless, understanding the modulation of fucosylation by culture conditions may prove important for other recombinant proteins.

34.5 FUTURE DIRECTIONS IN MICROCARRIER CULTURE

Microcarriers are increasingly employed for more biomedically oriented applications, including tissue engineering, stem-cell culture, and *in vitro* toxicology (116). This has resulted in new culture modalities, new microcarrier chemistries, and new cell lines. While a comprehensive review of this area is beyond the scope of this chapter, a few key references and reviews are discussed below.

King and Miller recently reviewed bioreactor development for stem-cell expansion and differentiation (117). They note that greater expansion of stem cells is observed in agitated cultures than in static culture for both aggregates and cells cultured on microcarriers. However, they pointed out that, as has been observed for cells producing recombinant proteins, shear must also be considered for cells on microcarrier beads. Microcarriers have also been employed in tissue-engineering studies of liver (118,119) and bone and cartilage (120), for extracorporeal devices, cell expansion, and cell transplantation. New chemistries include chitosan (121), poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (122), and polyethylene glycol (123). New culture modalities include rotating-wall-vessel bioreactors (124) and single-use bioreactors (33–35).

TABLE 34.6. The Relative Percentage of N-Linked Glycans of SEAP under Different Culture Conditions

	Neutral N-Linked Glycans (%)		Sialylated N-Linked Glycans (%)							
			Monosialylated		DiSialylated		TriSialylated			
Culture Condition	Fucosylated	Nonfucosylated	Fucosylated	Nonfucosylated	Fucosylated	Nonfucosylated	Fucosylated	Nonfucosylated	Total Sialylated	Total Fucosylated
Suspension	35.1	20.0	11.3	30.1	0	3.5	0	0	44.9	46.4
Cytodex 3	11.3	14.4	2.2	55.1	6.7	6.1	0	4.2	74.3	20.2
Cytopore 1	27.0	13.1	3.3	42.2	0	10.4	0	4.1	59.9	30.3

34.6 CONCLUSIONS

Microcarriers play an important role in the culture of mammalian cells, particularly for industrial applications such as viral vaccine and recombinant protein production. A wide variety of chemistries exist, permitting cultivation of a myriad of cell types. Advantages of microcarrier culture include high surface area-to-volume ratios for adherent cultures, good scalability, and ease of perfusion in packed or fluidized beds as well as stirred tanks. These advantages must be weighed against mass-transfer limitations, particularly for macroporous carriers and fixed beds, and the possibility of increased shear sensitivity. Novel applications of microcarrier technology, such as tissue engineering, stem-cell cultivation, and *in vitro* toxicology, have renewed interest in microcarrier development, leading to new microcarrier compositions and culture modes. As new vaccines and therapeutics, particularly enzymatic compounds, enter the biopharmaceutical pipeline, microcarriers will remain an important technology in the bioprocessing arena.

MONOCLONAL ANTIBODY PRODUCTION, CELL LINES

JULIA F. MARKUSEN AND DAVID K. ROBINSON
Bioprocess Research & Development, Merck Research Laboratories, Rahway, New Jersey

35.1 INTRODUCTION

Production of recombinant antibodies begins with construction of the cell line that will be used for expression of the final MAb product (Fig. 35.1). There are many steps downstream of cell line construction for ensuring safety, efficacy, quality, productivity, and regulatory acceptability of the cell culture process. Consideration of these attributes at the initial point of cell line selection is critical. This chapter outlines how the cell line can influence each of these key attributes and, in this context, reviews the host cell lines and expression systems that are commonly used to produce MAb products.

35.2 ROLE OF THE CELL LINE

MAbs are produced in biological systems, because their structural complexity prohibits their construction by chemical synthesis. Production occurs in ascites fluids of immunized animals, in hybridomas that result from the fusion of a B cell with a mouse myeloma cell or in a recombinant system as a heterologous gene product.

Due to the high therapeutic dosage requirements, production of MAbs occurs at scales ranging from kilograms to hundreds of kilograms per year which makes productivity and high reproducibility of product quality important selection criteria. Additionally, the limitations of using potentially immunogenic murine MAbs (1) have resulted in a trend toward using humanized or human MAbs. These MAbs are most often expressed as recombinant gene products that can be produced in a wide array of biological systems including animal cell lines, fungi, bacteria, and transgenic plants and animals. All currently licensed therapeutic MAbs in the United States are produced in animal cells, and all but two are produced as recombinant gene products (2).

35.2.1 Most Important Features of a Cell Line

The cell line chosen for production can heavily impact the MAb being expressed. It ultimately influences the productivity of the process and the drug product quality, safety, and regulatory acceptability. The role of each of these features is highlighted in the subsections that follow. Other factors that should be considered are economics and rapid development. Increased pressure on the pricing of pharmaceuticals (3) forces manufacturers to pay careful attention to the cost of production and purification as well as all royalties that may be associated with licensing the host cell line and expression system. Rapid development of gene into purified protein is a vital component of the overall drug development timeline, as it dictates the speed in which preclinical candidates can move into clinical studies.

35.2.1.1 Regulatory Acceptability. It is instructive to look at the cell lines that produce MAbs that are currently licensed for use as human therapeutics, since it is safe to assume that these cell lines were deemed acceptable by the regulatory agency that granted the license. Looking at the 20 therapeutic antibodies licensed in the United States up to December 2007, one sees that they are all mammalian cell lines including Chinese hamster ovary (CHO), murine myeloma (NS0 and SP2/0), or hybridoma

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

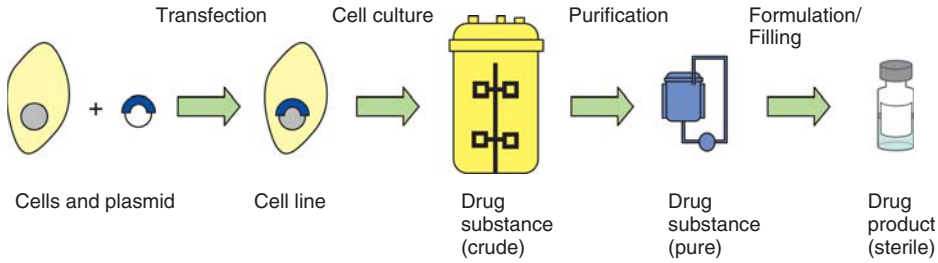

Figure 35.1. Schematic overview of a process for the production of therapeutic recombinant antibodies. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

(Table 35.1). To date, there are no approved therapeutic MAbs in the United States that are produced in human, fungal, bacterial, or transgenic systems. However, one therapeutic protein that is produced in a human cell line has been approved in the United States which suggests that such cell systems may also receive regulatory approval for MAbs (see section titled "Human Cell Lines"). The reader should refer to the relevant regulatory guidance documents with the ICH guidelines on viral safety Q5A (4), the analysis of expression constructs Q5B (5), and the derivation of cell substrates Q5D (6) being of particular interest.

35.2.1.2 Safety. The safety of an antibody drug product can be greatly impacted by the quality and the handling of the cell line used to produce it. Two primary safety concerns are adventitious agents (e.g. viruses) and host cell impurities [e.g. Deoxyribonucleic acid (DNA)].

Cell lines can become contaminated with adventitious agents and could potentially serve as a source for the propagation and potential transmission of these agents to patients. There are three major routes by which contamination with adventitious agents might occur: (i) carryover of residual viruses that are harbored within the host cell line, (ii) introduction through contaminated raw materials (e.g. serum, screening antibodies) used to propagate or isolate the cell line, and (iii) through contact with contaminated personnel, equipment, or facilities. Though patient risk remains hypothetical, since a host cell line has not as of yet been implicated as the cause of any known transmission, special care

TABLE 35.1. FDA-approved MAbs (Therapeutic Full length, Unconjugated IgGs), Hamster (CHO) and Murine Cell Lines (SP2/0 and NS0) Predominate the Industry (as of 2007)

Product	Manufacturer	Launch	Indication	Production Host
Orthoclone OKT3	J&J	1986	Transplant rejection	Hybridoma

must still be taken to minimize this risk by appropriately documenting, handling, and testing the cell substrate (ICH Q5A) (4). Likewise, a detailed history of the host (ICH Q5D) (6), the raw materials, and the propagation techniques are helpful for devising procedures for clearing and testing for these agents. Detailed guidance is available in the regulatory documents (ICH Q5B) (5).

Contaminating residuals like DNA pose a similar hypothetical risk. However, since the process for the production of antibodies typically clears these to very low levels and ensures the absence of any live cells in the final product, additional testing such as tumorigenicity testing is rarely required for most cell lines of animal origin that are generally assumed to be tumorigenic.

35.2.1.3 Product Quality

35.2.1.3.1 Glycosylation. The basic structure of IgG antibodies consists of two heavy chains and two light chains that form two Fab regions that provide the specific antigen binding site. The Fab regions connect through a hinge region to the Fc region that interacts with receptors that activate clearance mechanisms of the target (see Jefferis (7), Fig. 35.1, p. 12). IgG antibodies have a conserved glycosylation site on the constant region of the heavy chain in the hinge region. The nature of the glycans subtly influences the three-dimensional orientation of the hinge region and can alter the binding of a variety of Fc receptors to the antibody (7,8). This change in binding can affect the half-life of the antibody as well as its ability to evoke effector functions like complement-dependent cytotoxicity (CDC) and antibody-dependent cellular cytotoxicity (ADCC). These properties depend on the interactions that occur between the antibody and the Fc receptor, for example, FcRn mediates half-life and FcγRIII mediates ADCC (9). The extent of these interactions is controlled by the antibody isotype, that is, whether the antibody is of isotype IgG1, IgG2, IgG3 or IgG4, and if the interaction involves receptor binding to the hinge region (10).

The product quality attribute most likely to be influenced by the cell line chosen for manufacture of an antibody is glycosylation. The extent to which an antibody is glycosylated and the structure and heterogeneity of those glycans is controlled by properties of the host cell line and, to an important but lesser extent, by the culture and purification conditions. For example, *E. coli* and other prokaryotes typically do not produce any posttranslational modification, whereas animal or yeast cell lines can provide species-specific glycosylation. The NS0 (mouse) cell line produces unique glycans such as the nonhuman galactose-α1,3-galactose glycan structure (7). The CHO (hamster) cell line produces the α2,3-linked sialic acid, but not the α2,6-linked sialic acid commonly found in human glycoproteins (11). Yeast cells produce nonhuman, *N*-linked glycans with high mannose structures (12). These nonhuman, host cell-dictated glycans can have a detrimental effect by increasing the immunogenicity of the antibody when administered in a clinical setting to a human. They also have the ability to evoke different levels of Fc effector function (reviewed in Jefferis (7)). Barbin *et al*. (13) demonstrated this with an anti-CD19 IgG1 for which the oligosaccharide structure and ADCC activity varied greatly depending upon whether the antibody was expressed in insect cells, human 293T cells, or modified 293T cells that over expressed a glycosylation enzyme GnTIII.

Rather than producing a highly homogeneous oligosaccharide structure, most host cell lines produce antibodies with an array of different oligosaccharide structures. The extent and degree of this microheterogeneity is greatly influenced by the culture conditions. Factors including the pH of the medium, the nutritional environment (14), the osmolarity, and the buildup of certain metabolites such as ammonia combine to impact upon the decoration of the antibody with oligosaccharides (15). Since it is important to reproducibly control both the type of oligosaccharide present and the extent of micro-heterogeneity, careful control of these factors is essential to ensure a reproducible product.

Lately, a number of efforts have started to bear fruit with regard to genetic manipulation of host cell systems for controlling both the type and homogeneity of glycosylation. This includes recent efforts to alter the expression of fucosyltransferase: an enzyme responsible for addition of a core fucose unit. Antibodies with fucose-deficient glycans confer higher ADCC activity as a result of higher binding affinity of the Fc region to FcγRIII (16). For certain MAbs, ADCC may be a very important therapeutic mechanism such that increasing ADCC by targeting methods to obtain fucose-deficient glycans may enhance the therapeutic activity of the antibody. In one report, a knock out CHO cell line was used to produce afucosylyated anti-CD19 antibodies that had significantly higher ADCC (17). In another report, a RNA interference construct was used during expression of an anti-CD30 antibody to favor production of afucosylated glycans in the plant *Lemna minor*. The resulting antibody had higher ADCC activity (18). It is interesting to note that removing glycosylation eliminates FcγRIII binding (10) which may be a desirable property when ADCC activity is not desired. There is no evidence currently that shows removing glycosylation affects binding to FcRn; and therefore, it presumably does not affect the antibody's circulating half-life (7).

Yeast cells are able to carry out *N*-linked glycosylation but typically attach complex high mannose structures that are rapidly cleared from the body (19). Scientists recently demonstrated that they could knock out selected yeast glycosylation pathways. In addition, they cloned five human glycosidases into the *Pichia pastoris* yeast strain enabling

the expression of antibodies with human oligosaccharide structures (12).

35.2.1.3.2 Proteolytic and Glycolytic Activity. A common posttranslational modification observed in recombinant protein production is the removal of the C-terminal lysine or arginine residue that is expected based on the gene sequence. This modification has been reported in a number of host cell lines (see Harris (20), Table 35.1, p. 131). Cleavage of the C-terminal lysine or arginine seems to occur to a variable extent (0, 1, or 2 residues cleaved) and may be due to activity of a carboxypeptidase (20). However, this posttranslational modification does not appear to negatively impact product quality or pose a regulatory concern (20).

Another subtle effect of the host cell line is the extent to which the cell line secretes glycosidases that might be active in culture conditions. For example, extracellular CHO cell sialidase was shown to trim terminal sialic acid from the recombinant glycoprotein gp120 (21). Mammalian cell lines can also express other proteases that can have a negative impact on product quality (22), but given that the glycans on the heavy chain are relatively inaccessible and that antibodies usually have greater resistance to proteolytic activity, the effect of endogenous sialidases and proteases is typically not severe.

35.2.1.3.3 Antibody Dissociation. Most of the recombinant antibodies used as therapeutics are of the immunoglobulin class IgG1. For some applications, isotypes such as IgG4 that are much less active in invoking effector functions may be preferable. However, this isotype is known to have a propensity to dissociate into "half-molecules" consisting of a heavy and light chain (reviewed by Aalberse and Schuurman (23)). The extent of dissociation can be influenced by both the choice of the host cell line and the choice of the clone itself (24).

35.2.1.3.4 Clonal Variability. Recombinant cell lines show great variability in properties such as cell growth and productivity. Although rare, genetic variations can occur during transfection, selection, and amplification of the gene transcripts that can lead to subpopulations of cells that express altered protein sequences (25). Therefore, selected cells are typically isolated from transfections under conditions that increase the probability of starting growth from a single cell. These methods include selection by multiple rounds of limiting-dilution cloning and/or selection of single cells by flow cytometry. Given the potential for each cell clone to exert different influences on the product, the selection criteria for a clone should include measures of cell growth and productivity, and analyses of the resultant antibody for appropriate mass, integrity, and glycosylation patterns.

"Clonal" recombinant cell lines can show a high degree of variation in growth and productivity in the presence or absence of selective pressure (26,27). Further, variability in growth has also been reported after three rounds of cloning of the untransfected host NS0 cell lines (28). Therefore, regulatory guidelines suggest passaging cells beyond the planned level of use for routine manufacturing and analyzing the product to verify that critical properties remain unchanged (ICH Q5D) (6).

35.2.1.4 Productivity. The cell line has a large impact on the overall productivity of a process through two different attributes, antibody production and cell density. The amount of antibody produced by each individual cell is often expressed as the specific productivity in units of picograms per cell per day (pcd). Typically, cell lines can be isolated that produce antibody at specific productivities ranging from 10 to 50 pcd (29) that is usually sufficient to generate amounts necessary to support clinical or commercial needs.

Other key attributes are the ability of the cell line to grow to high cell densities, typically 2–10 million cells per mL, and to maintain their viability for extended periods of time while continuing to secrete high levels of antibody (30) (Fig. 35.2). Although many methods are available for the propagation of cells, industry has largely settled into growing these cell lines in stirred tank reactors and fed-batch cultures, where nutrients are periodically added in a concentrated form to maintain high cell density and viability (2). Improvements in the selection of high producing, recombinant cell lines and in the optimization of fed-batch processes have allowed the typical titer of antibodies produced in a fully developed industrial process to increase almost 10-fold each decade since the first production of monoclonal antibodies (Fig. 35.3). See Wurm (31) and Birch and Racher (32) for reviews on MAb production improvements.

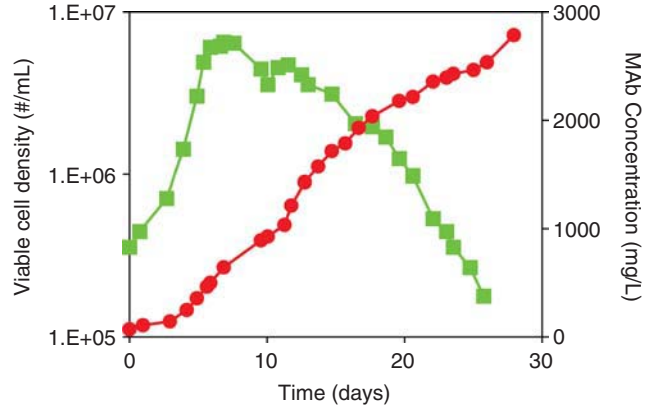

Figure 35.2. Example of the productivity (●) and viable cell concentration (■) as a function of culture time from an optimized fed-batch process. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

References for the range of titers reported include: Bibilia and Robinson (30) (Table 35.1, p. 3), Wurm (31) (Figure 35.2, p.1395), Birch and Racher (32) (Table 35.2, p. 680), Birch *et al*. (35) (Figure 4.6.b., p. 827), and Luan (36). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Scientists have tried to clarify the connection between phenotypic and genetic parameters that determine the productivity and stability of recombinant protein production in mammalian cells. Overall, the level of mRNA expression tends to correlate with the protein productivity, whereas the number of copies of genes integrated into the host cells does not (33,34). These two parameters are related to the general attributes of the cell line and expression system used; these properties are discussed next.

35.3 PROPERTIES OF MOST-COMMONLY USED MAMMALIAN CELL LINES AND VECTOR SYSTEMS

Productive recombinant protein expression systems used in the biopharmaceutical industry are achieved by obtaining high levels of gene transcription using appropriately designed expression vectors in concert with the intended host cell line. For MAbs, the host cell lines must be capable of efficient translation of heavy and light chain mRNAs into correctly assembled MAbs and effective secretion of the product with reproducible quality attributes that are aligned with the intended therapeutic effect. Since all of the currently licensed MAbs are expressed in mammalian host cells, this section focuses on the important genetic elements of the expression vector and methods that are used to improve protein expression by overcoming transgene silencing or by cell line engineering. A review of the methods currently used for transfection, selection, and screening for the most established mammalian cell lines is also included.

35.3.1 Mammalian Cell Expression Vectors

Expression vectors are used to deliver the genes coding for the therapeutic protein of interest to the host cell line. Therapeutic protein expression, in mammalian cell lines, relies on integration of the transgene into the host cell chromosome. The vector contains genetic elements that control transcription and translation. These elements typically include a 5' (upstream) promoter, a multiple cloning site (MCS) where the genes of interest are inserted, and a 3' (downstream) transcription terminator (polyadenylation) sequence. A mammalian selectable marker is required for selection of stable integrants in the host cell line. The most frequently used selectable markers include glutamine synthetase (GS) (37), dihydrofolate reductase (38–40) and hypoxanthine–guanine phosphoribosyl transferase (41,42). Alternatively, a resistance marker to an antibiotic like geneticin (G418, also known as *neomycin*) (43) or hygromycin (44) can be used. The most common promoters are human cytomegalovirus (hCMV) and simian virus 40 (SV40). The relative strength of the promoter is used to alternatively drive the heavy and light chain transcription rate higher than the selectable marker, or an internal ribosome entry site (IRES) can be inserted between the gene of interest and the selectable marker to drive the expression off a single promoter (45). The final essential components that are included in the mammalian expression vector are elements for bacterial cell propagation. These elements include a bacterial replication origin and a resistance marker to the antibiotic kanamycin or ampicillin. A generic example of a mammalian cell expression vector is shown in Fig. 35.4. The use and position of these elements within the vector can greatly affect gene expression (38,46,47).

Expression vectors also include translation control elements (e.g. Kozak sequence) and 5' and 3' untranslated regions (UTR) that increase efficiency of translation for improved mRNA stability. For MAbs, a leader (signal) sequence is needed for efficient intracellular transport and secretion. Intron (noncoding) sequences can affect promoter performance as well as transcription efficiency of the genes of interest and the selectable marker (45,46). Further, codon usage can be optimized to improve translational efficiency as a means to increase protein expression, because the frequency of different codons varies significantly between different organisms. In one series of experiments, optimized codon usage for CHO cell lines was shown to improve product yields, whereas removal of introns in heavy chain sequence did not affect productivity (48).

A frequent challenge with mammalian cell line selection is low and unstable recombinant protein expression that is caused by position effect, which is gene silencing at the level of chromatin due to the random nature of the transgene integration into the cell line chromosome. If the site of integration of the transgene is within or near

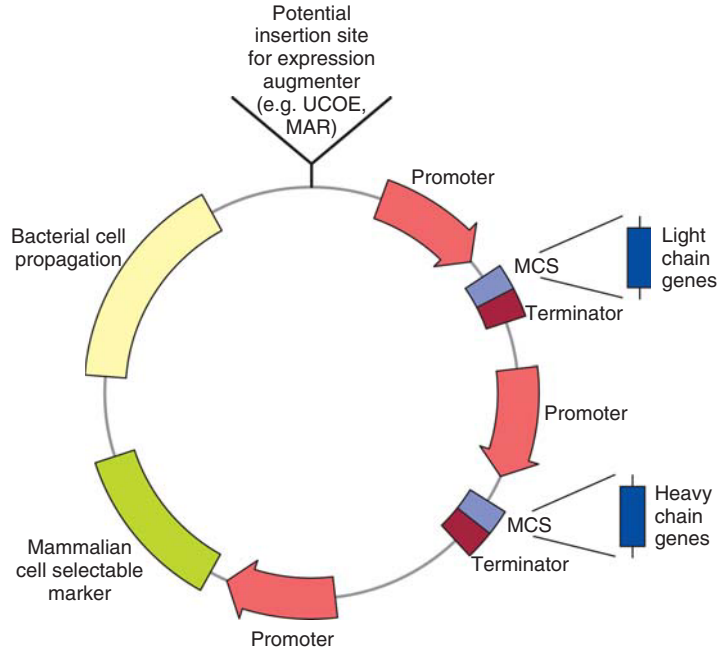

Figure 35.4. Generic schematic of a mammalian cell expression vector (MCS = multiple cloning site). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

heterochromatin (i.e. highly condensed regions), transcription is repressed, whereas integration of the transgene into euchromatin (i.e. open regions) generally results in active transcription. A number of approaches have been developed to overcome epigenetic gene silencing that include: (i) incorporating specific DNA elements into the expression vector, (ii) interfering with posttranslational modifications to the histones, proteins that are directly associated with DNA structure, and (iii) targeting specific integration sites of high gene expression (reviewed in Kwaks and Otte (49)). These approaches are outlined briefly below.

Incorporating specific DNA elements into mammalian expression vectors (Fig. 35.4) can reduce the effect of integration into heterochromatin. Some examples of these elements are scaffold attachment sequences (SARs) or matrix attachment sequences (MARs) (40,50), ubiquitous opening elements (UCOEs) (44), and expression augmenting sequence elements (EASEs) (51). Other DNA elements will block chromatin-associated repressors which are also known as stabilizing and anti-repressor (STAR) elements (52). Effectiveness of these elements for increasing protein expression and stability is largely dependent on the design of the expression vector, the host cell line, the selection system, and the experimental conditions (40,45,53,54).

Another alternative used to overcome epigenetic gene silencing is interfering with posttranslational modifications to the histones. The basic building block of chromatin consists of double-stranded DNA wrapped around proteins called *histones*. Acetylation, methylation, phosphorylation, and ubiquitination of lysine and serine residues located in the *N*-termini of histones have an impact on gene activity (55). Active transcription of DNA in the euchromatin is associated with histone acetylation and demethylation. One method commonly used to block deacetylation of histones is the addition of sodium butyrate to the culture medium (56) which has been shown to improve MAb productivity (57,58). In another example, the demethylating drug 5-azacytidine was used to overcome cholesterol auxotrophy that was associated with gene silencing while establishing cholesterol-independent NS0 cell lines (59).

The third approach for overcoming epigenetic gene silencing is to target site-specific integration. In this approach, enzymes are used to exchange the transfected DNA into the donor "hot spots" in the preestablished host cell line. Three examples include the Cre recombinase-mediated recombination at a loxP site (60), Flp recombinase-mediated recombination at a Flp recombination target (FRT) site (61), and zinc finger nuclease-mediated recombination (62).

35.3.2 Transfection, Selection, and Screening Methods

Recombinant proteins can be expressed as transient or stable gene products in mammalian cells. Transfection is used to shuttle the genes encoding for the protein of interest into the host cell nucleus. Transient transfections are generally

performed to generate microgram to milligram quantities of protein within a short amount of time (e.g. 3–14 days). No selection agent is applied after transfection; therefore, the plasmid DNA is not retained after cell division and protein production decreases rapidly. Stable transfections, that are the focus of this chapter, are performed to generate gram to kilogram quantities of protein and generally take a couple of months to screen the cell population for the rare high producing cells. A selection agent is applied after transfection; therefore, surviving cells have the plasmid DNA integrated into their genome, and protein expression is maintained with cell division.

Prior to transfection, the expression vector, which is in the form of plasmid DNA as described in section titled "Mammalian Cell Expression Vectors", is propagated in *E. coli* cells and then purified. A number of transfection methods can be successfully used to deliver DNA into a mammalian cell's nucleus including the use of electroporation or transfection reagents such as calcium phosphate, cationic polymers or cationic lipids (63). The DNA is linearized before transfection to improve the efficiency of stable integration into the chromosome of the host cell line. After transfection, the cells are diluted in culture medium and plated into petri dishes or microwell plates at a suitable concentration to obtain single colony outgrowth (i.e. limiting-dilution cloning). The selection agent is applied a day or two after transfection so that only cells expressing the selectable marker survive. A large numbers of cells are usually transfected to obtain an array of transfectants that can be expanded and measured for productivity. At each expansion stage, the cultures are evaluated and strategically reduced so that only the most productive cultures are carried forward. The cell line and expression system, as well as the methods used to screen, can affect the amount of time required to identify a high producing cell line. Examples of screening methods are shown in Fig. 35.5 as well as in Birch *et al*. (35) (Fig. 4.3, p. 817), Wurm (31) (Fig. 35.1, p. 1394), and Charlebois (64).

It typically takes 3–6 months to produce a relatively small number of high producers (Fig. 35.5), but transfection and selection conditions such as electroporator settings, concentration of selection agent, and seeding density can be optimized to increase the number of colonies that grow out of selection as well as the range of productivity (35,47,65). Flow cytometry can be used to identify highly productive cells earlier in the screening process using fluorescent-activated cell sorting (FACS). This approach permits analysis of attributes like protein expression to be performed on a single cell basis. Some reported examples include direct measurement of protein secretion by cell encapsulation in gel microdrops (66,67), membrane trapping of secreted proteins (68), and binding to a cellular affinity matrix (69,70). Other FACS screening methods measure surrogate markers for protein expression such as RNA expression levels using fluorgenic epitope tags (71) or selectable marker expression using fluorescent analogs like fluorescein-conjugated methotrexate (F-MTX) (39,72). These flow cytometry sorting methods have the potential to identify high producer cell lines much more rapidly than the traditional limiting-dilution cloning approach.

35.3.3 Cell Line Engineering

Cell lines can be further engineered to improve protein expression. Considerable effort has been placed in development of anti-apoptotic cell lines, reviewed by Vives (73). During production, cells are exposed to adverse conditions including nutrient depletion, buildup of toxic by-products, oxygen limitation, and shear stress that leads to programmed cell death, or apoptosis. This effect can be mitigated by over-expressing the anti-apoptosis genes involved in different phases of the apoptotic cascade, including those belonging to the protective Bcl-2 family and those involved in caspase inhibition. Over-expression of the Bcl-2 gene is the most extensively studied approach (35,73). Cell lines expressing this anti-apoptosis gene generally can be sustained for longer culture periods, primarily due to improved cell viability. However, the overall results vary particularly when evaluated under commercially relevant conditions. A successful case was reported using another Bcl-2 family member, Bcl-X_L, using chemically defined medium at 2000-L scale (74). More recently, expression of a combination of inducible anti-apoptosis genes Aven and EIB-19K was found to significantly improve cell viability and MAb expression in extended CHO cultures (75).

Finally, proteomics is being used to elucidate further bottlenecks in recombinant MAb production. Chaperone proteins, such as BiP and PDI that are present in the endoplasmic reticulum that affect immunoglobin folding and assembly, have been shown to increase in abundance with increasing recombinant protein production in murine myeloma cells (76). Incorporation of discrete chaperones into genetically engineered mammalian cell lines have not as of yet increased their capacity for protein production. However, this approach has successfully enhanced production of mammalian recombinant proteins in yeast and insect cells (77).

35.3.4 Mammalian Cell Lines

CHO and mouse myelomas are the most frequently used mammalian cell lines for production of MAbs (Table 35.1). These cell lines originated in the 1950–80s after selection for nutritional mutant cells that are deficient in an essential amino acid and/or enzyme required for survival. These cell lines are ideal for recombinant gene transfection, because their amino acid or enzyme deficiencies can be exploited

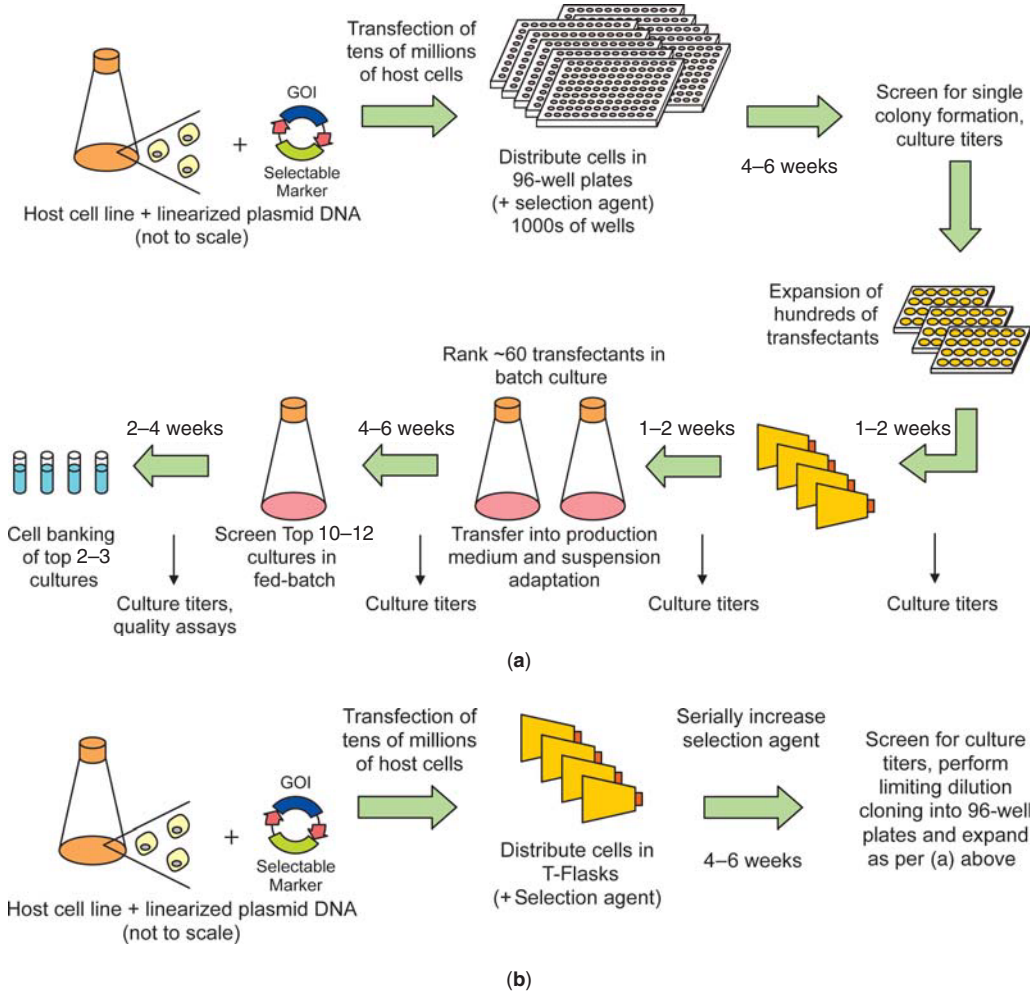

Figure 35.5. Example time lines for mammalian cell line screening (a) starting with limiting-dilution cloning immediately after transfections, and (b) starting with pools and including amplification. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

during the selection process through the use of a strategically designed expression vector and deficient selection medium.

35.3.4.1 Chinese Hamster Ovary. CHO cells used for commercial manufacture of MAbs were originally isolated by Puck *et al*. (78) from outbred hamsters from G. Yerganian's lab. Multiple lineages of proline deficient (pro-) mutants were subsequently derived (79,80) including CHO/pro-K1 (81), also known as *CHO-K1*, and *CHOpro-3* (82), also known as *CHO Toronto*, as it was used extensively by L. Siminivitch and his colleagues in that city (communication from L. Chasin).

Cell lines originating from CHO-K1 and CHOpro-3 were subjected to chemical mutagenesis and exposed to γ irradiation to generate cell lines deficient in dihydrofolate reductase (dhfr-), an enzyme required for nucleotide metabolism. Two resulting cell lines known as *DXB11* (83) and DG44 (84) are used in biopharmaceutical industry for the production of MAbs. Cell line DXB11 is also sometimes referred to as *DUK-XB11*, *DUK-B11* or *DUKX* (communication from L. Chasin). When these cell lines are used as part of a selection system, cells transfected with an expression vector containing the dhfr gene can grow in medium lacking glycine, hypoxanthine, and thymidine (GHT). Methotrexate (MTX), a cytotoxic folate analog specific for the DHFR enzyme, can be added to the GHT-free medium to increase selection pressure or to amplify gene transcripts for increased productivity (38,39), but some cases of instability have been observed (34,85) as well as appearance of genetic variants (25). An antibiotic resistance gene can often be used in conjunction with DHFR expression vectors (38–40) to permit rapid selection using antibiotic resistance and MTX to amplify

the dhfr transcript co-localized with the gene of interest. Reff and colleagues demonstrated that DHFR selection combined with an impaired neomycin gene as a dominant selectable marker can further facilitate selection of cell lines that only have transgenes integrated into hot spots within the genome (86).

Another common selection system used with cell lines derived from CHO-K1 is the GS system (35). GS is an enzyme involved in glutamine synthesis from glutamate and ammonia. Since glutamine is an essential amino acid, cell lines that lack endogenous GS must be fed glutamine for survival. When used as a selection system, cells transfected with the GS gene can grow in glutamine-free medium (37). Methionine sulfoximine (MSX), an inhibitor of GS, can be added to the medium to increase selection pressure if the cells such as CHO-K1 have endogenous GS, or to amplify gene expression (37,87).

35.3.4.2 Mouse Myeloma. Mouse myeloma cells were isolated originally from a mineral oil induced plasmacytoma by peritoneal injection in a BALB/c female mouse (88). The original mutant P3K (MOPC) was selected to be deficient in hypoxanthine-guanine phosphoribosyl transferase (hgprt-), an enzyme required for purine metabolism; however, the cells still expressed endogenous immunoglobin. Many rounds of selection and subcloning were performed to identify cells that no longer expressed the endogenous heavy and light chains. Three cell lines from slightly different lineages were derived from P3K, and represent the mouse myeloma cell lines frequently used today.

The first subclone, X63/Ag8.653, was derived from P3-X63/Ag8 (89). Another subclone, Sp2/0-Ag14 (also called Sp2/0), was derived from the fusion of P3-X63/Ag8 with the spleen of a BALB/c mouse immunized with sheep red cells and subsequently identified for its lack of immunoglobin expression (90). The third non-immunoglobin secreting subclone, NS0 (also called NS0/1), was a subline identified from NSI/1-Ag4-1, a light chain synthesizing subclone of P3K lineage (91). Table I, p.12 in Galfre and Milstein (91) has a clear summary of these lineages.

Due to their lineage as immunoglobin secretors, myeloma cells are a natural choice for recombinant gene transfection (reviewed in Yoo (92)). The GS expression system works particularly well for NS0 cell line, since they do not express endogenous GS. Cell line selection can be achieved in glutamine-free medium (35). MSX can be added to increase selection pressure (37). As compared to NS0, Sp2/0 cells were found to have a higher frequency of glutamine-independent variants (37).

Alternatively, myeloma cells can be transfected with selection vectors containing the xanthine–guanine phosphoribosyl transferase (gpt) gene or in combination with the neomycin gene (93). Mycophenolic acid is added for selection and MTX can be used to further inhibit the purine biosynthesis pathway to increase the stringency of this expression system. Myeloma cell line expression systems with gpt and/or neomycin genes have been used to express MAbs of commercial significance (41,42,94,95).

35.3.4.3 Hybridomas. The earliest antibodies created with predefined specificity were produced by hybridomas that were generated by fusing MAb-producing murine B cells with a tumor cell line (96). This procedure involves immunizing mice with a complex antigen mixture that gives rise to murine B cells expressing diverse antibodies directed against different antigens and epitopes. The B cells are isolated from the spleen or peripheral lymph nodes from the mice and fused with myeloma cells such as SP2/0-Ag14 or X63-Ag8.653. Supernatants from the resulting hybridomas are either screened by ELISA using plates coated with the antigen of interest or are analyzed by FACS for recognition of the native protein expressed on the surface of target cells. The origin of hybridomas and their impact on the field were reviewed by Milstein, one of the founding scientists (97).

Unfortunately, MAbs produced by hybridomas isolated from murine B cells were found to be immunogenic to humans (1). This issue was improved by creating recombinant chimeric or humanized MAbs in which portions of the mouse DNA sequence were replaced with the human sequence (10). However, now B cells can be taken from transgenic mice that possess an immune system in which the mouse antibody-producing genes were inactivated and functionally replaced by human antibody-producing genes. When immunized with human antigens, the mouse immune system recognizes the antigen as foreign, yet the transgenic mouse produces fully human antibodies rather than murine antibodies (98,99). This approach has been successfully used to generate investigational MAbs for human clinical studies.

35.3.4.4 Human Cell Lines. To date, no human cell lines have been licensed for the production of MAbs, and only one therapeutic protein has been approved by the FDA that is produced in human embryonic kidney (HEK293) cells (100,101). The HEK293 cell line was originally isolated after transfection with adenovirus-5 DNA (102). HEK293 is one of the most widely used cell line for large-scale transient transfection because it is highly susceptible to gene transfer (reviewed in Pham (103)). Two variants of this cell line were engineered for transient transfection: HEK293E which stably expresses the nuclear antigen of the Epstein–Barr virus (EBNA-1) and HEK293T which stably expresses the T-antigen of Simian virus 40. These cell lines can be transiently transfected with expression vectors containing either the EBV or SV40 origin of replication to produce large quantities of MAbs within a short

time (103,104) as compared to stable transfections. This approach is frequently used to produce MAbs for preclinical evaluation.

Another human cell line, PER.C6®, was derived by immortalizing human embryonic retina cells with the E1 gene of adenovirus (105). PER.C6® cells were originally generated for production of viral vectors, but recently MAbs have been produced from this cell line using G418 (neomycin) as the selection agent (43). Several vaccines and one MAb are reported to be in clinical trials (106).

35.3.4.5 Baby Hamster Kidney. One additional mammalian cell line that has been used to produce therapeutic proteins is the baby hamster kidney cell line, BHK-21. The BHK-21 cell line was derived from the polyoma-virus-induced transformation of kidney cells from one day old hamsters (107). The FDA has approved several recombinant blood factors produced as recombinant gene products in BHK cells. Thus far BHK cells have not been widely adopted for commercial MAb production which is probably because higher productivity can be achieved with CHO and murine myeloma cell lines. But, there are a few reports of MAbs expressed in BHK cells (108,109) including efforts to improve productivity using an inducible promoter for labile or toxic proteins (110).

35.4 OTHER HOST PLATFORMS

Despite the continued advancement of mammalian cell culture productivity (Fig. 35.3), there are several other host platforms that have some technical and economic advantages over mammalian cells. They have faster growth rates and can be grown to higher cell densities; and therefore, they usually have shorter production cycle times. Their growth media are less complex and can be well-defined resulting in less expense (111). However, as previously reviewed in "Product Quality", glycosylation plays an essential role in the function of many therapeutic products. Robust industrial fermentation organisms such as *E. coli* and fungi have been used successfully to produce simple nonglycosylated recombinant proteins. Prokaryotic organisms like *E. coli* do not glycosylate proteins. Lower eukaryotic hosts like yeast, insect, and plant cells produce glycan structures distinct from mammalian cells. The native *N*-glycan structures of these host cells are potentially immunogenic to humans and can adversely affect the safety and pharmacokinetic properties of the product. But, the availability of the genomic sequences for these organisms has enabled substantial headway to be made in the genetic modification of the *N*-glycan processing pathways for generation of mammalian-like *N*-glycans (review by Betenbaugh *et al*. (112) and Sethuraman and Stadheim (113)). Some of these advances are mentioned in the following sections.

35.4.1 Fungi

All yeast-based therapeutic proteins (e.g. anticoagulants, growth factors) and vaccines currently on the market are produced in *Saccharomyces cerevisiae* (111). Yeasts are capable of glycosylating proteins, but the resulting high mannose structures are nonhuman forms that are highly immunogenic (114) and result in rapid clearance (19,115). For this reason, yeast systems were not considered for MAb production. Recently, however, human glycosylation pathways were genetically engineered into *Pichia pastoris* that resulted in the production of MAbs with human *N*-glycosylation (116). There are at least seven therapeutic proteins under development using *P. pastoris* (12). Although yet to be approved for production of MAbs for human clinical trials, success of this technology will likely have a great impact on the future landscape of host cell lines used for MAb production.

35.4.2 Bacteria

E. coli is a very effective host system for production of simple recombinant proteins (e.g. insulin, human growth hormone, growth factors, interferons, and interleukins) and antibody fragments (111). Because antibody fragments lack the Fc domain, they do not bind to the FcRn receptor and are cleared *in vivo* rapidly. This attribute limits their therapeutic effectiveness (117). Initial attempts to express full length MAbs in *E. coli* resulted in the formation of insoluble aggregates called *inclusion bodies* that were biologically inactive. Efforts were made, with limited success, to solubilize and refold MAbs *in vitro* from denatured conditions (118). Recent improvements were made to the expression cassettes by Simmons and colleagues (119), in which a two promoter system with optimized translation initiation regions was used to control heavy chain and light chain distribution, resulting in the correct assembly of full length MAbs. The *E. coli*-expressed antibodies were active, and as expected for aglycosylated antibodies, they did not bind to C1q or FcγRI receptors. In addition, the *E. coli* antibodies showed similar circulating half-life in chimpanzees as those produced in mammalian cells (119). This approach appears promising, as there are appropriate therapeutic indications for which effector function leading to target cell depletion is undesirable (120,121).

35.4.3 Insect Cells

The insect cell–baculovirus expression system has been widely used to produce recombinant proteins and glycoproteins, see reviews by Kost *et al*. (122) and Jarvis (123). Despite its extensive use in research, only one vaccine comprised of recombinant viral proteins has been successfully licensed in the European Union for human use (124).

This host system has been limited from gaining traction for therapeutic use, particularly for MAb production, because insect cells are unable to produce human *N*-glycan structures (123), and mammalian cells have served as more predominant and suitable host for these products (111). Recently, the lepidopteran insect cell line has been engineered to express multiple enzymes for the expression of humanized glycoproteins, including glycosyltransferase, sialyltransferase, *N*-acetylglucosamininyltransferase, sialic acid synthase, and CMP-sialic acid synthetase (125). These cells produce sialylated recombinant glycoproteins in serum-free medium and represent the most extensively processed structures produced by any transgenic insect line described to date.

35.4.4 Plants

The first generation of recombinant proteins produced in plants is approaching commercial status for vaccines, human hormones or growth regulators, and antibodies (reviewed in Schillberg *et al*. (126)). A MAb against EGFR has been expressed in corn. In this example, the aglycosylated MAb possessed similar *in vivo* pharmacokinetics in primate studies compared to the mammalian cell culture derived MAb, whereas the glycosylated MAb had poor pharmacokinetics due to its rapid clearance (127). A number of plants have been genetically engineered to eliminate nonhuman glycan structures. Human antibody production has been optimized in a small green aquatic plant, *Lemna minor*, by co-expressing the antibody with an RNA interference construct that targets expression of β1,2-xylosyltransferase and core α1,3-linked fucosyltransferase genes (18). Tobacco plants have been genetically modified to produce mouse antibodies devoid of plant carbohydrate epitopes (128). And knockout *Arabidopsis thaliana* plants have been created that are free of immunogenic *N*-glycan structures like β1,2-linked xylose and core α1,3-linked fucose residues found in endogenous oligosaccharides (129). The economic implications for this type of production will certainly drive further progress in modifying plant *N*-glycan pathways for the production of humanized oligosaccharides.

35.4.5 Transgenic Animals

The production of recombinant proteins in milk or other body fluids using transgenic animals is another potential method that has been extensively investigated (reviewed by Houdebine (130)). For mammary gland expression, the genes coding for the protein of interest are introduced into the animal germ line using an expression vector fused to milk-specific regulatory elements (reviewed in Pollock *et al*. (131)). As with all other host systems, expression level varies with the expression vector and regulatory sequence. A humanized IgG1 MAb has been expressed in transgenic goat milk in multiple grams per liter quantities (131). Chimera chickens have been bred that express a MAb in the tubular gland cells of the oviduct that is secreted into the egg white to yield eggs that contain milligram quantities of the MAb (132). The oligosaccharide profile of this MAb was different from those produced in CHO cultures, in that the chicken-produced MAb contained high mannose type *N*-glycans, very low levels of galactose residues, and no α1,6-fucose residues (132). Progress in improving and simplifying therapeutic MAb expression in transgenic animals continues to make it a compelling process for future large-scale production.

35.5 CLOSING COMMENTS

Mammalian cell lines, in particular, CHO and mouse myeloma, are currently established as the dominant host cell platform for commercial production of recombinant MAbs because of their regulatory acceptance and ability to effectively and efficiently produce MAbs with consistent human-like glycan structures. Mammalian cell culture productivity has improved significantly over the past 20 years, due in part to enhanced vector design and optimized transfection, selection, and screening techniques for identification of the most highly productive cell lines. Progress in cell line engineering indicates further opportunity for improvement. Recent advances made in genetically engineering human *N*-glycan pathways into yeast and plants have the potential to alter the mammalian cell line dominance in the field. The impact of this paradigm shift in MAb production is yet to be realized; however, the establishment of high producing host cell lines that are used to develop robust manufacturing processes and demonstrate safe and consistent product quality attributes is one of the paramount requirements for gaining regulatory acceptance.

PLANT CELL CULTURE, LABORATORY TECHNIQUES

MARK RICHARD FOWLER
Leicester School of Pharmacy, De Montfort University, Leicester, United Kingdom

36.1 INTRODUCTION

Plant cell cultures are proving to be extremely useful model systems in a wide variety of investigations. They have several advantages over the use of whole plants, conceptually the most important being the ability to precisely control and manipulate the growth environment of a homogeneous population of cells. The effects of specific treatments on metabolism, growth, and division can be investigated without the complicating factors present when working with whole plants. Cell cultures therefore, find widespread use as systems to study gene expression (particularly during the cell division cycle and in studies of plant growth regulator function), the degradation or biotransformation of xenobiotics, and the production of secondary metabolites.

As with any model system, results obtained using plant cell cultures must be interpreted with some caution. The formation of cell cultures involves a degree of dedifferentiation and reprogramming of gene expression. Cell cultures may not therefore, be a true representation of the situation in plants. However, for fundamental studies and applied research, they often remain the system of choice.

This chapter will cover the basic techniques (and facilities) required to establish, maintain, and monitor plant cell cultures. Where possible, the theoretical background will be given to help the reader fully appreciate the advantages and limitations of plant cell cultures.

36.2 LABORATORY FACILITIES

The growth of plant cell cultures places some novel technical and infrastructural problems on the laboratory (1,2). In order to successfully grow plant cell cultures, certain facilities must be available. The equipment required must not only include items needed for the maintenance of the cell cultures themselves, but also facilities for the growth of donor material if cell cultures are to be established routinely. The laboratory should therefore provide areas suitable for:

1. growth media production, sterilization, and storage;
2. the manipulation of plant material under aseptic conditions;
3. the growth of both donor plant material and the cell cultures themselves under controlled conditions.

A media room suitable for producing plant cell culture media need not be very complicated, as it requires little equipment that would not be present in any laboratory. Required items include both a top pan balance and a fine analytical balance, stirrer plates (heated ones can be useful), a source of high-purity water, pH meters, an autoclave (a large pressure cooker can be used, but only if small volumes of media are to be used), and refrigerators and freezers. Useful additions to this list would include a steamer or microwave oven (for melting agar-gelled media) and an automatic pipetter unit.

Growth rooms or growth chambers should be used to provide areas where plant cell cultures and donor plant material can be grown in controlled conditions. Growth rooms are ideal if a large volume of plant cell culture work is to be undertaken, and with cultures that grow in the same conditions. Growth chambers provide smaller areas for the growth of plants or cell cultures, but are self-contained

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

and can therefore provide facilities dedicated to a particular plant or cell culture type. The growth rooms or growth chambers should be equipped with time-controllable lights, a temperature control system (capable of dealing with the large amount of heat given out by any lighting), and some way of controlling humidity. Plant cell cultures are usually grown at about 25°C, and the humidity should not be lower than 50% or culture media will dry out very quickly (3). There should also be areas where cultures can be grown in complete darkness. Conditions in growth rooms used for growing donor plants should match as closely as possible the natural conditions for that particular plant (although this may be less important for plants that are to be used eventually to establish cell cultures, as they are not normally required to flower or set seed unless specialized cell types such as endosperm or pollen are required), as the condition of the donor material may prove to be critical in being able to establish a cell culture.

Cell suspension cultures require constant agitation and therefore a shaker bed must be available in a controlled environment room. Shaker beds are gyratory (orbital) with platforms, and with clips of various sizes to hold conical flasks. They should have variable speed settings.

Areas for the manipulation of plant material under aseptic conditions should ideally be self-contained rooms in which laminar-flow transfer cabinets can be placed. Laminar-flow transfer cabinets should be used for all manipulations that require an aseptic environment. Transfer cabinets are available in a variety of sizes, and consist basically of a high-efficiency filter to remove airborne contaminants and a fan to produce a laminar flow of air, from the back of the cabinet toward the user (or from the top to the bottom of the cabinet). They are made of a variety of materials, stainless steel probably being the best as it is robust, and easy to keep clean and surface-sterilize. The cabinets can also be supplied with a gas source for a burner, although self-contained gas burners can be used. Items within the cabinet should ideally be kept to a minimum, as anything that interferes with the laminar flow of the filtered air can compromise performance. Laminar-flow cabinets should be serviced regularly to ensure that the filter is working correctly. The performance of transfer cabinets can also be checked by placing unlidded petri dishes of media in the cabinet and checking for the growth of any microorganisms. If genetically manipulated plant material that may still be harboring microorganisms is to be used, a transfer cabinet specially designed to prevent contamination of the environment should be used. Laminar-flow cabinets may be provided with a UV light source to maintain a sterile environment, although the use of such devices is of questionable efficiency and can present some health risks (4).

Additional equipment that should be present in a plant cell culture laboratory includes both binocular (dissecting) and high-magnification microscopes, the latter preferably with a UV light source. The binocular microscopes should be portable so as to allow their use in a laminar-flow transfer cabinet. Both types of microscope should have attachments to allow photography.

36.3 PLANT CELL CULTURE MEDIA

The culture media must provide all the essential elements and nutrients necessary for the growth of the cell culture. As such, plant culture media are composed of three basic components:

1. a supply of essential elements, which are supplied in the form of a complex mixture of salts;
2. an organic supplement that supplies essential vitamins and other organic supplements (although plants are capable of synthesizing vitamins and amino acids, the biosynthetic capability of plant cell cultures often differs from that of whole plants, necessitating the supply of these in the culture medium);
3. a fixed carbon source (again, although whole plants are capable of fixing carbon from atmospheric carbon dioxide, plant cell cultures are, except in specialized cases, not autotrophic; this necessitates a supply of carbon in the medium), usually sucrose (which is cheap and readily available).

The three basic components of plant cell culture media can be further divided into categories that become apparent if the formulations of particular media are examined (Tables 36.1–36.3). The supply of essential elements falls into three groups:

1. macroelements (or macronutrients),
2. microelements (or micronutrients),
3. iron source.

Plant cell culture medium is therefore usually made by combining several different components to give a complete medium. Concentrated stock solutions of macroelements, microelements, iron source, and organic supplement are commonly made, while the carbon source is usually added as a solid.

36.3.1 Stock Solution Components

Macroelements. As the name suggests, this stock solution contains the elements required in large amounts for plant growth (these are elements that generally comprise at least

TABLE 36.1. Formulations of Gamborg's B5 Medium

Essential Element	Concentration in Stock (mg/L)	Concentration in Medium (mg/L)
	Macronutrients (50 mL)	
KNO_3	50,000	2,500
$CaCl_2 \cdot 2H_2O$	3,000	150
$(NH_4)_2SO_4$	2,680	134
$MgSO_4 \cdot 7H_2O$	5,000	250
$NaH_2PO_4 \cdot H_2O$	3,000	150
	Micronutrients (25 mL)	
KI	30	0.75
H_3BO_3	120	3
$MnSO_4 \cdot 4H_2O$	400	10
$ZnSO_4 \cdot 7H_2O$	80	2
$Na_2MoO_4 \cdot 2H_2O$	10	0.25
$CuSO_4 \cdot 5H_2O$	1	0.025
$CoCl_2 \cdot 6H_2O$	1	0.025
	Iron source (10 mL)	
FeNaEDTA	3,670	36.7
	Vitamins (1 mL)	
Myo-inositol	Add as solid	100
Pyridoxine–HCl	1,000	1
Phiamine–HCl	10,000	10
Nicotinic acid	1,000	1
	Carbon source	
Sucrose	Add as solid	20,000
pH 5.5		

Note: Formulations of plant cell culture media have been adapted from Refs 5 and 6. The composition of the various stock solutions is given, as is the amount of each stock solution needed for 1 L of medium. It should be noted that the composition of plant cell culture media varies to some degree from source to source. A full list of media formulations can be found in Ref. 7.

TABLE 36.2. Formulations of Murashige and Skoog Medium

Essential Element	Concentration in Stock (mg/L)	Concentration in Medium (mg/L)
	Macronutrients (50 mL)	
NH_4NO_3	33,000	1,650
KNO_3	38,000	1,900
$CaCl_2 \cdot 2H_2O$	8,800	440
$MgSO_4 \cdot 7H_2O$	7,400	370
KH_2PO_4	3,400	170
	Micronutrients (5 mL)	
KI	166	0.83
H_3BO_3	1,240	6.2
$MnSO_4 \cdot 4H_2O$	4,460	22.3
$ZnSO_4 \cdot 7H_2O$	1,720	8.6
$Na_2MoO_4 \cdot 2H_2O$	50	0.25
$CuSO_4 \cdot 5H_2O$	5	0.025
$CoCl_2 \cdot 6H_2O$	5	0.025
	Iron source (5 mL)	
$FeSO_4 \cdot 7H_2O$	5,560	27.8
$Na_2EDTA \cdot 2H_2O$	7,460	37.3
	Vitamins (5 mL)	
Myo-inositol	20,000	100
Nicotinic acid	100	0.5
Pyridoxine–HCl	100	0.5
Thiamine–HCl	100	0.5
Glycine	400	2
	Carbon source	
Sucrose	Add as solid	30000
pH 5.7–5.8		

Note: Linsmaier and Skoog (LS) medium is basically the same except for the small variations in the vitamins.

0.1% by dry weight of plants) (5). The macronutrients are usually considered to be carbon (which is supplied as a separate component and is considered later), nitrogen, phosphorus, potassium, magnesium, calcium, and sulfur.

Nitrogen is usually supplied as nitrate and/or ammonium salts. To be incorporated into biological macromolecules, nitrogen must be in the reduced form (such as ammonium ions). Nitrate ions present in the media must be reduced in order to be incorporated into molecules, an energetic process. Therefore, there is a theoretical advantage in supplying nitrogen solely as ammonium ions. Ammonium ions, however, can be toxic in high concentrations (although plant cell cultures are generally less susceptible to ammonium toxicity than are animal cell cultures, for example) and uptake of ammonium ions causes acidification of the medium. Hence, the use of ammonium ions as the sole nitrogen source requires that the culture medium be buffered. Most plant cell culture media supply nitrogen as a mix of nitrate and ammonium salts which also has the advantage of weakly buffering the media. Uptake of ammonium ions causes H^+ ions to be excreted into the culture medium, whereas nitrate uptake causes OH^- ion excretion. The buffering depends on both nitrate and ammonium ions being present in the medium, and the fact that ammonium ion uptake is reduced at acidic pH while the uptake of nitrate ions is reduced at alkaline pH (5).

Phosphorus (involved in energy transfer and a component of RNA and DNA), is usually supplied as the phosphate ion and is present at lower concentrations than nitrate/ammonium ions. High concentrations of phosphorus in media can lead to precipitation of other elements as insoluble phosphates.

Potassium is usually supplied as the chloride, nitrate, or orthophosphate salt, and is an important cellular cation involved in many processes.

TABLE 36.3. Formulations of Schenk and Hildebrandt Medium

Essential Element	Concentration in Stock (mg/L)	Concentration in Medium (mg/L)
	Macroelements	
KNO_3 (25 mL)	101,000	2525
$MgSO_4 \cdot 7H_2O$ (15 mL)	24,640	36.6
$NH_4H_2PO_4$ (25 mL)	11,500	287.5
$CaCl_2 \cdot 2H_2O$ (15 mL)	14,680	220.2
	Microelements (10 mL)	
$MnSO_4$	1,320	13.2
H_3BO_3	500	5
$ZnSO_4 \cdot 7H_2O$	100	1
KI	100	1
$CuSO_4 \cdot 4H_2O$	20	0.2

$CoCl_2 \cdot 6H_2O$	10	0.1
	Iron source (10 mL)	
$FeSO_4 \cdot 7H_2O$	1,500	15
Na_2EDTA	2,000	20
	Vitamins (10 mL)	
Thiamine–HCl	500	5
Nicotinic acid	500	5
Pyridoxine–HCl	50	0.5
Myo-inositol	Add as solid	1,000
	Carbon source	
Sucrose	Add as solid	30,000

Magnesium is usually supplied as magnesium sulfate. Like potassium, it is an important cellular cation, and can, in some cases, substitute for potassium.

Calcium is usually supplied as the chloride salt (although calcium nitrate is used in some medium formulations). Calcium has important structural and regulatory roles.

Sulfur is usually supplied as magnesium sulfate or occasionally as ammonium sulfate (many micronutrients are also supplied as sulfates). Sulfur is an important component of some amino acids and as such, helps to determine protein structure.

A 10× or 20× stock solution of macroelements is usually made in deionized water and can be stored at 4°C for several months.

Microelements. These are elements required in trace amounts for plant growth and development and have diverse roles. Microelements comprise manganese, copper, cobalt, boron, molybdenum, and zinc, which are usually considered to be essential (5,8). Nickel is included in the microelement formulations of some media (such as Heller's medium) and as a component of urease (5), may be necessary for the growth of some cell cultures (9). Other elements (such as aluminum and iodine) are also often present in microelement formulations, but whether these are strictly necessary is doubtful.

A more concentrated (100x or 200x) stock solution can be made, as these elements are present at much lower levels than the macroelements. Store the stock solution at 4°C, where it should be stable for several months.

Iron source. Iron is usually supplied as iron sulfate (iron citrate can also be used) and is generally considered to be the most important micronutrient. EDTA (ethylene diamine tetra-acetic acid; the disodium salt) is usually used in conjunction with the iron sulfate to chelate the iron, so as to allow a slow and continuous release into the medium (the commercially obtainable ferric-sodium salt of EDTA can also be used as the iron is already complexed). Uncomplexed iron can undergo rearrangement and precipitate out of the medium as ferric oxide (5). The iron source should be specially prepared so as to ensure chelation of the iron. The Na_2EDTA should be dissolved in almost boiling water, after which the iron sulfate should be added, the solution allowed to cool, and then made up to volume (7). The Fe/EDTA stock solution (100x) should be protected from light (10) and stored at 4°C. It has been observed that EDTA, which chelates other divalent cations, can have inhibitory effects on some plant cultures (11).

It has been reported that Fe/EDTA produced by this method can lead to precipitation of iron from media (such as Murashige and Skoog), if used at standard concentrations. One-third of the original amount of iron (with the same amount of EDTA) can be used in order to avoid this problem (7).

Vitamins/organic supplements. These are included in plant cell culture media, often for historical reasons. Only two vitamins are considered to be essential, thiamine (vitamin B_1) and myo-inositol, although this may vary from culture to culture (5,9,12). Other vitamins, although not essential, may improve the growth of certain cell cultures (13).

Reduced nitrogen can also be supplied to plant cell cultures in the form of amino acids (usually arginine, glutamic acid, glutamine, and glycine). The uptake of amino acids, like the uptake of ammonium ions, causes acidification of the medium (5). Glycine is a standard component of many media, but in most cases is not required. Casein hydrolysate can be used as a source of amino acids (and therefore reduced nitrogen) and is also rich in calcium and phosphate (5).

Stock solutions of organic supplements (100x–1000x) should be stored in the freezer (in suitable aliquots). Generally, the vitamin or organic supplement stock is added before the media is autoclaved; however, if specific studies on vitamins are being conducted, they should be filter-sterilized and added after the medium has been autoclaved (7).

Carbon source. For several reasons, sucrose is by far the most used carbon source. It is cheap, readily available, relatively stable under autoclaving, and readily assimilated by plant cells. Other carbohydrates can be used, such as glucose (glucose is easily caramelized though), maltose, and galactose, as can the sugar-alcohols glycerol and sorbitol. Many of the latter are used only in specialized circumstances though. The carbon source is added to the medium as a solid.

These then, are the basic components of most plant cell culture media formulations. However, other components are commonly added for specific purposes.

Gelling agents. These are used to "solidify" the plant culture medium so plant cells can be grown on the surface of the medium. Agar is the most common agent used for gelling (incorrectly called solidifying) media. A natural product from seaweed, it is relatively cheap. Agar is insoluble in cold water, but produces relatively inert gels at about 100°C and "solidifies" at around 45°C. Agar is used at concentrations of 0.6–0.8% (w/v). Low pH inhibits gelling. Agar is relatively impure, and the use of special "Plant Cell Culture" grade agar is recommended. Being a natural product, its quality can vary from batch to batch and manufacturer to manufacturer; so it is best to stick to one supplier. Some agar preparations also contain significant amounts of some salts which can alter the composition of the medium (14). Purified agar or agarose can be used for more demanding procedures (such as protoplast culture) but the routine, large-scale use of agarose is expensive.

Alternative gelling agents such as the gellan (a bacterial product) gums Gelrite or Phytogel are becoming more popular as they may be more suited to the growth of some cells. These gellan gums are more expensive (per unit weight) than agar, but can be used at concentrations as low as 0.2% (w/v). Gellan gums are used in the same way as agar. A variety of other gelling agents are also available commercially. All gelling agents have effects on the water potential of the medium and affect the rate of diffusion of nutrients (and toxic by-products).

For plant cell cultures to proliferate, further additions to the medium may be required. Plant growth regulators are often required by plant cell cultures for cell division and expansion (and other developmental pathways). These plant growth regulators are most commonly plant hormones or their synthetic analogues, and thus give the cells the correct signals for proliferation. These are supplied in the medium because the biosynthetic capability may not be present in plant cell cultures. Plant growth regulators can be divided into several groups (Table 36.4).

1. Auxins
2. Cytokinins
3. Gibberellins
4. Abscisic acid (ABA)
5. Ethylene
6. Others

TABLE 36.4. Plant Growth Regulators Commonly Used in Plant Cell Culture Medium

Regulator	Molecular Weight
Auxins[a,b]	
IAA (indole-3-acetic acid)	175.2
IBA (3-indolebutyric acid)	203.2
2,4-D (2,4-dichlorophenoxyacetic acid)	221
2,4,5-T (2,4,5-trichlorophenoxyacetic acid)	255.5
NAA (1-naphthylacetic acid)	186.2
NOA (2-naphthyloxyacetic acid)	202.2
Picloram (4-amino-3,5,6-trichloropicolinic acid)	241.5
Dicamba (2-methoxy-3,6-dichlorobenzoic acid)	221
MCPA (2-methyl-4-chlorophenoxyacetic acid)	200.6
Cytokinins[b,c]	
Zeatin (4-hydroxy-3-methyl-trans-z2-butenylaminopurine)	219.2
IPA [N^6-(2-isopentyl)adenine]	203.3
BAP (6-benzylaminopurine)	225.2
Kinetin (6-furfurylaminopurine)	215.2
Thidiazuron (N-phenyl-N′-1,2,3-thiadiazol-5-ylurea)	220.25
Gibberellic acid (GA_3)[d]	346.4
Abscisic acid[d]	264.3

[a] Auxins are usually titrated into solution with NaOH (0.1 ***M***). DMSO can also be used, as can 95% ethanol.
[b] If auxins and cytokinins are dissolved in alkali and acid, the pH of the stock solutions should be brought to the pH of the medium before use.
[c] Cytokinins are usually dissolved in a small volume of HCl. Cytokinins can also be dissolved in DMSO.
[d] Gibberellic acid (GA) and ABA are soluble in water.

Auxins. Indole-3-acetic acid (IAA) is the only (or predominant) natural auxin, but its use in *in vitro* cell cultures is complicated. IAA is not very stable to heat and is also photolyzed (stock solutions are degraded within a few days) (15). IAA can also be rapidly inactivated in plant cells by conjugation, which makes the internal concentration of IAA uncertain. In order to partially alleviate this problem, relatively stable amino acid conjugates of IAA (such as indole-acetyl-L-alanine and indole-acetyl-L-glycine) can be used, although their use is not widespread (5). Stable chemical analogues of IAA are therefore, usually used in plant cell culture media. 2,4-Dichlorophenoxyacetic acid (2,4-D) is perhaps the most commonly used auxin and is very effective. Others, such as indole-3-butyric acid (IBA), 1-napthylacetic acid (NAA), 2-napthyloxyacetic

acid (NOA), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), 2-methyl-4-chlorophenoxyacetic acid (MCPA), 2-methoxy-3,6-dichlorobenzoic acid (dicamba), and 4-amino-3,5,6-trichloropicolinic acid (piclorom) are also available. Not all are equally efficient at promoting growth and cell division, and there may be species-to-species variation in efficacy. Synthetic auxins should be handled with care as many (or contaminants present in the preparation) are mammalian carcinogens. Synthetic auxins are also known to promote somaclonal variation (5).

There also exists a class of compounds that are known to antagonize auxin action, the so-called anti-auxins. Anti-auxins act either by inhibiting auxin transport or the correct recognition of auxin molecules by cells and can prove useful in studies of auxin action. Commonly used anti-auxins include 2,3,5-triiodobenzoic acid (TIBA), *p*-chlorophenoxyisobutyric acid (PCIB), and 2,4,6-trichlorophenoxyacetic acid (2,4,6-T).

Auxins are usually included in plant cell culture media in order to promote cell division and cell growth.

Cytokinins. The natural cytokinins are a wide variety of related (purine derivative) compounds. Some naturally occurring cytokinins used in cell culture media are 4-hydroxy-3-methyl-trans-2-butenylaminopurine (zeatin) and -(2-isopentyl) adenine (2iP or IPA). These naturally occurring compounds are very expensive (especially zeatin) and relatively unstable. The synthetic analogues 6-furfurylaminopurine (kinetin) and 6-benzylaminopurine (BA or BAP) therefore find widespread use in plant cell culture media. Other, non-purine-based chemicals (such as substituted phenylureas) also find use as cytokinins (9). Cytokinins are often included in plant cell culture media along with auxins, in order to promote cell division.

Combinations of auxins and cytokinins can be used to initiate specific forms of organogenesis in plant tissue cultures. Generally, high levels of cytokinin coupled with low levels of auxins promote shoot formation, while high levels of auxin in conjunction with low levels of cytokinins promote root formation.

Gibberellins or GAs. There are many variations on the gibbane carbon skeleton that, in plantae, are involved in regulating cell elongation. Commercially, only a few of the possible gibberellins are available. Anti-gibberellins, which act by preventing synthesis (such as ancymidol), are available.

ABA. ABA is generally regarded as inhibiting cell growth. It is most commonly used in media to promote specialized developmental pathways such as somatic embryogenesis.

Ethylene. Ethylene is a naturally occurring gaseous plant growth regulator, most commonly associated with controlling fruit ripening in climacteric fruits. It is not often used in plant cell tissue cultures, but can be supplied to cultures as a gas or by ethephon (2-chloroethylphosphoric acid). Ethylene action can be antagonized by silver ions, and aminoethoxyvinylglycine (AVG) which inhibits ethylene biosynthesis.

Others. A bewildering array of other compounds (polyamines, phenolic compounds, and jasmonic acid, among others) have been postulated to have growth regulatory properties. In general, it is the auxins and cytokinins that find the most widespread use in plant cell culture.

Stock solutions (10 mg/mL or 10 m*M*) of plant growth regulators are usually prepared. If the plant growth regulators are to be added after the culture medium has been sterilized, the pH of the stock solutions should be brought to the pH of the medium.

Plant cell culture media can be bought from a variety of commercial suppliers, and may offer some advantages for routine cell culture work. But, buying pre-made media is relatively expensive, and does not allow the easy manipulation of individual media components. It has also been observed that some commercial plant cell culture media have a tendency to precipitate out during autoclaving.

36.3.2 Preparation of Media

Stock solutions of the basic medium components (such as macronutrients) can be prepared and stored as indicated. They are then added to deionized water (about half the final volume) in the indicated proportions, along with the sucrose. Any other heat-stable components can also be added. When the sucrose has dissolved, the volume is brought to about 90% of the final, and the pH of the medium adjusted to the desired value. The medium is then brought to the correct final volume (with thorough mixing) and dispensed into suitable containers for autoclaving. After autoclaving, the media should be clear with a slight yellow color from the iron source. Any browning of the medium indicates that the carbon source has caramelized and it should be discarded.

It is important to remember that while most components of plant cell culture medium are considered to be thermostable, some are not and there are conflicting data on others. Gibberellins are rapidly degraded by autoclaving, and therefore should be filter sterilized and added to the medium after autoclaving (16). Auxins are generally considered to be thermostable (although there is some disagreement, and for some applications better results have been achieved using filter-sterilized auxins) (7,15,17). Cytokinins (except zeatin) are also considered to be thermostable (although some substituted phenylureas are not), as are most vitamins (calcium pantothenate excepted and thiamine is destroyed if the medium pH is too high) (7,9). Some plant growth regulators are soluble in ethanol, which results in a stock solution that is inherently sterile and can therefore be added after sterilization; the final concentration of alcohol in the

medium is negligible. Sucrose is also added to the medium before autoclaving, although this results in a degree of hydrolysis (approximately 5%, depending on the duration of autoclaving) to a mixture of D-glucose and D-fructose (18).

36.3.3 Media Sterilization

In most cases, plant cell culture media are sterilized by steam in an autoclave. This is usually done for 20–30 min at 121°C (103 kPa). These criteria are set on the general rule that 121°C must be maintained for at least 15 min in order to kill thermophilic indicator microorganisms such as *Bacillus steriothermophilus*. It should be remembered that this standard autoclave regime will be insufficient to ensure sterilization of large volumes of media (5). However, thermophilic organisms are rarely a problem in plant cell cultures, and standard autoclave cycles of 20–30 min at 121°C are widely used regardless of culture vessel size. Excessively long autoclave cycles should be avoided, as they result in caramelization of the carbon source and may well result in the breakdown of other medium components.

The efficacy of steam sterilization can be checked by the use of special indicator tubes that change color when they have been exposed to a certain temperature, for a set length of time (various combinations can be obtained). Ideally, they should be placed in a vessel containing a liquid of similar volume if media are being sterilized, to ensure that the medium is sterile. A cheaper alternative is to use special tape having indicator strips that change color when autoclaved. However, this tape only indicates that the vessel has been autoclaved, not whether the contents are sterile.

The heat-labile components of media can be sterilized by filtration through a sterile fine-pore membrane (0.45 or 0.22 μm). These are available commercially, either as presterilized sealed units or as self-assembly units that are autoclaved before use. They are simple to use, as either the liquid is forced through the membrane into a sterile receptacle from a syringe or on larger units, a vacuum source is used. These filter units will remove bacteria and fungi, but not viruses, viroids, and mycoplasma.

36.3.4 Aseptic Technique

It is obviously important to ensure that any plant cell cultures are sterile, in order to avoid loss of the culture and invalidating any experimental results. It is vital then that all possible precautions against contamination are taken. We have already seen that plant cell culture media can be sterilized by autoclaving and that any heat-labile components can be filter-sterilized. However, when manipulating plant material and/or plant cell cultures, the whole environment should be as free from contamination as is possible.

Hands should thoroughly washed before any work is commenced, and latex gloves can be worn. These gloves can be occasionally swabbed with 70% ethanol to ensure that they are sterile. Face masks can also be worn to prevent airborne contaminants spreading, and long hair should be tied back (or a hair net used).

Any surfaces where aseptic techniques are to be used, should be surface sterilized before and after use. This is usually done by swabbing the area with a 70% (v/v) solution of ethanol or isopropanol, although industrial methylated spirit can be used and is much cheaper. Acidified alcohol (70%, pH 2) or a solution of phenolic disinfectant can also be used. As a further precaution, any manipulation can be carried out on autoclaved ceramic tiles that can be changed regularly to ensure asepsis.

Any vessels, surfaces and so on that are going to be used within the aseptic environment, should be sterile. This can be achieved by autoclaving or by dry heat. If items are autoclaved, the openings should not be sealed so tightly so as to prevent the steam from penetrating into them. This is because steam sterilizes by transfer of its thermal energy to any surface in contact with it. Simply heating to 121°C will not ensure sterility. Dry heat can also be used to sterilize items (check if they will withstand the temperature), but it is less efficient and therefore requires longer times. Any small items to be sterilized by dry heat can be wrapped in aluminum foil. The total time taken for dry heat sterilization is considered to be well over 3 h (5) at about 180°C (1 h for the load to reach the sterilization temperature, 2 h at the sterilization temperature and a cooling-down period). Prior to sterilization, glassware used for plant tissue culture can be rinsed in water with any commonly used detergent. Traces of detergent, which can be detrimental to plant tissue culture growth, can be removed by rinsing in dilute acetic acid.

Instruments used for the manipulation of plant material should initially be sterilized by autoclaving or dry heat (dry heat will blunt scalpels). They can be kept sterile during use by placing them in a container of 80% (v/v) ethanol which is quickly flamed off. There is no need to heat instruments in a flame for a long period; this will blunt scalpel blades and cause delays while instruments are allowed to cool down. Obviously, precautions need to be taken to ensure that the ethanol does not ignite (this is particularly so with transfer cabinets, where the flow of air will blow the fire toward the user); so it should be kept capped whenever possible and kept in a container that will not smash or tip over (a boiling tube with cotton wool in the end, which is then placed in a weighted beaker to prevent tipping over, works well).

Any plant material that is going to be used to establish a cell culture needs to be surface-sterilized. This is usually achieved by treating the plant material with chemicals such as bleach. The conditions needed to ensure sterility have to be determined on a case-by-case basis. It will depend on many factors such as the initial degree of contamination, the type of contaminating microorganism, the morphology

of the material to be sterilized, and the susceptibility of the plant material itself to damage from the bleach. It is important that the plant material is not exposed to the sterilizing agent for too long a period, as this will have detrimental effects. If explants can be taken from seedling tissue, a good way of producing sterile donor material is to sterilize seeds and produce sterile plants *in vitro*; otherwise, the explant source must be surface-sterilized.

Most workers use a commercial bleach (such as Domestos), which contains approximately 5% sodium hypochlorate. The commercial bleach is usually diluted before use with water, but the precise dilution needs to be determined. The addition of surfactants (0.1–1% v/v) such as Tween or Triton (or Teepol, which is cheaper, though less pure) can improve sterilization, presumably by improving contact with the bleach solution. A 70% solution of ethanol is also commonly used in conjunction with bleach to sterilize explants. If treatment with bleach proves ineffective at ridding contamination, the tissue can also be treated with Virkon (a commercial disinfectant that has a pH different from than that of bleach). In cases where this proves ineffective, alternative chemical sterilization agents include hydrogen peroxide (about 10%), bromine water (about 1–2%), and mercuric chloride (0.1–1%), although some of these are extremely dangerous (such as mercuric chloride). After treatment with chemical sterilizing agents, the plant tissue must be washed thoroughly with copious amounts of sterile distilled water to ensure removal of the chemical. Some surface sterilization methods are given:

Tobacco or Arabidopsis seeds (or other small, smooth seeds)

1. Submerge in 70% ethanol for 10 s.
2. Submerge in 10% household bleach for 20 min.
3. Wash three times in sterile distilled water.

1. *Sugar beet seeds (seeds with a rough seed coat).* Submerge in 70% ethanol for 10 s.
2. Submerge in 50% household bleach or 0.1% Teepol for 30 min.
3. Wash three times in sterile distilled water.

Tobacco leaves

1. Submerge in 10% household bleach for 15 min.
2. Wash three times in sterile distilled water.

36.3.5 Vessels for Cell Culture *In Vitro*

A wide variety of vessels for cell cultures can be obtained commercially, and so long as they are capable of fulfilling the basic needs of containing the cell culture and its medium and excluding contaminants, all are acceptable. Unless they are disposable and purchased presterilized, the culture vessels must be capable of being sterilized.

Petri dishes are widely used vessels for plant cell cultures. They are cheap, can be stacked (and therefore occupy little space), and can be bought presterilized. Originally designed for work with microorganisms, their main drawback is the lack of space for vertical growth. They are, however, ideal for the initiation of callus cultures. Petri dishes must be sealed with a plastic film such as "cling-film" (plastic food wrap), Nescofilm, or Parafilm to prevent the medium from drying out and the entry of contaminants.

A variety of plastic containers for the growth of plants *in vitro* can be obtained commercially. These are either disposable or made from autoclaveable plastic. They have the advantage of offering more height than Petri dishes. Glass "jam" or "powder" jars can be used in the same way. These vessels have tighter-fitting lids than Petri dishes, but it may still be necessary to seal them with a plastic film.

Cell suspension cultures are usually grown in glass conical flasks (Erlenmyer), which are stoppered with foam, paper, or cotton wool bungs and aluminum foil.

36.4 CELL CULTURE SYSTEMS

36.4.1 Callus Cultures and Cell Suspensions

Cell suspension cultures are usually initiated by producing a callus culture (an unorganized mass of cells) from a suitable explant (a piece of plant tissue such as leaf, root, or cotyledon) or from a specific cell type (such as endosperm). The size of the explant used to initiate the callus is not usually considered to be critical (although explants of a very small size may not be viable). Callus is usually produced by placing explants on a suitable medium gelled with agar which contains an auxin and/or a cytokinin. No hard-and-fast rule indicates which medium will prove successful, but general-purpose media such as Murashige and Skoog (19), Gamborg's B (5,12), or Schenk and Hildebrandt (20) are good starting points. Again, no hard-and-fast rules indicate the precise nature or concentration of the plant growth regulators that will be needed in order for the callus to form. A grid of various concentrations (0 to 10 μM) of an auxin (often 2,4-D) and a cytokinin (often BAP or kinetin) is usually set up in order to establish the levels of plant growth regulators needed (6). The plant growth regulator regime necessary to induce callus formation must be determined empirically because of the difference in biosynthetic capability of different plant cell types, and its composition will depend, at least partly, on the plant hormone composition and levels in the donor material. Therefore, the age of the explant material, its position on the plant, and the cell type that forms the callus, will all have an effect on the conditions needed for callus initiation. Sterile explants are gently pressed on to the surface of the medium to ensure

good contact and left (often in the dark). Callus, which is observed as a lump of unorganized cell growth usually at the cut surface (wounding the explant may be beneficial for callus formation), will then form on media of the correct composition, usually within 2 months.

Then, cell suspension cultures are usually initiated by transferring lumps of callus into a liquid medium of the same composition, which is then shaken to encourage the formation of a cell suspension culture. The callus transferred into the liquid medium should be friable (easily broken up into smaller cell clumps), and a relatively large inoculum should be used so that cell density builds up quickly. However, if the inoculum is too large, toxic products (presumably from the stress of transfer to liquid medium) can quickly build up to lethal levels. Callus established from some plants or from some particular cell types may not be friable, and will not easily form a good cell suspension, instead growing as large cell clumps. The friability of the callus may be improved by changes to the composition of the medium or by repeated subculturing (21). Alternatively, the formation of cell suspensions can sometimes be encouraged by culturing the callus on lower concentrations of agar before transferring to the liquid medium, or by placing a small amount of liquid on the surface of the solid medium. After the initial cell suspension culture has formed, any remaining large cell clumps can be removed by filtering the suspension, allowing large clumps to settle out, or by transferring the suspension with a small-bore pipette.

Cell suspensions are most easily grown as batch cultures, usually in conical flasks. The cell suspension culture occupies 20–33% of the total graduated volume of the conical flask. If the culture volume occupies a greater proportion of the culture vessel, then problems can be encountered with gaseous exchange across the surface of the media, leading to anoxia. Cell suspension cultures are continually propagated by transferring a small volume of the culture into fresh medium, a process called subculture. This subculturing results in the dilution of the cell suspension culture (the amount of culture added to fresh medium during subculture; therefore, the degree of dilution depends on the individual culture and must be determined empirically), after which the biomass of the culture increases in a characteristic fashion until the nutrients present are used up and/or toxic by-products accumulate to inhibitory levels (22). This is called the stationary phase, where no further increase in biomass or cell number is evident. Cells left in the stationary phase of the batch growth cycle for extended periods usually lose viability and die, leading to loss of the cell suspension or an extension of the subsequent lag phase upon subculturing. It is therefore important that the growth of the culture is monitored to determine the optimum batch culture cycle length. The degree of dilution of the culture at subculture also has to be determined (one part in five is a good starting point), as too great a dilution will result in an extension of the lag phase, the death of the culture, or the need for the use of culture medium with special supplements (23,24). Cells can be transferred by using a simple plugged pipette (the ends may be removed if large cell aggregates are present), or a "Howell" syringe equipped with a large-diameter cannula.

Although termed cell suspension cultures, plant cell suspension cultures very rarely consist of separated single cells. Usually small clumps of cells are formed. These clumps can cause problems in some experiments as the metabolism of individual cells in these clumps may vary (25–27). Cell suspensions can be filtered in an attempt to reduce the size of these cell clusters; however, it is often observed that this filtering has an inhibitory effect on the growth of the culture, often until cell clumps are formed again. Alternatively, low concentrations of macerozyme and cellulase can be added to the culture medium to reduce cell clumping (25). Cell suspension cultures need to be aerated; this is usually achieved by placing the cultures on a gyratory (orbital) shaker. Speeds are usually around 30–150 rpm, with displacements of 2–4 cm. Again the precise speed needs to be determined for each cell suspension culture, as it will depend on the size of the cell clusters and cell density. However, speeds much above the higher limit quoted are likely to cause excessive cell damage, and speeds below 30 rpm will almost certainly result in the cells settling out and not being properly aerated.

Like many plant cultures, cell suspension cultures are prone to contamination due to the rich nature of the medium and the relatively slow growth rate of plant cells. Sometimes this contamination will be obvious, the culture may take on a cloudy appearance, a "slime" may be visible on the sides of the culture vessel, or small balls of fungi may be found floating in the medium. Surprisingly, a strange smell noticed at subculture or during experimental sampling can also be a good indicator of contamination problems that are not yet evident. Experience will indicate the strange smell! It is, therefore, worth testing the cell suspension culture for latent contamination at regular intervals. This can be done by plating out small aliquots of the cell suspension culture on microbiological media designed for the growth of fungi and bacteria (such as nutrient agar, malt extract, potato dextrose, and corn meal agars). Incubation of the plates in suitable conditions will reveal the presence of any contamination. See Contamination Detection and Elimination.

One source of contamination that is altogether more difficult to detect and deal with, is mycoplasma infection. Mycoplasma infection will not usually be fatal to the cell suspension culture, but can have deleterious effects on growth and may distort experimental data. Some antimycoplasma agents are now available, as are some

detection kits. These are often designed to treat and detect mycoplasma contamination in mammalian cell cultures and should be used with due caution.

In batch culture systems, the culture environment never stabilizes (as they are closed systems). Thus efforts to couple cellular metabolism to cell growth over a long culture period cannot succeed (24,25,28). This is a major drawback of batch culture systems and means that any investigation should be conducted over as short a time period as possible.

Cell suspensions can also be grown as continuous cultures, either in a chemostat or a turbidostat, which to some extent overcomes the problems of batch cultures. Continuous cultures are used when investigations are conducted that require the cells to be kept in a constant, steady state of growth. The setup of continuous cultures is technically much more demanding than the growth of batch cultures, and therefore, the use of continuous cultures is limited.

The plant growth regulator requirements of cell suspension cultures should be periodically checked to see whether such additions are still required. This is because cell suspensions (and indeed callus cultures,) can develop the ability to grow in the absence of an external supply of plant growth regulators, a process referred to as habituation. This phenomenon is not noted with all cell cultures, but is prevalent in, for instance, cell cultures of *Beta vulgaris* (29,30). The mechanism by which habituation occurs has not been clearly established, although factors such as the plant growth regulators used to establish the culture and changes in cellular biochemistry have all been implicated (31,32).

Plant growth regulator autonomy, or habituation, may be of value in specific circumstances. Synthetic auxins such as 2,4-D can interfere with the assembly of the mitotic spindle and increase the duration of the cell cycle (33–35).

36.4.2 Assessing Cell Growth

It is vital that the growth of the cell suspension is monitored in order to establish a batch growth cycle. The growth of cell suspension cultures can be assessed in several ways.

1. Packed cell volume (PCV)
2. Cell number
3. Fresh (or wet weight)
4. Dry weight
5. Medium conductivity
6. Macromolecule content.

PCV. The determination of PCV is a quick and simple way of assessing the growth of cell suspension cultures, although it will not help to determine between cell division and cell expansion (without further examination of cell size). A known volume of cell suspension culture is centrifuged at low speed (approximately 500*g*) in a graduated centrifuge tube. The results are expressed as the percentage of the total volume occupied by the cell pellet.

Cell number. As its name suggests, this is a fairly simple (though time-consuming) technique where the number of cells per unit volume are counted using a microscope and a suitable graticule-etched slide. In cell suspensions that grow as very finely divided small cell clumps or as single cells, a hemocytometer can be used. A Sedgewick–Rafter counting slide or a "home-made" counting cell with a receptacle of known volume can also be used. However, as cell suspensions usually grow as cell clumps, which makes counting individual cells impossible, the accuracy of this technique can be improved by treating the cell suspension culture to remove or reduce these cell clumps. This can be done in two ways, by either treating the cell suspension culture with enzymes (such as pectinase at 0.25%) or more commonly, by treatment with chromium trioxide at 70°C. The exact treatment needed will have to be determined empirically, as it will depend on the degree of cell clumping (two volumes of 10% (w/v) chromium trioxide for 15 min is a good starting point, but if the cell clumps are large, a longer incubation time may be required). After the mixture has cooled, vortex mixing can be used to aid the breakup of the clumps into single cells. Care must be taken that the cells are not overtreated, as single cells or small cell clumps may be destroyed by harsh treatments.

Fresh weight. It can be determined fairly simply by filtering under reduced pressure, a known volume of cell suspension culture onto a glass or nylon fiber filter paper (weighed in the wet condition), which can then be reweighed and the weight of the cells calculated by difference.

Dry weight. It can be determined after wet weight, by drying the filter papers and cells to a constant mass in an oven (at 60–80°C).

Medium conductivity. Combinations of these techniques allow average cell volume and cell mass to be calculated and to determine increases in biomass. Cell division and cell expansion can also be distinguished.

Macromolecule content. Other techniques are also used, although less often. In some cell suspensions the conductivity of the medium has been found to be related to the fresh weight of the cells in suspension culture. The protein and DNA content of a known aliquot of cell suspension culture can also be used to assess growth, although this is a relatively time-consuming approach.

36.4.3 Assessing Cell Viability

These techniques (with the exception of identifying obviously dead cells while counting) do not, however, directly indicate whether cells are alive or dead. Not all the cells in a culture will be viable, and some measure of viability

gives useful insights into the health of the cell suspension culture. A simple method to determine cell viability is to use a dilute solution (0.025% w/v) of Evan's blue. Healthy cells will exclude this dye, whereas damaged or dead cells will stain blue. These can be scored under a microscope and the results expressed as a percentage of total cell number. Fluorescein diacetate can also be used to assess viability. This method relies on functioning esterases being present in healthy cells; these produce fluorescein which can be observed with the aid of a UV microscope. A simple method is given (6):

1. Add fluorescein diacetate to a concentration of approximately 0.01% (make a 0.5% stock solution in acetone and store at 4°C).
2. Leave for 5 min.
3. Examine the cells under a UV microscope; living cells fluoresce green; score as a percentage of total cell number.

Other methods rely on the reduction of tetrazolium salts such as 2,3,5-triphenyltetrazolium chloride (TTC); respiratory efficiency is monitored by spectrophotometric measurement of the red dye formazan. The TTC method is more labor-intensive, and it should be optimized with respect to pH, time, and % TTC (6).

36.4.4 Synchronization of Cell Suspension Cultures

One area where plant cell suspension cultures find widespread use, is in studies of gene expression during the cell division cycle. Cell suspensions are particularly suited to this type of investigation, as a homogeneous population of cycling cells can be produced.

Early attempts at synchronizing the cell division cycle of suspension cultured plant cells relied either on the withdrawal and subsequent re-supply of a nutrient (36–38) or a plant growth regulator (39,40). These treatments caused the cells to arrest at a particular point in the cell division cycle and, following addition of the substance back to the medium, resume cell division in a synchronous fashion. However, these techniques may not be universally applicable or result in arrest at more than one point in the cell cycle (35,41). More recent work has focused on the use of chemicals that prevent either DNA replication, such as aphidicolin and hydroxyurea (42,43), or mitosis, such as colchicine, oryzalin, or other antimicrotubule drugs (44).

36.5 SUMMARY

Plant cell cultures provide excellent experimental model systems. Unfortunately, due to the wide variation in the requirements of individual plant cell cultures, there is no real substitute for experience in plant cell culture. However, with knowledge from this chapter it should be possible to initiate, maintain, and monitor the growth of cell cultures from most plant species. These provide the basic steps necessary for any investigations involving the use of cell cultures.

SCALE-UP OF BIOTECHNOLOGICAL PROCESSES

MARKO ZLOKARNIK
Chemical Process Engineering, University of Köln, Cologne, Germany

37.1 INTRODUCTION

A chemical engineer is generally concerned with industrial implementation of processes in which chemical or microbiological conversion of material takes place in conjunction with transfer of mass, heat, and momentum. These processes are scale-dependent; that is, they behave differently on a small scale (in laboratories or pilot plants) and a large scale (in production). They include heterogeneous chemical reactions and most unit operations. Understandably, chemical engineers have always wanted to find ways of simulating these processes in models to gain insights that will assist them in designing new industrial plants. Occasionally, they face the same problem for another reason. An industrial facility already exists but will not function properly, if at all, and suitable measurements have to be carried out to discover the cause of difficulties and provide a solution.

Irrespective of whether the model involved represents a "scale-up" or a "scale-down", certain important questions always apply:

1. How small can a model be? Is one model sufficient or should tests be carried out in models of different sizes?
2. When must or when can physical properties differ? When must measurements be carried out on a model with an original system of materials?
3. Which rules govern the adaptation of process parameters in model measurements to those of a full-scale plant?
4. Is it possible to achieve complete similarity between the processes in the model and those in its full-scale counterpart? If not: how should one proceed?

These questions touch on the fundamentals of the theory of models, which are based on dimensional analysis. Although they have been used in the field of fluid dynamics and heat transfer for more than a century—cars, aircraft, vessels, and heat exchangers were scaled up according to these principles—these methods have gained only a modest acceptance in chemical engineering. University graduates are usually not skilled enough to deal with such problems at all. On the other hand, there is no motivation for this type of research at universities since, as a rule, they are not confronted with scale-up tasks and are not equipped with the necessary devices on the bench-scale. This gives a totally wrong impression that these methods are, at most, of marginal importance in practical chemical engineering, otherwise they would have been taught and dealt with in greater depth.

37.2 DIMENSIONAL ANALYSIS

37.2.1 Fundamental Principle

Dimensional analysis is based on the recognition that the mathematical formulation of a physicotechnological problem can be of general validity only when the process equation is dimensionally homogenous.

37.2.2 What is a Dimension?

A dimension is a purely qualitative description of a perception of a physical entity or a natural appearance. Length can be experienced as height, depth or breadth. Mass presents itself as a light or a heavy body, time as a short moment or a long period. The dimension of length is Length *L*, the dimension of mass is Mass *M*, and so on.

37.2.3 What is a Physical Quantity?

Unlike a dimension, a physical quantity represents a quantitative description of a physical quality (e.g. mass of 5 kg). It consists of a measuring unit and a numerical value. The measuring unit of length can be a meter, a foot, a cubit, a yardstick, a nautical mile, a light year, etc. The measuring unit of temperature can be °C (Centigrade), R (Rankine), F (Fahrenheit) or K (Kelvin). (It is therefore necessary to establish measuring units in an appropriate measuring system.)

From these definitions, we conclude that a measuring unit is the counterpart of a dimension.

37.2.4 Basic and Derived Quantities, Dimensional Constants

We distinguish between basic and secondary quantities, the latter often being referred to as *derived quantities*. The basic quantities are defined. They are based on standards and are quantified by comparison with them. The secondary units are derived from the primary ones according to physical laws (e.g. velocity = length/time). The borderline separating both types of quantities is largely arbitrary: 50 years ago a measuring system was used in which force was a primary dimension instead of mass!

All secondary units must be coherent with the basic units (Table 37.1). For example, the measuring unit of velocity must not be miles per hour or kilometres per hour, but meters per second!

A secondary unit that has been established by a physical law may sometimes contradict another one. For example, according to the Newton's second law of motion, the force F is expressed as a product of mass m and acceleration a: $F = ma$, having the measuring unit of kilogram meter per second square or N. According to Newton's law of gravitation, the force is defined by $F \propto m_1 m_2 / r^2$, which leads to a completely different measuring unit (kg^2/m^2). To remedy this, the gravitational constant G—a dimensional constant—had to be introduced to ensure the dimensional homogeneity of this equation: $F = G m_1 m_2 / r^2$.

Another example entails the universal gas constant R, the introduction of which ensures that in the perfect gas equation of state $p\,V = n\,R\,T$ the secondary unit for work $W = pV[\mathrm{M\,L^2/T^2}]$ is not offended.

Another class of derived quantities is represented by coefficients in diverse physical equations (e.g. transfer equations). They are established by respective equations and determined by measuring their constituents (e.g. mass and heat transfer coefficients).

TABLE 37.1. Base Quantities, their Dimensions and Units According to SI

Base Quantity	Base Dimension	Base Unit
Mass	M	kg
Length	L	m
Time	T	s
Thermodynamic, temperature	Θ	K
Amount of substance	N	mol
Electric current	I	A
Luminous intensity	J	cd

37.2.5 Dimensional Systems

A dimensional system consists of all primary and secondary dimensions and corresponding measuring units. The currently used International System of Dimensions (*Système International d'Unités*; SI) is based on seven base dimensions. They are presented in Table 37.1, together with their corresponding base units. For some of them, a few explanatory remarks may be necessary.

Temperature expresses the thermal level of a system and not its energetic contents. (A five-fold mass of matter has a five-fold thermal energy at the same temperature!). Thermal energy of a system can indeed be converted into mechanical energy (base unit Joule).

Moles are a certain amount of matter and must not be confused with the quantity of mass. Molecules react as individual entities regardless of their mass: 1 mole of hydrogen (2 g/mol) reacts with 1 mole of chlorine (71 g/mol) to produce 2 moles (73 g) of hydrochloric acid, HCl.

Table 37.2 shows the most important secondary dimensions. Table 37.3 refers to some very frequently used secondary units that are named after famous researchers.

TABLE 37.2. Important Secondary Measuring Units in Mechanical Engineering, Named after Famous Researchers

Secondary Quantity	Dimensions	Measuring Unit	Name
Force	$\mathrm{M\,L\,T^{-2}}$	$\mathrm{kg\ m\ s^{-2} \equiv N}$	Newton
Pressure	$\mathrm{M\,L^{-1}T^{-2}}$	$\mathrm{kg\ m^{-1}\ s^{-2} \equiv Pa}$	Pascal
Energy	$\mathrm{M\,L^{-2}T^{-2}}$	$\mathrm{kg\ m^{-2}\ s^{-2} \equiv J}$	Joule
Power	$\mathrm{M\,L^{2}T^{-3}}$	$\mathrm{kg\ m^{2}\ s^{-3} \equiv W}$	Watt

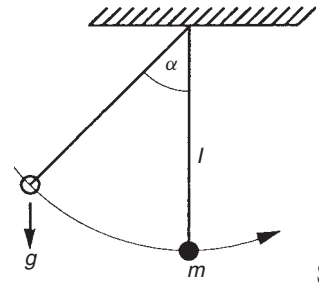
Thermal conductivity	$M\,L\,T^{-3}\Theta^{-1}$	$L^{-1}T^{-1}\Theta^{-1}H$
Heat transfer coefficient	$M\,T^{-3}\Theta^{-1}$	$L^{-2}T^{-1}\Theta^{-1}H$
Stefan–Boltzmann constant	$M\,T^{-3}\Theta^{-4}$	$L^{-2}T^{-1}\Theta^{-4}$

37.2.6 Dimensional Homogeneity of a Physical Content

The aim of dimensional analysis is to check whether physical content of the case under consideration can be formulated in a dimensionally homogeneous manner or not. The procedure necessary to accomplish this consists of two parts:

1. All physical parameters necessary to describe the problem are listed. This "relevance list" of the problem consists of the quantity in question and of all the parameters which influence it. In each case, only *one* target quantity must be considered. It is the only dependent variable. On the other hand, all the influencing parameters must be primarily independent of one another.
2. Dimensional homogeneity of physical content is examined by transferring it into a dimensionless form. (Note: A physical content which can be transformed into dimensionless expressions is dimensionally homogeneous.)



The information given thus far will be made clear by a well-known example (1):

37.2.7 Example 1

37.2.7.1 What Determines the Period of Oscillation of a Pendulum? First, a pendulum will be sketched and all the quantities that could be involved written down. It may be assumed that the period of oscillation of a pendulum depends on the length and mass of the pendulum, gravitational acceleration, and the amplitude of swing.

(In the case of a real pendulum, density and the viscosity of air, which both cause friction resistance, should also be included in the relevance list. However, this would unnecessarily complicate the problem at this stage. Therefore, we will consider a physical pendulum with a point mass in vacuum.)

Physical Quantity	Symbol	Dimension
Period of oscillation	θ	T
Length of pendulum	l	L
Mass of pendulum	m	M
Gravitational acceleration	g	LT^{-2}
Amplitude (angle)	α	—

Sketch of the pendulum

Our aim is to express θ as a function of l, m, g, and α:

$$\theta = f(l, m, g, \alpha).$$

Can this dependence be dimensionally homogeneous? No! The first thing that now becomes clear is that the base unit of the mass M occurs only in the mass m itself. Changing this base unit (e.g. from kilograms to pounds) would change the numerical value of the function. This is unacceptable. Either our list should include a further variable containing M, or mass is not a relevant variable. If we assume the latter, the above relationship is reduced to:

$$\theta = f(l, g, \alpha).$$

Both l and g incorporate the base unit of length. When combined as a ratio (l/g) they become dimensionless with regard to L and thus independent of changes in the basic unit of length:

$$\theta = f(l/g, \alpha)$$

Because the angle α has no dimension, we are left with the dimension T on the left-hand side of the equation and T^2 on the right. To remedy this, we will have to write

$$\sqrt{l/g}$$

This expression will keep its dimension T only if it remains unchanged, so we have to take it out of the function f and we finally obtain:

$$\theta = \sqrt{l/g} \quad f(a) \quad \text{or} \quad \theta\sqrt{g/l} = f(\alpha)$$

The dependence between four dimensional quantities, containing two basic dimensions (L and T) is reduced to a $4 - 2 = 2$ parametric relationship between dimensionless expressions ("numbers")!

This equation is the only statement that dimensional analysis can offer in this case. It is not capable of producing information as to the form of f. The integration of Newton's equation of motion for small amplitudes leads to $f = 2\pi$ and is independent of α. The relationship can now be expressed as:

$$\theta\sqrt{g/l} = 2\pi$$

The elegant solution of this first example should not tempt the reader to believe that dimensional analysis can be used to solve any problem at his desk. To treat this example by dimensional analysis, the law of free fall had to be known. This knowledge was gained empirically by Galilei in 1604 through his *experiments* with the inclined plane. Bridgman's (1) comment on this situation is particularly appropriate:

> "The problem cannot be solved by the philosopher in his armchair, but the knowledge involved was gathered only by someone at some time soiling his hands with direct contact."

This transparent and easy example clearly shows how dimensional analysis deals with specific problems and what conclusions it allows. It should now be easier to understand the sarcastic comment with which Lord Rayleigh began his short essay on "The Principle of Similitude" (2):

> "I have often been impressed by the scanty attention paid even by original workers in physics to the great principle of similitude. It happens not infrequently that results in the form of "laws" are put forward as novelties on the basis of elaborate experiments, which might have been predicted *a priori* after a few minutes' consideration."

From Example 1, we also learn that a transformation of a physical dependence from a dimensional into a dimensionless form is automatically accompanied by an essential *compression* of the statement: the set of dimensionless numbers is smaller than the set of quantities contained in them, but it describes the problem equally comprehensively. In the above example, the dependence between four dimensional parameters is reduced to a dependence between only two dimensionless numbers! This is the proof of the so-called pi theorem (pi after Π, the sign used for products), which is given below.

37.3 THE PI THEOREM

Every physical relationship between $\boldsymbol{n}$ *physical quantities can be reduced to a relationship between* $\boldsymbol{m} = \boldsymbol{n} - \boldsymbol{r}$ *mutually independent dimensionless groups, whereby* $\boldsymbol{r}$ *stands for the rank of dimensional matrix, made up of the physical quantities in question and generally equal to the number of the base quantities contained in them*.

(The pi theorem is often associated with Buckingham, who introduced this term in 1914, but the proof of it was already accomplished in 1911 in the course of a mathematical analysis of partial differential equations by Federmann (3).

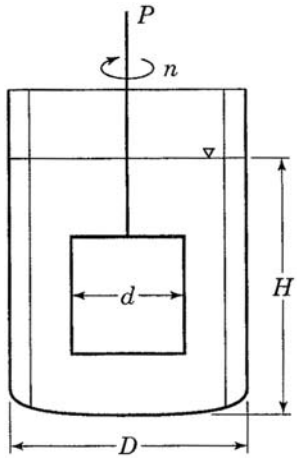
37.4 DETERMINATION OF A PI SET BY MATRIX CALCULATION

37.4.1 Establishment of a Relevance List for a Problem

As a rule, more than two dimensionless numbers will be necessary to describe a physicotechnological problem and therefore, they cannot be derived by the method described above. In this case, the easy and transparent matrix calculation introduced by Pawlowski (4) is increasingly used. It will be demonstrated by the following example, which treats an important problem in industrial chemistry and biotechnology because the mixing vessel is an important production equipment.

37.4.2 Example 2

37.4.2.1 Which is the Pi Set for the Mixing Power of a Stirrer? In this case, too, first a sketch of the device is drawn. Then we facilitate our work by proceeding systematically.



Target quantity: mixing power P

Parameters:

(a) geometrical: stirrer diameter d

(b) physical properties: fluid density ρ and kinematic viscosity ν

(c) process-related: stirrer speed n

Sketch of the mixing vessel.

We obtain the following relevance list:

$$\{P; d; \rho, \nu; n\} \tag{37.1}$$

We interrupt the procedure by asking an important question concerning the determination of the characteristic geometric parameter.

37.4.3 Determination of the Characteristic Geometric Parameter

Obviously, we could name all the geometric parameters indicated in the sketch. They were all the geometric parameters of the stirrer and the vessel, especially its diameter D and the liquid height H. In case of complex geometry, such a procedure would deflect from the problem. It is therefore advisable to introduce only one (or a few) characteristic geometric parameters, knowing that all the others can be transformed into dimensionless geometric numbers by division with this one or a few of them.

In the case of Example 2, we introduced the stirrer diameter as the characteristic geometric parameter. This is reasonable. One can only think of how the mixing power would react to an increase in the vessel diameter D. It is obvious that above a certain size, D would have no influence, but a small change in the stirrer diameter d would always have an impact.

We now set forth a procedure for solving Example 2.

37.4.4 Constructing and Solving the Dimensional Matrix

In transforming the relevance list (Eq. 37.1) of the five physical quantities into a dimensional matrix, we can minimize calculations required by keeping to the following points:

1. The dimensional matrix consists of a square core matrix and a residual matrix.
2. The rows of the matrix are formed of basic dimensions, contained in dimensions of the quantities, and they will determine the rank r of the matrix. The columns of the matrix are presented by the physical quantities or parameters.
3. Quantities of the square core matrix may appear later on in all dimensionless numbers as "fillers", whereas each element of the residual matrix will appear only in one dimensionless number. For this reason, the residual matrix should be loaded with essential variables like the target quantity and the most important physical properties and process-related parameters.
4. By the (extremely easy) matrix calculation (linear transformations), the core matrix is transformed into a matrix of unity. The main diagonal consists only of ones and the remaining elements are all zero. One should therefore arrange the quantities in the core matrix in such a way as to facilitate this procedure.
5. After the matrix of unity has been generated, dimensionless numbers are created as follows. Each element of the residual matrix forms the numerator of a fraction, while the denominator consists of the fillers from the matrix of unity with exponents indicated in the residual matrix.

Let us return to Example 2. The dimensional matrix reads as follows:

	ρ	d	n	P	ν
Mass M	1	0	0	1	0
Length L	−3	1	0	2	2
Time T	0	0	−1	−3	−1
	Core matrix			Residual matrix	

Only one linear transformation is necessary to transform −3 in the cell formed by the L-row and the ρ-column into zero. The subsequent multiplication of the T-row by −1 transfers −1 to 1:

	ρ	d	n	P	ν
M	**1**	0	0	1	0
$3M + L$	0	**1**	0	5	2
$-T$	0	0	**1**	3	1
	Unity matrix			Residual matrix	

The residual matrix contains only two parameters, therefore only two Π numbers result:

$$\Pi_1 \equiv \frac{P}{\rho^1 n^3 d^5} = \frac{P}{\rho n^3 d^5} \equiv \text{Ne (Newton number)}$$

$$\Pi_2 \equiv \frac{\nu}{\rho^0 n^1 d^2} = \frac{\nu}{n d^2} \equiv \text{Re}^{-1} \text{ (Reynolds number)}$$

The interdependence of five dimensional quantities of the relevance list (Eq. 37.1), is reduced to a set of only $5 - 3 = 2$ dimensionless numbers:

$$\{\text{Ne, Re}\} \text{ or } f(\text{Ne, Re}) = 0 \qquad (37.2)$$

thus again confirming the pi theorem.

37.4.5 Determination of the Process Characteristics

The functional dependence (Eq. 37.2), is the maximum that dimensional analysis can offer here. It cannot provide any information about the form of the function f. *This can be accomplished solely by experiments*. But these experiments can now be conducted in a far easier manner, because it is the Reynolds number which has to be varied. This can be accomplished by altering the characteristic stirrer speed n, or the characteristic length d, or the kinematic viscosity ν. By choosing appropriate model fluids, the viscosity can be very easily altered by several orders of magnitude. In this way, measurements were conducted to determine the *power characteristic* Ne (Re) of a blade stirrer of fixed geometry in a vessel. From Fig. 37.1 it follows that

1. In the range $\text{Re} < 20$ the proportionality $\text{Ne} \propto \text{Re}^{-1}$ is found, which results in the expression $\text{Ne}\,\text{Re} \equiv P/(\eta\ n^2 d^3) = a$ constant. Density is irrelevant here since we are dealing with the *creeping* flow region.
2. In the range $\text{Re} > 50$ (vessel with baffles) or $\text{Re} > 5 \times 10^4$ (unbaffled vessel) a constant Newton number $\text{Ne} \equiv P/(\rho n^3 d^5)$ is found. In this case, viscosity is irrelevant because we are dealing with a *turbulent* flow region.
3. Understandably, the baffles do not influence the power characteristics in the creeping flow region. However, their influence is extremely strong at $\text{Re} > 5 \times 10^4$. Here, the installation of baffles under otherwise unchanged operating conditions increases the power consumption of the stirrer by a factor of 20.
4. When liquid is stirred in an unbaffled vessel, it begins to rotate and a vortex is formed. Gravitational acceleration g, and hence the Froude number $\text{Fr} \equiv n^2\ d/g$, plays no role under these circumstances as determined experimentally (Fig. 37.1). For confirmation, one needs only to look at the points on the lower Ne (Re) curve, where the *same* Re value was set for fluids with *different* viscosities. This was possible only with a proportional alteration of the stirrer speed. Where Re = idem (= identical value), Fr was clearly not idem, but this has no influence on Ne. g is therefore irrelevant!

37.5 FUNDAMENTALS OF THE THEORY OF MODELS AND OF SCALE-UP

37.5.1 Theory of Models

The results in Fig. 37.1 could also have been acquired by changing the stirrer diameter. It does not matter, how a relevant number is changed. This is a clear evidence that the representation of a physicotechnological problem in a dimensionless form is independent of scale, it is *scale-invariant*. This aspect is of special importance with respect to changes in linear dimension because it is the foundation of a reliable scale-up:

Two processes may be considered completely similar if they take place in similar geometrical space and if all the dimensionless numbers necessary to describe them have the same numerical value (Π_i = identical or idem).

Clearly, the scale-up of a desired process condition from a model to industrial scale can be accomplished reliably only if the problem was formulated and dealt with according to dimensional analysis.

37.5.2 Model Experiments and Scale-Up in the Process Point

In Example 2, we evaluated process characteristics that presented a comprehensive description of the process. This is often an expensive and time consuming method, which is superfluous, if one has only to scale-up a given process condition from a model to an industrial plant (or vice versa). With Example 2, and assuming that the Ne (Re) characteristics like those in Fig. 37.1 are unknown, the task is to predict the power consumption of a leaf stirrer of $d = 2$ m, installed in a baffled vessel of $D = 4$ m ($D/d = 2$) and rotating with $n = 10\ \text{min}^{-1}$. The kinematic viscosity of the liquid is $\nu = 1 \times 10^{-4}\ \text{m}^2/\text{s}$.

One only needs to know—and this is *essential*—that the hydrodynamics in this case are governed solely by the Reynolds number and that the process is described by an unknown dependence Ne (Re). Then the Re number of the industrial plant can be calculated:

$$\text{Re} \equiv n\ d^2/\nu = 6.7 \times 10^3$$

Let us assume that we have a geometrically similar laboratory device of $D = 0.2$ m and $d = 0.1$ m and that the stirrer speed can be arbitrarily chosen. What stirrer

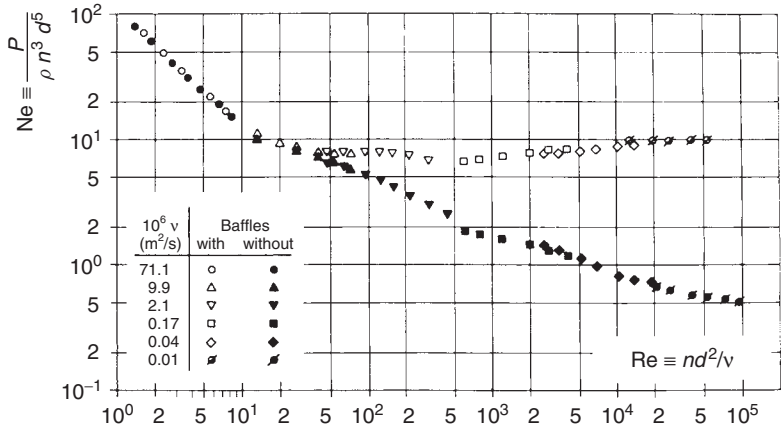


Figure 37.1. Power characteristics of a leaf stirrer of a given geometry and given installation conditions. [From Ref. 5.]

speed should be used to obtain Re = idem using water ($\nu = 1 \times 10^{-6}$ m^2/s) as a model liquid? The answer is

$$n\ d^2/\nu = 6.7 \times 10^3 \rightarrow \text{n} = 40\ \text{min}^{-1}$$

Under these conditions, the stirrer power must be measured and the power number $\text{Ne} \equiv P/(\rho n^3 d^5)$ calculated. We find Ne = 8.0. Due to the fact that Re = idem results in Ne = idem, the power consumption P_T *of the industrial stirrer can be obtained:*

$$Ne = idem \rightarrow Ne_\text{T} = Ne_\text{M} \rightarrow \left(\frac{P}{\rho n^3 d^5}\right)_\text{T} = \left(\frac{P}{\rho n^3 d^5}\right)_\text{M}$$

From Ne = 8.0 found in a laboratory measurement, it follows for the leaf stirrer having $d = 2$ m and a stirrer speed of $n = 10\ \text{min}^{-1}$

$$P = \text{Ne}\ \rho n^3 d^5 = 8.0 \times 1 \times 10^3 \times (10/60)^3 \times 2^5 = 1,185\ \text{W} \simeq 1.2\ \text{kW}$$

We realize that in scale-up, knowledge of functional dependence $f(\Pi_\text{i}) = 0$ (Fig. 37.1) is unnecessary. All we need to know is which pi space describes the process.

37.6 FURTHER PROCEDURES TO ESTABLISH A RELEVANCE LIST

37.6.1 Consideration of Acceleration due to Gravity g

If a natural or universal physical constant has an impact on the process, it has to be incorporated into the relevant list, regardless of whether it will be altered. In this context a major mistake is made with regard to gravitational constant g. Lord Rayleigh (2) complained bitterly, saying:

> "I refer to the manner in which gravity is treated. When the question under consideration depends essentially upon gravity, the symbol of gravity (g) makes no appearance, but when gravity does not enter the question at all, g obtrudes itself conspicuously."

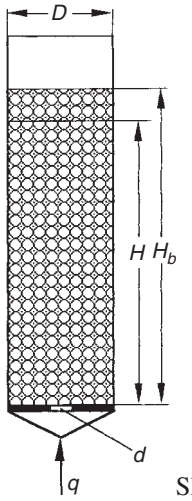
This is all the more surprising in view of the fact that the relevance of this quantity is easy enough to recognize if one asks the following question:

> "Would the process function differently if it took place on the moon instead of Earth?"

If the answer to this question is affirmative, g is a relevant variable.

Gravitational acceleration g can be effective solely in connection with the density as gravity $g\rho$. When inertial forces play a role, the density ρ has to be listed additionally. Thus, it follows that

1. in cases involving the ballistic movement of bodies, the formation of vortices in stirring, the bow wave of a ship, the movement of a pendulum and other processes affected by the Earth's gravity, the relevance list comprises $g\rho$ *and* ρ;
2. creeping flow in a gravitational field is governed by the gravity $g\rho$ alone;
3. in heterogeneous physical systems with density differences (sedimentation or buoyancy), the difference in gravity $g\Delta\rho$ *and* ρ play a decisive role.



In the next example, we shall treat a problem where gravitational constant is of prime importance, due to extreme differences in the density in the gas–liquid system. Dealing with this example, we will have the opportunity to improve our skills in solving dimensional matrices and to

gain deeper insights into possibilities offered by dimensional analysis.

37.6.2 Example 3

37.6.2.1 Gas HoldUp in Bubble Columns. Bubble columns are important appliances for the absorption of gases in liquids and, consequently, for the execution of chemical and biotechnological reactions in a gas–liquid system. In this context, the attainable interface ($\hat{=}$ sum of the surfaces of all gas bubbles) is of considerable interest because it affects mass transfer in a directly proportional manner. If a gas throughput q is introduced into a bubble column with diameter D and liquid height H, the liquid height rises by the amount occupied by the gas bubbles in the liquid. The gas fraction in the liquid, the so-called gas holdup H^* can be determined from the liquid height H_b of the gassed and the non-gassed liquid H (see sketch).

$$H^* \equiv \frac{V_G}{V_L} = \frac{H_b - H}{H} \tag{37.3}$$

Sketch of the bubble column.

In the course of extensive measurements (6) on bubble columns of different dimensions, the gas holdup H^* proved to be directly proportional to the volume-related mass transfer coefficient $k_L a$. For this reason, H^* will be the *target number* in the following considerations. Bubble columns with a single-hole plate as gas distributor (see sketch) were used in these investigations. D, H, and d (= hole diameter) therefore describe their *geometry* in full.

The densities (ρ and ρ') and the viscosities (ν and ν') of both phases (gas) and the surface tension, σ, must be taken into account as *physical properties*.

The *process parameters* are the gas throughput q and, on account of extreme differences in density, the gravity difference $g\Delta\rho = g(\rho - \rho')$.

The complete relevance list is therefore

$$\{H^*; D, H, d; \rho, \rho', \nu, \nu', \sigma; q, g\Delta\rho\}. \tag{37.4}$$

If we exclude the (dimensionless) target number H^* and the trivial numbers H/D, d/D, ρ'/ρ and ν'/ν, the remaining relevance list is

$$\{D; \rho, \nu, \sigma; q, g\Delta\rho\}$$

from which, via the dimensional matrix, the following three dimensionless numbers result:

$$\Pi_1 \equiv \frac{\sigma D}{\rho\nu^2} \equiv \frac{\mathrm{Re}^2}{\mathrm{We}} \quad \Pi_2 \equiv \frac{q}{D\nu} \equiv \mathrm{Re}$$

$$\Pi_3 \equiv \frac{g\Delta\rho D^3}{\rho\nu^2} \equiv \mathrm{Ar} \equiv \frac{\mathrm{Re}^2}{\mathrm{Fr}}$$

	ρ	D	ν	σ	q	$g\Delta\rho$
M	1	0	0	1	0	1
L	−3	1	2	0	3	−2
T	0	0	−1	−2	−1	−2
M	**1**	0	0	1	0	1
$3M \equiv L \equiv 2T$	0	**1**	0	−1	1	−3
$-T$	0	0	**1**	2	1	2

This dimensional analysis produces two dimensionless numbers, Π_1 and Π_3, which, apart from the column diameter, contain only physical properties, and the Reynolds number Π_2 as the process number (because it contains q).

However, this is unsatisfactory because we must expect the hydrodynamics of a bubble column to be substantially governed by $g\Delta\rho$. Consequently, the process number must contain $g\Delta\rho$. We must therefore combine Π_2 and Π_3 in order to obtain the modified Froude number Fr*, which is probably the *true process number*:

$$\Pi_2^2\ \Pi_3^{-1} \equiv \frac{q^2\rho}{D^5 g\Delta\rho} \equiv \mathrm{Fr}^*$$

The complete pi set now becomes:

$$\{H^*; H/D, d/D; \rho'/\rho, \nu'/\nu, \mathrm{Fr}^*, \mathrm{Re}, \mathrm{We}\}$$

Comprehensive measurements (6) were performed to verify this pi space and to evaluate the following process characteristics:

1. The relationship $H^* = f(\mathrm{Fr}^*)$ was examined using a bubble column of given geometry. Water was used

as the liquid and the physical properties of the gas were varied over a wide range. Air, nitrogen, and nitrogen–hydrogen mixtures were used. The result in Fig. 37.2 demonstrates that Fr* takes full account of the influence of both densities and that ν'/ν is obviously irrelevant. The process equation is

$$H^* = 15.0\mathrm{Fr}^{*0.35} \tag{37.5}$$

2. Further measurements were carried out with one single material system (water/air) in bubble columns of different geometries (Fig. 37.3). The extended process relationship now reads

$$H^* = 16.7\mathrm{Fr}^{*0.35}(H/D)^{-0.25}(d/D)^{-0.125}$$

As far as the scale-up of a bubble column from a laboratory to an industrial scale is concerned, one will have to keep in mind that the scale-up rule is not $v =$ idem, as is often stated in the chemical engineering literature, but $\mathrm{Fr} \equiv v^2/(D\ g) =$ idem. This means

$$v_\mathrm{T} = v_\mathrm{M}\sqrt{D_T/D_M} = v_\mathrm{M}\ \mu^{0.5} \tag{37.6}$$

μ being the scale factor $\mu \equiv D_\mathrm{T}/D_\mathrm{M}$.

3. The influence of physical properties of the liquid phase was also investigated in one single model bubble column using water and, in addition, 12 different pure organic liquids, the physical characteristics of which varied substantially [given in Table 37.2 in (6)]. The result of these measurements is presented in Fig. 37.4. The dimensionless numbers had to be combined as follows in order to correlate the measured values:

$$B \equiv \frac{\rho/\rho'\ \mathrm{Fr}^*}{\mathrm{Re}\ \mathrm{We}^{0.5}} \equiv \frac{\nu(\sigma\rho)^{0.5}}{D^{2.5}g\Delta\rho}$$

The disadvantage of the number combination B is that it is not a pure material number, but it still contains the column diameter, D. For safe scale-up, the validity of this correlation will therefore have to be examined on columns of different diameters and with simultaneous alteration of the material system.

The presented example, in which the column diameter D was varied by a scale factor of $\mu = 1{:}2$ and the extended Froude number was enlarged—by employing air and mixtures of N_2/H_2 —by a factor of 4, shows that the extended Froude number clearly represents the pertinent scale-up criterion for bubble columns. This means that using the same material system in a four-fold bubble diameter ($\mu = 4$) entails a double superficial velocity v.

37.6.3 Introduction of Intermediate Quantities

Many engineering problems involve several parameters, a condition that impedes the elaboration of the pi space. Fortunately, in some cases a closer look at a problem (or previous experience) facilitates reduction of the number of physical quantities in the relevance list. This is the case when some relevant variables affect the process by way of a so-called intermediate quantity. Assuming that this intermediate variable can be measured experimentally, it should be included in the problem relevance list if this facilitated the removal of more than one variable from the list.

Example 3 shows that the so-called superficial velocity $v = q/S$ (q the gas throughput, $S = \pi D^2/4$ –superfice of the device) is by no means an intermediate quantity; it replaces the fluid throughput q but not the diameter D of the device. The fluid motion in pipes, mixing vessels, and bubble columns is described with kinematic dimensionless numbers such as Re and Fr, which all contain a characteristic linear dimension; the fluid motion is an extremely scale-dependent process.

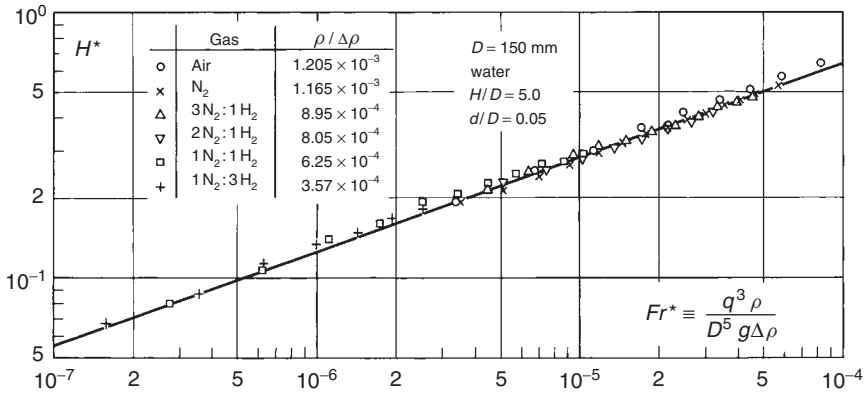


Figure 37.2. The relationship $H^*(\mathrm{Fr}^*)$ confirms the expectation that the gas holdup H^* in a bubble column is dependent on the process number Fr*. [From Ref. 6.]

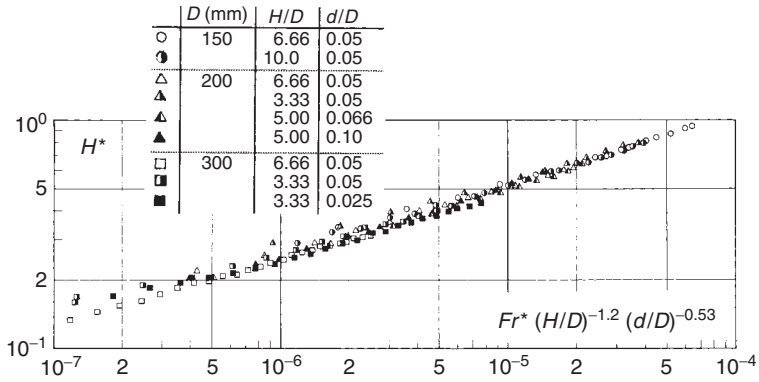

Figure 37.3. Dependence of the gas holdup H^* on the geometry of the column. [From Ref. 6.]

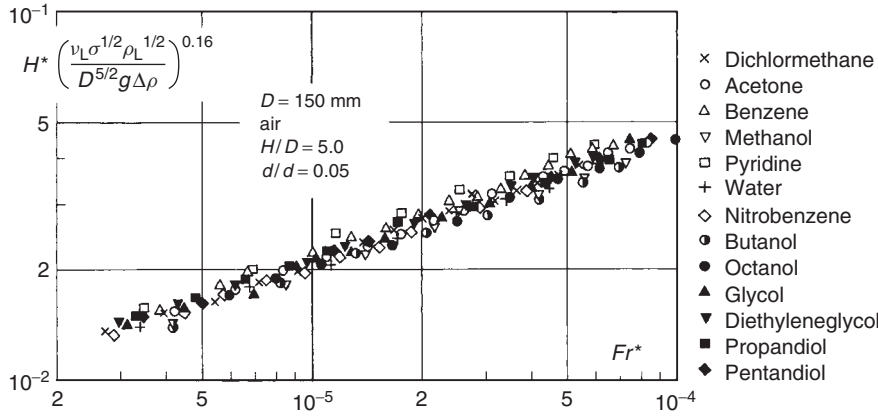

Figure 37.4. Influence of the physical properties of the liquid phase on the gas holdup H^* in a bubble column of a given geometry. [From Ref. 6.]

There are a lot of important processes where a set of material and physical parameters can be replaced by an intermediary quantity:

1. A settling process (sedimentation) depends on the parameters of the dispersed phase. They can be substituted by the sedimentation velocity v_s:

$$v_s = f(d_p, g\Delta\rho, \varphi_p, \mu)$$

(d_p is mean particle diameter, $g\Delta\rho$ the weight difference, φ_p the volume portion of the solid phase, μ is the dynamic viscosity of the liquid.)

2. In a flotation process, it is possible to replace a great many influencing parameters with only one or two intermediate quantities. Then it is legitimate to speak of intermediate quantities as "lumped parameters" (Example 4).
3. A tablet-making process depends on the physical parameters such as mean particle diameter d_p, bulk density (porosity), and flow behavior (lubricating ability) of the powder which also depends on humidity. These physical properties can be replaced by the lumped parameter powder compressibility κ [Example 36 in (3)].

The importance of introducing intermediate quantities will now be demonstrated by the following example.

37.6.4 Example 4

37.6.4.1 Description of the Dissolved Air Flotation Process. In a flotation process tiny gas bubbles adhere to the naturally or artificially hydrophobic surface of solid particles, making them float to the liquid surface from where they can be removed as foam. For the removal and concentration of activated sludge in the biological wastewater purification process, both dissolved air and degasifying flotation (7) can be used. In both cases, a gas mixture (air and $CO_2 + N_2$, respectively) is first dissolved in the respective liquid under higher pressure and is

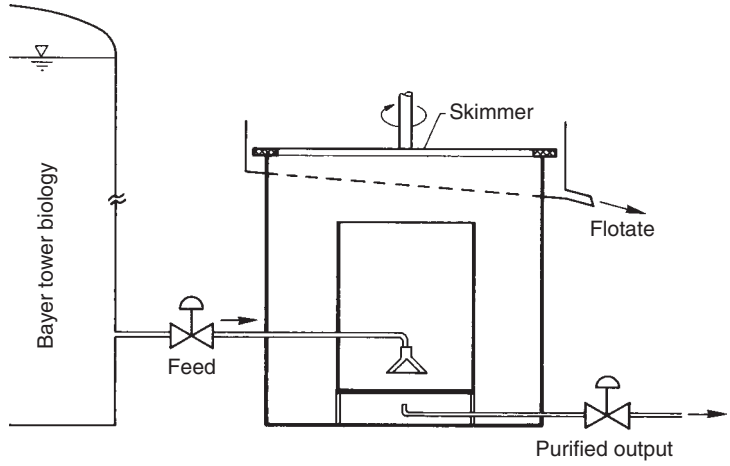

Figure 37.5. Sketch of a flotation cell with spatially separated aeration and separation zones for dissolved air flotation [from Ref. 7].

released after decompression, in the form of tiny gas bubbles. The devices for this procedure consist of either longitudinally streamed-through basins or of flotation cells (Fig. 37.5). To enable a vertical flow through the flotation cell, the cell is spatially separated into a flotation chamber and an annular space. In the latter, the liquid flows slowly downward and the residual flocks rise upward. In this way, a complete removal of the particles is achieved.

Flotation is a depletion process, hence it obeys a time law of the first order and is described by the flotation rate constant, k_F. The target quantity, "solids discharge A", corresponds to the chemical conversion, X, in first order reactions:

$$A \equiv X \equiv (c_0 - c)/c_0 = 1 - c/c_0 = 1 - \exp(-k_F t)$$

Now, we will examine a flotation process taking place in the described flotation cell of a given geometry (characteristic linear dimension of length being the cell diameter D).

The problem here consists in listing the material parameters because, in activated sludge, they fluctuate strongly (in contrast to ore flotation for example). Surely, the degree of hydrophobicity (wettability) of the particle surface (contact angle, Θ) will be of importance. Furthermore, the pH value, the flocculant (polyelectrolyte) concentration c_F, the portion of solids in the system φ, and the weight difference between the bacteria and the liquid $g\Delta\rho$—just to mention a few—will play an important role.

In contrast, it is easy to list all of the process parameters involved: liquid input q_{in}, which leaves the cell divided into the flotate discharge q_F and the processed liquid output q_{out}; releasable gas content of the liquid feed $q_G/q_{in} = H_y \Delta p/\rho_G$. ($H_y$ is the Henry's law constant).

The relevance list now reads

$$\{A;\ D;\ \Theta,\ pH,\ c_F,\ \varphi;\ q_{in},\ q_{out};\ q_G/q_{in},\ g\Delta\rho\} \qquad (37.7)$$

This relevance list, which is certainly incomplete with respect to physical properties, can be streamlined significantly by introducing two intermediate quantities:

1. the *superficial velocity*, v, in the annulus of the flotation cell (Fig. 37.5):

$$v = f_1(q_{in},\ D)$$

and

2. the *rising velocity*, w, of the flocks:

$$w = f_2(\Theta,\ pH,\ c_F,\ \varphi,\ q_G/q_{in},\ g\Delta\rho)$$

[w has to be separately determined with an appropriate measuring device, refer (7)].

The 10-parametric relevance list in Equation 37.7, which has been assumed to be fairly complete, is now reduced to a 5-parametric one:

$$\{A,\ v,\ w,\ q_{in},\ q_{out}\} \qquad (37.8)$$

This relevance list delivers the following simple three-parametric pi set:

$$\{A,\ v/w,\ q_{in}/q_{out}\} \qquad (37.9)$$

In this pi space, measurements performed in a bench-scale flotation cell (Fig. 37.5) of $D = 0.6$ m were evaluated. The flotation cell input consisted of biologically purified wastewater, containing ≈ 3 g TS/L activated sludge (TS being total solids), which was processed in the 30-m high bubble columns, the so-called "Tower Biology" of BAYER AG/Leverkusen, Germany.

The result in Fig. 37.6 cannot be considered satisfying. This is certainly not surprising because the processed

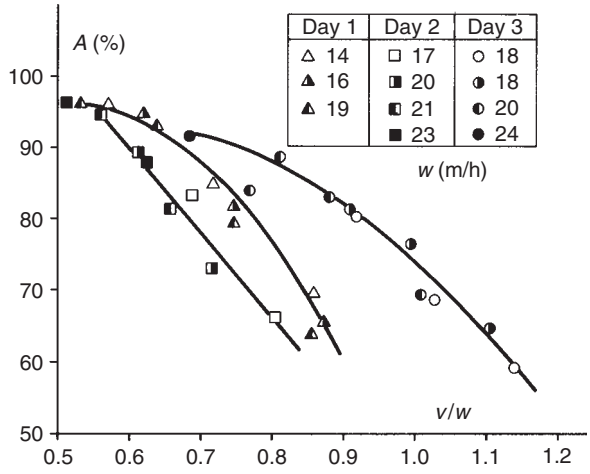

Figure 37.6. Correlation between the activated sludge discharge A and the ratio v/w of the superficial velocity, v, to the rising velocity of flocks, w [from Ref. 7].

wastewaters of this chemical giant originated from about 150 production sites and constantly changed their composition. Nevertheless, it can be seen that at least the process parameters are correctly taken into account with the ratio v/w. (The rising velocity w, was varied to a small extent each day by the addition of different amounts of polyelectrolitic flocculants.)

The results of this examination show that biologically purified wastewater can be completely freed from activated sludge under the precondition that the superficial velocity of the input v, amounted to the half value of the rising velocity of the flocks w. (The fact that $A = 100\%$ was never achieved is understandable because in the determination of the solid content by drying, the dissolved inorganic salts were also measured, which, of course, cannot be removed by flotation.)

In the preceding example, one only needs to compare the tentative relevance list (Eq. 37.7) with the final five-parametric relevance list (Eq. 37.8) to fully realize the advantage of introducing intermediate quantities in complex interrelations.

37.6.5 Material Systems of Unknown Physical Properties

With foams, sludges, and slimes often encountered in biotechnology, we are confronted with the problem of not being able to list the physical properties because they are still unknown and therefore cannot be quantified. This situation often leads to the opinion that dimensional analysis would fail in such cases.

It is obvious that this is the wrong conclusion. Dimensional analysis is a *method* based on logical and mathematical fundamentals (1,3,4). If relevant parameters cannot be listed because they are unknown, one could hardly blame the method! The only solution is to perform model measurements with the same material system and to change the scale of the model .

37.6.6 Example 5

37.6.6.1 Scale-Up of a Mechanical Foam Breaker. The question posed is about the mode of performing and evaluating model measurements with a given type of mechanical foam breaker (foam centrifuge, sketch in Fig. 37.7) to obtain reliable information on dimensioning and scale-up of these devices. Preliminary experiments have shown that for each foam emergence—proportional to the gas throughput q_G—for each foam breaker of diameter d, a minimum rotational speed n_{min} exists which is necessary to control it (8). The dynamic properties of the foam (e.g. density and viscosity, elasticity of the foam lamella etc.) can neither be fully named nor measured. We will have to content ourselves by listing them wholesale as material properties S_i. In our model experiments we will of course be able to replace S_i by the known type of surfactant (foamer) and its concentration c_f (in ppm).

In discerning the process parameters, we realize that the gravitational acceleration g has no impact on the foam breaking *within* the foam centrifuge. The centrifugal acceleration n^2d exceeds the gravitational one (g) by far! However, we have to recognize that water content of the foam entering the centrifuge depends very much on gravitational acceleration. On the moon, the water drainage would be by far less effective! In contrast to the dimensional analysis presented elsewhere (8), we are well-advised to add g to the relevance list:

$$\{n_{min};\, d;\ \text{type of foamer},\, c_f;\, q_G,\, g\}. \tag{37.10}$$

For the sake of simplicity, in the following n_{min} will be replaced by n and q_G by q. For each type of foamer we obtain the following pi space:

$$\left\{\frac{nd^3}{q}, \frac{n^2d}{g}, c_f\right\} \text{ or abbreviated } \{Y, \mathrm{Fr}, c_f\} \tag{37.11}$$

To prove this pi space, measurements in different-sized model equipment are necessary to produce reliable process characteristics. For a particular foamer (Mersolat H of Bayer AG, Germany) the results are given in Fig. 37.7. They fully satisfy the pi space of Equation 37.11.

The straight line in Fig. 37.7 corresponds to the analytical expression

$$Y = \mathrm{Fr}^{-0.4} c_f^{0.32}$$

which can be put down to

$$n\, d = \text{constant}\, q^{0.2} f(c_f)$$

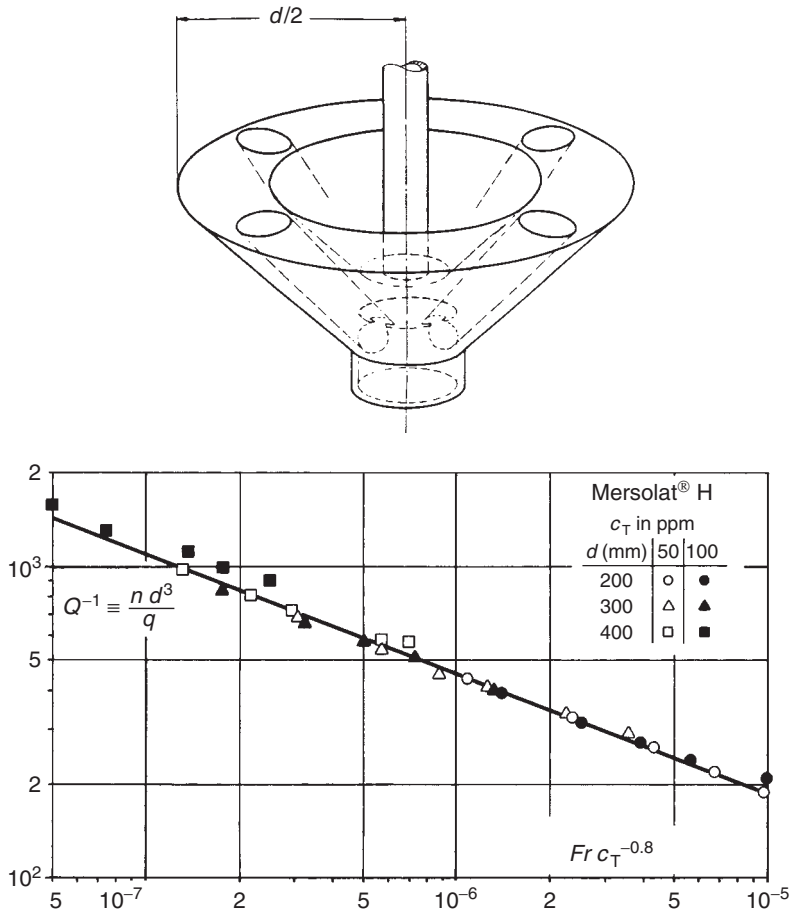

Figure 37.7. Process characteristics of the foam centrifuge (insert) for a particular foamer (Mersolat H, Bayer AG, Germany). [From Ref. 8.]

Here, the foam breaker will be scaled up according to its tip speed $u = \pi nd$ in model experiments, which will also moderately depend on the foam yield (q).

In all the other foamers examined in (8), the correspondence $Y \propto \mathrm{Fr}^{-0.45}$ was found. If the correlation

$$Y \propto \mathrm{Fr}^{-0.5} f(c_\mathrm{f})$$

proves to be true, then it can be deduced to

$$n^2\, d/g = \text{constant } (c_\mathrm{f}).$$

In this case, the centrifugal acceleration ($n^2\ d$) would present the scale-up criterion and would depend only on foamer concentration and not on foam yield (q).

Since the exponent of Fr in the process (Eq. 37.11) exhibits a numerical value of $a = 0.45$ for four foaming agents and $a = 0.40$ for Mersolat $H^{®}$ (8), the numerical value of the constant at Fr = constant can be plotted for all five foaming agents as a function of the foaming agent concentration. In this way, the mechanical stability of foams produced by individual surfactants can be quantified. [It is shown in (8) that the effect of the type of foaming agent on the foam stability is surprisingly low.]

In order to design and scale-up a foam centrifuge of the type presented, measurements with the material system in question would have to be performed by means of an appropriate model appliance. In this manner, the design of the full-scale foam centrifuge presents no problem. Apart from that, these tests and their representation in the sense of Fig. 37.7 give manufacturers of foaming agents a quantifiable assessment of the mechanical stability of the foams produced.

In addition to the information given so far, this example also indicates the following. If material properties of the systems in question are not known, one is compelled (i) to perform the measurements with the given system in differently sized models, that is under change of scale, and (ii) to indicate the chemical or trade name of the product and its concentration instead of its unknown (nor measurable) physical properties.

37.7 SHORT SUMMARY OF THE ESSENTIALS OF THE DIMENSIONAL ANALYSIS AND SCALE-UP

37.7.1 Advantages Gained by Proper Use of Dimensional Analysis

The advantages made possible by correct and timely use of dimensional analysis are as follows:

1. *Reduction of the number of parameters required to define the problem*. The Π theorem states that a physical problem can always be described in dimensionless terms. This has the advantage that the number of dimensionless groups which fully describe it is much smaller than the number of dimensional physical quantities. It is generally equal to the number of physical quantities minus the number of base units contained in them.
2. *Reliable scale-up of the desired operating conditions from the model to the full-scale plant*. Due to the fact that a dimensionless pi space is scale-invariant, two processes may be considered similar to one another if they take place under geometrically similar conditions and all dimensionless numbers which describe the process have the same numerical value.
3. *A deeper insight into the physical nature of the process*. By presenting experimental data in a dimensionless form, one distinct physical state can be isolated from the other (e.g. turbulent or laminar flow region) and the effect of individual physical variables can be identified.
4. *Flexibility in the choice of parameters and their reliable extrapolation within the range covered by dimensionless numbers*. These advantages become clear if one considers the well-known Reynolds number, $\mathrm{Re} = vL/\nu$, which can be varied by altering the characteristic velocity v, or the characteristic length L, or the kinematic viscosity ν. By choosing appropriate model fluids, the viscosity can very easily be altered by several orders of magnitude. Once the effect of the Reynolds number is known, extrapolation of both v and L is allowed within the examined range of Re.

37.7.2 Area of Applicability of Dimensional Analysis

The application of dimensional analysis is indeed heavily dependent on the available knowledge. The following five steps (Fig. 37.8) can be outlined as follows:

1. The physics of the basic phenomenon is unknown. Dimensional analysis cannot be applied.
2. Enough is known about the physics of the basic phenomenon to compile the first, tentative relevance list. The resultant pi set is unreliable.
3. All the relevant physical variables describing the problem are known. The application of dimensional analysis is not problematic.
4. The problem can be expressed in terms of a mathematical equation. A closer insight into the pi relationship is feasible and may facilitate a reduction of the set of dimensionless numbers.
5. A mathematical solution of the problem exists. The application of dimensional analysis is superfluous.

It must, of course, be said that approaching a problem from the point of view of dimensional analysis also remains useful even if all the variables relevant to the problem are not yet known. The timely application of dimensional analysis may often lead to the discovery of forgotten variables or the exclusion of artifacts.

37.7.3 Experimental Methods for Scale-Up

In the introduction a number of questions were posed which are often asked in connection with model experiments.

How small can a model be? The size of a model depends on the scale factor L_T/L_M, and on experimental precision of measurement. Where $L_T/L_M = 10$, a ± 10% margin of error may already be excessive. A larger scale for the model will therefore be chosen to reduce the error.

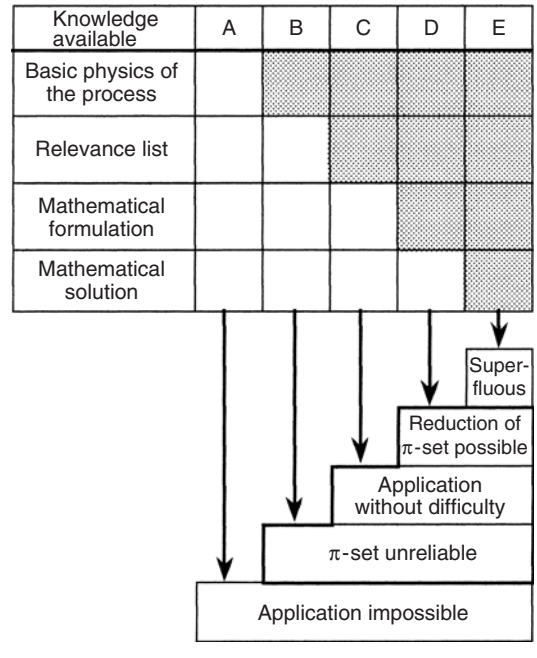

Figure 37.8. Graphical representation of the four levels of knowledge and their impact on the treatment of the problem by dimensional analysis. [After J. Pawlowski. Taken from Ref. 3.]

Is one model scale sufficient or should tests be carried out in models of different sizes? One model scale is sufficient if relevant numerical values of dimensionless numbers necessary to describe the problem (the so-called "process point" in the pi space describing the operational condition of the technical plant) can be adjusted by choosing appropriate process parameters or physical properties of the model material system. If this is not possible, process characteristics must be determined in models of different sizes, or the process point must be extrapolated from experiments in technical plants of different sizes.

When must model experiments be carried out exclusively with the original material system? If a material model system is unavailable (e.g. in the case of non-Newtonian fluids) or relevant physical properties are unknown (e.g. foams, sludges, slimes) model experiments must be carried out with the original material system. In this case, measurements must be performed in models of various sizes (Example 5).

37.7.4 Carrying Out Experiments by Changing the Scale

As a rule, model experiments are carried out in the laboratory in one and the same apparatus. There are certain reasons why this is often inadequate:

1. If you assume that the process in question essentially depends on acceleration due to gravity, g—which cannot be changed on Earth—experiments have to be performed by changing the scale. Relevant examples are scale-up rules for bubble columns as well as for surface aerators in wastewater treatment.
2. If physical properties cannot be varied, one is compelled to perform experiments by a change in the scale in order to vary the operational (process) number. A pertinent example is elaboration of the scale-up rules for a mechanical foam breaker.
3. If laboratory measurements are performed in a single vessel (d = constant) filled with water or a liquid of similar viscosity ($\nu \approx$ constant), one cannot differentiate whether the Reynolds or the Froude number represents the process number. In mixing experiments in which d, ν, and g remained practically constant it follows:

$$\mathrm{Re} \equiv nd^2/\nu \rightarrow \text{constant} \times n$$
$$\mathrm{Fr} \equiv n^2 d/g \rightarrow \text{constant} \times n^2$$

   To find out if the process depends on Re or Fr number or on both of them, one must perform the experiments in differently scaled models.

4. In mass transfer in G/L system in volume aeration, the target number $k_L a$ is an intensively formulated (volume-related) quantity. This implies that process parameters (mixing power P and the gas throughput q) also have to be formulated as intensive quantities. The question occurs whether the gas throughput q has to be related to the liquid volume V as q/V, or to the cross-sectional area S of the vessel as the superficial velocity $v \propto q/S$. To determine this, laboratory measurements have to be performed by a change in the scale.

37.8 TREATMENT OF VARIABLE PHYSICAL PROPERTIES BY DIMENSIONAL ANALYSIS

A complete similarity between a model and its technical realization implies geometric, material, and process-related similarity. The geometric similarity can be realized without a problem in most cases. The same is true of process-related similarity, as could be seen from the examples presented so far. Material similarity can cause difficulties if in model experiments, materials used must be different from those in the technical plant.

The scale invariance of the pi space allows working with different material systems in the model as compared to the industrial scale. This presents one of the essential advantages offered by the scale invariance of the pi space. A lot of conditions of flow in the technical plant can only be scaled down to the model scale when an appropriate model material system has been chosen. This will be clearly shown by the following example:

The Reynolds number for a mixing vessel is given by $\mathrm{Re} \equiv n\, d^2/\nu$. Due to the fact that the scale of length (stirrer diameter d) enters Re with its square, in an essential scale-down, it will also be necessary to diminish essentially, the kinematic viscosity of the liquid in order to work with a reasonable stirrer speed.

The process point of the technical plant is given by

$$d = 1 \text{ m}; n = 1 \text{ s}^{-1} (= 60 \text{ min}^{-1});$$
$$\nu = 1 \times 10^{-4} \rightarrow \mathrm{Re} = 10^4.$$

In a laboratory device which is scaled down by a relatively big scale factor of $\mu = 10{:}1$ and which applies the same fluid ($\nu = 1 \times 10^{-4}$), stirrer speed must have an extreme value of $n = 100 \text{ s}^{-1} (= 6000 \text{ min}^{-1})$ in order to sustain the same flow condition ($\mathrm{Re} = 10^4$). If on the other hand, the measurements are performed with water ($\nu = 1 \times 10^{-6}$), the experiment can be carried out with a reasonable stirrer speed of $n = 1 \text{ s}^{-1} (= 60 \text{ min}^{-1})$.

In this example it is assumed that the liquid is a Newtonian one and the temperature is constant. So physical

properties of the fluid (viscosity μ and density ρ) remain constant.

However, constancy of physical properties cannot be assumed in every physical process. A temperature *field* may generate a viscosity *field* or even a density *field* in the material system treated. In non-Newtonian (pseudoplastic and/or viscoelastic) liquids, a shear rate will also produce a viscosity *field*.

The variability of viscosity is of essential importance in biotechnology in view of the fact that this discipline deals with heterogeneous material systems exhibiting mostly non-Newtonian viscosity behaviors, which often change their properties under shear stress. This is an additional reason for treating this topic more comprehensively here.

37.8.1 Dimensionless Representation of the Material Function

Similar behavior of a certain physical property common to different material systems can only be visualized by dimensionless representation of the material function of that property. This can be achieved by its dimensionless "standard representation".

Figure 37.9 presents the dependence of the dynamic viscosity μ on the temperature T for eight different fluids,

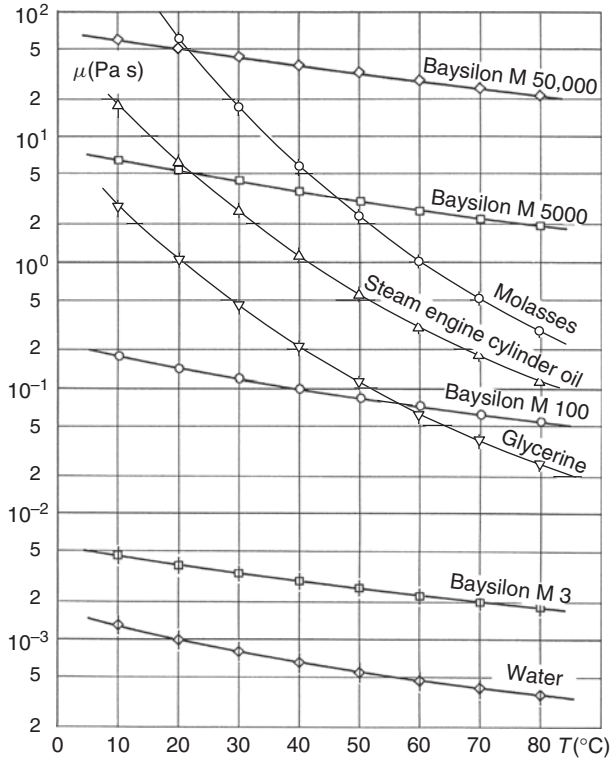

Figure 37.9. The dependence $\mu(T)$ for eight different fluids, which differ strongly in their temperature coefficient of the viscosity [from Ref. 9].

which differ in the viscosity at room temperature for five decades. Five of them show a relatively small temperature dependence of the viscosity (water and 4 Baysilone, the silicone oils of the Bayer AG), the remaining three (glycerin, steam engine cylinder oil, molasses) a pronounced one.

From the representation $\mu(T)$ a similarity between the eight fluids cannot be concluded. To determine this, the dimensional space $\mu(T)$ must be transformed into a dimensionless one. This is possible through a standardization (normalization) of this dependence.

For the purpose, we choose a reference temperature T_0 (preferably the mean temperature of the measuring range), to which a reference viscosity is related. Further on, we determine in the point T_0 the gradient $\Delta\mu/\Delta T$, with which the temperature coefficient of the viscosity

$$\gamma_0 \equiv \left(\frac{1}{\mu}\frac{\partial\mu}{\partial T}\right)_{T_0} < 0$$

is calculated.

By doing this, the dimensional space $\mu(T)$ is widened by three parameters. Now the relevance list

$$\{\mu, \mu_0, T, T_0, \gamma_0\} \tag{37.12}$$

delivers without a problem three dimensionless numbers

$$\{\mu/\mu_0, T/T_0, \gamma_0\Delta T\} \tag{37.13}$$

The following can be realized (Fig. 37.10):

1. With respect to the temperature dependence $\mu(T)$ all investigated fluids behave similarly to each other; they correspond to the same standard representation $\mu/\mu_0 = f(\gamma_0\Delta T)$.
2. The standard representation proves invariant to the reference temperature T_0: The parameter T/T_0 in the equation (Eq. 37.13) has no influence.
3. The fitting curve corresponds to the reference invariant χ function after Pawlowski (10). Water values are described with $\mu = -1.2$ and a logarithmic variance of 5.25×10^{-3}. For all remaining materials $\mu = -0.167$ and the log variance amounts to 1.51×10^{-2}.
4. Water is obviously a special stuff. Its μ/μ_0 values coincide with the other values only in the range near to the reference point (i.e. at $\gamma_0\Delta T \approx 0\pm 1$). Outside this range they deviate stronger.
5. The thinly plotted straight line is a very good approximation of this dependence in the range near the reference point (at $\gamma_0\Delta T \approx 0 \pm 1$). This is the engineering representation of the temperature dependence of the viscosity of a liquid $\ln(\mu/\mu_0) = \exp(\gamma_0\Delta T)$.

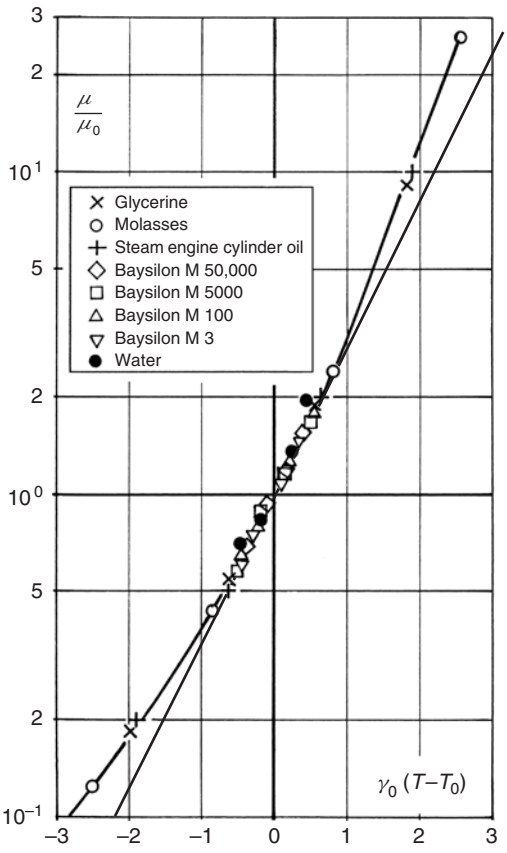

Figure 37.10. Standard representation $\mu/\mu_0 = f(\gamma_0 \Delta T)$ for fluids from Fig. 37.9. Reference temperature $T_0 = 50^\circ$C. The fitting curve corresponds to reference invariant χ-function [details in (10)].

Due to the equivalence between μ/μ_0 and $\gamma_0 \Delta T$ the quotient μ/μ_0 is preferably used in the engineering literature as the viscosity number $Vis \equiv \mu_w/\mu$ (μ_w is wall viscosity, μ is bulk viscosity); see the heat transfer characteristics given in Fig. 37.17.

In this way, variable physical properties are treated. In (3) the dependence of the density on temperature, the dependence of the particle strength on the particle diameter, the dependence of the diffusion coefficient of a polymer mass on temperature and on moisture content are presented and discussed.

37.8.2 Rheological Standardization Functions

In Newtonian liquids, it is the dynamic viscosity μ (Pa s), which combines the shear stress τ (Pa) with the shear rate $\dot{\gamma}(s^{-1})$ in the rheological equation of state

$$\tau = \mu \, \dot{\gamma} \tag{37.14}$$

μ is a constant, depending only on material and temperature.

In non-Newtonian fluids μ depends on the actually effective shear rate $\dot{\gamma}$ and occasionally also on history. Such fluids are subdivided into classes according to their flow behavior, only two of which—pseudoplastic and viscoelastic ones—are treated in the following.

37.8.3 Flow Behaviour of Non-Newtonian Fluids of the Type Pseudoplastic Fluids

Pseudoplastic ("shear-thinning") fluids are those in which stress viscosity is *decreased* due to shear. Under shear stress solid aggregates of a dispersion L/S (e.g. dye pigments) or L/L decompose into single particles, which then orientate themselves toward flow direction. Intermingled chains of macromolecules of a polymer solution or melt are stretched to the flow direction; spheres of erythrocytes of blood are elongated. In all these cases, the viscosity is decreased due to shear.

The rheological material function $\mu(\dot{\gamma})$ is formulated in a dimensionless way with material standardization parameters μ_0 or μ_∞ (or similar) and $\dot{\gamma}_0$ or $\dot{\gamma}_\infty$ (or similar) and transformed into a rheological standardization function:

$$\mu/\mu_0 = f(\dot{\gamma}/\dot{\gamma}_0) \tag{37.15}$$

Liquids whose rheological equation of state coincide in this dimensionless frame—whose standardization functions are identical—are rheologically similar to one another.

An important subclass of pseudoplastic fluids consists of those fluids whose material function is represented in the whole measured range in a log–log scale by a straight line with a negative slope. In this case, one speaks of an *Ostwald–de Waele* Fluid, whose viscosity curve obeys the so-called *"power law"* (K being consistency index, m the flow index):

$$\mu_0 \, \dot{\gamma}_0^{1-m} = K \;\rightarrow \tau = K \, \dot{\gamma}^m \rightarrow \mu_0 = K \, \dot{\gamma}^{m-1} \tag{37.16}$$

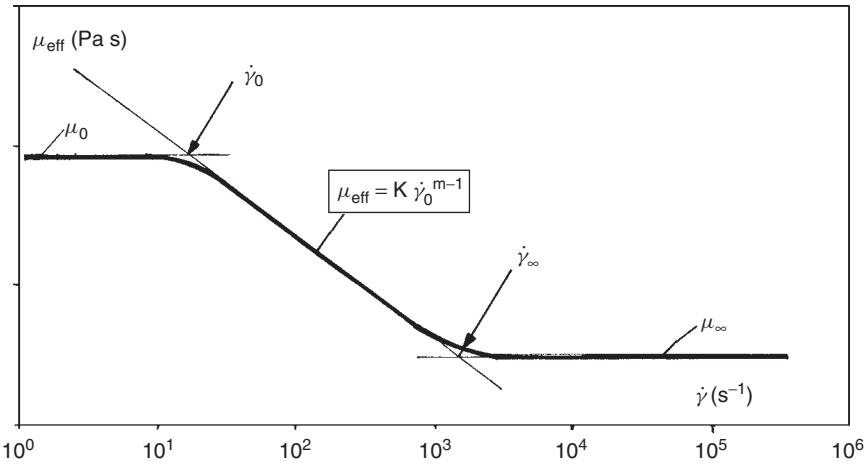
To demonstrate this flow behavior in the form of a standardization function, $\dot{\gamma}_0$ is arbitrarily chosen and μ_0 assigned to it. This degree of freedom facilitates the choice of reference points for the standardization of the material function.

Pawlowski (4) has already pointed out that Equation 37.16 is against the principle of consistency of physical quantities because the dimension of $[K] = ML^{-1}T^{m-2}$ depends on the numerical value of exponents. This brings about that in the case of a temperature-dependent viscosity in a temperature field, the quantity K changes its dimension from point to point and therefore neither *grad* K nor K/K_0 can be built.

Physical consistency of Equation 37.16 remains preserved if it is transformed by Equation 37.15 to the relationship

$$\mu/\mu_0 = f(\dot{\gamma}/\dot{\gamma}_0)^{m-1} \tag{37.17}$$

whereas K is eliminated.



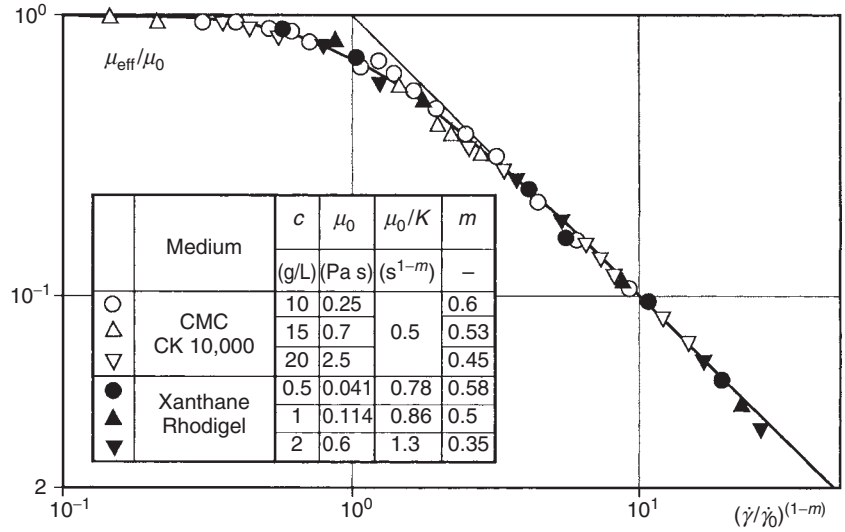


Figure 37.11. Principal course of viscosity of a pseudoplastic fluid which in a certain $\dot{\gamma}$ range behaves like an *Ostwald–de Waele* Fluid.

	Medium	c (g/L)	μ_0 (Pa s)	μ_0/K (s^{1-m})	m –
○	CMC CK 10,000	10	0.25	0.5	0.6
△		15	0.7		0.53
▽		20	2.5		0.45
●	Xanthane Rhodigel	0.5	0.041	0.78	0.58
▲		1	0.114	0.86	0.5
▼		2	0.6	1.3	0.35

Figure 37.12. Dimensionless standardization functions of some pseudoplastic fluids (11). For the meaning of $\dot{\gamma}$ refer Fig. 37.11.

In most pseudoplastic fluids at sufficiently low and sufficiently high shear rates $\dot{\gamma}$ Newtonian flow behavior can be observed (Fig. 37.11). Viscosity approaching a constant value with low shear rates is called zero-shear viscosity, μ_0, and its constant value at very high shear rates is called the infinite shear viscosity, μ_∞. Classic model fluids of this type are aqueous solutions of macromolecular organic compounds as for example carboxy-methyl-cellulose (CMC), poly-acryl-amide (PAA), Carbopol (very sour acrylic acid polymerisates of Goodrich Co.), but also of biopolymers such as Xanthane.

In mixing vessels, shear rates usually appear in the range of $\dot{\gamma} = 50\text{–}500\ s^{-1}$ in which many pseudoplastic fluids behave like *Ostwald–de Waele* Fluids. This explains why the "power law" is often used to describe the rheological behavior.

In these pseudoplastic fluids, the rheological standardization function can be presented in the pi space

$$\{\mu/\mu_0,\ \dot{\gamma}/\dot{\gamma}_0, \Pi_{rheol}\} \text{ or } \{\mu/\mu_\infty,\ \dot{\gamma}/\dot{\gamma}_\infty, \Pi_{rheol}\}$$

In the publication of Henzler (11), $\dot{\gamma}_0/\dot{\gamma}_\infty$ is represented by the exponent m of the straight line, which stands for an upsetting/stretching of the course of the curve belonging to the power law. In Fig. 37.12, CMC and Xanthane solutions of various concentrations are correlated in this pi space.

These materials are obviously not thoroughly similar to one another. They would be, if the exponent m were

constant and the dependences could be correlated in the space $\mu/\mu_0 = f(\dot{\gamma}/\dot{\gamma}_0)$. Here, the exponent varies by factor two: $m = 0.35–0.6$.

In the introduction to this chapter it was pointed out that the importance of the rheological standardization function consists in recognizing materials which are similar to one another and thus build a class of material belonging to a common master curve, and are therefore suitable as model substances. Figure 37.13 presents a class of aqueous PAA solutions of different concentrations which correlate excellently with one another in the space

$$\mu/\mu_0 = f(\dot{\gamma}/\dot{\gamma}_0).$$

The finding and working out of model substances of a family of those building a master curve is a task of prime importance when model measurements are necessary for dimensioning a process in which non-Newtonian fluids take place.

37.8.4 Flow Behaviour of Non-Newtonian Fluids of the Type Viscoelastic Fluids

In viscoelastic fluids, the distortion work performed by shear stress is not completely, immediately, and irreversibly transformed into friction heat but partially elastically stored in order to relax with delay. In this respect they are similar to solids. The liquid strains give way to the mechanical shear stress as do elastic bonds by contracting. This is shown in shear experiments as a restoring force acting against the shear force which, at the sudden ending of the effect of force, moves back the plate to a certain extent. In mixing a viscoelastic fluid it climbs up the stirrer shaft, in order to evade the shear stress which the rotating stirrer shaft exerts on the liquid on its surface ("Weissenberg phenomenon") [Example 17 in (3)].

For dimensionless presentation of viscoelastic behavior of a fluid normally the ratio of normal stress N_1 to shear stress τ is used. The so-called Weissenberg number Wi is defined as

$$\mathrm{Wi} \equiv N_1/\tau \tag{37.18}$$

The material function of a viscoelastic fluid is presented in space $\mathrm{Wi}(\dot{\gamma})$ the standardization function here is $\mathrm{Wi}/Wi_0 = f(\dot{\gamma}/\dot{\gamma}_0)$.

On the right side of Fig. 37.12 the correspondence $(\psi_1 \equiv 2\ \psi_2)\dot{\gamma}_0/\mu_0 = f(\dot{\gamma}/\dot{\gamma}_0)$ is shown. This figure does not represent a standardization function. The proof of similarity for two material functions (congruence separately for each kind of function as well as for its relative position to each other) can only be obtained if these functions refer to quantities of equal dimension. Material functions $(\psi_1 \equiv 2\ \psi_2) = f(\dot{\gamma})$ do not fulfill the condition of congruence of the relative position to the corresponding material functions. Only after the transformation to $(\varphi_1 \equiv 2\ \varphi_2) = f(\dot{\gamma})$ with $\varphi \equiv \psi/\dot{\gamma}$, it follows that the fluids in Fig. 37.13 can really be used as model substances to one another [details in (13)].

37.8.5 Process Equations for Non-Newtonian Fluids

In the introduction to this chapter it was already pointed out that certain parameters of the rheological normalization functions have to be included into the relevance list of a given process in order to be assured that the process equation is also valid for the treatment of non-Newtonian

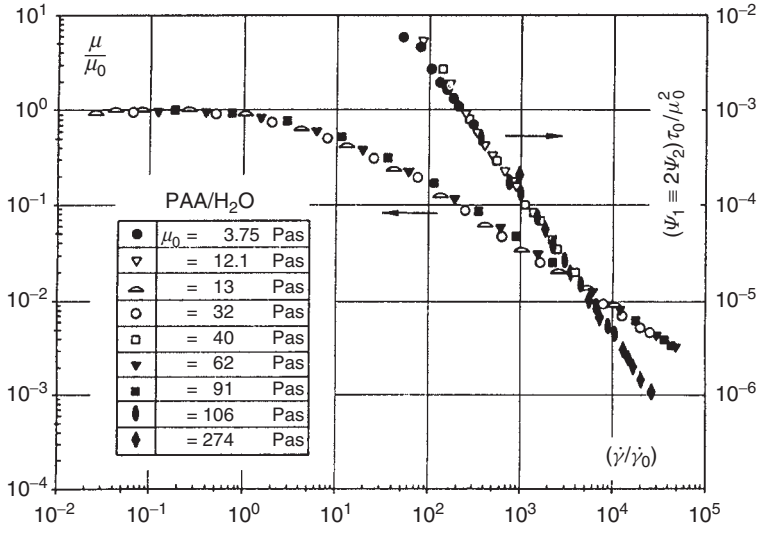

Figure 37.13. Master curves μ/μ_0 and $(\psi_1 \equiv 2\psi_2)\dot{\gamma}_0/\mu_0 = f(\dot{\gamma}/\dot{\gamma}_0)$, respectively, for a class of aqueous PAA solutions of different concentrations and viscosities [from Ref. 12].

liquids. This will be shown here with some examples from mechanical and thermal process engineering in connection with pseudoplastic and viscoelastic fluids.

Unfortunately, it is still current engineering practice to formulate the process number Re according to the Metzner–Otto concept (14) with a so-called effective viscosity μ_{eff} as $\text{Re}_{\text{eff}} \equiv v\ l\rho/\mu_{\text{eff}}$. and to ignore clear dimensional analytical rules for non-Newtonian fluids (3,4). This fact makes it necessary to discuss this quantity first. [A detailed critical argument with this concept is given in 12,15).]

37.8.6 Concept of the Effective Viscosity μ_{eff} According to Metzner–Otto

This concept has been developed in association with the determination of the stirrer power in a non-Newtonian liquid (14). It is assumed that in the immediate surroundings of the stirrer, a representative shear rate $\dot{\gamma}_{\text{MO}}$ exists, which is proportional to the stirrer speed, n:

$$\dot{\gamma}_{\text{MO}} = k_{\text{MO}} n \tag{37.19}$$

k_{MO} is a constant, depending only on the type of stirrer and on geometric conditions in the stirring vessel. The determination of $\dot{\gamma}_{\text{MO}}$ proceeds as follows:

1. A stirrer arrangement is used for which the power characteristics Ne (Re) for Newtonian liquids is known.
2. Using the non-Newtonian fluid, the stirrer power is determined for some stirrer speeds and the Ne numbers are calculated.
3. With these Ne values the corresponding Re values are taken from the Ne (Re) correlation for Newtonian liquids.
4. With these Re values the effective viscosity μ_{eff} is determined.
5. From the flow curve $\mu = f(\dot{\gamma})$ of the used liquid the representative shear rate $\dot{\gamma}_{\text{MO}}$ is found.

The concept of "effective viscosity" is well-known in rheology. For the "viscosimetric flow" in a capillary viscosimeter it is theoretically justified, but it is valid only for creeping flow and fluids without viscoelastic properties. In case of a mixing vessel, we deal with a *field quantity* which cannot even describe the flow behavior in the immediate surroundings of the stirrer where the power is dissipated (Fig. 37.14).

37.8.7 Process Equations for Mechanical Processes with Non-Newtonian Fluids

In a relevance list of a process, there is no place for field variables such as μ_{eff}, because these are results and not arguments known in advance. These can only be the rheological normalization parameters μ_0, $\dot{\gamma}_0$, $N_{1,0}$ etc.

As it has already been pointed out with regard to the pi space, the transition from a Newtonian to a non-Newtonian fluid requires the following consequences:

1. All pi numbers of the Newtonian case also appear in the non-Newtonian case, whereby instead of μ the normalization parameter of the same dimension, mostly μ_0, appears.

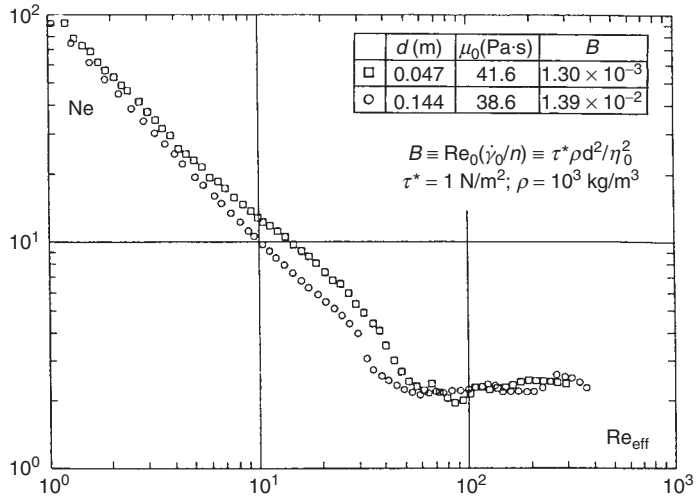

Figure 37.14. Power characteristics of a turbine stirrer ($D/d = 2$, $h/d = 1$) under geometrically similar conditions in two mixing vessels of different size, $\mu \approx 1{:}3$. The employed aqueous PAA solutions have practically the same viscosity. [From Ref. 12]. Re_{eff}, is built with μ_{eff} according to Metzner–Otto. $\tau* = 1$ Pa.

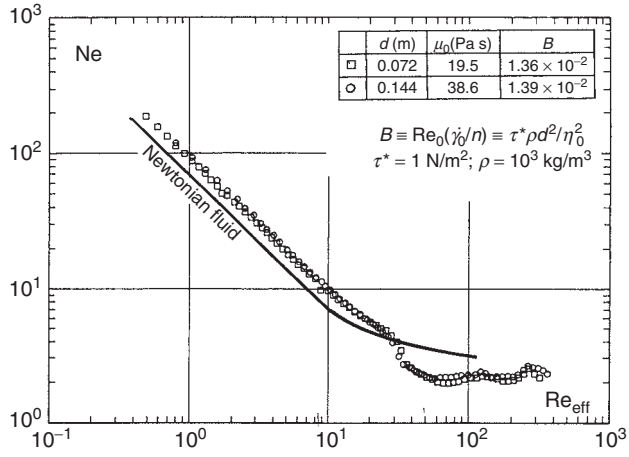

Figure 37.15. Power characteristics $Ne(Re_{eff})$ of a turbine stirrer as in Fig. 21 determined in two geometrically similar mixing vessels of different shape (scale-up factor $\mu = 2.0$) with two aqueous PAA solutions of adopted viscosity (B = idem). [From 12.]

2. An additional pi number appears which contains the normalization parameter, mostly $\dot{\gamma}_0$.
3. Pure material numbers are increased by $\Pi_{rheol} = m, Wi_0$ etc.

The power characteristics of a stirrer in a Newtonian liquid was produced from the relevance list

$$\{P; d, \rho, \mu, n\}$$

and leads to the dimensionless dependence

$$\mathrm{Ne} = f(\mathrm{Re}) \text{ with } \mathrm{Ne} \equiv P/(\rho\, n^3 d^5) \text{ and } \mathrm{Re} \equiv n\, d^2\rho/\mu$$

In a pseudoplastic liquid, both normalization parameters $\dot{\gamma}_0$ und μ_0 have to be introduced. This means that the relevance list is enlarged by $\dot{\gamma}_0$ and μ is replaced by μ_0:

$$f(P; d, \rho, \mu_0, \dot{\gamma}_0, n) = 0 \tag{37.20}$$

Therefore, the pi set is enlarged with regard to Equation 37.2 by one pi number

$$\mathrm{Ne} = f(R_0, Q) \text{ with } \mathrm{Re}_0 \equiv n\, d^2\rho/\mu_0 \text{ and } Q \equiv \dot{\gamma}_0/n \tag{37.21}$$

Because both process numbers Re_0 and $Q \equiv n/\dot{\gamma}_0$ contain stirrer speed, it is advisable to combine them in a way that the stirrer speed is eliminated. The number consequently produced, B, is identical to the Hedström number He, where μ_0 is related to the liquids exhibiting the yield stress, τ_0:

$$B \equiv \frac{\mathrm{Re}_0}{n/\dot{\gamma}_0} \equiv \frac{d^2\rho\dot{\gamma}_0}{\mu_0} \equiv \frac{d^2\rho\tau_0}{\mu_{0^2}} \tag{37.22}$$

Thus it follows:

$$\mathrm{Ne} = f(R_0, B) \tag{37.23}$$

Due to the correspondence $d^2 \propto \mu_0^2$ in Equation 37.22, in doubling the scale (here the stirrer diameter d) the viscosity also has to be doubled. Fig. 37.15 documents that at B = idem the function $\mathrm{Ne} = f(\mathrm{Re}_{eff})$ has an identical course in differently shaped vessels.

37.9 DIMENSIONAL ANALYTICAL TREATMENT OF HEAT TRANSFER PROCESSES

37.9.1 Driving Force and the Target Quantity of the Process

At first, it is to be pointed out that heat transfer is normally an indirect process. In the case of cooling, for example, the part which receives heat is divided by a wall from the part where heat is produced. We deal with three different heat transfer steps, two of which belong to heat transfer by convection (under obviously different conditions) and the third one is heat conduction through a solid wall.

In the following, we will investigate only that part of the mixing vessel where a reaction takes place and the reaction heat produced has to be removed through the wall. The driving force of the process is the temperature difference ΔT between both spaces separated by the wall because the temperature stands for energy levels of the systems which are to be equalized.

The target quantity of this process is heat transfer coefficient at the inner wall, h. It can be regarded as the heat conductivity, k, in the boundary layer, divided by its thickness, δ that is, $h = k/\delta$. Because of the unknown δ, h is not measurable. It can only be calculated from the general heat transfer equation by using it as the determining equation for h:

$$h \equiv Q/A\Delta T.$$

(Q is heat flow through the heat exchanger area, A)

37.9.2 Steady-State Heat Transfer in Mixing Vessels

The pi space of the heat transfer characteristics of a mixing vessel is obtained by the following relevance list:

Target quantity: heat transfer coefficient at the inner wall, h

Geometric parameters: vessel and stirrer diameters: D, d

Material parameters: density ρ; viscosity of liquid bulk, μ, and at the inner wall, μ_w; heat capacity, C_p; heat conductivity, k

Process parameter: stirrer speed, n.

The complete nine-parametric relevance list reads as follows:

$$\{h; D, d; \rho, \mu, \mu_w, C_p, k; n\} \tag{37.24}$$

Here two characteristic lengths were introduced. D stands for that geometric part of the device where the heat is transferred (in the case of cooling coils, coil diameter D_c had to be introduced instead), whereas d is the stirrer diameter which together with n governs the hydrodynamics of the vessel.

This nine-parametric relevance list leads to $9-4 = 5$ dimensionless numbers, the fourth base dimension being the temperature Θ:

$$\{\text{Nu, Pr, Re, Vis}, D/d\} \tag{37.25}$$

where:

$\text{Nu} \equiv hD/k$–Nusselt number, the target number
$\text{Pr} \equiv C_p\mu/k$–Prandtl number, pure material number
$\text{Re} \equiv nd^2\rho/\mu$–Reynolds number, the process number
$\text{Vis} \equiv \mu_w/\mu$–Viscosity ratio
D/d–Wall clearance, the geometric number

Figure 37.16 shows the dependence (Eq. 37.25) for an anchor stirrer with two arms and a close wall clearance ($D/d = 1.02$). The figure consists of two parts representing the same measuring results in two different pi spaces: above as $\text{Nu} = f$ (Re), below as $\text{Nu} = f$ (Re, Pr).

A comparison of both representations verifies that the consideration of the Prandtl number by $Pr^{1/3}$ starts gaining weight increasingly from about $\text{Re} > 200$; in the range $\text{Re} < 200$ its contemplation is rather negative. [For the heat transfer from tube wall to the fluid flowing under laminar conditions, Levêque (16) found that the heat transfer coefficient h is proportional to the third root of the shear rate at the wall.]

The scattering of the measuring data in the range of $\text{Re} < 200$ is well-founded by the measuring technique applied here. The mean bulk temperature in the vessel in the laminar flow region could not be measured with a thermometer because an insulating border layer was formed round its wall. In this range, the average temperature of the bulk liquid had to be calculated from the heat balance. In the range $Re > 200$ the correspondence between the calculated and measured values was approximately 10% (9).

The fitting lines in the lower figure verify the following dependences:

$$\text{Re} > 200 : \text{Nu} = 0.28\ \text{Re}^{2/3}\ \text{Pr}^{1/3} \tag{37.26}$$

$$\text{Re} < 200 : \text{Nu} = 0.8\ \text{Re}^{1/3}\ \text{Pr}^{1/3} = 0.8\ \text{Pe}^{1/3} \tag{37.27}$$

This is compulsory. If in the creeping flow range ($\text{Re} < 200$) the influence of the Prandtl number is considered by $\text{Pr}^{1/3}$, then the Reynolds number must also have the same exponent. Only then the result is a number (Peclet number Pe) which does not contain the liquid viscosity and the liquid density ρ is combined with the *mass* related

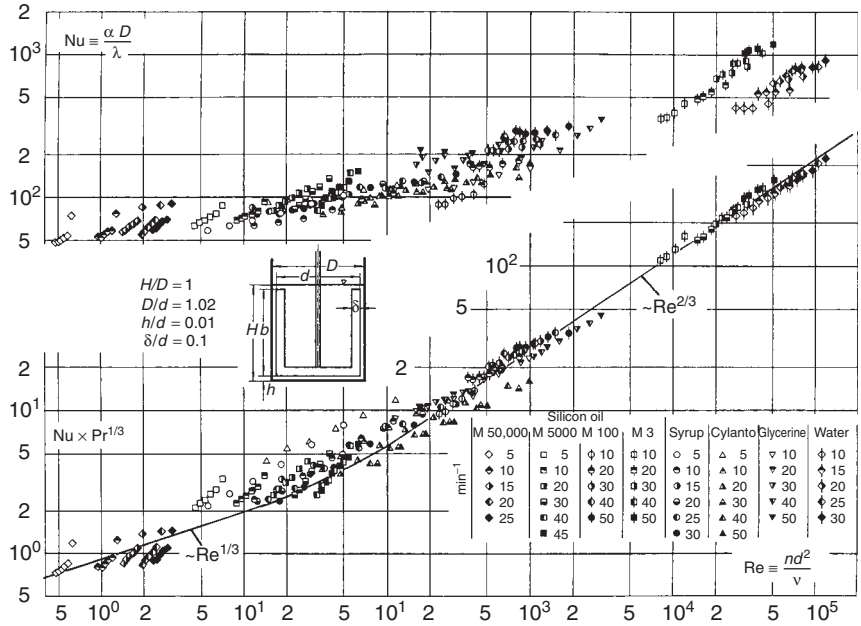

Figure 37.16. Heat transfer characteristics of a mixing vessel with an anchor stirrer with two arms and $D/d = 1.02$ [from Ref. 9].

heat capacity C_p to produce the *volume*-related one. In the creeping flow range liquids behave like solids and then neither viscosity nor density affect heat transfer:

$$\mathrm{Pe} \equiv \mathrm{Re} \cdot \mathrm{Pr} \equiv n\, d^2 \rho C_p / k \equiv n\, d^2 / a$$

$a \equiv k/(\rho C_p)$ means thermal conductivity.

Judat, in (5), investigated heat transfer in a mixing vessel with an anchor stirrer with four arms equipped with wipers ($D/d = 1$). With the wipers, the liquid border layer at the wall is completely removed. As a result, the Nu values ($\hat{=}$ α_i values) in the creeping flow area are increased by a full decade and, in addition, the creeping flow range expands up to $\mathrm{Re} = 2 \times 10^3$ because the stirrer beams dip into the laminar border layer. Here, too, $Nu \propto Pe^{1/3}$ holds.

Delaplace *et al*. (17) studied heat transfer in a vessel ($D = 0.346$ m) equipped with an Ekato-PARAVISC stirrer ($d = 0.32$ m, $D/d = 1.08$) and found for Newtonian as well as for non-Newtonian liquids the same heat transfer equations (Fig. 37.17):

$$\mathrm{Re} > 200 : \mathrm{Nu} = 0.27\ \mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\ \mathrm{Vis}^{-0.14} \qquad (37.28)$$

$$\mathrm{Re} < 200 : \mathrm{Nu} = 1.59\ \mathrm{Pe}^{1/3}\ \mathrm{Vis}^{-0.14} \qquad (37.29)$$

The fact that no difference was found between heat transfer in Newtonian and in non-Newtonian liquids (fluids of the pseudoplastic and yield stress type were investigated and their viscosity considered according to the Metzner–Otto concept), verifies that non-Newtonian fluid behavior affects only the turbulent flow region. A comparison of process equations between the Paravisc stirrer and the old-fashioned anchor stirrer (at $D/d \simeq$ similar) shows that the Paravisc stirrer delivers better heat transfer values only in the creeping flow area ($\mathrm{Re} < 200$) by a factor of 2. But in the turbulent region every stirrer delivers the same results!

In the optimization of stirrers to achieve the optimum heat removal in a cooling process, it should not be forgotten that the removable heat flow, Q [kW], increases in the range of $\mathrm{Re} > 200$ (in technical mixing vessels $\mathrm{Re} < 100$ is seldom achieved) according to the heat transfer characteristic with $\mathrm{Re}^{2/3} \propto n^{2/3}$, whereas the thereby associated stirrer power ($\hat{=}$ stirring heat) increases substantially over-proportionally according to the power characteristic of the stirrer with P [kW] $\propto n^3$. Thus it follows that there is an optimum stirrer speed at which the maximum process heat such as chemical reaction heat, R, can be removed:

$$R + Q - P$$

Figure 37.18 illustrates this situation with a concrete example. It shows that the optimum range with respect to the stirrer speed is very flat, 90% of the maximum value being removed in the range $n_{opt} = 20\ \mathrm{min}^{-1} \pm 60\%$.

To compare an anchor stirrer (at $D/d = 1.02$) with Ekato-PARAVISC stirrer (at $D/d = 1.08$), their power characteristics have to be taken into account. In the range of $\mathrm{Re} < 100$ they read:

Anchor stirrer: $\mathrm{Ne} \times \mathrm{Re} = 420$

Ekato-PARAVISC stirrer: $\mathrm{Ne} \times \mathrm{Re} = 250$

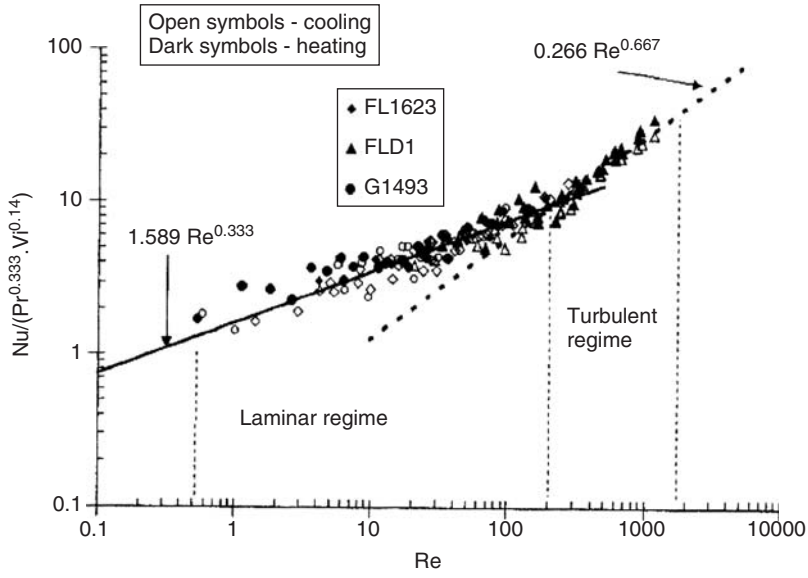

Figure 37.17. Heat transfer characteristics of a mixing vessel equipped with an Ekato-PARAVISC stirrer ($D/d = 1.06$) and measured with three different Newtonian fluids. Open signs stand for cooling, dark ones for heating [from Ref. 17].

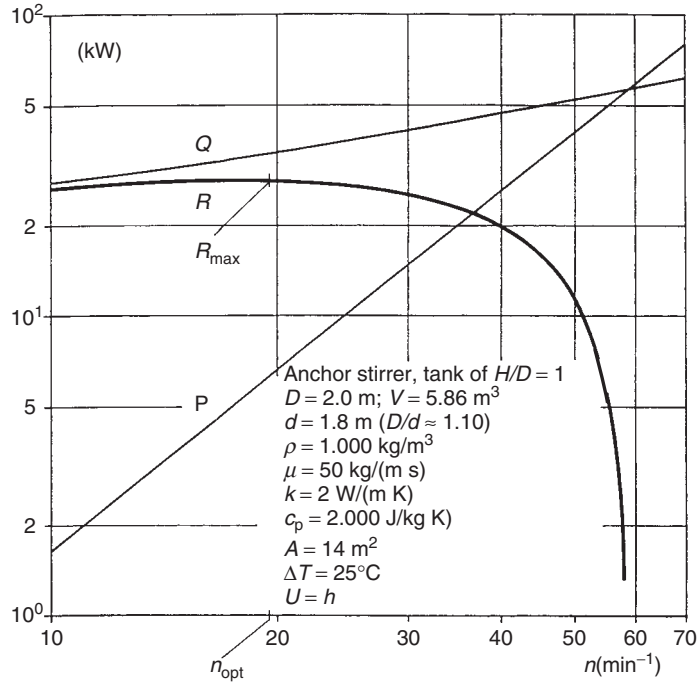

Figure 37.18. Graphical representation of the course of $R \equiv Q - P$ as a function of the stirrer speed n for the example given in the plot [from Ref. 18].

For Re > 100 see (5) and (17). Obviously, the Paravisc stirrer is more suitable than the anchor stirrer for heat removal. The reason for this advantage lies possibly in the pumping action of the stirrer, with which the liquid is more effectively removed from the wall.

37.10 DIMENSIONAL ANALYTICAL TREATMENT OF MASS TRANSFER PROCESSES

37.10.1 Driving Force and Target Quantities of the Process

In mass transfer processes, mass is transferred from one phase to the other through an interface. This can be either solid (dissolution in the systems S/L) or a fluid one: L/L, G/L (absorption and desorption processes). In the first case, the interface is known, in the second case the fluid interface is neither known nor measurable. This distinction has a big impact on dimensional analytical treatment of the process.

In mass transfer, the driving force consists of the removal of an equilibrium disturbance and concerns a thermodynamic quantity; namely, the chemical potential μ.

It is often presumed that the leveling out of concentration differences between two phases is the cause for mass transfer. That is not the case. This fact can easily be demonstrated with a number of examples. It should suffice to remark that a material system consisting of granular cooking salt in saturated aqueous solution is in equilibrium. The chemical potential in both phases is equal, but the concentration of NaCl in granular cooking salt is 100%, whereas in the saturated aqueous solution it is only 26.4% (at 20°C).

The bridge between the chemical potential, which is very difficult to determine, and the concentration difference, which is easily determined, was erected by Lewis and Whiteman in 1923/24, who postulated in their "Two Film Theory" (with regard to the system G/L) the following:

1. On both sides of the interface, laminar boundary layers exist which the gas can pass only by *diffusion*.
2. In the interface, the thermodynamic equilibrium immediately occurs.

In the material system G/L, the transfer from the gas phase to the interface can be neglected because it is by at least 50% faster than the transfer from the interface through the laminar liquid boundary layer to the bulk of a liquid. If, as postulated, a thermodynamic equilibrium always exists in the interface then also the saturation concentration c_s of the gas is always present. Under these conditions the driving force of mass transfer is in fact given by concentration difference:

$$\Delta c = c_s - c \tag{37.30}$$

Thus the general mass transfer equation is given by the following relationship:

$$G = k_L\ A\ \Delta c \tag{37.31}$$

where:

G [kg gas/s] –	mass transfer rate through the interface
A [m^2] –	interfacial area (e.g. the sum of the surfaces of all gas bubbles)
k_L [m s^{-1}] –	liquid-side mass transfer coefficient
Δc [kg m^{-3}] –	characteristic concentration difference of the dissolved gas between the interface and the liquid bulk

k_L can physically be comprehended as $k_L \propto D/x_L$, where D is the diffusion coefficient of the gas in the liquid-side laminar boundary layer of thickness x_L. Thus k_L represents a definition quantity, which is as little measurable as the interfacial area A. Both of them are influenced by the kinematics of the process and by material conditions. In surface aeration, they are combined into only one quantity, which can easily be determined by constituents of the overall mass transfer (Eq. 37.31):

$$k_L A \equiv G/\Delta c \tag{37.32}$$

$k_L A$ represents the target quantity of mass transfer in *surface aeration*.

In volume (bulk) aeration it is assumed that the process takes place in a liquid which is turbulently mixed and thus an equal number of gas bubbles of an equal size exist in each volume element. Under these circumstances, it is advisable to formulate the general mass transfer equation (Eq. 37.31) as a volume-related one:

$$G/V = k_L(A/V)\Delta c \tag{37.33}$$

(This contains an additional advantage because Δc, too, is a volume-related quantity per definition.) A/V is abbreviated to $a \equiv A/V$ and since it is not measurable, combined with k_L to the "overall liquid-side mass transfer coefficient" $k_L a$:

$$k_L a \equiv G/(V\,\Delta c) \tag{37.34}$$

$k_L a$ is easily measured by Equation 34 and represents the target quantity of mass transfer in *bulk aeration*.

From the point of view of dimensional analysis, there is a considerable distinction between the two target quantities $k_L A$ and $k_L a$.

$k_L A$ is an extensively defined quantity, which therefore must compulsorily depend on extensive parameters like the stirrer diameter d and the stirrer speed n.

$k_L a$, in contrast, is a volume-related, intensive quantity, which therefore must compulsorily depend on intensively formulated process parameters like power per liquid volume P/V and gas throughput q per aerated cross-sectional area S, the so-called superficial velocity, $v \propto q/S$.

37.10.2 Mass Transfer G/L in Surface Aeration

The supply of atmospheric oxygen to municipal sewage purification plants has been performed for decades by turbine surface aerators installed in the liquid surface of shallow wastewater treatment ponds (H $\leq$ 4 m). The stirrers work as water pumps: they suck in waste water, spray it over the liquid surface and, in addition, they whirl it up. In this way the mass transfer G/L is effected.

Target quantity: mass transfer coefficient in surface aeration, $k_L A$

Geometric parameter: diameter of the turbine stirrer, d

Material parameters: density and kinetic viscosity of the liquid, ρ, ν

Process parameters: stirrer speed of the turbine, n acceleration due to density, g

The acceleration due to gravity, g, is essential in this process because it influences the parabolic throw of the ejected liquid. Two further possible parameters, the diffusion coefficient D and the surface tension σ, will be renounced, because in wastewater treatment the only liquid of interest is water. Thus the constricted relevance list reads:

$$\{k_L A;\, d;\, \rho,\, \nu, n,\, g\} \tag{37.35}$$

This six-parametric set delivers the following three dimensionless numbers:

$(k_L A)^* \equiv \dfrac{G}{d^3\ \Delta c}\left(\dfrac{\nu}{g^3}\right)^{1/3}$ sorption number

$\mathrm{Re} \equiv nd^2/\nu$ Reynolds number

$\mathrm{Fr} \equiv n^2 d/g$ Froude number

To ensure that the only variable process parameter, n, does not appear in both process numbers (Fr and Re), we first determine which of the two process numbers is essential, and then we free the other one by combining it with the first one from n.

The process takes place in water, and the state of flow will be a turbulent one. Hence, Re cannot play an important role. The process will be governed essentially by the Froude number. We will combine Re with Fr and obtain

$$\mathrm{Ga} \equiv \frac{\mathrm{Re}^2}{\mathrm{Fr}} \equiv \frac{d^3 g}{\nu^2} \quad \text{Galilei number}$$

Thus, the pi space reads:

$$\{(k_L A^*, \mathrm{Fr}, \mathrm{Ga}\} \tag{37.36}$$

Due to the circumstance that the second essential parameter, acceleration due to gravity, g, cannot be varied on Earth, measurements must be performed with measuring devices of different scale. (This is the only way to decouple Fr and Re.)

The process equation for a turbine stirrer ("Rushton turbine"), the disk of which was installed in the water surface, reads:

$$(k_L A)^* = 1.41 \times 10^{-4}\mathrm{Fr}^{1.205}\mathrm{Ga}^{0:115}$$
$$\mathrm{Fr} = 0.02 - 0.34;\ \mathrm{Ga} = 1.5 \times 10^9 - 2 \times 10^{11}$$

The investigated range of the scale-up factor was $\mu = 1{:}5$; details in (19).

37.10.3 Mass Transfer G/L in Bulk Aeration in Mixing Vessels

There are a number of chemical and biotechnological reactions between gas (G) and liquid (L) which take place in mixing vessels: hydrogenation, oxydation, chlorination, phosgenization, aerobic bioconversion. The relevance list for this operation reads as follows:

- Target quantity: volume-related mass transfer coefficient, $k_L a$
- Geometric parameters: none
- Material parameters: density and kinetic viscosity of the liquid, ρ, ν diffusivity of the gas in the liquid, D bubble coalescence behaviour of the liquid, S_i
- Process parameters: volume-related mixing power, *P/V* superficial velocity of the gas, v gravitational acceleration, g

Here, some remarks are to be made: first, despite extensive research, bubble coalescence phenomena have still not been clarified to such an extent as to permit explicit formulation of the coalescence parameters (5). In the following, they will be taken into consideration in a lump as S_i. Second, the decision in favor of *P/V* and v instead of *P/V* and *q/V* is based on extensive research results (Fig. 37.19).

We start from the relevance list:

$$\{k_L a, \rho, \mu, D, S_i, P/V, v, g\} \tag{37.37}$$

and obtain the pi space

$$\{(k_L a^*, (P/V)^*, v^*, \mathrm{Sc}, S_i^*\} \tag{37.38}$$

where:

$(k_L a)^* \equiv k_L a \left(\frac{v}{g^2}\right)^{1/3}$ – sorption number

$(P/V)^* \equiv \frac{P/V}{\rho(\nu g^4)^{1/3}}$ – dimensionless *P/V* number

$v^* \equiv \frac{v}{(\nu g)^{1/3}}$ – dimensionless superficial velocity number

$\mathrm{Sc} \equiv D/\nu$ – Schmidt number

S_i^* – unknown numbers describing the bubble coalescence

Figure 37.19 shows a correlation of mass transfer measurements in this pi space. The measurements were performed under unsteady-state conditions by several authors in a water–air system, which is bubble coalescent, using a turbine stirrer as a mixing device. The measurements cover an extreme experimental scale of $\mu \approx 1$–80. The geometric parameters were broadly varied: $d = 0.05$–3.1 m; $D = 0.15$–12.2 m; $H = 0.15$–6.1 m, $V = 1.5$ l –906 m^3. Between B and v^* the following correlation exists: $B = (\pi/4)v^*$.

The process equation reads:

$$(k_L a^* = 9.8 \times 10^{-5}(P/V)^{*0.40}/$$
$$(B^{-0.60} \equiv 0.81 \times 10^{-0.65/B})$$

Ignoring the additive term in this equation, we find $(k_L a)^* \propto (P/V)^{*0.40}\ B^{0.60}$.

In contrast, Fig. 37.20 shows the results of mass transfer in the system: aqueous 1 N sodium sulphite solution–air. These measurements were carried out under steady-state conditions in vessels with hollow stirrers on the scale $\mu = 1{:}5$ (21,22). In this material system, the high salt concentration (70 g Na_2SO_3/L) fully suppresses bubble coalescence. In the case of the self-aspirating hollow stirrer, the stirrer power and gas throughput were coupled via the stirrer speed and were therefore dependent on each other. Consequently, v^* does not occur explicitly in the representation in Fig. 37.18, because it is a function of $(P/V)^*$.

Here, the process equation reads:

$$(k_L a)^* + 1.1 \times 10^{-4}(P/V)^{*0.80} \tag{37.39}$$

These results can be summarized as follows: in the case of a coalescent material system, for example in pure liquids of low viscosity (e.g. water), the absorption rate depends to an equal extent on *P/V* and on $v \propto q/D^2$:

$$(k_L a)^* \propto (P/V)^{*0.4} v^{*0.5} \tag{37.40}$$

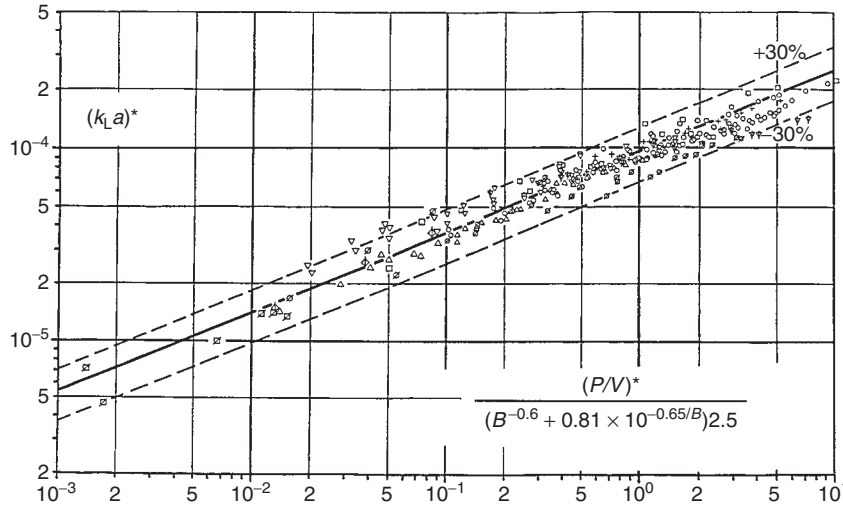

Figure 37.19. Sorption characteristic of a mixing vessel with a turbine stirrer for a coalescing material system (water/air) [from 20].

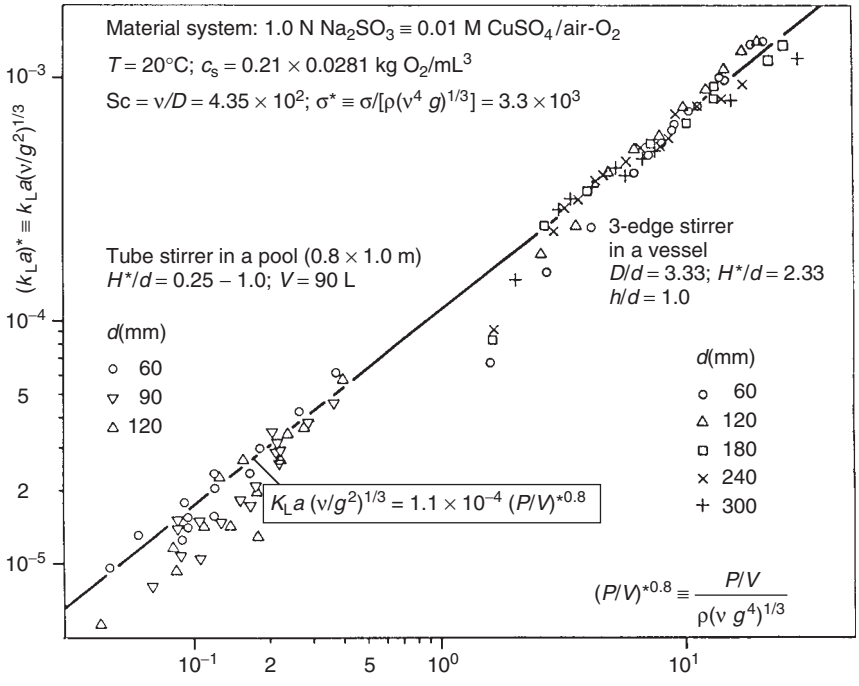

Figure 37.20. Sorption characteristic of a mixing vessel with a self-aspirating hollow stirrer in a material system with fully suppressed coalescence [taken from Ref. 19].

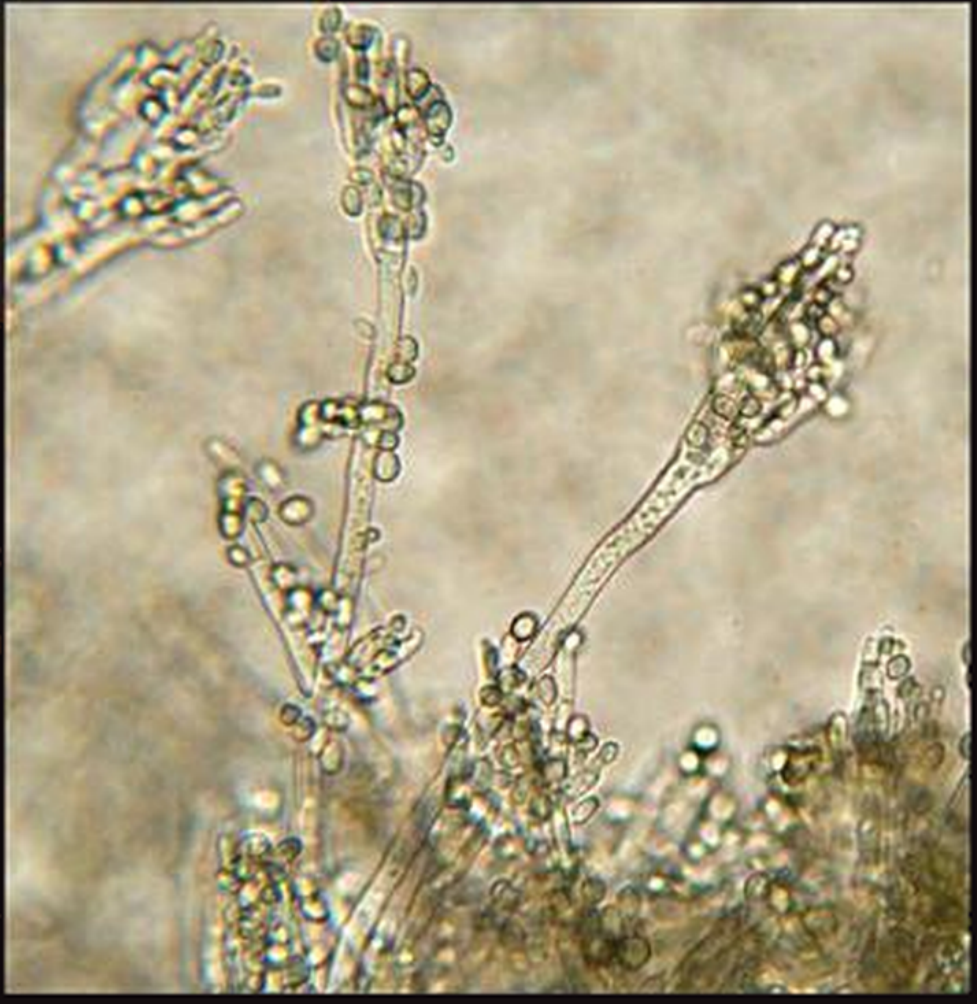
In completely coalescence suppressed systems, for example in many highly concentrated aqueous salt solutions (5), in contrast to the above, the following applies:

$$(k_La)^* \propto (P/V)^{*0.7} v^{*0.2} \tag{37.41}$$

Only with self-aspirating hollow stirrers, where v^* is not an independent process parameter, the correlation (Eq. 37.39) was found.



From the above, the following conclusion can be made. High power inputs (P/V) are justified only in coalescence-inhibited material systems. In other words, the generation of very fine primary gas bubbles in coalescent-prone systems is not economically justified.

Dimensional analysis and scale-up rules for two component nozzles ("injectors") for mass transfer in the G/L system in bubble columns are given in (24).

38.1 INTRODUCTION

Animal cells have an innate ability for proper folding, posttranslational processing, and secretion of proteins, which makes them preferable as hosts for producing biological components of therapeutic and diagnostic interest; as a result, culture of mammalian cells has been used extensively for the production of biologics, including virus vaccines, monoclonal antibodies (MAbs), hormones, enzymes, growth, and blood factors. Although the industrial exploitation of animal cell cultures started over five decades ago with the production of Salk polio virus vaccine in primary monkey kidney cells (1), it has been during the last 21 years that there has been a rapid increase in the number of Food and Drug Administration (FDA)-approved products produced in mammalian cell culture, starting in 1986 with the production of recombinant tissue plasminogen activator (tPA) with genetically engineered Chinese hamster ovary (CHO) cells and the simultaneous introduction of the first MAb, ORTOCLONE OKT3 (muromonab-CD3), as a treatment for solid transplant rejection. Since then, 29 MAbs and many other therapeutic agents have been approved for marketing in the United States for the diagnosis or treatment of diverse diseases, a majority of which are produced in animal cell cultures (2,3). By 2005, one estimate of the world market for antibodies produced in animal cell culture was $14 billion, and this number was expected to grow to more than $16 billion by 2006 (4). While the specific and/or volumetric productivity continues to improve, that is, greater than 5 g/L of product is now considered the norm, this rapid growth in the number and demand of biologics has driven the industry to expand the size and the number of production facilities, and has led to statements that shortfalls in manufacturing capacity exist (5). All of this positive growth puts significant pressure to continually improve the size and productivity of commercial animal cell culture systems.

Despite the fact that reports exist showing that animal cell culture has been conducted for over a 100 years (6,7), no universally accepted method of design or scale-up of animal cell culture has been developed. Diverse culture methodologies including static cultures (T-flask), roller bottles, cultures on microcarriers and freely suspended cells in batch, fed-batch or perfusion systems, among others, have evolved. While freely suspended, fed-batch processes have emerged as the predominant methodology, much of this evolution has been guided by the particularities of the process, the cell line and, most importantly, the in-house expertise of the researchers, specific to each organization. Although there are reports of large-scale (1000–2000 L) airlift bioreactors for protein/antibody production (8–10), at least 70% of the licensed processes for recombinant proteins, antibodies, and vaccines using microcarriers or freely

suspended cultures use traditional stirred tank bioreactors with reported capacities up to 20,000 L (11–13). Several reasons account for this preference including the vast empirical knowledge accumulated for the design, scale-up, and operation of this type of reactor in the chemical and biochemical industries over the last century, the versatility of this reactor type allowing its adaptation to several different processes with minor or no modifications and, finally, the relative simplicity. As a result, most guidelines for bioprocess design and scale-up are based on stirred tank reactors and as such will be the primary focus for the remainder of this review.

All animal cell processes are aerobic; oxygen is a crucial nutrient involved in growth and energy production in such cells. Unfortunately, because of its low solubility in water-based media, dissolved oxygen (DO) is consumed quickly, requiring a continuous supply in order to keep cells alive. The easiest way of providing oxygen to a stirred culture is through surface aeration; however, surface aeration is not generally sufficient for cultures beyond ~100 L. Other aeration methods [i.e. perfluorocarbons (PFCs), membrane aeration, oxygen carriers] have been used successfully at scales of up to 500 L, but their use is limited by high cost and downstream concerns (PFCs) or by limited design data and difficulties in maintenance (membrane aeration). These limitations have placed air and oxygen-enriched air sparging as the most common and the simplest method for continuously providing oxygen in bioreactors.

Agitation, on the other hand, is essential for satisfactory mass transfer and homogeneity in a bioreactor with or without sparging; this homogeneity is crucial for process control. Although sparging provides some degree of agitation by itself, most animal cell cultures rely on some sort of mechanical device to impart enough kinetic energy to the fluid.

Both agitation and sparging are essential for the success of industrial cultures of animal cells; yet, both are associated with cell damage as a result of cell–bubble, liquid–cell, and/or solid–cell interactions. Significant progress has been made over the last two decades in the understanding of cell damage mechanisms, and in this chapter, we will attempt to present an overview of the current practices and protocols for aeration and mixing in the bioreactor design and operation, as well as their connection to hydrodynamic damage in animal cell processes.

38.2 AERATION

Oxygen is a key substrate in animal cell cultures; unfortunately, its sparing solubility in water-based media (7.8 mg/L when bubbling air in water at 760 mmHg and 25°C) requires a continuous supply throughout the culture for most larger-scale situations. At high cell concentrations, the rate of oxygen consumption may exceed the rate of oxygen supply; in those conditions, the DO concentration falls to a point (the critical oxygen concentration) where it becomes limiting. Reported critical oxygen concentration for animal cells ranges typically between 1% and 10% of air saturation (14,15). Below this range, the oxygen consumption rate as well as the mitochondrial activity typically decreases, while the specific glucose and glutamine consumption rates increase (to compensate for ATP production) with a corresponding increase in the lactate and ammonium formation rates (16–18). Together with a reduced mitochondrial activity, there is a reduction in the specific secretion rate of proteins and volumetric accumulation of product, which translates into higher cell viability, delayed death, and lower chromosomal damage, but lower product yield (17,19).

Conversely, elevated oxygen concentration (~100% of air saturation) may stimulate the generation of reactive oxygen species (ROS) that can alter cellular macromolecules such as DNA, proteins, and lipids, impairing cell growth or even causing death (15).

As a result, cell cultures should be constrained within an optimal range of DO that must be determined experimentally, taking into account that optimal DO values for cell growth may be different than optimal values for protein production. Oh *et al*. (20) reported satisfactory cultivation of mammalian cells from approximately 5–100% of air saturation. Jan *et al*. (21) studied the effect of DO from 10% to 150% of air saturation on the growth of a murine hybridoma cells at steady state in serum-free continuous culture; while no significant effect on cell viability, growth rate, or specific antibody production rate was reported, an increase in the amount of glucose utilized at higher oxygen concentrations was detected. It was speculated that this increased glucose consumption rate was associated with an increased activity of antioxidant enzymes needed to reduce the cytotoxic effect of ROS. Using the same system, Kunkel *et al*. (22) described an increase in the level of galactosylation of the MAb chains with increased DO.

For common animal cell lines under favorable oxygen supply, reported specific oxygen uptake rates (q_{O2}) range between 6.4×10^{-18} and 4.5×10^{-16} mol oxygen/cell/s (Table 38.1). Given that, currently, cell densities of up to 10^7 cells/mL are common place at the commercial scale (23–25), the actual oxygen uptake rate in a typical culture may range from $6.4 \times 10^{-5} - 4.5 \times 10^{-3}$ mol oxygen/m^3/s; this value is at least one or two orders of magnitude lower compared to yeast [i.e. 2.2×10^{-2} mol oxygen/m^3/s for *Candida guilliermondii* (26)] and bacteria [i.e. 3.3×10^{-1} mol oxygen/m^3/s for *E. coli*, corresponding to q_{O2}= 12–21 mmol/gDW/h (27) and up to 190 gDW/L (28)]. This relatively low oxygen requirement may help explain why even with an agitation intensity for animal cell cultures about 100-fold lower than for

microbial or fungi cultures (average power drawn per unit volume ~10 W/m^3 vs ~1000 W/m^3 respectively), current bioreactors are still able to provide enough oxygen to meet animal cell needs (9,29). However, with the advent of perfusion cultures, fortified media, and improved fed-batch culture strategies, it is expected that cell concentrations will increase by an order of magnitude (30). Therefore, an equivalent increase in oxygen transfer rate (OTR) must be achieved to supply enough oxygen to the culture.

The OTR is determined from the product of the mass transfer coefficient, k_La (s^{-1}), and the driving force, which is the difference between the saturated DO concentration in the medium, $C^*_{O_2}$, and the actual DO concentration in the broth, C_{O_2}:

$$OTR = k_La \cdot \left(C^*_{O_2} - C_{O_2}\right) \tag{38.1}$$

The saturating DO concentration in the medium in equilibrium with the gas phase, is determined by

$$C^*_{O_2} = \frac{y_{O_2} \cdot P_T}{\mathcal{H}} \tag{38.2}$$

where y_{O_2} is the molar fraction of oxygen in the gas (0.21 for air), P_T is the total pressure of the gas, and $\mathcal{H}$ is the Henry's constant, which is a function of the temperature and the composition of the medium. A simple inspection of Equation 38.1 reveals that in order to increase OTR, it is necessary to increase either k_La or $C^*_{O_2}$, since C_{O_2}can only be reduced to a minimum threshold to avoid productivity issues as explained above. An increase of $C^*_{O_2}$can be achieved by an increase in the pressure of the gas (Eq. 38.2); but this action also results in an increase in the concentration of dissolved carbon dioxide (CO_2), and this may result in inhibitory effects. OTR also may be increased up to five times by increasing the molar fraction of oxygen in the gas using oxygen-enriched air or even a separate stream of pure oxygen into the broth. While this strategy is commonly used in bench bioreactors, it can lead to increased levels of dissolved CO_2, which can have a negative effect on pH control and osmolality (25).

Although, k_La can be affected by several different factors, most proposed correlations in the literature (some of them presented in Table 38.2) adopt the form of an equation dependent on two parameters that are independent of the impeller type, the media composition, and the scale:

$$k_La = A \cdot \left[(\overline{\varepsilon}_T)_g\right]^{\alpha} \cdot [V_S]^{\beta} \tag{38.3}$$

where α and β are approximately 0.5 ± 0.1, respectively (25). In Equation 38.3, the coefficient A is associated with the influence of the chemical composition on interface characteristics, V_s is the superficial velocity of the gas, and $(\overline{\varepsilon}_T)_g$ is the average total energy dissipation rate (EDR) drawn into the liquid by both the impeller $(\overline{\varepsilon}_T)_{Ig}$ and the gas sparging $(\overline{\varepsilon}_T)_S$:

$$(\overline{\varepsilon}_T)_g = (\overline{\varepsilon}_T)_{Ig} + (\overline{\varepsilon}_T)_S \tag{38.4}$$

The energy delivered to the system from air sparging can be calculated from

$$(\overline{\varepsilon}_T)_S \approx V_S \cdot g \cdot \rho \tag{38.5}$$

The correlation was derived by the authors of this chapter exclusively from data in Figures 38.3 and 38.5 of Langheinrich *et al*. (52).

where g is the acceleration due to gravity (9.81 m/s^2), ρ is the liquid density, and V_s is the superficial velocity, given by

$$V_S = \frac{Q}{A} = \frac{4 \cdot Q}{\pi \cdot T^2} = \frac{4 \cdot \left[\frac{\varphi \cdot V_R}{60}\right]}{\pi \cdot T^2} \qquad (38.6)$$

where Q is the air flow rate (cubic meter per second), T is the vessel diameter (meter), V_R is the volume of the medium in the reactor (cubic meter), and ϕ is the air flow rate expressed as vvm. Since cell damage as a result of bubble bursting (see section titled "Detrimental Effects of Sparging") is typically minimized at low air flow rates, $(\overline{\varepsilon}_T)_S$ can often be neglected for stirred tank reactors used for animal cells.

The energy drawn into the liquid by one impeller under the gassed conditions, $(\overline{\varepsilon}_T)_{Ig}$, can be estimated as

$$(\overline{\varepsilon}_T)_{Ig} = P_{0_g} \frac{\rho \cdot N^3 \cdot D^5}{V_R} \qquad (38.7)$$

where N is the impeller speed (s^{-1}), D is the impeller diameter (meter) and P_{0g} is the power number under aerated conditions, which depends on the Reynolds number, the impeller type, and the gas flow rate. For typical culture conditions, the properties of the fluid are quite similar to those of water, so the flow is essentially turbulent ($Re = \rho_L \cdot N \cdot D^2/\mu \sim 10^5$). When turbulent, P_{0g} becomes independent of the Reynolds number; additionally, as the gas flow rate (ϕ) is low, typically ranging from 0.005 to 0.01 vvm (53), P_{0g} is essentially equal to the power number of the impeller under nongassed conditions (P_0). In spite of that, the relationship between P_{0g} and P_0 is typically important in impeller selection. Values for P_0 are presented in Table 38.3 for impellers typically used in animal cell bioreactors (25). Further details about P_0 and P_{0g} are presented in the section titled "Mixing".

The term A in Equation 38.3, and therefore, k_La, are very sensitive to composition. For example, by introducing ions in water up to a limiting concentration of ~10 g/L NaCl, Van't Riet (50) showed that k_La can easily increase by a factor of 100% with respect to the value for distilled or tap water at the same conditions of $(\overline{\varepsilon}_T)_{Ig}$ and V_S; the presence of ions strongly changes the coalescent characteristic of pure water, drastically increasing the interfacial area. In contrast, Metz *et al*. (58) showed that in a stirred bioreactor with otherwise constant conditions (400 rpm, $V_S = 30.6$ m/h), the addition of 0.5 ppm of a surfactant reduced the k_La from ~180 to ~115 h^{-1}. Similar results were presented by Morão *et al*. (59) for three different types of antifoaming substances. Addition of Pluronic F-68 also lowers k_La (60); therefore, caution should be exercised when choosing a particular correlation for designing purposes.

TABLE 38.3. Power Number for Selected Impellers for Turbulent Regime

38.2.1 Surface Aeration

Oxygen transfer through the headspace is, obviously, the most common and easy method of gas exchange used for small vessels at the laboratory scale, including T-flasks, spinners, roller bottles, and small bench-scale reactors. The maximum volume at which surface aeration can be used alone depends on a series of factors such as cell concentration, whether or not the headspace gas is enriched with oxygen, and whether or not bubble entrainment is allowed (if the system is agitated). However, a general principle, which holds for scale-ups, is that the area per unit volume for mass transfer decreases with the reciprocal of the diameter of the vessel. To alleviate this problem at moderate scale, the use of surface impellers (an impeller close to the liquid–gas interface) can significantly increase the OTR as a result of an increased renewal of the liquid directly in contact with the gas. If bubble entrainment occurs, a further increase in OTR can be achieved as a result of the significant increase in the interfacial surface. Working with a 500-mL spinner vessel, Aunis *et al*. (61) reported a 50% increase in the OTR by moving the impeller within 0.13 times of the impeller diameter from the liquid surface. Hu *et al*. (62) reported an increase in the oxygen supply up to four times in their reactor by using an additional surface impeller. Another approach for high values of surface OTR involves the use of special impeller types inducing bubble entrainment such as helical and double helical ribbons together with surface baffles (63).

A variation in the surface aeration approach is the disposable bag reactor (i.e. the Wave® bioreactor), which can range in size from 100 mL to 300 L. This system achieves sufficient OTR by means of a rocking motion that induces a wave within the bag, which is sufficient to suspend the cells, mix the medium, and provides a virtually bubble-free oxygen transfer through the rapid turnover of the medium surface. Singh (64) presents data for Wave reactors from 100 mL up to 100 L, with corresponding k_La values ranging from 1.6 to 4 h^{-1}. While for a small scale, these values of k_La are in the same range as for other surface aerated reactors, it is in the lower end of the range for sparged, mechanically stirred reactors (60). However, for volumes larger than 10 L, the k_La in a wave reactor can still be up to one order of magnitude larger than for a spinner or reactor of comparable size; consequently, it is reported to be able to support cell growth up to concentrations of 7×10^6 cells/mL (64).

38.2.2 Perfluorocarbons

PFCs are hydrocarbons whose hydrogen atoms are partly or totally replaced by fluorine. They are hydrophobic and immiscible in water-based media; therefore, the addition of PFCs yields a four-phase (two liquid, one solid, and one gas phase) mixture in sparged bioreactors. Because of the much higher solubility of oxygen in PFCs than in water (see Table 38.4), there has been an active interest in using them as gas vectors to improve oxygen transfer and CO_2 removal in bioreactors. The benefits of using PFCs are summarized by Lowe *et al*. (65) and presented in Table 38.5, together with their main disadvantages.

Several studies have been conducted with animal cell cultures in which the medium was supplemented with PFC emulsions. Cho and Wang (67) employed perfluoromethyldecalin to oxygenate mouse-hybridoma cells, resulting in increased cell density and rate of MAb

TABLE 38.4. Relative Oxygen-Carrying Capacities (k) of Water, Perfluorochemicals and Gas Vesicles (Modified from Sundararajan and Ju (66))

Substance	k (at 37°C) (mol $O_2/m^{3/}$ Mpa)	k/k_{water}
Water	9.7	1.0
Perfluoro-decaline	164	16.9
Perfluoro-tripropylamine	176	18.1
Perfluoro-tributylamine	156	16.1
Gas vesicles	388	40

TABLE 38.5. Benefits and Drawbacks of PFCs [modified from Lowe *et al*. (65)]

Benefits	Drawbacks
High oxygen carrying capacity	Dispersion is unstable requiring high amounts of surfactants and energy
Ease of sterilization (e.g. by autoclave)	Surfactants may become toxic to cells
Provide a two-phase (perfluorocarbon–liquid and aqueous medium) interface and physical support for cell division (in stationary cell culture)	Once suspension is formed it is difficult to separate PFCs for reoxygenation
Chemically and biologically inert scavengers of gaseous cellular products (e.g. ethylene)	Downstream concerns
Recoverable and recyclable	Expensive

synthesis. Using the PFC FC40™, Ju and Armiger (68) found that the exponential growth phase of mouse hybridoma cells was prolonged, along with a more than sixfold increase in viable cell concentration, which was consistent with theoretical predictions based on the enhanced oxygen transfer. Although the high concentration of surfactants needed to keep PFCs in suspension might be deleterious for cells or for downstream operations, such effects have not been reported. It has also been suggested that the formation of emulsions itself might be problematic for recycling and reoxygenation. Gotoh *et al*. (14,69) proposed two interesting alternatives to solve this potential problem with emulsions: they developed a loop column reactor having a wetted-wall of PFCs to culture insect cells (Sf9). With this arrangement, the oxygen was transferred by direct contact of the broth with the liquid film created on the annular wall of the column. They reported a twofold increase in the viable cell density and specific growth rate of the cells, as well as a fivefold reduction in the specific lactate yield. In the second permutation, the same authors grew cell suspensions using a planar layer of PFC at the medium–PFC interface in a spinner flask, and the PFC was recirculated and reoxygenated in an outer aeration unit. With this arrangement, the maximum cell density attained in the PFC-mediated aeration culture was higher than that in a surface aeration control culture; also, the recombinant protein production by virus-infected insect cells was significantly increased. The PFC itself did not seem to cause any negative effects on insect cell growth, viral infection, or recombinant protein production. However, in spite of all the previous advantages, PFCs introduce additional costs and the potential problems in downstream processing have kept PFCs in the research laboratory (9).

38.2.3 Oxygen Carriers

At least two other oxygen carriers, in addition to PFC, have been suggested for use to enhance oxygen supply in cell culture: cyanobacterial gas vesicles (GVs) and hemoglobin (66). While the use of hemoglobin as an oxygen carrier has only been tried in microbial cultures and it has been limited by its high cost and by its high affinity for oxygen (i.e. it requires long residence times in the reactor to effectively release the bound oxygen), GVs have actually been tested in animal cell culture. GVs in cultures of Vero cells on microcarriers have been reported to increase by 30%, the glucose uptake rate, although no effect on cell concentration was described. GVs can be produced at a relatively low cost from simple cyanobacterial cultures; they do not require any suspension stabilizing agent (unlike PFCs), and they have more than twice the oxygen carrying capacity as PFCs (Table 38.4). However, they can not be autoclaved; consequently, sterilization is cumbersome and time-consuming (66). It remains to be seen if a commercial application will be found for GVs.

38.2.4 Membrane Aeration

In membrane aeration, the membrane provides enough interfacial area for oxygen diffusion, while it acts as a physical barrier that keeps cells away from gas–liquid interfaces, eliminating any cell damage related to bubble-bursting phenomena or cell entrapment in foam. This methodology has been reported to give high OTRs (i.e. $\sim$0.5 g O_2/L/h) that are comparable to sparging, although they require higher gas pressure and flow rates (70,71). Ma *et al*. (29) categorize the different types of membranes into two groups: a microporous type and a diffusional type. The microporous type typically is a thin membrane made up of nylon, polyvinylidene fluoride, polyester, and so on, with pore sizes ranging from 0.01 μm to about 20 μm, and where the medium is in direct contact with the air in the micropores of the membrane. The liquid–gas interface is held stationary via both hydrophobic forces and gas pressure. In the diffusional type of membrane, the oxygen diffuses through the actual membrane material. Some of the most common examples are silicon tubing and silicon hollow-fiber membrane oxygenators.

There are reports of the use of membranes for oxygen transfer up to 150 L (72,73); however, their use at larger scales is problematic. While there is always the risk of rupture, clogging, and fouling of the membranes, these risks significantly increase during scale-up, since one is faced with classical surface-to-volume ratio problems; that is, as the volume of the vessel increases, one needs to increase the surface area of the membranes, typically tubing, even faster. At some point, the amount of tubing required becomes

unmanageable, especially when one considers the challenge of cleaning and sterilizing large vessels (29,74).

38.2.5 Sparging

Despite all of the alternatives reviewed above, the most commonly used way to introduce and remove gaseous nutrients and by-products from animal cell culture, after simple head space mass transfer, is by sparging the gas directly into the medium. While potentially catastrophic effects can occur (i.e. cell death of the whole culture in a few hours), the use of specific additives can prevent a majority of the cell destruction. More on both the mechanism(s) of death and prevention will be presented later.

38.2.6 Sparger Design

Proper selection of a gas sparger involves a compromise between maximizing gas transfer (O_2 and CO_2), minimizing cell damage and foam formation, and complying with good manufacturing practices (GMP) considerations (easily cleanable, steam sterilizable, and free draining). Ideally, spargers should be designed to disperse bubbles sufficiently to avoid coalescence into larger bubbles as they rise within the vessel (75); however, excessive pressure drop across the orifice may create sufficient hydrodynamic forces to inhibit net cell growth (76) and therefore, should be avoided.

There are three commonly used designs in cell culture: the point sparger, ring sparger, and frit sparger (75). Point sparger is the simplest design consisting of a pipe ending in a nozzle through which air is introduced into the vessel; its simplicity makes it ideal for cleaning and sterilization. However, the moderate control of the bubble size that can be achieved by changing the nozzle diameter, gas flow rates, and position (depth) of the nozzle results in the formation of large bubbles (77). Although Orton and Wang (78) suggested the use of macrospargers producing large bubbles (diameter in the range of 6–8 mm) to minimize foaming and bubble-related cell death, the low surface per unit volume created with these spargers results in the use of higher flow rates in order to provide enough oxygen to the culture.

To address the high flow rates needed when a single point sparger is used, and yet allow easy cleaning and sterilization, a common approach is to add a number of air nozzles drilled at the bottom of a ring, allowing for free drainage from the tube. While it is an improvement with respect to a reduction in air flow through a single hole, it has been argued that this enhancement is not sufficient to justify the added expense and cleaning difficulties (75). Recently, Harris *et al*. (79) presented a new approach for a multipoint sparger design called the *multiple slot disperser*, which consists of an assembly of flat, parallel arrays of slot nozzles. In water, it produced a dense, three-dimensional plume of air bubbles with a consistently narrow bubble size distribution and a relatively sharply defined median bubble diameter. Most importantly, the plume attributes may be modified within wide limits by changing the slot width, plate, and array dimensions, as well as the gas flow rate. Additionally, the method of construction is highly adaptable, avoiding the need for pores or drilled holes and it is relatively easy to clean and autoclave.

A significant alternative to the single or multiple hole disperser, is the well-known and well-used frit sparger that utilizes porous materials (ceramic, sintered stainless steel, or Teflon) to create an almost unmeasureable amount of very small bubbles within the bioreactor. These bubbles are nearly ideal for gas transfer because of the large interfacial gas–liquid area they provide and the extended time of contact as a result of lower rising velocities of the smaller bubbles. However, disadvantages of these spargers include cleaning difficulty, more stable foam, and reduced CO_2 stripping capability, forcing in some cases the use of both a frit and a large bubble sparger, and the use of antifoaming chemicals (75). The cleaning challenge can be so significant that the authors know of at least one commercial process in which the frit sparger is replaced after every batch. Documenting some of these reported advantages and disadvantages, Nehring *et al*. (80) tested both a stainless steel porous sparger and a porous ceramic (TiO_2) microsparging system for the cultivation of Madin–Darby canine kidney (MDCK) cells from a 2- to 100-L scale. The ceramic system produced bubble diameters of 100–500 μm, and values of $k_L a$ up to 50 h^{-1}, three times higher than those produced by the stainless steel sparger at the same gas flow rate; however, formation of compact, stable foam, and pH problems were observed. Similarly, Chisti (81), found the use of a multihole sparger to be preferable over a porous metal sparger for scale-up of a bioreactor as a result of foaming problems caused by the smaller bubble size generated by the fritted sparger.

38.2.7 CO_2 Accumulation and Removal

Somewhat ironically, as animal cell culture progressed from a research scale to a relatively large-scale commercial process, the addition of oxygen became less of a concern and the removal, and in some cases the initial addition, of CO_2 became more problematic. This results from a number of issues as a consequence of the complex role CO_2 plays in cell culture. Carbon dioxide is a nutrient needed for synthesis of nucleic acid components such as purines and pyrimidines (82); therefore, low levels of this component may inhibit cell growth. Alternatively, CO_2 is also a by-product of aerobic metabolism and high levels of dissolved CO_2 are inhibitory for cells and have been reported to strongly affect cell growth and metabolism (83–85). To further complicate the situation, carbon dioxide forms part

of a complex buffer system given by the next set of equilibrium reactions:

$$CO_{2(g)} \leftrightarrow CO_{2(\text{dissolved})};\ [CO_2]_{\text{dissolved}} = \frac{pCO_2}{\mathcal{H}} \tag{38.8}$$

$$CO_{2(\text{dissolved})} + H_2O \leftrightarrow H_2CO_3;$$

$$K_h = \frac{[H_2CO_3]}{[CO_2]_{\text{dissolved}}} = 1.70 \times 10^{-3} \text{ at } 25^\circ\text{C} \tag{38.9}$$

$$H_2CO_3 \leftrightarrow H^+ + HCO_3^-;$$

$$K_{a1} = \frac{\left[HCO_3^-\right] \cdot \left[H^+\right]}{[H_2CO_3]} = 2.5 \times 10^{-4} \text{ mol/L at } 25^\circ\text{C} \tag{38.10}$$

$$HCO_3^- \leftrightarrow H^+ + CO_3^{2-};$$

$$K_{a2} = \frac{\left[CO_3^{2-}\right] \cdot \left[H^+\right]}{\left[HCO_3^-\right]} = 5.61 \times 10^{-11} \text{ mol/L at } 25^\circ\text{C} \tag{38.11}$$

Since sodium bicarbonate is typically used as a pH buffer in the culture medium, from the previous set of reactions it is easy to deduce that a change in the dissolved CO_2 concentration could lead to a change in the pH through the following relationship

$$\left[H^+\right] = \frac{10^{-14}}{\left[H^+\right]} + \frac{K_h \cdot K_{a1} \cdot pCO_2}{\left[H^+\right] \cdot \mathcal{H}} + 2\frac{\cdot K_{a1} \cdot K_{a2} \cdot pCO_2}{\left[H^+\right]^2 \cdot \mathcal{H}} \approx \sqrt{10^{-14} + \frac{K_h \cdot K_{a1} \cdot pCO_2}{\cdot \mathcal{H}}} \tag{38.12}$$

where pCO_2 is the partial pressure of CO_2 in the exit gas in equilibrium with the medium. A rise of pCO_2 at a controlled pH typically leads to an associated increase in the medium osmolality as a result of both an increased dissolved CO_2 concentration and the addition of a base, such as sodium hydroxide, to maintain a constant pH. The combined influence of high osmolality and pCO_2 might lead to an even more significant change in the metabolism of the cell. Finally, to add a final level of complexity to the situation, CO_2 is much more soluble than O_2, and this CO_2 solubility is sufficiently sensitive to pressure, such that a significant gradient in CO_2 can exist between the top and bottom of a 1000-L, weakly mixed, animal cell culture bioreactor.

Several published examples of the effect of the concentration of dissolved CO_2 on a cell culture exist. Drapeau *et al*. (86) studied the effect of increasing dissolved CO_2 concentration from 53 to 165 mmHg on recombinant CHO cells for the production of human macrophage colony stimulating factor (hM-CSF) in a 2500-L reactor. At the highest pCO_2, the specific cell growth rate decreased by 52% and the specific production rate of hM-CSF dropped by 56% relative to the culture with the lower pCO_2. While the DO and pH were constant and equal in both cultures, it is unclear if the osmolality was kept constant. Gray *et al*. (42) also described an inhibitory effect in CHO cell density and specific production rate with reported reductions of 33% and 44%, respectively, in a system in which pure oxygen microbubbles using a fritted sparger or silicone diffusion aerators were used to transfer oxygen to the culture. Mostafa and Gu (84) also reported a 40% drop in the specific production rate of a therapeutical glycoprotein produced by CHO cells when pCO_2 increased from 68 mmHg in bench-scale (1.5 L) reactors to 179 mmHg in pilot-plant (1000 L) bioreactors. In the last two cases, osmolality was not controlled, so the real cause of the dramatic effects observed is potentially a combination of the effects of increased pCO_2 and osmolality.

To isolate the impact of pCO_2 and osmolality on CHO cell growth, Zhu *et al*. (85) performed experiments in bench-scale bioreactors where they changed only one variable at a time. Raising pCO_2, from 50 to 150 mmHg, under a controlled osmolality of approximately 350 mOsm/kg, resulted in a 9% reduction in specific cell growth rate. Increasing osmolality from 316 to 450 mOsm/kg, resulted in a linear reduction in specific cell growth rate (0.008 h^{-1} per 100 mOsm/kg) of up to 60%. The combined effects of high pCO_2 (140–160 mmHg) and osmolality (400–450 mOsm/kg) caused a 20% drop in viable cell density.

In contrast to CO_2 buildup as a result of low levels of gas-medium exchange, the high rates of aeration in bubble columns or airlift reactors may lead to excessive CO_2 stripping, which can have equally inhibitory effects (87). To solve this problem, the gas for aeration usually includes a certain amount of CO_2 to both keep the pH in a proper value and avoid a reduction of pCO_2 below 40–50 mmHg range, usually considered optimal for animal cell culture (88).

38.3 MIXING

Mixing can be defined as "the operation in which two or more materials (gas, liquid and/or solid) are distributed throughout a mass in varying degrees of uniformity dependent upon the change and state to be accomplished" (89). In animal cell bioreactors, this mixing is typically accomplished by the addition of energy to the broth in the form of mechanical agitation and gas sparging. Ideally, this energy should be delivered to the culture broth in a completely homogenous manner such that any fluid element, or in this case any cell, will experience a similar distribution of

energy in a similar period of time. Also ideally, this energy delivery should be sufficient to distribute both the cells, and molecularly sized nutrients and by-products, in such a manner that no "process effecting concentration gradients" exist in the vessel. The term, *process effecting concentrations*, is used since a concentration gradient is also a time-dependent phenomenon in a dynamic environment such as a bioreactor, and the characteristic time scales need to also be considered. As it will be discussed below, far from ideal situations exist in most animal cell bioreactors.

In general, the hydrodynamic environment experienced by a particular cell in a culture is a function of its spatial position in the interior of the bioreactor, the characteristics of the mixing system, and time. With the exception of fungal and some microbial cultures, the rheological characteristics of the broth do not change dramatically with time, remaining essentially Newtonian and very similar to water. Depending on the final cell concentration and the potential release of nucleic acids into the culture, a slight increase of the viscosity at the end of the culture may become apparent, but typically this is not considered important. However, in spite of the low viscosity, a poor design of the mixing system may lead to catastrophic consequences. If the mixing is not intense enough, cells will settle at the bottom of the reactor creating zones with limitations of mass and energy transfer and unsatisfactory homogeneity, rendering the control systems of the reactor inefficient and ending up with low viability and productivity. Even if the agitation is sufficient to maintain a suspended culture, a number of reports exist of an undermixed commercial animal cell culture process in which significant dissolved CO_2 concentrations exist between the top and the bottom of the bioreactor, and "zones" of relatively unmixed, high-pH "clouds" exist in the vessel after base addition for considerable periods of time. Langheinrich and Nienow (90) measured pH in three different zones of an 8 m^3 bioreactor equipped with a 0.225T Rushton turbine intended for the culture of mammalian cells; they found pH gradients close to one unit between the alkali addition zone and the impeller discharge when addition of the Na_2CO_3 was done on the liquid surface. Ozturk (91) observed "snow-ball" aggregation of mammalian cells, corresponding to alkaline cell lysis, close to the headspace addition point of base in a poorly agitated bioreactor: the concept of an animal cell suspended in a "pool" of pH 9 or 10 is not a desirable thought!

On the other hand, a common concern that is substantiated with little data is that if suspended animal cell cultures are mixed too aggressively in typically designed bioreactors, the hydrodynamic forces experienced by the cells may inhibit cell growth, productivity, or have other undesirable effects. Unfortunately, historically, no universally accepted algorithm or protocol allowing for a fundamentals-based design of mixing systems for animal cell cultures has existed; consequently, an empirical, case-by-case process has typically been conducted at each organization (company) as an animal cell process was scaled up. Also, many of these established processes might be undermixed. While this approach has resulted in a number of organizations having significant "in-house" expertise, well-documented, fundamentally based, peer reviewed scale-up protocols are still lacking. However, a sufficient amount of experimental data is beginning to accumulate, which allows for the development of such scale-up algorithms.

The importance of mixing to animal cell culture is far from unique; in fact, specific professional societies, such as the North American Mixing Forum, are dedicated solely to understanding and optimizing mixing in the chemical process industry. Taken in a proper perspective, the challenge of mixing in animal cell culture is not nearly as complex as mixing in many other industries. Consequently, much can be learned from this community.

38.3.1 Stirred Tank Reactors

As mentioned before, for a number of reasons, not the least of which is the relative simplicity and considerable knowledge/database, the classical stirred tank reactor is the predominate method to culture animal cells from bench-scale up through large-scale, commercial systems. While a complete review of stirred tank bioreactors is beyond the scope of this chapter, a quick summary will be presented. The interested practitioner is encouraged to read more complete discussions on the topic (54,92,93).

38.3.2 Geometry

A typical, stirred tank, animal cell bioreactor is a mixing vessel with an aspect ratio of tank height (H) to tank diameter (T) of approximately (H/T) 2–3 (see Fig. 38.1). This tank is penetrated by a shaft that extends down the center line of the tank; the outside end of this shaft is attached to a motor, while the other end is attached to one or more impellers, which are suspended in the culture broth. Typically, the impeller diameter (D) is about one-third to one-half of the tank diameter. The tank is filled with broth up to a height (H_L) of $\sim 0.7\ H$. The off-bottom clearance (C), is usually around $\sim 0.1–0.3\ T$. In the case of multiple-impeller systems, the separation between impellers (ΔC) is highly variable as it will be discussed next, but normally is set around one impeller diameter.

38.3.3 Impeller

A number of different impeller designs exist and are used (see Fig. 38.2), ranging from radial-flow impellers such as the traditional Rushton turbine (RT) used extensively in the

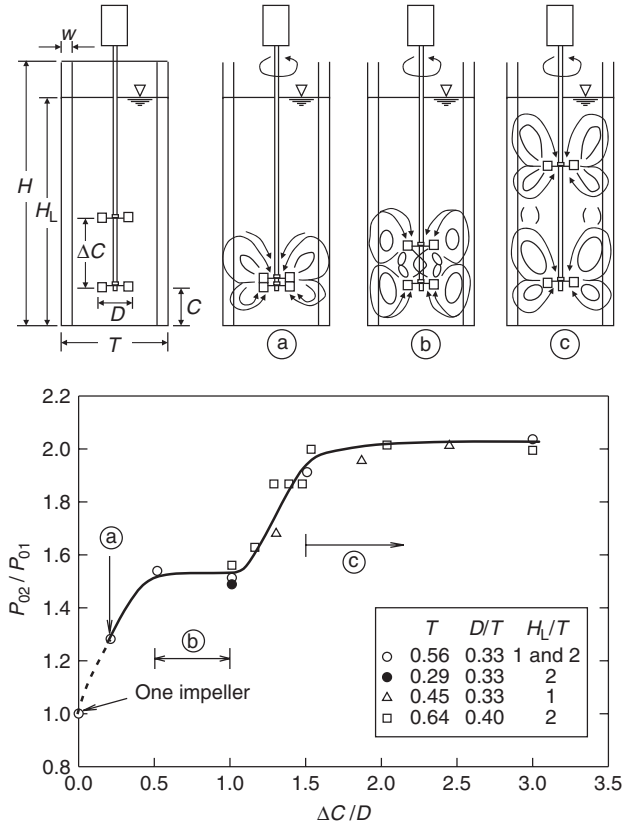

Figure 38.1. Geometrical configuration, flow patterns, and total nongassed power drawn into the liquid as a function of impeller spacing for a mixing system with multiple Rushton turbines. [Adapted from Hudcova *et al*. (94).]

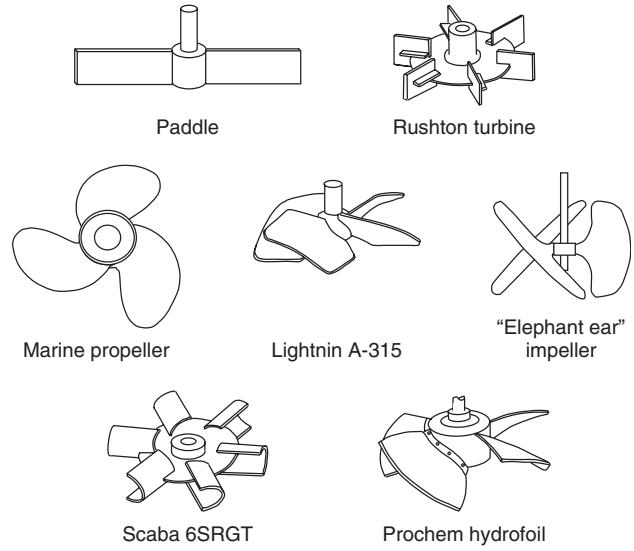

Figure 38.2. Impeller configurations commonly employed in animal cell culture.

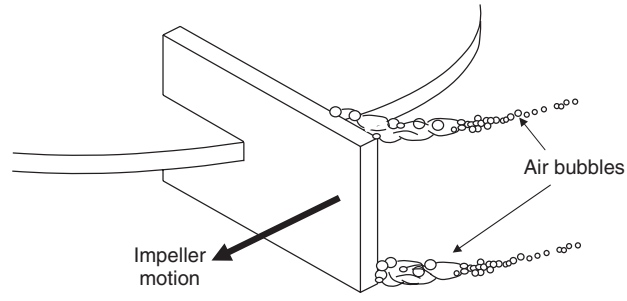

Figure 38.3. Regions of highest shear rate and highest energy dissipation rate; behind the blades of a Rushton turbine.

mixing community to provide a high level of intense mixing by way of a high local shear rates, to axial-flow impellers like the marine propeller, which provide better bulk movement of the broth, relative to the Rushton. Impeller selection is based on a series of considerations including its power number (P_0) and its pumping number (Nq). Impellers with larger ratio Nq/P_0 are superior in producing better bulk mixing at lower shear rates. At the same average energy per unit volume drawn into the liquid, $(\overline{\varepsilon}_T)_{Ig}$, impellers with a larger diameter have a higher pumping capacity, and therefore, may have a better mixing performance. Impeller designs generating lower shear rates are thought to be superior in reducing alleged cell damage as a result of hydrodynamic forces. In this sense, hydrofoils are superior to pitched blade turbines (PBTs) and PBTs are superior to Rushton turbines (29). Chen *et al*. (95) presented a novel methodology to evaluate impellers based on dinoflagellates: when stimulated by hydrodynamic forces, these organisms generate light. At speeds corresponding to the same oxygen transfer coefficient, a Rushton turbine (150 rpm) generated a much higher luminescence (~20,000 counts in 10 ms) compared to marine propellers (170 rpm; ~2000 counts in 10 ms) indicating that much higher forces are created in the bioreactor with the former impeller.

In nongassed conditions, the power drawn by an impeller is a function of Reynolds number, impeller type, and its geometry. For impeller Reynolds numbers over 10^4 (normal conditions in culture), the power number becomes independent of Reynolds and depends only on variables such as blade angle, number and width, baffle number and width, and clearance ratio (C/D).

Equation 38.7 governs the power drawn by a single impeller under gassed conditions. In such circumstances, the gas reaching the impeller is driven to the back of the blades (see Fig. 38.3) of the impeller, generating air cavities that are stabilized by the lower pressure in such zones and reduce the amount of power the liquid is able to transmit to the broth; depending on the amount of gas, the size of such cavities may grow to a point where they surround the whole impeller; this phenomena is known as *flooding*, and reduces drastically the amount of power the impeller is able to draw

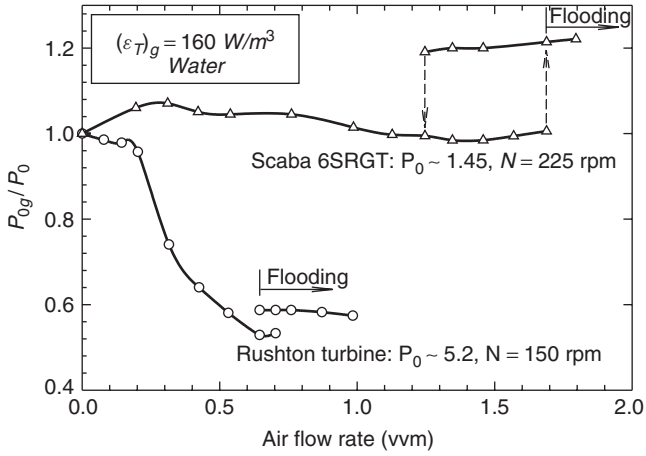

Figure 38.4. Effect of the gas flow rate on the power drop under gassed conditions for two impeller geometries in Newtonian, water-like fluids. [Adapted from Galindo and Nienow (96).]

into the liquid, because now the impeller is practically rotating in air. Characteristic curves of P_{0g}/P_0 are presented in Fig. 38.4; observe that impellers like the Scaba, are much less prone to flooding than the Rushton turbine and the reduction in power drawn is limited or nonexistent as a result of their design.

When the tank is sufficiently large, multiple impellers can be attached to a single shaft, with the potential to use a combination of impellers (i.e. both a Rushton and a marine type) to improve the mixing performance. Under nonsparged conditions, the power drawn into the liquid by the different impellers depends on the distance between them. Hudcova *et al*. (94) established that in the case of Newtonian, low-viscosity media, the power drawn in nongassed conditions by two Rushton turbines is maximized when the impellers are placed apart by a minimum ~1.8 times the impeller diameter. At this distance, the flow patterns generated by each impeller do not significantly interfere with each other (see Fig. 38.1); consequently, the total power drawn into the system is simply the sum of the power drawn by each impeller. Similar results were obtained by Machon *et al*. (97) for a diversity of combinations of impellers. Under gassed conditions, however, there is an uneven distribution of the gas between the impellers: the lower impeller draws less power than the upper one and usually works as a gas disperser. A similar behavior (uneven power drawn) is observed when the separation of the impellers is increased until a maximum is reached when the impellers are apart by a distance greater than $2D$; in this situation, the prediction of the total power drawn into the liquid is much more complex. Correlations proposed by Cui *et al*. (98) to calculate the power drawn by individual impellers in gassed systems with multiple (one to three) Rushton turbines are presented in Table 38.6. Linek *et al*. (99) also developed gassed power correlations for a system with four Rushton turbines; the interested reader is advised to consult their work.

38.3.4 Baffles

To further improve the effectiveness of the impeller, baffles are used, typically up to four, in which case they are placed perpendicular to the tank wall at 90° increments around the vessel. The width of the baffles influences the power drawn into the liquid, and therefore, the mixing performance (Fig. 38.5). A typical width of the baffle is on the order of 10% of the tank diameter.

38.3.5 Mixing Times and Energy Dissipation Rates

Many bioreactors have been designed assuming that cells have a high "shear sensitivity," which translates into suboptimum mixing performance and a corresponding lack of homogeneity. In turbulent systems under nongassed conditions, the time required for mixing the content of a bioreactor up to a certain degree of homogeneity (usually 95% of the final response), which is referred to as the *mixing time*, θ_m, is independent of the impeller type, and can be related to design and operational parameters by the next set of equations (29):

$$\theta_m = 5.3 \cdot \left[N^{-1} \cdot P_0^{-(1/3)} \cdot (T/D)^2 \right] \quad \text{for } H_L/T = 1 \tag{38.13}$$

$$\theta_m = 3.3 \cdot \left[N^{-1} \cdot P_0^{-(1/3)} \cdot (T/D)^{2.43} \right] \quad \text{for } H_L/T > 1 \tag{38.14}$$

TABLE 38.6. Correlations Derived by Cui *et al*. (98) for Power Drawn in Systems with Multiple Rushton Impellers

Condition	Impeller	Equation	Mean Deviation
$Q \cdot N^{0.25} \cdot D^{-2} \leq 0.055$	Bottom	$1 - P_{0g}/P_0 = 9.9 \cdot \left(Q \cdot N^{0.25} \cdot D^{-2}\right)$	<6%
$Q \cdot N^{0.25} \cdot D^{-2} > 0.055$	Bottom	$1 - P_{0g}/P_0 = 0.52 + 0.62 \cdot \left(Q \cdot N^{0.25} \cdot D^{-2}\right)$	<6%
$Q \cdot N \leq 0.013$	Middle and Top	$1 - P_{0g}/P_0 = 37.6 \cdot (Q \cdot N)$	2.3%
$Q \cdot N > 0.013$	Middle and Top	$1 - P_{0g}/P_0 = 0.375 + 8 \cdot (Q \cdot N)$	1.4%

Q: gas flow rate (cubic meters per second); N: impeller rotational speed (s^{-1}). Conditions for correlated data: $0.238 < T < 1.83$ m; 1–3 impellers; $0.92 < N < 10\ s^{-1}$; $D/T = 1/3$–$1/2$; $Fl = 0$–0.26

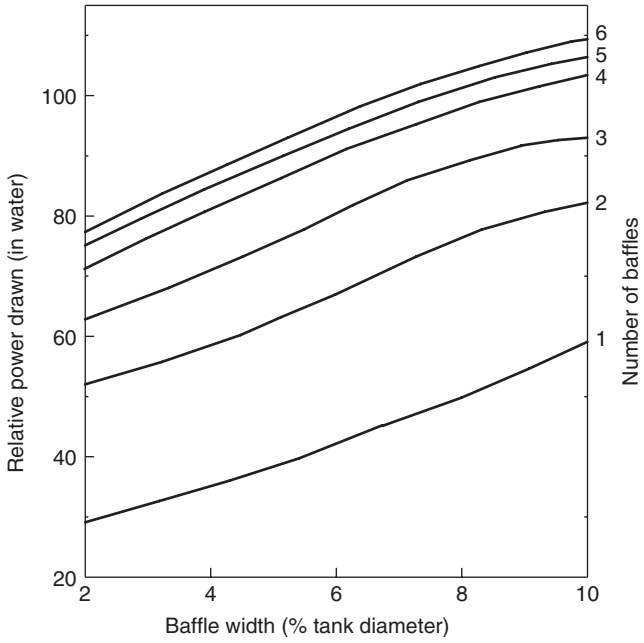

Figure 38.5. Effect of the number and size of the baffles on the power drawn by an impeller in a cylindrical stirred tank reactor. [Adapted from Oldshue (92).]

where θ_m will be in the units of the inverse of the impeller rotational speed. Equation 38.13 correlates very closely for a wide variety of impellers with an almost identical equation derived by Kresta *et al*. (100), except the coefficient changes from 5.3 to 5.8. For clarity purposes, Equation 38.13 can be rearranged by assuming a cylindrical tank $\left(V_R = (\pi/4) \cdot T^2 \cdot H_L\right)$ and using Equation 38.7 to give

$$\theta_m = 57.4 \cdot (T/D)^{(1/3)} \cdot \left[(\overline{\varepsilon}_T)_g\right]^{-(1/3)} \cdot T^{2/3} \text{ for } H_L/T = 1 \tag{38.15}$$

where θ_m will be in seconds and the remaining variables are in SI units. For the derivation of Equation 38.15, it was assumed that the density of the fluid is very close to that of water (1000 kg/m^3), and that usual gas flow rates are so low in animal cell culture that $P_{0g} \approx P_0$ and $(\overline{\varepsilon}_T)_g \approx (\overline{\varepsilon}_T)_{Ig}$. Equation 38.15 is identical to that obtained by Nienow (101) and indicates that during scale-up (increase of T) for geometrically similar tanks (*T/D* constant), the mixing time can be kept constant only if the power input per unit volume is increased. In contrast, the concern of potential hydrodynamic cell damage has resulted in many (a majority?) of large-scale animal cell bioreactors designed with power per unit volume significantly decreased relative to laboratory-scale vessels.

One concept commonly used in the mixing industry is the EDR, which has units of power per unit volume (i.e. watts per cubic meter). On a bulk or average basis, this is a very appealing parameter, since the average total EDR, $(\overline{\varepsilon}_T)_g$, is just the rate of energy added to the system divided by the volume where the energy is delivered. From a fundamental point of view, the *EDR*, ε, can be determined using the following first principle equation (102,103):

$$\varepsilon \equiv \tau : \nabla U \tag{38.16}$$

where τ is the stress tensor and ∇U is the velocity gradient tensor. For an incompressible Newtonian fluid, Equation 38.16 becomes (103)

$$\varepsilon \equiv \tau : \nabla U = \mu \left[\nabla U + (\nabla U)^T\right] : \nabla \mathrm{U} = \mu \sum_i \sum_{\mathrm{j}} \left[\nabla U + (\nabla U)^T\right]_{ij} \nabla U_{ji} \tag{38.17}$$

In Equation 38.17, μ is the viscosity of the medium, ∇U^{T} is the transpose of ∇U, and ∇U is the gradient of the velocity vector given by:

$$\nabla U = \begin{bmatrix} \frac{\partial U_x}{\partial x} & \frac{\partial U_y}{\partial x} & \frac{\partial U_z}{\partial x} \\ \frac{\partial U_x}{\partial y} & \frac{\partial U_y}{\partial y} & \frac{\partial U_z}{\partial y} \\ \frac{\partial U_x}{\partial z} & \frac{\partial U_y}{\partial z} & \frac{\partial U_z}{\partial z} \end{bmatrix} \tag{38.18}$$

Equation 38.16 can be derived from first principles using the second law of thermodynamics. More specifically, Equation 38.16 emerges from the loss term in the energy balance equation. Much like the Navier–Stokes equation, Equation 38.16 is valid for any flow regime, be it laminar, transitional, or fully turbulent.

It is this dual nature, a pragmatic value (the power of the mixing motor turning the impeller shaft going into the bioreactor divided by the number of liters in the vessel) and the fundamental, first principle definition, that has lead to the use of EDR to characterize the flow conditions acting on cells for over 30 years (104), and has been extensively used in the fluid mechanical/mixing community for even longer (105).

As it might be imagined, but not typically fully appreciated, the flow in a stirred tank reactor is highly inhomogeneous. Qualitatively, this was demonstrated in the 1970s, visually, by demonstrating that very strong vortices emanate from the tips of the impeller blades; such vortices are responsible, for example, for gas dispersion in the impeller blades (Fig. 38.3). These qualitative observations have been quantified by experimental studies, using a variety of experimental techniques to demonstrate that the local EDR in the impeller region, and specifically in these vortices, has been reported to be over 103 times

higher than the local EDR in the bulk fluid away from the impeller (106–109).

Given the importance that high, local EDR levels have on rapid, molecular mixing, Zhou and Kresta (108,110) conducted a significant number of quantitative studies on the maximum and distribution of EDR as a function of a number of variables in stirred tank vessels, including tank volume, impeller type, and impeller rotational speed (rpm). These studies were, in general, consistent with other published studies. Several important conclusions that are relevant to animal cell bioreactors can be made:

1. The EDR is always high in the *impeller discharge stream*. Specifically, 43.5% of mechanical energy added to the vessels is dissipated in the impeller discharge region of a Rushton turbine, which represents only about 10% of the volume of the tank. In contrast, for the PBT, 70.5% of the energy is dissipated in the larger impeller discharge region. In addition, the "average" EDR is over an order of magnitude higher in the impeller region when compared to bulk average for the whole vessel.
2. For a given impeller type, the *maximum*, *local EDR* in the impeller region can be approximated using a nondimensional constant and to a specific, nondimensional location relative to the impeller. This nondimensional constant, ψ, is given by:

$$\psi = \varepsilon_{max}/\rho \cdot N^3 \cdot D^2 \qquad (38.19)$$

3. where D is the impeller diameter and N is the impeller speed with units of s^{-1}. If specific geometric ratios are held constant (including the type of impeller), it has been shown that ψ did not vary significantly over a large range of impeller speeds (108,110). If the *D/T* (impeller diameter/vessel diameter) or *C/T* (off-bottom clearance/vessel diameter) ratio changed, within certain limits, up to a 46% increase in the value of ψ was observed when working with an RT. These observations also held for the PBT impeller.

Using this relationship for the maximum EDR in a stirred tank vessel, along with the classical P_0 and P_{0g}, one can approximate the mean and the maximum local EDR as one scales the stirred tank mixing, keeping the H_L/T, D/T, and *C/T* ratios nearly the same and using the same type of impeller. Figures 38.6–38.8 present predictions of vessel size and dimensions, maximum local EDR, and average EDR. Specifically, Fig. 38.6 presents the change in the tank diameter and impeller diameter as the volume of the vessel increases from 0.5 to 10,000 L, keeping geometrical ratios constant. Figure 38.7 presents lines of constant, maximum EDR as a function of RPM and impeller diameter, and

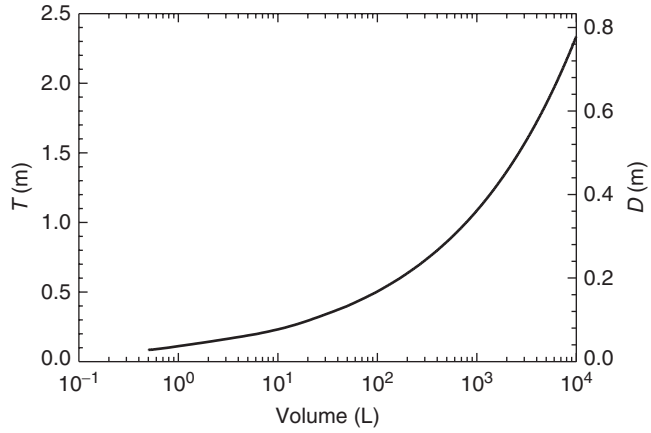

Figure 38.6. Change in the tank diameter and impeller diameter as the volume of the vessel increases from 0.5 to 10,000 L keeping constant the geometrical ratios $H/T = 1$ and $T/D = 3$.

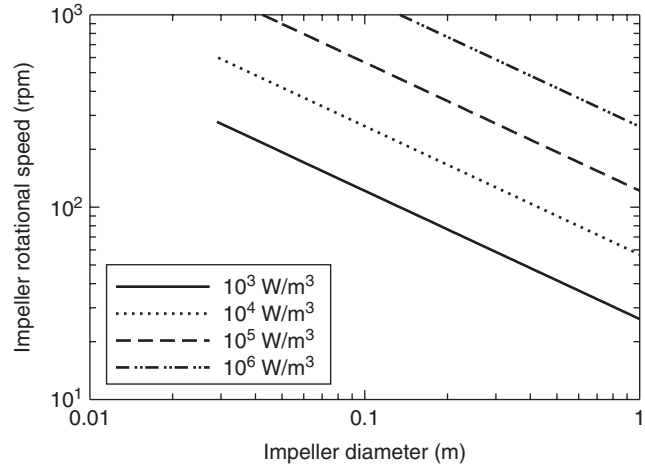

Figure 38.7. Lines of constant, maximum EDR in a vessel as a function of impeller rotational speed and diameter for Rushton turbine in water. $H/T = 1$ and $T/D = 3$.

Fig. 38.8 presents the average EDR for the whole vessel as a function of impeller diameter and RPM.

Alternatively, Fig. 38.9 presents the mean and the maximum EDR, calculated respectively with the power number (Eq. 38.7) and the maximum EDR relationship (Eq. 38.19, using a value of $\psi = 13.7$), as a function of impeller rotational speed. This plot corresponds specifically to a 2-L Applikon® bioreactor, which was mixed with a standard Rushton turbine impeller. The circle and square data points correspond to specific values of EDR measured with a particle tracking technology (109).

While all of this discussion on EDR is helpful, a significant question should be raised with respect to how EDR relates to cells. This will be addressed in the next section.

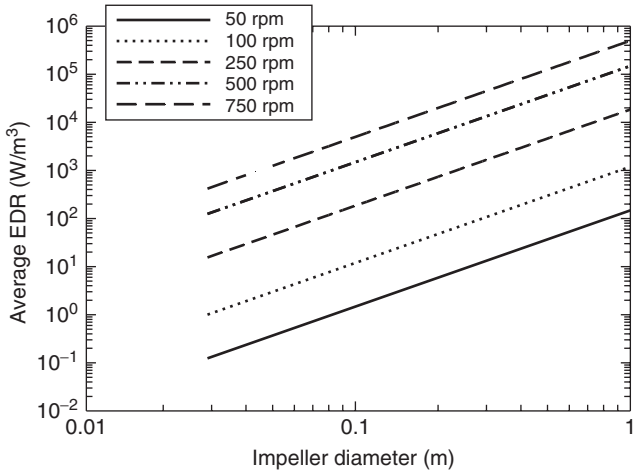

Figure 38.8. Average EDR for the whole vessel as a function of impeller diameter and RPM using a Rushton turbine in water. $H/T = 1$ and $T/D = 3$.

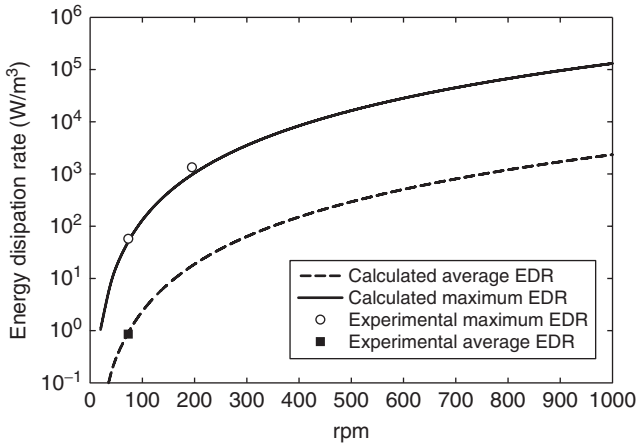

Figure 38.9. Calculated maximum and average energy dissipation rate as a function of RPM for an Applikon bioreactor containing four baffles. The single points correspond to experimental measurements without baffles. [Adapted from Mollet *et al*. (109).]

38.4 THE RELATIONSHIP OF ANIMAL CELLS TO HYDRODYNAMIC FORCES

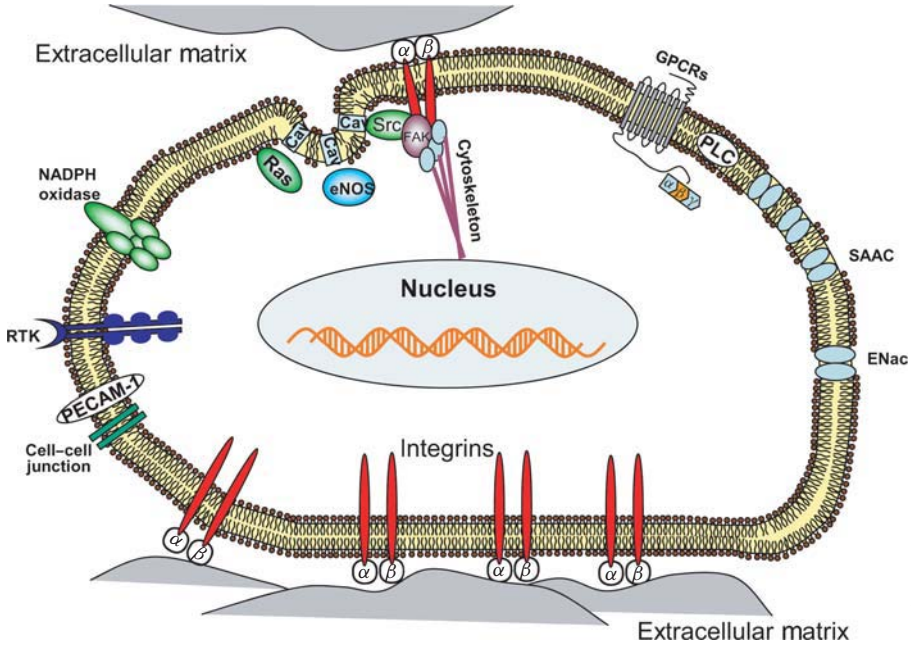
Historically, there is probably no subject in animal cell culture cultivation that is more misunderstood and misquoted as being a "major limitation" to large-scale animal cell culture than the "shear sensitivity" of the cells. This misunderstanding, at least partially, arose from early reports (111,112), whose significance will be discussed later on. It also seems logical to think that a sufficiently intense force could disrupt the integrity of the cell membrane, causing cell death, especially, when animal cells lack a "cell wall" compared to robust bacteria. To further reinforce this perception, there are clear, well-established studies, which demonstrate almost complete cell destruction as a result of purely hydrodynamic forces and forces associated with gas sparging.

This misunderstanding has had a negative impact on the field in the past, and its legacy continues to this day in both the perception of many cell culturists, as well as in the under mixed, large-scale animal cell culture bioreactors that are currently in operation in many facilities. To begin establishing some structure to the notion of the "shear sensitivity" of animal cells, a number of concepts need to be further defined and/or refined:

1. The term *shear stress* is misleading. In reality, except for specific studies in specifically designed vessels, at the most fundamental level, cells are subjected to time varying shear and elongational forces in typical bioprocessing equipment. In addition, it has been argued that elongational forces might be more damaging to cells than shear forces (113).
2. There is a big difference between the hydrodynamic forces needed to create lethal or nonlethal effects on a cell attached to a surface relative to a cell in free suspension. This difference will be quantified below.
3. There is a big difference in the potential to damage cells when gas–medium interfaces are present relative to their absence, and this is especially true when protective surfactants are not present. This also will be discussed later on.
4. The sensitivity of animal cells to hydrodynamic forces can vary from one cell line to another and even within different clones of the same cell line; however, these differences have not been documented to prevent most cells of commercial interest to be cultured in bioreactors.
5. Because of the complexity of hydrodynamics, and especially under turbulent conditions, fundamental, first principle, mathematical models describing the hydrodynamic forces operating on cells in most bioprocessing equipment do not exist and probably never will. Consequently, we are left with continually improving empirical models and experimental studies that allow us to develop reasonable scale-up methodologies.

With this introduction, what is known on the effect of hydrodynamic forces on cells, both attached and in free suspension, as well as a scale-up methodology will be presented next.

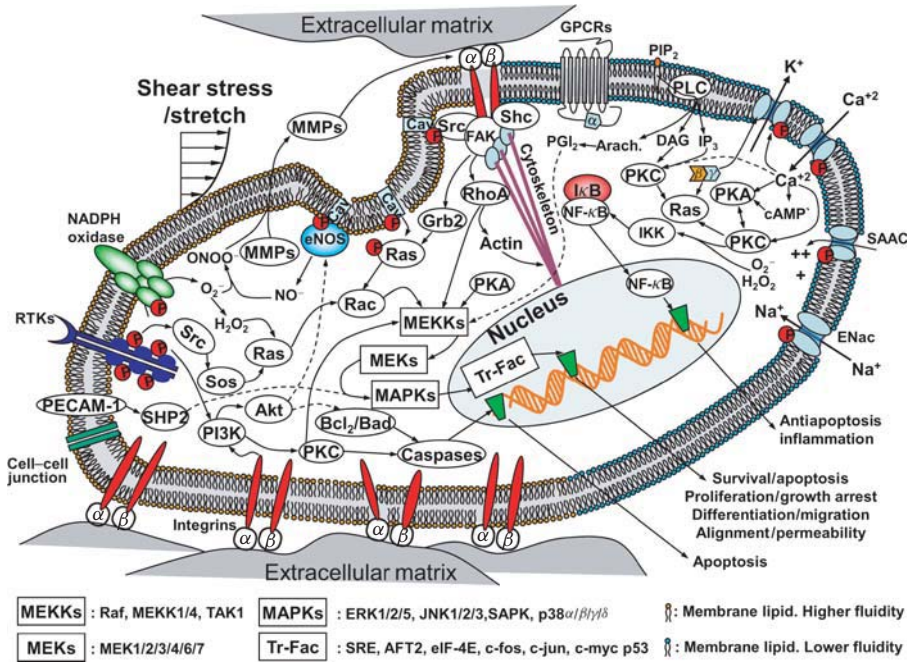
38.4.1 Molecular Mechanism Involved in the Response of Animal Cells to Mechanical Forces



Liquid–cell interactions resulting from fluid flow have been extensively studied, predominately with cells that normally experience fluid flow, such as endothelial cells (ECs). Particularly interesting are models of the interactions of fluid forces with EC and their subsequent response to small changes of shear stress in laminar flow. Related to the EC response is that of smooth muscle cells (SMCs) to cyclic stretch resulting from the pulsatile nature of blood flow. These studies provide models to begin understanding the physiological responses to mechanical forces inside the human and animal circulatory and respiratory systems. While it is challenging to extrapolate the results from experiments with EC/SMC cells in laminar flow chambers to non-EC/SMC cells in the much more complex nature of turbulent flow in bioreactors, the significant, nonlethal effects of hydrodynamic forces provide insight into potential mechanisms and responses to investigate.

Several excellent reviews, including those of Malek and Izumo (114), Li *et al*. (115), Lehoux *et al*. (116), Tzima (117), Li and Xu (118), Chien (119) and Haga *et al*. (120), document what is known about the response of vascular endothelial and SMCs to sublethal hydrodynamic forces. One of the hallmarks of the EC response appears to be the rearrangement of the cell's cytoskeleton under the influence of fluid flow (121). The cytoskeleton is a three-dimensional intracellular network of several different types of protein filaments (i.e. actin) that determines the shape, mechanical properties, and movements of the cell. The filaments interplay closely with the cellular and nuclear membranes by anchoring to specific membrane proteins. When the cell is exposed to mechanical forces, the cytoskeleton attempts to resist them and undergoes deformation, especially if the cell is attached to a solid surface. Such deformation implies spatial reorganization of the cytoskeletal lattice; it is presumed that this reorganization is able to transmit the mechanical force along the whole cytoplasm to the nucleus. This mechanism suggests that the deformation of the cell brings together different cell components (i.e. proteins, enzymes, transcription factors and nucleic acids) in both the cytoplasm and the nucleus, originating a cascade of reactions that may lead to a wide diversity of cell responses.

A second proposed mechanism that allows cells to respond to fluid flow involves molecules at the luminal cell surface since they are in direct contact with the fluid. These molecules can be activated by direct conformational change as a result of flow (i.e. rupture or formation of disulfide bonds or bending/stretching of protein domains) or indirectly through mass transfer gradients. Such molecules include the following (115):



1. *Integrins.* These are a family of more than 20 transmembrane heterodimers normally connected to specific extracellular ligands such as fibronectin, vitronectin, and collagen. After the onset of flow, the integrin activation starts within 1 min and lasts for more than 6 h, originating an intracellular cascade involving kinases and cytoskeletal proteins.
2. *Ion channels.* Shear stress increases Ca^{+2} influx; higher Ca^{+2} concentration can lead to multiple Ca^{2+}-dependent cellular responses, including regulation of other channels (Cl^- and K^+). The response of this receptor is fast (within a minute) but subsides ~5 min after the beginning of the stress.
3. *Receptor Tyrosine Kinases.* These are a series of surface proteins (like Flk-1) transiently activated by shear stress, resulting in their oligomerization, tyrosine phosphorylation, association with other proteins (i.e. Shc), and a series of consequent gene transcription events.
4. *GPCRs and G Proteins.* G proteins are activated within 1 s after the onset of shear stress and they are involved in shear-induced Ras-GTPase activity that serves as molecular switches for a variety of cellular signaling events.
5. *PECAM-1.* Shear stress causes the transient phosphorylation of PECAM-1 within 1 min, a glycoprotein expressed in EC, platelets, and leucocytes that plays an important role in leucocyte aggregation and EC–leukocyte interaction.
6. *Membrane Lipid Bilayer.* Application of shear stress to EC cells causes an immediate (<10 s) increase in the fluidity of their membrane lipid bilayer in the upstream direction followed by a secondary, larger increase reaching a peak at 7 min. Alternatively, the fluidity of the membrane is reduced on the downstream side of the cell, indicating that the EC membrane lipid bilayer can sense the applied shear stress with spatial discrimination.

After sensing mechanical forces, the transduction of shear stress to the interior of the cell ends up in a series of fast signaling cascades that include opening of K^+ and Ca^{+2} channels, activation of heterotrimeric G proteins, production of NO^-, tyrosine phosphorylation of proteins such as Shc, c-src, and focal adhesion kinase (FAK), activation of mitogen-activated protein kinase (MAPK), protein kinase C (PKC), and C-Jun-*N*-terminal kinase (JNK), release of ROS, and activation of transcriptional regulators such as c-fos, c-jun, c-myc, and nuclear factor (NF)-κB. Slower responses include increased expression of genes for intercellular cell adhesion molecule (ICAM)-1, nitric oxide synthetase (NOS), platelet-derived growth factor (PDGF), tissue factor, transforming growth factor

(TGF)-β, and monocyte chemoattractant protein (MCP)-1 and decreased expression of the vasoconstrictor endothelin 1 (Et-1) (117). Figure 38.10a and b describe the signaling cascade in EC/SMC that ends up in effects such as increased gene expression, proliferation or apoptosis, cell migration and alignment, increased cell membrane permeability, and changes in the mechanical properties of the cell.

While these results are interesting from a molecular biology point of view, few of these observations have been confirmed in suspended cells of biotechnological interest.

However, they do provide potential responses and mechanisms to investigate.

38.4.2 Cell Damage Mechanisms

The ambiguity in defining the concept of cell damage may arise owing to the fact that conditions that generate biological responses in cells may not be the same that generate negative effects on the process from the point of view of yield or productivity. Consider, for example, the culture of murine neural stem cells (NSCs) in 125-mL spinner flasks (122). Obviously, NSCs are not selected in nature to stand hydrodynamical forces as they grow in still environments and we might anticipate that increased hydrodynamical forces could affect cells' behavior. However, Fig. 38.11 shows that increasing agitation rate (starting from static culture in T-flask) increases significantly the number of viable cells, probably as a result of improved mass transfer and control of environmental variables inside the spinner; at the same time, viability is notoriously increased at higher stirring speeds and the mean diameter of aggregates is reduced, which translates into avoiding limiting conditions (specially oxygen) in the core of aggregates that could conduce to apoptosis or necrosis. The combined effect of an improved mass transfer and a decreased resistance to the transport of nutrients to every cell overcomes any negative effect of cellular damage that may exist, resulting in an increment of cell productivity. Quite similar results were obtained by Moreira *et al*. (70) for BHK cells grown as suspended natural aggregates, where again the maximum stirrer speed evaluated was 100 rpm.

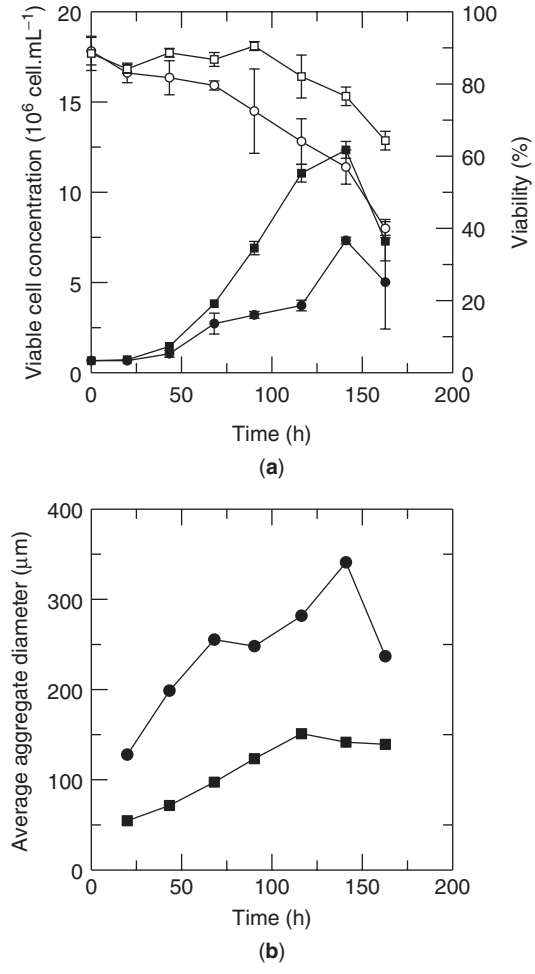

Figure 38.11. Effect of agitation rate on cell concentration, viability, and aggregate diameter of murine NSC, in batch suspension in a 125-mL spinner flask. Data points are average of duplicate runs. (a) Cell concentration: (●) 60 rpm; (■) 100 rpm. Viability: (○) 60 rpm; (□) 100 rpm. (b) Average aggregate diameter:(●) 60 rpm; (■) 100 rpm. [Adapted from Sen *et al*. (122).]

On the other hand, several reports indicate that highly stirred environments can *per se* affect viability of suspended mammalian cell cultures. As an example, Hirtenstein and Clark (123) showed that while agitation has a beneficial effect in the growth of Vero cells on microcarriers in spinner vessels, a further increase in stirrer speed after the optimum level dramatically affects the cell concentration in the system (see Fig. 38.12). Similarly, Kunas and Papoutsakis (124) reported that stirrer speeds above 700 rpm reduced the cells' viability on cultures of suspended hybridoma CRL-8018 when no bubbles are present, while not damage was seen at speeds less than 600 rpm. To further add complexity to the observations, Venkat *et al*. (125) and Croughan *et al*. (126) reported that 150–210 rpm in spinner vessels can result in significant damage to CHO cells attached to microcarriers.

From the two previous paragraphs the obvious conclusion is the existence of a maximum threshold of stirring speed beyond which stresses from hydrodynamic

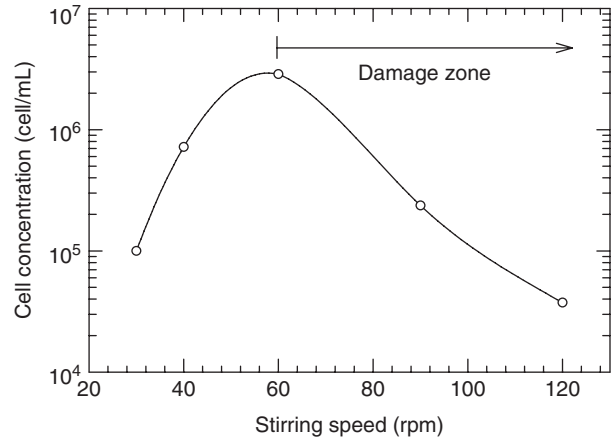

Figure 38.12. Effect of stirring speed on cell concentration after 7 days of culture of Vero cells on Cytodex microcarriers on 250-mL spinner vessels. [Data from Hirtenstein and Clark (123).]

forces can cause detrimental effects. However, how stirring speed relates to more fundamental properties of the fluid, the flow, and the cells remains more of an experimental exercise than a theoretically one. For practical purposes, detrimental effects can extend beyond conditions causing cell death (reduced viability, increased necrosis or apoptosis) to poorer product quality or lower productivity as compared with an appropriate control.

Reports detailing cell hydrodynamical damage or death are abundant; the first reports appeared simultaneously with early attempts to scale-up cultures of mammalian cells (111,112). Augenstein *et al*. (127) passed cultures of HeLa S3 and mouse L929 through capillary tubes of different diameters. Cell death occurred during the residence time of cells in the capillary and it could be correlated to average wall shear stress (10–200 N/m^2) as well as the power dissipated. Midler and Finn (128) reported that damage to shear-sensitive protozoa cells in a uniform shear device showed a two-phase behavior: a rapid primary damage followed by a slow decline of viable cells. This indicates that not only the magnitude of the hydrodynamic force, but also the exposure time should be taken into account when considering cell damage.

A diversity of methodologies has been used in the literature to assess the effects of mechanical forces on cells; the most representative are presented in the Table 38.7. Rheometers and parallel-plates laminar flow chambers have been often used to study cell sensitivity to shear stress, as the stress tensor can be defined with great precision and can be kept constant for long periods in those devices; Joshi *et al*. (129) present an extensive review of the use of rheometers on animal cells and outline a number of limitations of these devices, including

- Limited or null oxygenation capacity restricts experiments to short periods.
- Settling of cells forces continuous mixing and also restricts experiments to short intervals.
- Normal stresses (i.e. extensional flow) can not be applied to cells, even though it has been suggested that they can be as harmful or even more damaging to cells than shear (113,144,152).
- Hydrodynamic stress fluctuations, normally found in turbulent flows, may be even more damaging that steady shear stresses. Although laminar flow chambers are suitable to apply such fluctuations, the ability of rheometers to exert them is limited.
- It is difficult to apply the results obtained within these devices to figure out proper conditions for the cells inside bioreactors, given the much greater complexity of the turbulent flow and the wide range of hydrodynamic forces that a single cell may experience along the culture time.

Because of the previous limitations, studies performed in stirred tanks are often preferred from a design point of view (see Table 38.7). Unfortunately, the wide diversity of geometrical configuration of bioreactors and bioprocess equipment, and the corresponding conditions used for such studies makes it difficult to also translate the results from these studies to other systems. For that reason, authors normally resort to try to explain their results based on a series of parameters, some of them based on fluid-dynamics theory, some of them strictly empiric. Some of those parameters are presented in Table 38.8 and a rationalization for their use will be presented in the next section.

Harmful effects other than cell lysis or death caused by hydrodynamic forces are often referred to as *sublethal*;

TABLE 38.8. Some Parameters Reported in Literature to Correlate the Effect of Hydrodynamical Forces on Cells

Parameter	Definition	References
Agitation rate	N	Kunas and Papoutsakis (124); Moreira *et al*. (70)
Impeller tip speed	$\pi N D$	Middler and Finn (128); Croughan *et al*. (126)
Mean power input	$\overline{\varepsilon} = \frac{P}{V} = \frac{N_p \rho N^3 D^5}{V}$	Ujcová *et al*. (153)
Integrated shear factor	$\mathrm{ISF} = \frac{2\pi N D}{T - D}$	Sinskey *et al*. (154); Croughan *et al*. (126); Chen *et al*. (95)
Volumetric integrated shear factor	$\mathrm{VISF} = \frac{2\pi N D}{T - D}\left(\frac{V_s}{V}\right)$	Chen *et al*. (95)
Kolmogorov eddy size	$\eta = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4}$	Croughan *et al*. (126); Croughan *et al*. (155); Cherry and Papoutsakis (156); Oh *et al*. (20)

Shear stress tensor	τ	Keane *et al*. (143)
Turbulent collision severity	$\mathrm{TCS} = (\varepsilon\nu)^{3/4}\left(\frac{\pi^2 \cdot \rho_b \cdot \alpha \cdot d_b}{72}\right)$	Cherry and Papoutsakis (156)
Impeller collision severity	$\mathrm{ICS} = \left(\frac{9\pi^4 \cdot \rho_b \cdot n_b \cdot n^3 \alpha \cdot D \cdot d_b^4}{512 \cdot V}\right)$	Cherry and Papoutsakis (156)
Energy dissipation-circulation function	$EDCF = \frac{\varepsilon}{t_c}$	Jüsten *et al*. (157); Rocha-Valadez *et al*. (158)

studies focusing on sublethal effects in bioprocessing equipment have been limited and sometimes contradictory. Al-Rubeai *et al*. (159) found increased glucose consumption and mitochondrial activity under intense agitation and in the absence of air bubbles. Al-Rubeai *et al*. (160) also reported that in addition to cell death under conditions of intensive agitation (1500 rpm), sublethal effects included lost of microvilli on the cell's surface and changes in cycle distribution of the cell population. Al-Rubeai *et al*. (161) and Lakhotia *et al*. (162) reported changes in DNA synthesis rate at sublethal conditions; in contrast, Passini and Goochee (163) did not find any effect. Mufti and Shuler (164) observed that human hepatoma cells attached to microcarriers and grown in 50 mL spinners responded to moderate levels of agitation by inducing a cytochrome P450 monooxygenase (CYP1A1) activity; CYP1A1 is involved in the oxidation of arachidonic acid, a substance whose metabolism has been observed to be altered by hydrodynamic stress in ECs cultured in parallel-plate flow chambers (165).

38.4.3 Quantification of Cell Damage

The often contradictory nature of sublethal hydrodynamic effects may be the result of the combination of mechanism classified within the same category. As an example, cells growing attached to a surface (surface culture or microcarriers) could experience similar nonlethal effects as those described for ECs; however, cells growing freely in suspended culture are less likely to exhibit these effects since the cells now are free to rotate, reducing considerably the deformation of the cytoskeleton and varying continuously the surface exposed to the hydrodynamic forces. Consistent with this concept, Ma *et al*. (145) experimentally demonstrated that CHO cells in suspension are four to five orders of magnitude less sensitive to rupture as result of the same level of EDR, than CHO cells attached to 200 μm microcarriers. Cherry and Papoutsakis (156,166) invoked collision between microcarriers and solid parts of the bioreactor (impeller and walls) as the main factors behind the increased sensitivity of cells growing in microcarriers; as a logical consequence, new parameters (turbulence collision

severity and impeller collision severity) were proposed by the authors to correlate cell damage, parameters that can not be used properly in freely suspended cells as the inertia of free cells is much lower than that of microcarriers.

The core of the challenge to develop methodologies and parameters to assess cell damage is threefold. First, the difficulty to relate results obtained with laminar flow devices with those results obtained at the turbulent conditions prevalent in industrial bioreactors as a result of our inability to properly characterize and quantify the bulk and local hydrodynamic in the vessel; second, the lack of a biological model explaining how the cells are affected by hydrodynamic forces and how that effect changes depending on characteristics such as cell type, age, and mode of growth (i.e. anchorage dependent or suspended). Third, the lack of a relationship or mathematical model relating the first two points; such relationship should link the lethal and sublethal effects of hydrodynamic forces to both a hydrodynamic descriptor or parameter and to the time of exposure to it.

Having a single parameter (or at least a reduced set of them) that can be related to overall yield, productivity, cell growth, and so on, is highly desirable from an engineering point of view to facilitate design and scale-up of new processes. Garcia and Chalmers (113) suggested that "ideal" parameters should be independent of the geometric characteristics of the culture system as cells do not "sense" the average conditions of the bioreactor but the characteristics of the microenvironment surrounding each one of them at each time. Consequently, criteria as mean power input, agitation rate, impeller tip speed, impeller-based Reynolds number or integrated shear factor should not be used as they represent average values derived from the particular geometric configuration of every system and because it has been shown that it is not possible to hold constant more than one of these parameters at the same time during scale-up (167).

While the idea proposed by Garcia and Chalmers (113) is theoretically appealing, its real implementation is currently an impossible task; first, the microenvironment surrounding every cell is not only dependent on the position (three-dimensional) but also is time-dependent as most industrial cultures are batch or fed-batch and therefore their properties change constantly; second, the turbulent nature of the fluid dynamics inside an stirred bioreactor further complicates the parameter, as its description will require a second-order stress tensor consisting of nine distinct stress vectors. Third, the behavior of every cell is likely to be history-dependent: two cells obtained from the same culture and placed in *exactly* identical conditions will probably respond differently as their previous history is expected not have been the same. Finally, a precise characterization of turbulent phenomena is out of reach: from a theoretical point of view, the number of unknown variables is greater than the number of equations, so turbulent flow can not be solved mathematically from first principles; from a practical point of view, available techniques are limited to a very few points at a time (laser Doppler anemometry, constant temperature wire anemometry); increasing the number of points evaluated makes the cost prohibitive or imposes limitations in the resolution of the velocity profiles (particle tracking velocimetry). Therefore, in the end it is necessary to rely on some kind of *average* (time-average, spatial-average) or on a *very gross distribution* of some factor to describe hydrodynamic phenomena inside a bioreactor.

A commonly cited parameter for analysis of mixing phenomena is the Kolmogorov's mixing microscale, η, which is a function of the ratio between the turbulence intensity (represented by the local EDR, ε, and the kinematic viscosity of the liquid, ν:

$$\eta = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \tag{38.20}$$

Kolmogorov's mixing microscale (also referred to as *Kolmogorov eddy size*) was derived from classic dimensional analysis of turbulence by Andrey Kolmogorov in 1941; this theory of isotropic turbulence proposed that energy introduced into the liquid by the impeller undergoes a cascade from large, energy-containing scales to small, energy-dissipative scales. In the smallest scale, the fluid forms eddies where kinetic energy is ultimately converted into heat dissipation. As the Kolmogorov microscale depends only on fluid's and flow's properties and not on the system's geometry or large-scale flow patterns, it is a good candidate for a general parameter to correlate hydrodynamic conditions to cell damage. In fact, it has been proposed that cell damage occurs whenever the eddy-length η, reaches the size of a freely suspended cell or the size of a microcarrier. Good agreement was reported for small-scale vessels (126,156); however, this parameter suffers from several weaknesses: it requires turbulent flow (so it can not be properly applied to laminar flow); additionally, it has been shown experimentally that turbulence is not really isotropic although one can always assume "local" isotropy. Finally, the volume in which the energy is dissipated can not be determined from first principles. Suggested volumes used by some authors include the volume around the impeller or the small volumes associated with the trailing vortices emanating from the impellers (168).

In contrast to the Kolmogorov's mixing microscale, the EDR is a scalar parameter that is independent of the flow regime (turbulent/laminar) and accounts for both shear and extensional components of three-dimensional flow. EDR represents the rate at which work is done on a fluid element or, for the purpose of this review, a cell (169). The

EDR has been widely used to quantify local mixing performance in stirred tanks (105) as well as laminar flow devices (109,170); even Kolmogorov's mixing microscale is based on the local EDR. Therefore, it seems quite appealing to use this parameter to correlate the hydrodynamic cell damage in diverse devices. Although EDR can not be measured directly, it can be calculated in a relatively straightforward manner from Equations 38.17 and 38.18 provided that the broth behaves like an incompressible, Newtonian fluid (common situation in animal cell culture where the medium has water-like properties) and that the velocity vector has been accurately determined. This last requirement, however, limits the application of EDR to systems where the determination of the velocity vector U has been done experimentally or it can be determined analytically (laminar flow).

Ma *et al*. (145), designed and manufactured a microfluidic device in which suspended cells could be exposed to acute, high levels of EDR in a laminar flow environment; the advantages of this device include very well defined hydrodynamical characteristics and the possibility of emphasize the potentially more damaging extensional flow, although some degree of shear is present. Using such device, they subjected an insect cell line (Sf-9), a CHO cell line, a mouse-hybridoma cell line (HB-24) and a human breast cancer cell line (MCF-7) to single exposures of EDR and measured the release of the cytoplasmic enzyme lactate dehydrogenase (LDH) as an indication of cell membrane rupture. Every one of the cell lines studied showed significant cell lysis beginning around an EDR of 10^7 W/m^3 as observed in Fig. 38.13. This is in agreement with previous results from Zhang and Thomas (171), who demonstrated that an average EDR in the range of 10^8–10^9 W/m^3 in capillary tubes would completely disrupt TB/C3 hybridoma and NS1 myeloma cells.

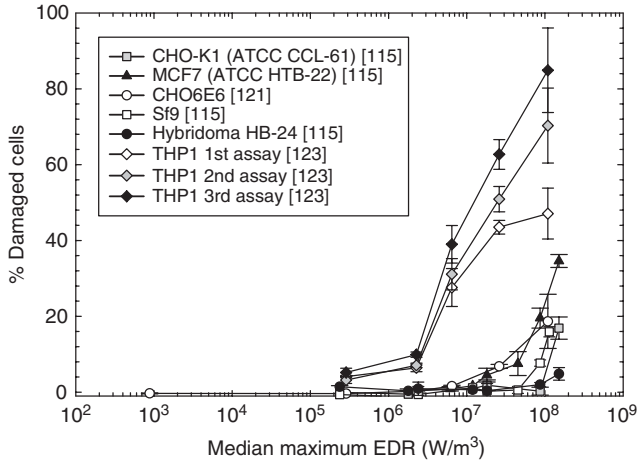

Figure 38.13. Experimental curves for the percentage of damage experienced by cells in a custom-design microfluidic device for single abuse experiments. [Adapted from Ma *et al*. (145) and Mollet *et al*. (172).]

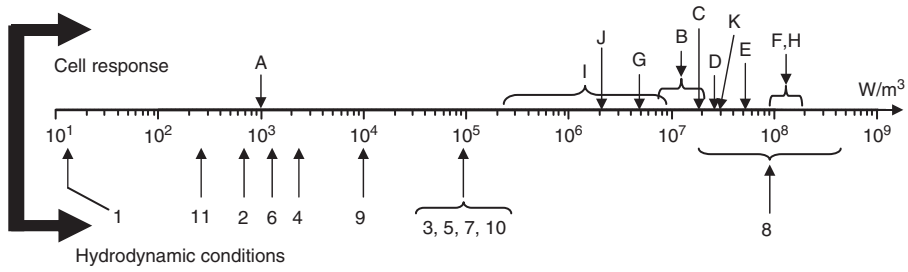
To better express their results, Ma *et al*. (145) developed a one-dimensional plot whose improved version is presented in Fig. 38.14. As it can be appreciated, the values of EDR required to cause significant lysis in industrial cells are at least two orders of magnitude higher than the maximum EDR measured under normal conditions in bioreactors. Mollet *et al*. (170) developed an improved, autoclavable second-generation microfluidic device to further investigate if besides the evident levels of necrosis already reported, the effect of single exposures to high levels of EDR could lead to apoptosis. In addition to being consistent with the previous work by Ma *et al*. (145) in the levels of necrosis obtained after passing the cells once through the microdevice, Mollet *et al*. (170) observed that only a small fraction of CHO cells (CHO-K1) became apoptotic when exposed to sublethal levels of EDR.



In a related subject, Mollet *et al*. (172) used the improved microfluidic device as well as computer fluid dynamics (CFD) commercial software to simulate the single passage of cells through the nozzle of a commercial fluorescence activated flow sorter (FACS). In the FACS, the cells experience high levels of EDR as a result of hydrodynamic focusing in the nozzle, with levels of cell necrosis on the order of 20–35% using CHO cells under typical operating conditions. They also found that nonadapted cells (THP1) may be much more sensitive to hydrodynamic stress than adapted, industrial cell lines (see Fig. 38.13).

38.4.4 Detrimental Effects of Sparging

It is a well reported observation that a dramatic reduction in cell number and viability of animal cells can be caused by sparging of gas into bioreactors (20,124,178,179). Even under conditions of unusually high stirring speeds, Oh *et al*. (20) and Kunas and Papoutsakis (124,146) showed that as long as there is no air introduction into the culture medium (i.e. sparging or bubble entrainment from the central vortex), hybridomas could withstand stirring speeds as high as 600 rpm without detectable cell damage.

The specific cause responsible for cell damage as a result of cell–bubble interactions may be attributed to four different events: bubble formation and detachment at the sparger, bubble break-up and coalescence in the impeller trailing vortices, bubble rising through the fluid or bubble disengagement at the surface of the culture. In the next lines, we present a brief summary of the results of research on each of these potential events.

Significant cell damage occurring near the sparger was suggested by Tramper *et al*. (180) who estimated that shear stress produced as a result of bubble formation and detachment could be up to one order of magnitude higher than that

Figure 38.14. Summary of the reported energy dissipation rate at which cells are affected as well as the reported levels of energy dissipation rate in various bioprocess environments. [Adapted from Ma *et al*. (145) and Mollet *et al*. (109).]

of bursting bubbles. Murhammer and Goochee (76) noticed an inverse correlation between the pressure drop across the sparger and the net growth of insect cells in airlift reactors, and suggested that the damage could be concentrated in the sparger zone as a result of the turbulent oscillation of the detaching bubbles or the fast liquid movement to fill in the space vacated by them.

In a series of insightful experiments under identical aeration and agitation conditions, Oh *et al*. (147) showed that bubble break-up as a result of the interaction of sparged air with the impeller is significant for cell damage. By comparing the results of placing the sparger in several positions, the authors showed that sparging air directly under the impeller led to an increase in the number of smaller bubbles and also to an increment in cell death, although it is difficult to say if it was caused by damage in the impeller region or was because of the increased bubble bursting in the medium-air interface.

Kioukia *et al*. (181) grew hybridoma cells in a 2.5-L reactor stirred with a Rushton turbine and oxygenated

only by surface aeration. In experiments with baffles in the reactor, successful growth and similar kinetic results were obtained at all speeds up to 400 rpm. In contrast, in experiments without baffles the peak cell density and growth rate decreased with increased speeds and cell death occurred from the start of the batch culture even though the average EDR was only 20% of that for baffled conditions. The authors argued that the cause for this behavior was the entrainment of air bubbles into the bulk of the liquid, and the further disengagement of these entrained bubbles at the top interface. This entrainment was the result of a vortex formed from the mixing; furthermore, since the bubbles never reached the impeller region, the damage could not be related to bubble break-up/coalescence in the impeller and only was associated with the bubbles bursting at the medium-air interface.

Tramper *et al*. (180) and Glasgow *et al*. (182) showed that values of shear stress derived from rising bubbles are extremely low (~0.1 Pa) and should, therefore, be neglected. To confirm these results, Handa-Corrigan *et al*. (183) and Jöbses *et al*. (184) introduced air in bubble columns of different sizes. With all other variables being constant, increasing column height, and thereby increasing the distance a bubble had to travel to rise to the top of the column, did not result in a reduction of viability for several cell types tested (hybridoma, BHK-21, myeloma, and lymphoblastoid cell lines).

Several researchers suggest that bubble-induced cell damage takes place only when a bubble, at the gas–liquid interface, ruptures (178,185,186). Phenomenologically, a bubble at a gas–liquid interface rises to a particular height above the flat liquid surface while the remaining part is submerged; the extent of the submerged part depends on the diameter. During rupture, the liquid drains by gravity from the film covering the raised part of the bubble up to a point where the film is so thin that a hole develops on the top and the bubble bursts; then, the liquid rapidly moves down the walls of the bubble cavity until the liquid reaches the bottom of the cavity; the resulting impact creates simultaneous upward and downward jets. Several studies indicate that this process creates a very high EDR over the very short period of time in which the rupture occurs. This bursting process was qualitatively presented by MacIntyre (187), in a series of cinephotography-derived profiles of the liquid–gas interface during the bubble break-up event. Subsequently, Boulton-Stone and Blake (188) and Garcia-Briones *et al*. (189) reported the results of computer simulations of bubble break-up with simulated profiles very close to those photographed by MacIntyre (187); their model indicates that the film at the top of the bubble retreats at speeds as high as ~8 m/s. Of more significance, the calculated maximum EDR is many orders of magnitude higher than those typically generated by an impeller. Additionally, such maximum EDRs are a function of the bubble radius being larger for smaller bubbles, indicating that smaller bubbles are potentially more damaging to cells. Interestingly, this result has been observed experimentally in several different studies (183,184).

The maximum EDRs (watts per cubic meter) calculated by García-Briones *et al*. (189) during bubble break-up ranged from 9.52×10^7 and 1.66×10^7 for bubbles with diameters of 0.77 and 1.70 mm, respectively. In contrast, for a 6.32 mm bubble, the EDR is only 9.4×10^4 W/m^3. Inspection of Fig. 38.14 indicates that these higher EDR values are well within the range of EDR values that were able to kill cells in the flow contraction device. This consistency between the simulated values of EDR during a bubble rupture, the values of EDR shown to kill cells in the flow contraction device, and the significantly lower EDR values in the impeller region provide an overall consistent picture that cell damage occurs because of bubble rupture at the liquid surface and the foam layer. The question that remains is whether enough cells are killed because of bubble bursting to account for all the cell death one can observe in a sparged culture.

To address this question, a study showed that on average $\sim 10^3$ cells are killed per 2 mm bubble burst (186) and the cell concentration collected from the upward jet is twice the bulk concentration in the culture. This result is in agreement with observations by Chalmers and Bavarian (190) and García-Briones and Chalmers (191), who, using video microscopy, detected cell attachment and accumulation on gas–liquid interfaces, especially in rising bubbles and the foam layer in the surface of the liquid in the reactor.

Parker and Barsom (192) reported that the chemical composition of the film surrounding air–liquid interfaces contained more hydrophobic materials compared to the bulk water; therefore, the phenomena of cell attachment to such film (microlayer) could potentially be explained as a result of the hydrophobic characteristics of the cell membrane. Chattopadhyay *et al*. (193,194) attempted to explain thermodynamically the cell adhesion to the gas–liquid interface and suggested a model for the variation of free energy as a function of the surface tension of the interfaces involved (gas–liquid–cells). According to their model, modifying the gas–liquid surface tension via chemical additives (such as Pluronic F-68) may create a condition where the change in free energy becomes positive and so the adherence stops being spontaneous. While a number of different surface active agents have been studied, including serum, dextran, hydroxyethyl starch, polyethylene glycol, or polyvinyl alcohol, Pluronic F-68 continues to be the additive of choice. Pluronic F-68 is a block copolymer of poly(oxyethylene) and poly(oxypropylene) and it is typically added to the culture medium in concentrations of 0.5–3 kg/m^3 (195).

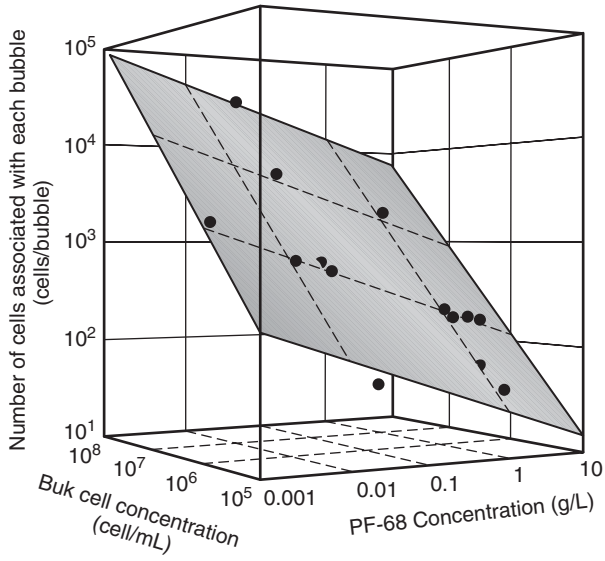

Figure 38.15. A three-dimensional plot of the number of cells associated with each bubble as a function of cell concentration (cells per milliliter) and Pluronic F-68 concentration. The dots indicated experimental data and the surface is the plot of a multiple variable regression. [Adapted from Ma *et al*. (202).]

In addition to reducing or inhibiting cell adhesion to the microlayer (190,191) by changing either the bubble film (196,197) or the cell membrane properties (198,199), other mechanisms have been proposed to explain the reduction or virtual elimination by surfactant agents of cell death as a result of bubbling; they include the following:

1. Interaction of the surfactant with the cell membrane, reducing its fluidity and rendering it stronger to mechanical stresses (200,201).
2. Nutritive effects of the surfactant on the cells. As mentioned by Ma *et al*. (29), the short time needed for detection of protective effects after addition of most chemical substances suggests that this mechanism of protection is not important.

In spite of the success of Pluronic F-68, a word of caution is in order: as the cell densities increase, the effectiveness of surfactants, even at high concentration, diminishes. A recent study by Ma *et al*. (202) demonstrated that even at high concentrations of F-68, a significant number of cells can be retained in the foam layer. Figure 38.15 is a figure from that report and as it can be observed, at cell concentrations greater than 10^7 cells/mL (which can be routinely obtained in industrial cultures) and relatively high F-68 concentration, more than 200 cells/bubble are removed into the foam layer.

38.5 SUMMARY

Animal cell culture has been used extensively for the production of a wide variety of proteins with biological and therapeutic activity. In spite of being a mature area of development, no universally accepted method of design or scale-up, based on purely fundamental principles, exists; however, the success of commercial processes, and published, peered review studies provide sufficient information to allow rational scale-up principles to be followed.

BIOCATALYTIC MEMBRANE REACTORS

Lidietta Giorno and Enrico Drioli
Institute on Membrane Technology, ITM-CNR, At University of Calabria, Rende, Italy

39.1 INTRODUCTION

Membrane reactors using catalysts of biological origin represent a suitable technology for production, processing, and manufacturing operations.

Nowadays, a growing need for environmentally friendly and low energy input technologies is generally recognised, along with waste minimization and recycling that are consistent with the strategy of process intensification to guarantee sustainable development.

The process intensification strategy consists of the development of novel apparatuses and techniques that, compared to those commonly used today, are expected to bring improvements in manufacturing and processing; substantially decreasing equipment-size/production capacity ratio, energy consumption and waste production, thus resulting in sustainable technologies.

Governmental bodies formalize directives that strongly require industries to advance their processes with the best available technologies. Membrane technologies are listed among the best available technologies in EC directives (e.g. the Integrated Pollution Prevention and Control, IPPC—Directive, 1996). In this scenario, biocatalytic membrane reactors are well located, as they are able to work under mild conditions of temperature and pressure, do not require additives, reduce the formation of by-products, and can be highly selective, efficient and flexible systems.

The catalytic action of catalysts of biological origin is extremely efficient and selective when compared to ordinary chemical catalysts; they require milder reaction conditions, show higher reaction rates, and greater stereospecificity. The huge interest toward biocatalysts application has promoted research activities both at academic and industrial levels. This led to developments in various technological sectors including bioengineering techniques and membrane technology for their immobilization and related process design, respectively.

Since 1950, after protease was immobilized on diazotized polystyrene, many enzymes, microorganisms and cells have been used in membrane reactors to catalyze bioconversions of productive interest. The possibility of using biotransformation in productive cycles improves biocatalyst life-times. This makes possible the use of biocatalysts for production at large scales.

Artificial membranes are among the most suitable supports and devices to engineer biocatalysts which can be used suspended in solution and compartmentalised by a membrane in a reaction vessel, or immobilized within the membrane matrix itself. In the first case, the system might consist of a traditional stirred tank reactor combined with a membrane separation unit. In the latter one, the membrane simultaneously acts as a support for the catalyst and as a separation unit.

Reaction yield and selectivity may strongly depend on membrane characteristics. In fact, in addition to the effects of membrane selectivity on reactions (such as removal of product-poisoning components and/or supplying substrates at controlled rates), the physicochemical properties of membranes may influence catalyst structure (and therefore catalyst selectivity). Biocatalytic reactors more commonly use polymeric membranes as compared to inorganic ones since they work under mild conditions of temperature and pressure. The membrane can be flat-sheet shaped and assembled

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

in plate-and-frame or spiral-wound modules, or tubular and assembled in tube-and-shell modules; it can have symmetric or asymmetric structure. (Specific information on membranes and membrane processes can be found in Ref. 1.)

The biocatalyst can be flushed along a membrane module; segregated within a membrane module; immobilized in/on the membrane by entrapment, gelification, physical adsorption, ionic binding, covalent binding or cross-linking.

The choice of the reactor configuration depends on the properties of the reaction system. For example, bioconversions for which a homogeneous catalyst distribution is particularly important, are better performed in a reactor with the biocatalyst compartmentalised by the membrane in the reaction vessel. The membrane is used to retain large components (i.e enzyme and substrate) while permeating small molecules (i.e. the product).

The reactor with the biocatalyst segregated in the membrane module is suitable for those cell cultures and enzymes that can be deactivated by shear stress. Reactors with segregated cells are studied for therapeutic applications, for example, as bioartificial pancreas, bioartificial liver, and extracorporeal detoxification device.

As stated previously, besides functioning as a selective separation barrier, the membrane can also exhibit catalytic properties. In fact, the biocatalyst can be loaded within the porous structure or on the surface of the membrane. The objectives of immobilizing enzymes are to increase reactor stability and productivity, improve purity and quality of products, and minimize wastes.

The enzymes or cells can be entrapped within the polymeric matrix during the preparation of the membrane by phase inversion technique, or can be entrapped by filtration within the porous layer of asymmetric hydrophilic membrane, symmetric hydrophobic membrane and so on. When the biocatalyst is within the membrane, in order for the reaction to occur, the substrate has to be transported across the membrane to the catalyst and the product recovered as permeate from the other side of the membrane. In general, mass transport resistance is the parameter that most influences the performance of these reaction systems.

Actual gelation of enzyme proteins on the membrane surface is possible when the protein concentration at the membrane–liquid interface reaches the gel concentration value. When the biocatalyst is immobilized on the surface, flushing the substrate solution along the enzymatic gel causes conversion of substrate into product in the retentate stream also. If the enzyme is product inhibited, performance of the reactor at steady state is decreased.

Attachment of the enzyme can be obtained by ionic binding to ion exchanger supports; by adsorption through van der Waals interactions to hydrophobic supports; and covalent binding between amino or carboxyl groups of amino acids and the support.

In addition to the type of immobilization, membrane bioreactors are also named on the basis of type of solvents and/or separation process used. For example, "ultrafiltration (UF) membrane reactors", "affinity membrane reactors" where a chemical reaction is coupled to a separation by ultrafiltration or affinity membrane, respectively; "extractive membrane bioreactors" where organic molecules permeate across a membrane into the biological active reactor; "ion exchange membrane bioreactor" where ionic compounds are transported through nonporous ion exchange membrane into a biological active compartment; "biphasic membrane reactors" (or two-separate phase membrane reactors), where the membrane is placed between two different phases which are kept separated and in contact at the same time; and "enantioselective membrane reactors" where the membrane-assisted reaction system is able to distinguish between chiral molecules. Sometimes they are named on the basis of the type of membrane used: "flat-sheet membrane reactor," "hollow fiber membrane reactor" and so on. When hollow fibers are used, a membrane reactor is just a plug-flow reactor that contains an additional porous cylinder within it.

Biocatalytic membrane reactors can also be distinguished on the basis of membrane module location in the plant, that is there is a sidestream configuration and an immersed one. In the sidestream configuration the module is externally positioned with respect to the fluid to treat, and the fluid is recirculated along the membrane module by a pump. In the immersed configuration, the module is immersed in the fluid to treat and a suction pump is used to remove the permeate from the module.

The UF membrane reactor is used when the substrate has a higher molecular weight with respect to the product and both are soluble in the same solvents. In this way, by choosing a membrane with the appropriate pore size, the substrate is transported to the enzyme immobilized in or on the membrane but it cannot pass through the membrane, while the obtained product can freely permeate through it and can be recovered from the other side of the membrane.

If the substrate has a different solubility with respect to the product (as in the case of an ester and its hydrolysis product), then a biphasic membrane reactor can be used. In this type of system, the enzyme-loaded membrane is located between two immiscible liquid phases, in general an organic and an aqueous phase. The organic phase contains the substrate and it is flushed along one side of the membrane; the substrate is transported (by diffusion) to the enzyme, where the reaction takes place, and the product is extracted into the aqueous phase and flushed along the other side of the membrane. When the biocatalyst is selective for only one of the two enantiomers present in a racemic mixture, the system is useful for producing pure enantiomers. This field is receiving growing attention due to the importance of using bioactive molecules as pure isomers when they have

TABLE 39.1. General Properties of Biocatalytic Membrane Reactors

Technological Benefits	Needs for Further Technological Innovation
Enzymes are heterogenized by immobilization	—
Large surface per unit volume	—
Easy to separate enzyme from the other reagents	—
Increase of enzyme stability	Sometimes decrease of catalytic activity and selectivity
Combining of selective reactions with selective separation	Mass transfers through the membrane
Independent control of kinetic and separation parameters	—
Mild temperature and pressure conditions	—
Optimal substrate administration rate	—
Removal of inhibiting components	—
Increased reaction yield	—
Control of sequential reactions	—

[a] Biocatalytic membrane reactors used in organic solvents or nonaqueous media.

to be administered to human beings, animals, environment, and so on.

Traditionally, membrane reactors were applied in equilibrium limited reactions. Nowadays, new applications are growing, for example, in biocatalytic reactors, the membrane can be used to remove some intermediate or side product that might deactivate the biocatalyst. The membrane can assist the extraction of different intermediates into proper solvents that better preserve their stability. It can also allow controlling of complex multistep reaction systems.

Additional general properties of biocatalytic membrane reactors are summarised in Table 39.1.

Further insight can be found in Refs 1–6.

39.2 FUNDAMENTALS

Enzyme specificity is thought to be a consequence of its elaborate three-dimensional conformation which allows formation of the "active site" which is a hydrophobic cavity responsible for the catalytic ability of the enzyme. In general, binding to create the substrate-enzyme complex is due to weak attractive forces. Although a little controversial, the notions of active sites and the enzyme-substrate complex are universally accepted and form the starting point for most theories of enzyme action.

The relative chemical equation is as follows

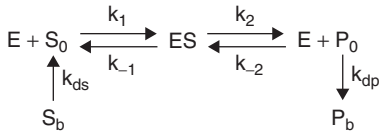
$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} E + P \tag{39.1}$$

The mathematical expression of the kinetic behavior of enzymes is commonly known as *Michaelis–Menten equation*:

$$V_0 = \frac{V_{\max}[S]}{K_m[S]} \tag{39.2}$$

The Lineweaver–Burk equation is obtained by rearranging the M–M equation in linear form:

$$\left[\frac{1}{V_0}\right] = \frac{K_m}{V_{\max}}\left[\frac{1}{[S]}\right] + \frac{1}{V_{\max}} \tag{39.3}$$



By plotting $\frac{1}{V_0}$ versus $\frac{1}{[S]}$ data, a straight line is obtained, where the intercept to y axis is $1/V_{\max}$ and the slope is $K_m/V_{\max}$.

From this graph it is easy to estimate K_m and V_{max}. Here, V_0 is the initial reaction rate, K_m is the Michaelis–Menten constant, S is the substrate, and V_{max} is the maximum reaction rate.

The modeling of biochemical membrane reactors mainly depends on the function of the membrane. For example, if the membrane works as a separation unit independent from the reaction, then the reactor is modeled according to traditional systems (e.g. continuous stirred tank reactors and plug-flow reactors) combined to a membrane separation; if the membrane is catalytic, then the intrinsic kinetic and mass transport at the membrane level must be considered.

When the enzyme is immobilized in a matrix such as a polymeric membrane, the observed reaction rate depends upon the reagent transport and intrinsic catalytic activity of the enzyme.

Under these conditions the Michaelis–Menten equation can no longer account for the intrinsic kinetics and a new reaction model that takes into account mass transfer is needed. In some cases the reaction mechanism of immobilized catalysts may also change and completely new approaches are needed. In general, when the Michaelis–Menten reaction model is considered valid, the kinetic mechanism for an immobilized enzyme can be simply represented as follows:

(39.4)

where, S_0 and P_0 are the concentrations next to the immobilised enzymes, while S_b and P_b are the concentrations in the bulk phase. The constant k_{ds} is related to the diffusion of substrate from the bulk to the enzyme and k_{dp} is related to the diffusion of product from the immobilized enzyme to the bulk phase. In Fig. 39.1 the concentration gradients for substrate and product through porous supports containing immobilized catalysts are schematized. The gradients in region A–B are due to diffusion in the outer diffusion liquid film. The gradients in region B–C are due to the joint effects of diffusion and reaction.

The use of Lineweaver–Burk plots with immobilized enzymes to determine apparent values for V_{max} and K_m is very common. For a kinetically controlled reaction system, a straight line is obtained. A linear extrapolation to the axes allows the apparent values of these parameters to be accurately determined.

In the presence of diffusional limitations, the Michaelis constant's apparent value obtained by extrapolation of the Lineweaver–Burk plot is usually larger than the intrinsic value obtained for the enzyme in soluble form.

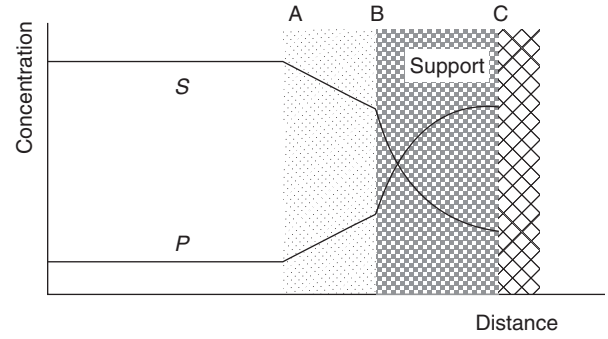


Figure 39.1. Concentration gradients through immobilized enzyme matrix.

39.2.1 Enzymes Immobilized on the Surface

For enzymes immobilized on the surface, a stagnant film (as called by chemical engineers) or Nernst diffusion layer(as called by biochemists) forms around the particle, through which the substrate molecules must diffuse to reach the surface. Thus, the surface concentration is less than the bulk concentration; the reaction proceeds less rapidly than the bulk substrate concentration would suggest (Fig. 39.2).

The Michaelis–Menten equation shows that an increase of k_m also corresponds to a decreased reaction rate. The flux of substrate from bulk to immobilized interfaces is given by $J_s = k_s(S - S_0)$, where J_s is the flux (moles per unit time per unit area); S and S_0 are the substrate concentration in the bulk phase and at immobilized enzyme interface; k_s is the mass transfer coefficient.

At steady state, at the interface, the mass transfer of substrate must be counterbalanced by the consumption rate of the substrate. Then, assuming that the Michaelis–Menten equation applies to systems immobilized on the surface

$$k_s(S - S_0) = \frac{V_{max}[S]}{k_m + [S]} \tag{39.5}$$

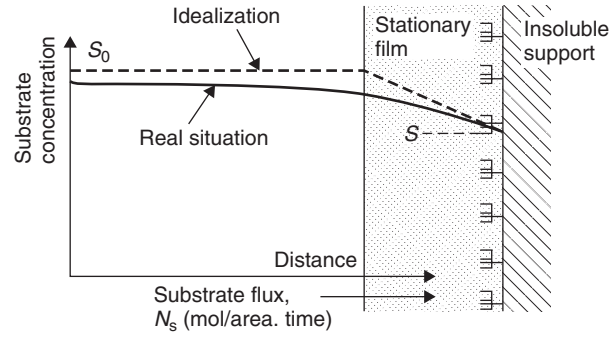

Figure 39.2. Schematic representation of transport for catalyst immobilized on the surface of insoluble support.

The following dimensionless variable

$$Da = \frac{V_{mx}}{k_s S_0} \tag{39.6}$$

known as the Damköhler number is the ratio between the maximum reaction rate and maximum mass transfer rate.

When $Da \ll 1$, the maximum transfer rate is much larger than the maximum reaction rate, which means that the system works at low mass transfer resistance. This is the case known as *reaction-limited regime*, where the system is kinetically controlled and the equation

$$V_{kin} = \frac{V_{max}\,[S]_b}{k_m + [S]_b} \tag{39.7}$$

can be assumed. Here, $[S]_b$ is the bulk substrate concentration.

When $Da \gg 1$, the reaction rate is larger than the mass transfer, which means that the mass transfer resistance is large and it is the limiting process. This is the case known as *diffusion-limited regime* and $V_{diff} = k_s[S]_b$.

The Damköhler number can be interpreted as the ratio of the slope of $V_{kin}(= V_{max}/k_m)$ to that of $V_{diff}(= k_s)$. If the slope of V_{diff} is less than that of V_{kin}, then $Da[= (V_{max}/K_M)/(k_s)] > 1$ and the reaction is diffusion controlled; while, in the opposite case, the reaction is kinetically controlled.

The influence of mass transfer on the overall reaction is usually represented using the effectiveness factor, η defined as

$$\eta = \frac{\text{Observed reaction rate}}{\text{Rate that would be observed in absence of mass transfer resistance}}$$

When $\eta \leq 1$ it means that the mass transfer resistance is large and the effect is a reduction of the observed activity of the catalyst.

For *Da* approaching zero (very slow reaction relative to maximum mass transfer rate), η approaches 1. This means that for the reaction-limited regime, the observed reaction kinetics can be approximate to the intrinsic reaction kinetics.

39.2.2 Enzyme Within the Porous Matrix

When enzymes are immobilized within the internal surface of porous supports (Fig. 39.3), calculation of the observed substrate conversion rate needs evaluation of the concentration profile of the substrate within the diffusion layer.

For these cases, it should be considered that the effective diffusion coefficient (D_{eff}) and the local rate of substrate conversion (V) differ conceptually from their counterpart in solution, and important quantitative difference can also arise.

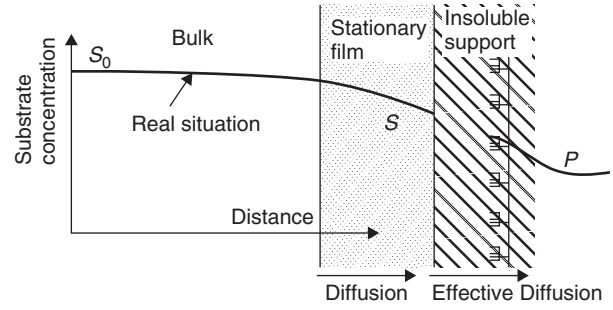

Figure 39.3. Concentration profiles through catalytic porous matrix.

Besides substrate diffusivity (D_{S_0}) in the bulk phase, diffusion rate through a porous support is influenced by porosity ($\varepsilon_{p,}$ = area of pores/area of support, only part of the support is void and available for diffusive transport, while most part is occupied by solids. The porosity value is less than 1); tortuosity (τ, the pore network is complex and not straight, diffusion occurs by changing direction continuously. The tortuosity factor is assumed to be in the range of 1.4–7); pores can have a very small diameter, similar to substrate molecular dimensions and lead to a situation of restricted diffusion (expressed as K_p/K_r roughly estimated as $[1 - r_{substrate}/r_{pore}]^4$).

Taking into account these considerations, the effective diffusion coefficient can be written as:

$$D_{eff} = D_{S_0}\frac{\varepsilon_p}{\tau}\frac{K_p}{K_r} \tag{39.8}$$

In the 1930s, Thiele, Damköhler, and Zeldovitch studied the influence of *diffusion within porous catalysts* upon reaction kinetics. They considered the example of a planar surface containing an enzyme distributed uniformlythroughout. The result of combining the steady-state diffusion equation with the applicable kinetics rate expression, the Michaelis–Menten equation, is:

$$D_{eff}\frac{d^2[S]}{dx^2} - \frac{V_{max}\,[S]}{K_m + [S]} = 0 \tag{39.9}$$

where D_{eff} is the effective diffusivity; $[S]$ is the substrate concentration; V_{max} is the maximum velocity of the reaction; K_m is the Michaelis constant, which means that, at steady state, the substrate diffusion rate through the porous support containing the enzyme is equal to the conversion rate.

The values V_{max} and K_m are those, which characterize the kinetic expression for the microenvironment within the porous structure.

A useful parameter to evaluate if an immobilized reaction system is limited by kinetics or mass transport, is the Thiele modulus, ϕ, given by

$$\phi = L\left(\frac{V_{\max}}{D_{\text{eff}}K_{\text{m}}}\right)^{1/2} \tag{39.10}$$

which has the physical meaning of a *reaction rate/diffusion rate*.

Finally, it should be noted that, as for the enzyme in solution, immobilized enzyme kinetics may differ from the irreversible single substrate Michaelis–Menten model. In the case where the intrinsic kinetics is inhibited by the substrate, if the substrate at the external phase is higher than the substrate concentration giving the maximum reaction rate, it happens that the local reaction rate inside the support is larger than that at the external phase. In this specific situation it is possible to observe an effectiveness factor higher than unity. Other frequent cases are heterogeneous systems, such as when the substrate reaches solubility limit or at the liquid–liquid interface.

Additional readings on immobilized catalyst kinetics and membrane bioreactors modeling can be found in Refs 1, 5, (7–11).

39.2.3 Process Design and Operation

General concepts in reactor design can be applied to the membrane reactor too. The information needed for reactor development are summarized in Fig. 39.4.

The building of models and their comparison with experimental data are useful and reasonable approaches to investigate and understand reactor performance.

Both kinetic and transport properties are needed.

The general procedure to formulate the mass balance is as follows:

- Choose the balance region so that the variables are constant or change little within the system, and draw boundaries around the balance region.

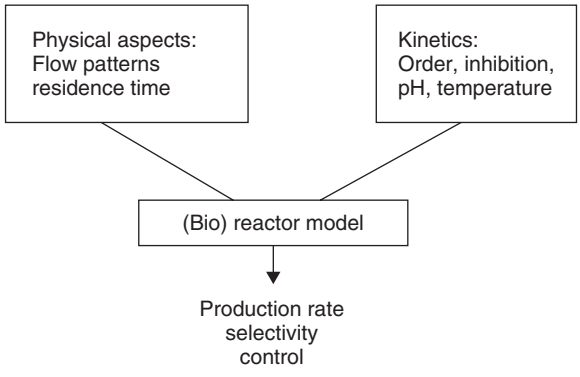

Figure 39.4. Data needed for reactor design.

- Identify the transport streams which flow across the system boundaries (e.g. convective in, convective out; diffusive in, diffusive out).
- Write the balance (e.g. rate of accumulation of mass of i = rate of i in by flow–rate of i out by flow + rate of production of i by reaction).
- Express each balance term by measurable variables in mathematical form. Pressure (P), volume (V), concentration (C), flow rate (F), are usually the measured variables (total mass = ρV; mass of $i = C_i V$).
- Introduce other relationships and balances so that the number of equations equals the number of dependent variables.
- Express the total mass balance:

$$\frac{\mathrm{d}VC}{\mathrm{d}t} = (FC_i)_{\text{IN}} - (FC_i)_{\text{OUT}} + (r_i V)_{\text{system}} \tag{39.11}$$

The steady-state balance equation for a membrane reactor working in reaction-limited regime can be written as

$$FC_{\text{f}} - FC_{\text{p}} + v_{\text{r}}V = 0 \tag{39.12}$$

where C_{f} and C_{p} are the feed and permeate concentration, respectively, v_{r} is the reaction rate, and V the reactor volume.

From this, the reaction rate can be derived:

$$V_{\text{r}} = \frac{F(C_{\text{f}} - C_{\text{p}})}{V} \tag{39.13}$$

Table 39.2 summarizes the component balances for various (membrane) reactor systems.

39.3 MEMBRANE REACTOR CONFIGURATIONS

Depending on various parameters (enzyme kinetics, membrane configuration, fluid dynamics, etc.), different reactors are used to optimize system yield. The most common types of reactors are summarized in Fig. 39.5 and the most common membrane processes combined with reactions are listed in Table 39.3.

Concentration polarization phenomena severely affect the performance of reactors where the membrane is used as a separation medium under pressure-driven processes. Then it is necessary to control the polarization layer on the membrane-pressurized side by means of reactor fluid dynamics or appropriate design. Membrane fouling is also a phenomenon to control and govern, in order to maintain good steady-state performances (1)

TABLE 39.2. Component Balances for Various Reactor Systems

Reactor type[a]	Terms in equation	Final form
Batch reactor	Flow term = 0	Acc = Production
Fed batch or Semicontinuous reactor	Flow term out = 0	Acc = In + Production
Steady-state CSTR	Accumulation = 0	In−Out + Prod = 0
Component Ci does not react	Production = 0	Acc = In−Out
Constant volume CSTR	simplifies to $V(ds/dt) = F(S_0 - S_1) + rsV$	Acc = In−Out + Prod

[a]The general term also includes membrane reactors.

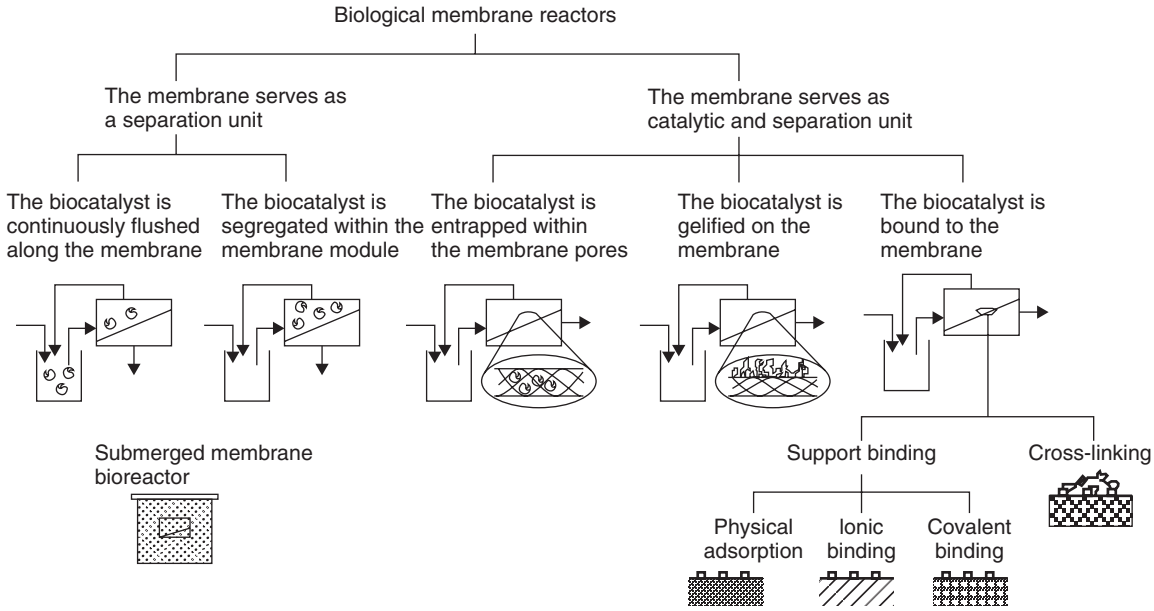

Figure 39.5. Common types of membrane reactors.

39.3.1 External Sidestream Membrane Bioreactors

39.3.1.1 Membrane Bioreactors with Membrane Used as a Separative Unit. This type of membrane reactor is based on the combination of a continuously stirred tank reactor (CSTR) with a membrane separation process. The membrane simply acts as a separation unit and does not directly take part in the reaction. The reactor works as a CSTR, but the product (or substrate) passes through the membrane unit where the enzyme is either retained and recycled back into the reactor or remains confined in the membrane module.

An appropriate membrane separation is used to keep larger components in the reaction vessel (i.e. cells, enzyme, and macromolecular substrates) and remove low molecular weight molecules (i.e. product, intermediates, and inhibitor). The biocatalyst is immobilized by the fact that it is compartmentalised by the membrane in the reaction vessel. This allows continuous processing with the biocatalyst suspended in a homogeneous solution. Direct contact between the substrate and biocatalyst limits diffusional resistance. Typical reactions that require a biocatalyst suspended in a solution are those that need cellular growth, high biomass density, and direct contact between substrate and biocatalyst. Examples of this kind of reaction systems include fermentation processes; plant cell culture (e.g. for secondary metabolite production); the hydrolysis of starch and cellulose; the hydrolysis of pectins; the hydrolysis of casein; the hydrolysis of collagen; and cofactor-dependent dehydrogenation reactions.

The most common separation process used in this kind of setup is ultrafiltration. Dead-end and continuous stirred ultrafiltration cells with flat membranes have been widely used; furthermore, cross-flow ultrafiltration through tubular membrane modules has also been investigated.

Additional applications include the use of hydrophobic microporous membranes for cell culture aeration; hydrophilic microporous membranes for nutrient supply to cultured cells and removal of catabolites from them; dense membranes and/or ion exchange membranes for organic and ionic contaminants separation; and supply of contaminants to biomass compartment for biodegradation.

Biocatalyst activity is usually not constant with time. Physicochemical changes in enzyme structure; thermal

TABLE 39.3. Most Common Membrane Processes Combined with Reactions

Process	Driving Force	Mode of Transport	Species Passed	Species Retained
Microfiltration (MF)	Pressure difference 100–500 kPa	Size exclusion convection	Solvent (water) and dissolved solutes	Suspended solids, fine particulars, some colloids
Ultrafiltration (UF)	Pressure difference 100–800 kPa	Size exclusion convection	Solvent (water) and low molecular weight solutes (< 1000 Da)	Macrosolutes and colloids
Nanofiltration (NF)	Pressure difference 0.3–3 MPa	Size exclusion, solution diffusion, Donnan exclusion	Solvent (water), low molecular, weight solutes, monovalent ions	Molecular weight compounds > 200 Da multivalent ions
Membrane-based solvent extraction (MBSX)	Chemical potential or concentration difference	Diffusion partition	Compounds soluble in the extraction solvent	Compounds insoluble in the extraction solvent
Gas separation (GS)	Pressure difference 0.1–10 MPa	Solution diffusion mechanism	Gas molecules having low molecular weight or high solubility-diffusivity	Gas molecules having high molecular weight or low solubility-diffusivity
Pervaporation (PV)	Chemical potential or concentration difference	Solution diffusion mechanism	High permeable solute or solvents	Less permeable solute or solvents
Membrane emulsifier (ME)	Pressure difference	Convection	Dispersed phase	—

denaturation, and microbial contamination cause enzyme activity to continuously decrease with time. When enzymes or cells are compartmentalised in UF cells, biocatalyst losses can occur even due to the wrong choice of chemical properties and morphology of the membrane. It is conventional to measure the biocatalyst stability in terms of its half-life time ($t_{1/2}$), that is the time at which the enzyme biocatalyst's activity is reduced to half its initial value. It can be calculated from the following equations:

$$K_{\mathrm{d}} = \frac{2.303}{\vartheta} \log \frac{A_{E_0}}{A_{E_\vartheta}} \qquad t_{1/2} = \frac{0.693}{K_{\mathrm{d}}} \tag{39.14}$$

K_{d} is the enzyme deactivation constant; ϑ is the operation time; A_{E_0} is the initial biocatalyst activity; A_{E_ϑ} is the enzyme activity at time ϑ.

Biotransformations by means of enzymes are continuous processes, as long as the reactor working life is longer than the native enzyme biocatalyst half-life. In these systems biocatalyst activity decay with time must be taken into account in order to correctly assess reactor performance.

The CSTR/UF reactor (Fig. 39.6) is useful for several types of reactions where a typical immobilized biocatalyst would not be effective.

A particular case of membrane reactors, with the biocatalyst flushed along the membrane, are the continuous membrane fermentors (or cell-recycle membrane fermentor), where microporous membranes are used to separate the fermentation broth from the product stream, thus retaining viable cells in the fermentor.

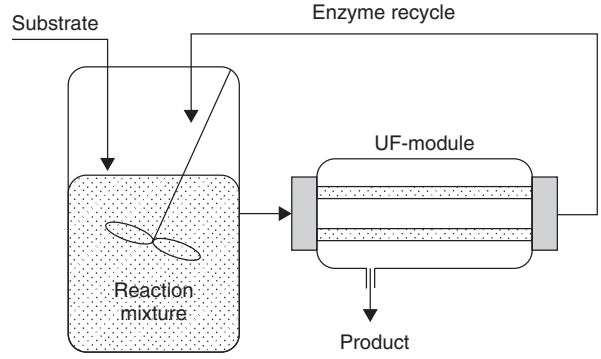

Figure 39.6. CSTR coupled with UF-module.

Membrane bioreactors coupling biological treatment to membrane separation processes, are effective and very promising for wastewater treatment. Mainly, two different configurations have been investigated: membrane bioreactors with the membrane module outside the activated sludge tank, and membrane bioreactors with the membrane submerged in the biological reactors. Due to lower energy requirements, the submerged membrane bioreactors (SMBRs) have been found to be more successful than the external ones, especially at the industrial level. They will be discussed in detail in a subsequent section.

Regarding the sidestream configuration, the most common function of the membrane is to remove the treated water while retaining cells and contaminants and recycling them back to the bioreactor.

Alternative uses have also been successfully explored, such as the use of membranes to selectively separate organic or ionic microcontaminants from water, and supply them to bioreactors for their metabolization to non-harmful components. This option has the advantage of wastewater pH and composition not affecting the biomass performance, as well as of not releasing biomass catabolites into the treated water. Examples of this kind of application can be found in Refs 12 and 13, where extractive membrane bioreactors employing silicon rubber membranes are used to selectively extract hydrophobic organic compounds from industrial water into a bioreactor; and in Refs 14 and 15, where ion exchange membrane bioreactor employing nonporous ion exchange membranes are used to remove ionic micropollutants from water into the microbial culture compartment.

39.3.1.1.1 Membrane Bioreactors with Biocatalyst Segregated in the Membrane Module. In these reactors, enzymes or cells are not linked but only confined in a defined region of membrane module space. The segregation of the biocatalyst is achieved by means of membranes with a suitable molecular weight cutoff. In this way, enzymes, as well as bacterial, plant, animal cells are not lost in the effluent stream, and low molecular weight products and inhibitors can be removed through the membrane (Fig. 39.7). The development of hollow fibers with diameters down to about 100 microns makes possible tube-and-shell reactors with a high surface-to-volume ratio.

Biocatalytic reactors can segregate enzymes or cells either within the hollow fiber lumen, within the shell surrounding the outer surface of the fibers, or within the porous membrane support. There is growing interest in therapeutic applications of compartmentalised cells or microsomes functioning as a bioartificial pancreas or extracorporeal detoxification device. Evaluation of stability and catalytic properties of the immobilized system must take into account possible pH differences between the site of the fiber, where the reaction takes place, and the bulk of the feed solution.

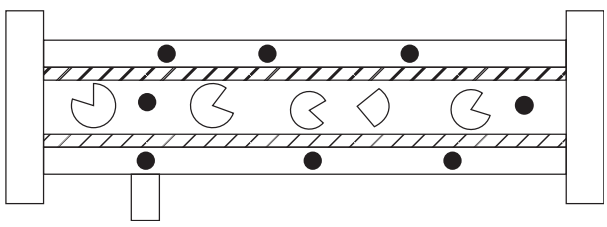

Figure 39.7. Membrane segregated enzyme reactor.

In order to avoid membrane plugging when using microorganisms or plant cells in this type of membrane reactor, cell growth must be appropriately controlled and if possible, kept in a "vegetative" stage. On the other hand, if cell growth is needed, then a different reactor configuration must be considered, such as a cell-recycle membrane bioreactor or a biofilm membrane bioreactor, depending on whether cells need to be suspended or attached to a support.

39.3.1.2 Biocatalytic Membrane Reactors. In these type of reactors, the membrane acts as a catalytic and separation unit. Biocatalysts are represented by enzymes or nongrowing cells. As shown in Fig. 39.5, reactors with biocatalyst-loaded membranes can be prepared in various ways. Important parameters which must be considered in immobilized enzyme reactors are: immobilization procedure; microenvironment conditions; optimal balance between molecular rigidity and flexibility (to guarantee both enzyme stability and catalytic activity and selectivity); enzyme activity; half-life time and activity decay profile; optimal substrate concentration; optimal residence time; pH and temperature; by-product formation; inhibitors; pressure drop; flow regime; particle size, shape and distribution; and mass transfer of reagents through the catalytic membrane. In the following paragraphs, the different types of reactors and their relative applications will be discussed.

39.3.1.2.1 Biocatalytic Membrane Reactors with Catalysts Entrapped within the Pores of Asymmetric Membranes. A number of microorganisms can withstand high temperatures and organic solvents and have been processed with polymeric solutions. Polysulfone and cellulose acetate membranes have been cast with microbial cells in the casting solution using the phase inversion technique. Microbial enzymes maintain their activity presumably because of cellular membrane protection. Cell-loaded membranes appear to be kinetically active and stable over a long period of time. It is noteworthy that cell entrapment can enhance microbial activity as compared to cell behavior in a homogeneous solution, an effect probably due to cellular membrane permeabilization as a consequence of the entrapment procedure.

Asymmetric hollow fibers can provide an interesting support for immobilizing enzymes. If the pores in the dense layer are small enough to retain enzyme molecules but large enough to allow the free passage of substrates and products, the enzymes are effectively immobilized or segregated within the spongy annular section (Fig. 39.8). Enzymes can be entrapped within the outer sponge layer of the fibers by cross-flow filtration of an enzyme solution and the amount of immobilized protein can be determined by the mass balance between initial and final solutions.

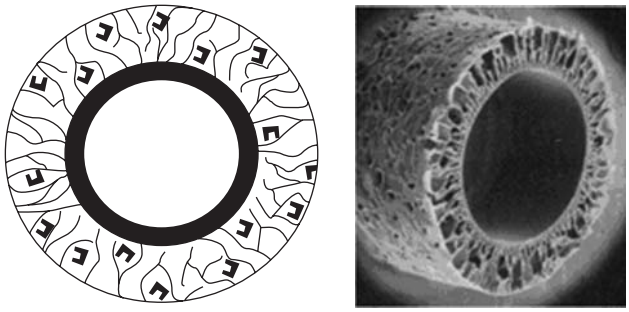

Figure 39.8. (a) Cross-section of CMBR with enzyme entrapped within the porous support. (b) Asymmetric hollow fiber membrane.

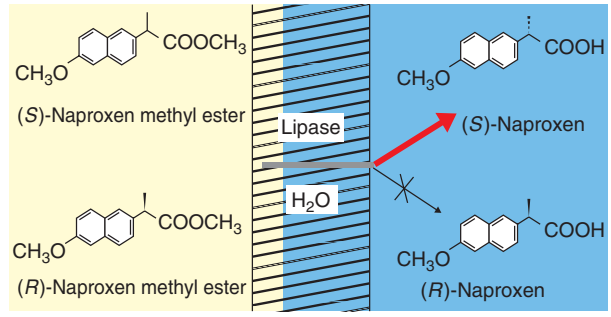

Figure 39.9. Biphasic membrane reactor for phase transfer catalysis. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

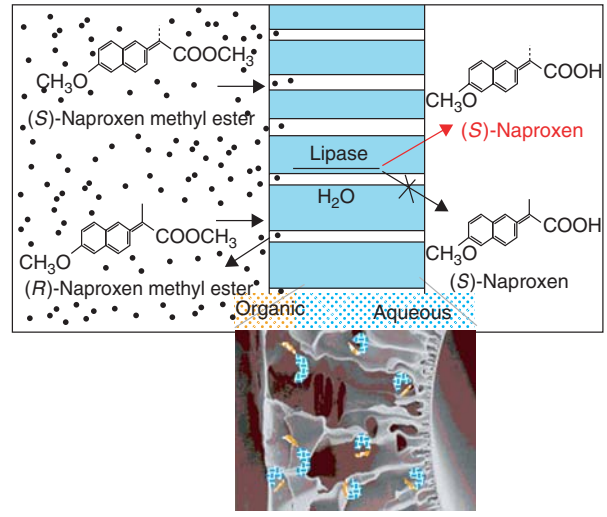

Figure 39.10. Schematic representation of an emulsion enzyme membrane reactor. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

The dynamics of substrate conversion depends on enzyme kinetics as well as on mass transport conditions. Enzymes are not able to work at high concentrations, hence the amount of immobilized catalyst strongly affects reactor performance. Usually, the reactor performance may strongly decrease at high enzyme loading because of both, deactivation effects due to macromolecular aggregation and additional barrier to mass transport. When the substrate is transported by convection through the enzyme-loaded membrane, the residence time is an important parameter to optimise.

For systems where the substrate is transported by diffusion, quick graphical procedures are available in literature for evaluating the extent to which external and internal diffusion affect immobilized enzyme kinetics (16). Suggested models can be used to predict reactor performances in the case of enzymes with relatively simple kinetics (such as α-galactosidase, invertase, glucose isomerase, and urease) and when the kinetic and transport parameters are known.

A widely reported case of reactor using enzymes entrapped within the pores is the biphasic organic/aqueous membrane reactor (or two-separate phase enzyme membrane reactor). A schematic representation of a biphasic membrane is reported in Fig. 39.9. The system is suitable for bioconversions of low water-soluble substrates. The enzyme-loaded membrane separates two immiscible phases: the substrate is present in the organic phase while the product is extracted in the aqueous phase. Particularly interesting is the case where the biocatalyst is enantiospecific and converts only one of the substrate isomers, giving in one step, the production and separation of enantiomers in the optically pure form.

The multiphase extractive membrane reactor targeted at the enzymatic resolution of chiral drug intermediates was developed in the early 1990s (17,18).

A further improvement on multiphase reactor systems (emulsion enzyme membrane reactors) has been reported recently where the organic–water interface within the pores at the enzyme level is achieved by stable oil-in-water emulsion prepared by membrane emulsification, so that each pore can work as a microreactor containing immobilized enzyme (Fig. 39.10) (19,20). In this way, the enzyme works in the membrane pores under the same conditions as in the stirred tank reactor, but with no shear stress due to stirring.

This configuration improved the selectivity and productivity of the biocatalytic system as well as its catalytic stability, confirming that the observed inversion relationship between activity and stability of immobilized enzymes is not a general rule.

A comparison between performances of different reactor configurations is reported in Table 39.4.

39.3.1.2.2 Catalytic Membrane Bioreactors with Biocatalysts Gelified on the Membrane. Concentration polarization phenomena, which are the main drawbacks of membrane processes, can be used to form a gel layer of enzyme proteins on a membrane. It is even possible to establish more

TABLE 39.4. Performance of Biphasic Membrane Reactors with Different Enzyme Immobilization Sites

Lipase	Membrane	Reactor	Immobilization Site	Lipase Amount (mg)	eep	*E*	Activity (mmol/h g)
Crude	PA 10 kDa	B-EMR	Thin	2.3	77	7.8	1.9

Crude	PA 50 kDa	E-EMR (emulsion by membrane)	Sponge	2.6 < 1	9496	3050	14.5

Note: eep, enantiomeric excess of the product.

than one enzyme layer and no coupling agent is needed to carry out the immobilisation. Reduced catalytic efficiency due to mass transport limitations and the possibility of preferential pathways in the enzyme gel layer can be typical systemic disadvantages.

Actual gelation of enzyme proteins, and hence their dynamic immobilisation, depends strictly on enzyme concentration at the membrane–liquid interface. When the maximum enzyme concentration is lower than the gel concentration value, enzymes are not immobilized. Although they are confined near the membrane surface at fairly high concentration levels, they are still in soluble form.

39.3.1.2.3 Catalytic Membrane Bioreactors with Biocatalyst Bound to the Membrane. Attachments of biocatalysts to membranes can result from ionic binding, cross-linking and covalent linking. In this section enzymes bound to synthetic polymeric membranes via covalent binding will be mainly discussed. Protease was the first covalently bound enzyme. This was achieved in 1950s. Since then, enzyme immobilisation via covalent bonds has been an established immobilisation technique, usually carried out by means of bi- or multifunctional reagents, such as glutaraldehyde. When the extent of initial denaturation is acceptable in the economics of the process, enzymes bound to membranes can be used in continuous flow reactors.

Applications of covalently immobilized systems are: membrane electrodes for analytical purposes; reactions of substrates whose molecular weight is low as compared to membrane molecular weight cut-off; and enzymatic conversion of macromolecules to lower molecular weight species able to permeate the supporting membrane.

39.3.2 Submerged Membrane Bioreactors

Submerged membrane Bioreactors are among the membrane operations that have received a huge amount of attention all over the world in the last few decades. They are mainly used for the treatment of wastewater at the industrial level.

This was also the result of the increase in demand for potable water and the increase in domestic and industrial wastewater discharges linked to population growth. In addition, more stringent legislation targeting environmental protection forces industries to minimize the input of energy and water.

The potentiality of the technology rests on low energy input, long-term operation without cleaning, and lower dependence on variation of rheology behavior with concentration. The main limitation is in the requirement for high membrane area which is due to the low fluxes linked to the low transmembrane pressure.

The combination of bioreactors and membrane technology enables an innovative and effective cleaning process. Conventional wastewater technology is characterized by large wastewater volumes. It usually uses open basins and needs high surface and long hydraulic retention time of wastewater flows. In conventional activated sludge processes, the purification stage (aeration tank) and the separation of the biomass from the purified wastewater (settling tank) are carried out separately and independently of each other. Large basin volumes are necessary for the aeration tank and the final clarifier. The biomass concentration in the aeration tank usually tends to be in the range of $3 - 5\ g_{dry\ weight}/L$.

The membrane bioreactor combines biological treatment with membrane separation. The treated water is separated from the purifying bacteria (active sludge) by a process of membrane filtration, rather than in a settling tank. Only the treated effluent passes through the membrane which is then pumped out, while the sludge is recovered. The sedimentation in the final clarifier is then replaced by the implementation of membrane filtration which allows separation of the biomass from the water, the quality of the purified water is also considerably improved. The use of microfiltration membranes with pore sizes usually between 0.1 and 0.4 μm ensures the complete retention of suspended matter and leads to a considerable reduction in the amount of bacteria in the outflow of the sewage plant.

Compared with conventional wastewater technology, membrane bioreactors have a short hydraulic retention time and high biomass concentrations of up to 20 $g_{dry\ weight}/L$. Additionally, because of the compact way in which they are constructed, membrane bioreactors have a relatively low surface area requirement.

SMBRs employ membrane module cassettes made of bundles of hollow fibers or flat-sheet membrane panels. The cassettes are vertically immersed within a tank containing wastewater and activated sludge and are aerated by a bubble system from the bottom of the units (Fig. 39.11). The

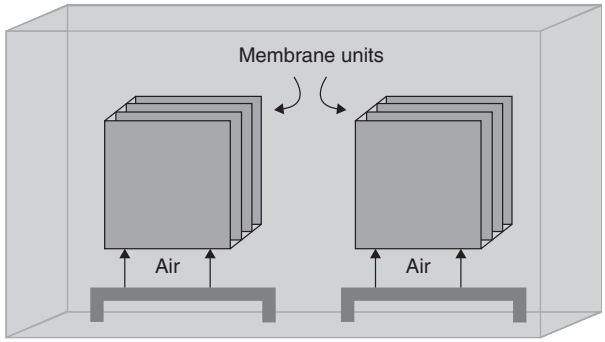

Figure 39.11. Submerged membrane cassettes with aeration by a bubble system from the bottom of the unit.

aeration serves to activate the sludge and to control concentration polarization and fouling at the membrane level as it generates an upward cross-flow over the membrane. In addition, it ensures effective tank mixing and even distribution of the biomass. The biomass can work at a very high level of concentration which enables a low tank volume and a long sludge age to be utilised; this substantially reduces sludge production. Treated effluent is removed from the membrane units using gravity head (typically 1–1.2 m), or a pumped suction operation can be utilised.

Similar to the bioreactors with the external module, the membrane in submerged bioreactors can also contain biocatalytic systems, which in principle can be obtained with the same approaches previously discussed. However, at the moment only few examples have been tested, mainly using biofilms growing on the membrane surface, to optimize the treatment process.

Membrane aerated biofilm reactors, where the biomass is immobilized on the membrane through which gas is supplied, seem the most promising configuration (21). The dissolved oxygen gradient across the membrane and the biofilm, offers an ideal environment for aerobic strains. However, biofilm growth should be controlled in order to avoid excessive biofilm thickness or density. In fact, this contributes to an increased resistance to mass transfer and may lead to decrease of gas fluxes (22).

An alternative biofilm membrane reactor configuration has been developed by integrating separate steps consisting of a moving-bed biofilm reactor followed by a submerged membrane module placed externally to the biomass compartment (23). This permits working with a very high biomass density with no or very limited effect on fouling of the submerged membranes.

39.4 APPLICATIONS

The use of biocatalysts is of particular interest for certain applications, specifically in terms of energy consumption, safety, pollution prevention, and the high quality of obtained products. Although the use of biocatalysts on an industrial level is not yet fully established, bioreactors running at large scale are increasing. A few examples are summarized here: (i) production of L-aspartic acid with *Escherichia coli* cells entrapped in polyacrylamides; (ii) lactase (β-galactosidase) entrapped into the fibers of cellulose acetate and used for the hydrolysis of milk and whey lactose; (iii) synthesis of the dipeptide Aspartame™ using thermolysin; (iv) production of L-alanine using *Pseudomonas dacunahe* immobilized with glutaraldehyde; (v) glucose isomerase reticulate with glutaraldehyde used in the production of fructose-concentrated syrups; (vi) L-amino acids produced from racemic mixtures by means of an amino acylase immobilized on DEAE-Sephadex; (vii) production of L-malic acid by *Brevibacterium ammoniagenes* entrapped in polyacrylamide; (viii) production of (2*R*,3*S*)-*trans* isomer of methyl ester of 4-methoxyphenylglycidic acid (a chiral intermediate of diltiazem, an important calcium-channel blocker used in the treatment of hypertension and angina, produced at 75 tons/year); (ix) production of phenylalanine.

The major technological difficulties of using biological immobilized systems on an industrial level include (i) the availability of pure enzymes at an acceptable cost (often the commercial enzymes are mixtures of several proteins); (ii) difficulties in immobilizing enzymes that often need expensive cofactors; (iii) the necessity for biocatalysts to operate at low substrate concentrations; (iv) microbial contaminations; and (v) the opposing requirements of crucial conditions (for example, treatment of solutions requires the use of microporous supports for creating high surface area per unit volume–thus equipment requirements are small–but by contrast, solutions with high turbidity cause fouling of pores thus reducing the advantages).

Currently, the development of catalytic systems specifically devoted to meeting the requirements of biomanufacturing and bioprocessing are likely to overcome these difficulties.

Examples of the most common membrane bioreactor applications are discussed in the following sections.

39.4.1 Biocatalytic Membrane Reactors in Food and Beverage Processing

Consumer demand for different food products has significantly changed in developed countries due to lifestyle changes, increasing incomes, demographic shifts, and so on. These countries share a rising trend toward higher consumption of meat, cheese, fruits, vegetables, and bottled drinks. And, the demand is for food products that are convenient to use and yet have all the qualities of a fresh product.

Simultaneously, significant structural changes in food production and processing sectors have been promoted

because of technological innovations, public policy and private attitudes to food safety, nutritional labeling, environmental concerns, farm policy and programmes, and competition in the international food market.

The most significant aspects in food manufacturing include the following:

Quality	maintenance or improvement of flavor, color, and texture
Safety	microbiologically and chemically, materials and methodologies used during processing and preservation do not introduce hazardous compounds
Stability	"fresh food" with medium to long-term shelf-life
Convenience	food is made into forms that are convenient (ease to use)
Wastes	prevention, minimization, valorization and recycling but prevention is better cleaning it up
Formulation	New products obtained from engineered raw materials and enabling processes
Sustainability	to meet today's needs without compromising the ability of future generations to meet their own needs

To achieve these challenges, all steps in food manufacturing have to be considered (e.g. where and how the food is produced, processed, packaged, preserved, distributed, prepared, consumed and disposed of).

To afford sustainable growth it is necessary to maximize mass and energy utilization as well as maximize recover and recycling. The technologies to be used need to be clean, safe, consume less energy, be able to preserve properties of products and coproducts, and allow new product formulations.

Membrane operations are among the most suitable technologies for food processing due to the peculiar properties mentioned earlier (Table 39.1). In the food and beverage industries, membrane filtration is state-of-the-art technology for clarification, concentration, fractionation, desalting, recycling, recovery and purification. The use of membrane technology in this field was dominated by its application in the treatment of whey and milk, whey protein concentration, followed by beverages, wine, beer, and juices. The integrated use of biocatalytic reactors and membrane processes is particularly suitable both for improving efficiency of more traditional membrane operations and for developing innovative production and processing systems. In the first case, for example, the combination of bioconversion with separation processes can be used as an initial or simultaneous treatment to reduce fluid viscosity, control membrane fouling, improve product quality and stability, govern coproduct formation, and minimize waste production. In the second case, the concept of biocatalytic membrane reactors is used to implement the formulation of new food products and functional food ingredients with improved texture and shelf-life.

The main applications are reported in Table 39.5 and are discussed in the following sections.

39.4.2 Milk and Dairy Products

The production of hydrolyzed milk, including dairy products, is of crucial importance for people who are lactose-intolerant. The use of membrane reactors to hydrolyze lactose in whole milk or cheese whey in continuous systems is a technique used on a large scale. Both lactose conversion and recovery of high molecular weight proteins can be accomplished in a single step. The hydrolysis of lactose is carried out using immobilized β-galactosidase.

An innovative process using hollow fiber membrane reactors to produce lactose-reduced skimmed milk without any ultrafiltration step before the enzymatic conversion was recently proposed (24). The system is composed by an UF unit that consists of a bundle of hollow fibers. The outside (shell side) compartment has closed circulation and is filled with the enzyme solution. A continuous flow of the substrate (skim milk) is applied to the inside (tube side) of the hollow fiber membranes. In this way, continuous, enzymatic lactose hydrolysis is possible without inherent problems of immobilized enzymes. The driving force for this system is the lactose diffusion, which mainly depends on the concentration gradient, the temperature and the flow rates of the substrate and the enzyme solution. In comparison to a batch process, enzyme activity could be used for a longer duration and enzyme release into the product does not occur. The system resulted in high conversion rates at high flow rates and consequently, high productivity.

Intolerance to milk is not only caused by lactose, but also by high molecular weight proteins. In fact, some children and old people have difficulty hydrolyzing proteins with molecular weight higher than 5 kDa; in other words they cannot digest such proteins, which causes them pain, stomachache, and can also lead to allergy. The hydrolysis of high molecular weight proteins into polypeptides lower than 5 kDa in biocatalytic membrane reactors is a new approach to producing low allergenic fresh milk with improved properties as compared to the reconstituted powdered milk that was traditionally used. The biocatalytic membrane reactor can be designed so that a membrane of appropriate cutoff can remove hydrolyzed fragments lower than 5 kDa while retaining the nonhydrolyzed proteins. In order to achieve high efficiency, the hydrolytic step should be part of an

TABLE 39.5. Applications of Biocatalytic Membrane Reactors in Food Processing

Reaction	Biocatalyst	Membrane Bioreactor	Application
Conversion of D-glucose to D-fructose	Glucose isomerase	Cross-linked enzyme	Sweetner industry
Hydrolysis of lactose to glucose and β-galactose	β-Galactosidase	Axial-annular flow reactor	Delactosization of milk or whey for human consumption
Hydrolysis of high molecular weight protein in milk	Trypsin and chymotrypsin	Asymmetric hollow fiber with enzyme	Production of low allergenic milk, and milk-based functional beverages
Hydrolysis of raffinose	α-Galactosidase and invertase	Hollow fiber reactor with segregated enzyme	Production of monomeric sugars
Hydrolysis of starch to maltose	α-, β-Amylase, pullulanase	CSTR with UF membrane	Production of syrups
Fermentation of sugars	Yeast	CSTR with UF membrane	Brewing industry
Anaerobic fermentation	Yeast	CSTR with UF membrane	Production of alcohol
Hydrolysis of pectins	Pectinase	CSTR with UF membrane	Production of bitterness and clarification of fruit juice and wine
Aerobic fermentation	*Lactobacillus bulgaricus*	CSTR with UF membrane	Production of carboxylic acids
Removal of limonene and naringin	β-Cyclodextrin	CSTR with UF membrane	Production of bitterness and clarification of fruit juice
Hydrolysis of K-casein	Endopeptidase	CSTR with UF membrane	Milk coagulation for dairy products
Hydrolysis of collagen and muscle proteins	Protease, papain	CSTR with UF membrane	Meat tenderization
Conversion of glucose to gluconic acid	Glucose oxidase and catalase	Packed bed reactor	Prevention of discoloration and off-flavour of egg products during storage
Hydrolysis of cellulose to cellobiose and glucose	Cellulase and β-glucosidase	Asymmetric hollow fiber reactor	Production of ethanol and protein
Hydrolysis of malic acid to lactic acid	*Lactobacillus oenos*	MF capillary membranes with entrapped cells	Improve taste in white wine
Hydrolysis of fumaric acid to L-malic acid	Fumarase	UF capillary membrane reactor	Production of food additives
Hydrolysis of oleuropein	β-Glucosidase	Hollow fiber reactor with entrapped enzyme	Production of antioxidants and bactericides
Hydrolysis of triglycerides to fatty acids and glycerol	Lipases	UF capillary membrane reactor	Production of foods, cosmetics and emulsifiers, treatment of fats and oils
		Hydrophobic plate-and-frame membrane reactor	
		Spiral-wound polypropylene membrane reactor	
Synthesis of dipeptide aspartame	Thermolysin®	—	Production of sweetner
Conversion of bitter naringin into no-bitter naringinin + glucose	Rhamnosidase and β-glucosidase	—	Improvement of fruit juice quality and stability
Conversion of bitter limonin to deoxylimonin acid	*Acinobacter* sp., *Corynebacterium* sp.	—	

CSTR, continuous stirred tank reactor; UF, ultrafiltration; MF, microfiltration.

integrated system where up- and downstream processing of milk is properly considered.

Biocatalytic membrane reactors can also be used to valorize coproducts of cheese-making processes. Cheese whey is a highly polluting product, containing protein (~0.7%), lactose (~5%), salts and water (~93%). The recovery and reuse of these valuable compounds allows increased cost-effectiveness and reduced wastes production. The whey proteins, having excellent functional properties (such as α-lactalbumin and β-lactoglobulin), can be recovered and concentrated by ultrafiltration and nanofiltration and hydrolyzed to polypeptides useful as pharmaceutical intermediates. In addition, permeates from the ultrafiltered milk and whey contain lactose that can be recovered and used in the production of glucose and galactose syrup.

39.4.3 Treatments of Oils

Biocatalytic membrane reactors using immobilized lipases and esterases represent a sustainable alternative for the treatment of oils and fats by replacing traditional chemical processes with biotechnological ones. The performance of different membrane reactors depends on the physicochemical properties of membrane and reaction components. The most advanced systems are represented by two-separate phase enzyme membrane reactors. In these systems, the mass transfer of triglycerides through the enzyme-loaded membrane can be improved by the presence of stable emulsion droplets within the internal liquid phase of the porous polymeric matrix. The optimized mass transfer properties allow working in a reaction-limited regime to maximize reaction efficiency. Immobilized enzymes increase their half-life time; in addition, if they are immobilized under proper conditions they can also maintain native catalytic activity. Biocatalytic systems using immobilized lipase on membranes have been used for hydrolysis of triglycerides in olive oil, palm oil and various other vegetable oils, for improving oil quality and producing foods, home and health-care ingredients. Recently, they have also been investigated for the production of energy-related components.

In addition to hydrolysis of triglycerides, an innovative strategy for oil processing is the use of β-glucosidase to hydrolyze oleuropein into dialdehydes with better taste and higher nutriaceutical and bactericidal properties.

39.4.4 Hydrolysis of Pectins in Fruit Juices

The interactions between pectins and sugars (e.g. galactose, arabinose, and rhamnose) are predominantly responsible for the high turbidity and viscosity of fruit juices. Pectinases (able to hydrolyze the polygalacturonic chain) and pectinesterases (able to hydrolyze the ester bonds of pectins to produce pectic acids) are largely used to reduce the viscosity of fruit juices. The use of pectinases immobilized in membrane reactors may allow reusing the enzymes and controlling membrane fouling during the clarification process by cross-flow ultrafiltration. Using the enzyme immobilized on the membrane (polysulfone spiral-wound module), the permeate flux can be increased by approximately 30% with respect to that obtained when the enzyme is freely suspended in solution. Nevertheless, the steady-state permeate flux needs further improvements for large-scale applications. Other important parameters affecting the permeate flux are (i) amount of immobilized biocatalyst; (ii) transmembrane pressure; (iii) axial velocity; and (iv) operation mode. High performance is obtained with low concentrations of immobilized enzyme, low transmembrane pressure, and high axial flow rate.

39.4.5 The Treatment of Wine

The characteristic organoleptic taste and color of wine depends on the polyphenolic compounds present in must. In order to stabilize musts, white and rosée wines, laccase is used to oxidize polyphenols in solution, as well as anthocianase immobilized on synthetic and natural polymers used in hydrolyzing anthocianes.

During the maturation process of white wine, a secondary fermentation occurs that converts malic acid into lactic acid. In order to obtain a wine with very good organoleptic properties the control of this reaction is of crucial importance. Cells of *Leuconostic oenos* immobilized in a microporous membrane can be used to carry out the malolactic fermentation in white wine. Cells are immobilized by cross-flow filtration through polypropylene capillary membranes and the wine is recycled along the membrane module and permeate is collected aside. Using the appropriate cell density on the membrane, it is possible to control the conversion to the desired degree. The conversion of malic acid to lactic acid allows increasing the pH of wine from 3.4 to 4.2 or higher desired values. This gives a better taste to the wine because the slightly higher pH prevents precipitation of proteins in the mouth.

39.4.6 Biocatalytic Membrane Reactors in Pharmaceutical Productions

Biocatalytic membrane reactors are used for the production of amino acids, antibiotics, anti-inflammatories, anticancer drugs, vitamins, and so on. Reaction systems are mainly constituted of enzyme or cells immobilized on membranes or by cells cultured in membrane-assisted devices. Some of the most common applications in pharmaceutical production are summarized in Table 39.6.

Most of the studies in this field concern the production of optically pure enantiomers. This is due to the fact that at the molecular level, asymmetry dominates biological processes as regulatory principles and biochemical reactions are based on chiral recognition phenomena. In view of this, it is clear that it is important for bioactive compounds having pharmacological activities to have the proper enantiomeric shape. In fact, this allows improvement of efficiency and reduction in the amount of pharmaceuticals to be administered.

Membrane technological strategies are widely exploited in the production of optically pure isomers. Many studies focus on the production of amino acids, arylpropionic acids, amines and carboxylic acids. The technological problems associated with the production of these compounds at a large scale are connected to the need for enzymes of expensive cofactors, low water solubility of substrates, and presence of products in complex solutions from which they have to be separated and purified.

TABLE 39.6. Biocatalytic Membrane Reactors in Pharmaceutical Applications

Reaction	Biocatalyst	Membrane Reactor	Purpose
Production of ampicillin and amoxycillin	Penicillin amidase	Entrapment in cellulose triacetate fibers	Production of antibiotics
Hydrolysis of a diltiazem precursor	Lipase	Entrapment in biphasic hollow fiber reactor	Production of calcium-channel blocker in optically pure form
Hydrolysis of a cyano-ester to (*S*)-ibuprofen; naproxen esters to (*S*)-naproxen, etc.	Lipase	Entrapment in biphasic hollow fiber reactor	Production of optically pure nonsteroidal anti-inflammatory drugs
Conversion of cortexolone to hydrocortisone and prednisolone	*C. lunata*/*C. simplex*	Entrapment in polyacrylamide gel	Production of steroids
Conversion of fumaric acid to L-aspartic acid	*E. coli* with aspartase	Entrapment in polyacrylamide gel	Pharmaceuticals and feed additives
Conversion of L-aspartic acid to L-alanine	*P. dacunhae*	Entrapment in polyacrylamide gel	Pharmaceuticals
Conversion of acetyl-D,L-amino acid to L-amino acid	Aminoacylase	Ionic binding to DEAE-sephadex	Production of L-amino acids for pharmaceutical use
Synthesis of tyrosine from phenol, pyruvate, and ammonia	Tyrosinase	Entrapment in cellulose triacetate membrane	Production of L-amino acids for pharmaceutical use
Hydrolysis of 5-p-HP-hydantoine to D-p-HP-glycine	Hydantoinase and carbamilase	Entrapment in UF polysulfone membrane	Intermediate for the production of cephalosporin
Dehydrogenation reactions	(NAD(P)H-dependent enzyme systems	Confination with UF-charged membrane	Production of enantiomeric amino acids
Hydrolysis of DNA to olygonucleotides	DNase	Gelification on UF capillary membrane	Production of pharmaceutical substances
Hydrolysis of hydrogen peroxide	Bovine liver catalase	Entrapment in cellulose tryacetate membrane	Treatment in liver failure
Hydrolysis of whey proteins	Trypsin, chymotrypsin	Polysulfone UF membrane	Production of peptides for medical use
Hydrolysis of arginine and asparagine	Arginase and asparaginase	Entrapment in polyuretane membrane	Care and prevention of leukemia and cancer
Complex biotransformation cycles	Cell cultures	UF CSTR	Production of pharmaceuticals

In reactor systems using coenzyme-dependent reactions, negatively charged membranes are used to retain the cofactor in the reaction vessel. The retention is obtained by electrostatic repulsion between both, the negatively charged cofactor and the membrane. In other cases, the cofactor can be attached chemically to water-soluble polymers in order to increase its size and be retained by an ultrafiltration or nanofiltration membrane. Degussa has developed such a system for ton-scale production of L-*tert*-leucine by means of leucine dehydrogenase (LEUDH), which converts α-chetoacid into L-leucine reducing the $NADH_2$ to NAD; the NAD is then regenerated into $NADH_2$ by formate dehydrogenase (Fig. 39.12) (25,26).

When substrates have low water solubility, the heterogeneous reaction is carried out in multiphase membrane reactors in two-separate phase configurations (see description in previous sections). In general, enzyme activity and enantioselectivity of immobilized enzymes are preserved, provided the mass transport of reagents through the enzyme-loaded membrane is not limiting and the oil/water interface is realised at the level where the catalyst is immobilized. Many studies have been carried out with enzymes in biphasic systems. Lopez *et al*. (27) reported an example of this process at a large scale. The reactor is used to produce the (2*R*,3*S*)-methylmethoxyphenylglycidate ester, a chiral intermediate for the preparation of diltiazem (Fig. 39.13).

The full-scale facility comprises two banks of 12 60-m^2 modules for a total effective membrane reactor area of 1440 m^2. The annualized plant production rate is 53 kg/ m^2/year of 99% enantiomeric excess ester. Tanabe Seyaku (Japan), which selected the lipase specific for the reaction of interest, and Sepracor Inc. (USA), which studied the membrane device, developed this reactor. Sepracor Inc. commercialized other membrane reactors, such as a full-scale enzyme membrane reactor plant used in the production of the angina and hypertension drug

Cardizem®. The company focused on developing improved single-isomer and active-metabolite versions of existing drugs, and markets or out-licenses a number of respiratory drugs including Allegra®, Clarinex®, and Xopenex®.

When the compound of interest is obtained by fermentation, it is present in complex solutions from which it needs to be separated and purified. In these cases, integrated membrane systems can be used for continuous production and downstream separation. For example, the production of L-amino acids is obtained by continuous fermentation in a cell-recycle membrane fermentor. During operation, the bioreactor volume is kept constant by adding fresh medium at the same rate at which it permeates through the ultrafiltration membrane. The solution recovered as permeate contains the product, L-amino acid, together with other small molecules not retained by the membrane, while the cells and macromolecules are recycled back to the bioreactor. The product is then in a clarified solution from which it needs to be purified and concentrated. The purification can be obtained by membrane-based solvent reactive extraction carried out through two membrane modules. This operation is based on the transport of the solute from an aqueous solution (feed) to another at different pH (stripping) via an organic phase (extracting) containing a reactive carrier. The two phases are kept in contact at the pore entrance of the membrane interposed between them. When specific carriers are used at the extracting phase, the separation can be very selective.

An integrated process based on membrane operations is used to produce L-phenylalanine from glucose fermentation by *E. coli* (Fig. 39.14) (26,28).

The L-phenylalanine is produced in a 40 L fermentor, clarified through a first membrane filtration step, and then selectively extracted through a kerosene solution containing 10% D_2EHPA as carrier. The L-phenylalanine is then lyophilized from the extracted solution. Degussa developed the enzyme membrane reactor process on a productive scale, in cooperation with the Research Center Julich in 1981.

Electrodialysis with bipolar membranes can be used for the recovery of organic acids from fermentation processes. There are many acids that can be produced by this technique (29). A commercially operated industrial plant has been installed for the production of lactic acid (30). The simplified flow diagram of the conventional lactic acid production and the production with integrated electrodialysis is given in Fig. 39.15a and b. In the conventional lactic acid production process which is shown in Fig. 39.15a, the separation and purification of lactic acid is achieved mainly by ion exchange and requires different ion exchange steps resulting in a large volume of wastewater from regeneration salts. In the production process with integrated electrodialysis, which is shown in Fig. 39.15b, a minimum of ion exchange resin is needed in a final purification step. The concentration of the lactate salt is achieved by conventional electrodialysis and the conversion of the lactate into lactic

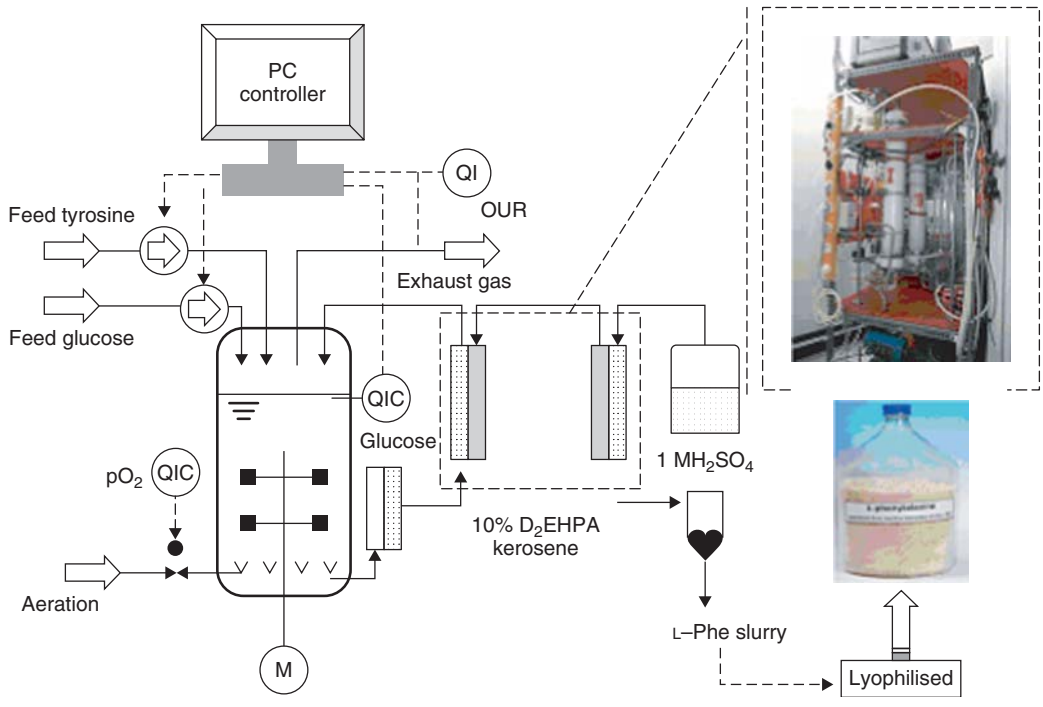

Figure 39.14. Integrated system for the production of L-phenylalanine (adapted from Refs 2, 17). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

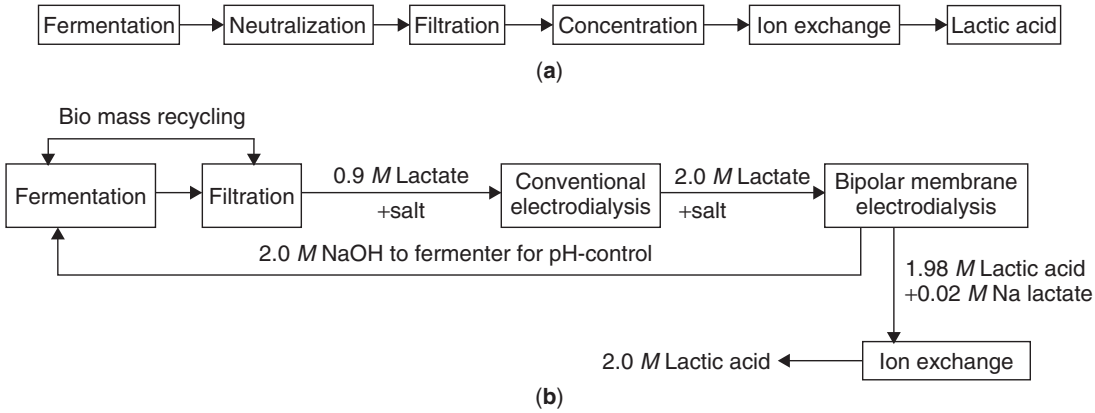

Figure 39.15. Simplified flow diagram illustrating (a) the conventional lactic acid production process and (b) the production process with integrated electrodialysis (2).

acid by bipolar membrane electrodialysis. The simultaneously produced base is recycled to the fermenter to control the pH-value.

Further readings for biocatalytic membrane reactors for enantiomers production are found in Refs 1, 4, 27, 31–34.

Producing pharmaceuticals from cell cultures is a complex and costly process which requires equipment and systems capable of handling fragile living cells without damaging them. Sterilization, cleanliness and quality control requirements are also extremely important. The bioreactor plays a central role in a cell culture facility. In the bioreactor, recombinant (genetically engineered) cells are grown and induced to produce the active pharmaceutical molecule which is then separated from the harvested cell culture and purified. Bioreactor systems for mammalian cell cultures and bacterial fermentation are available for pilot-scale as well as industrial-scale operations in sizes from 20 to 25,000 L (e.g. Alfa Laval Biokinetics. http://here.alfalaval.com/). Membrane filtration is already widely accepted for recovery of the active principles from mammalian cell cultures and fermentation. It is believed that the big challenge is combining the separation technology available with membrane filtration, to get the optimal solution. Cell separation is usually the first step after cell cultivation in the sequence of downstream processing. Cross-flow microfiltration has been used in separations involving different cell types. Membrane filtration also offers the possibility of washing and recycling the cells, for example by diafiltration. Cell washing is necessary to remove impurities in the culture medium if the cells themselves are products or the cells need to be disintegrated to release intracellular proteins. Recycling of cells is used to increase productivity in some fermentation processes.

The advantages of membrane filtration compared to conventional techniques such as centrifugation for the purification of biopharmaceuticals has largely been documented. Most of the information on process-scale membrane operations used in biotechnology is proprietary; numerous reports have appeared on laboratory or pilot-scale experiments; they deal primarily with separations of bacteria and yeast, and less with mammalian cells (35–40).

39.4.7 Biocatalytic Membrane Reactors in Biomedical Applications

Membrane processes play a key role in modern therapy for treating acute and chronic organ failure and in the management of immunologic diseases. In fact, membrane devices are employed in most extracorporeal blood purification methods, and the next generation of artificial organs and tissue engineering therapies are likely to be grounded on membrane technology. Intracorporeal uses of membrane devices include contact lens, biosensors, drug delivery systems, and artificial grafts.

The use of membrane reactors in the development of new artificial organs is currently attracting significant attention. Over 20 million patients are sustained by functional organ replacement. Most of recent research activity has been focused on organ replacement and extracorporeal treatment. Two main strategies are as follows: (i) the use of membranes as toxin separators and (ii) the use of cells combined with membranes to both remove toxins and supply metabolic organ functions. Membrane bioartificial pancreases, using isolated islets of Langerhans segregated by membranes, represent an alternative approach to the transplantation of whole pancreas in patients with insulin-dependent diabetes. Various investigations are directed to protect cells from immunorejection, maintain the cell viability and functions, reduce diffusion resistance of nutrients and metabolites, and study the kinetics of transformation of glucose into insulin.

39.4.7.1 Bioartificial Kidney. The limitation of dialysis, filtration, or adsorption to detoxify blood of patients with acute renal failure is that the artificial devices are not able to endow the readsorptive and endocrine functions expressed by the real kidney, thereby causing an accumulation of components or lack of metabolites that alter the physiological equilibrium.

To replace not only the filtration, but also the numerous other functions of the kidney, the combination of filtration with living cells seems a promising solution.

In 2001, Fissel reported a bioreactor system called the "renal assist device" (41). The multiple hollow fiber bioreactor contains renal tubule cells. After completion of animal experiments, the first clinical trials involving patients with acute renal failure have been executed successfully.

The kidney is the first organ whose function has been substituted by an artificial device; it is also the first successfully transplanted organ.

39.4.7.2 Bioartificial Liver. Isolated hepatocytes supported on membranes can work as a bioartificial liver for the temporary treatment of patients with acute liver failure. They are mainly used as extracorporeal devices where the membrane acts as a support for cell adhesion, as an immunological barrier between the patient's blood and the isolated hepatocytes, and as a selective mass transfer system allowing a sufficient exchange of small-molecular-weight solutes such as toxins and smaller proteins.

The extracorporeal biohybrid systems are suitable for short-term treatments to sustain the patient for the period they need to wait for an available organ or after transplantation, to give sufficient time for the transplanted organ to get grafted. In addition to acting as a "bridge" for transplants, the bioartificial liver gives damaged livers time to recuperate and enables as many as 20% of the patients to recover without transplants. Since the liver is an extremely complex organ and it performs a variety of functions, many of which are still poorly understood, artificial liver support is one of medicine's longest-standing challenges, with nearly 40 years of basic and clinical research. For a long time, it seemed impossible to develop an artificial liver by trying to design devices to perform each of the liver's functions. A breakthrough occurred when Kenneth Matsumura took a completely different approach and designed a device that used liver cells obtained from animals. The device contained both biological and manufactured components so it is called a bioartificial liver. Matsumura (42) published the first clinical report of a bioartificial membrane liver in 1987. The equipment used is reported in Fig. 39.16.

In the system, a patient's blood circulates through this bioartificial liver, where a synthetic membrane separates it from the animal cells. The membrane prevents immunologic rejection of the cells, but allows the cells to detoxify

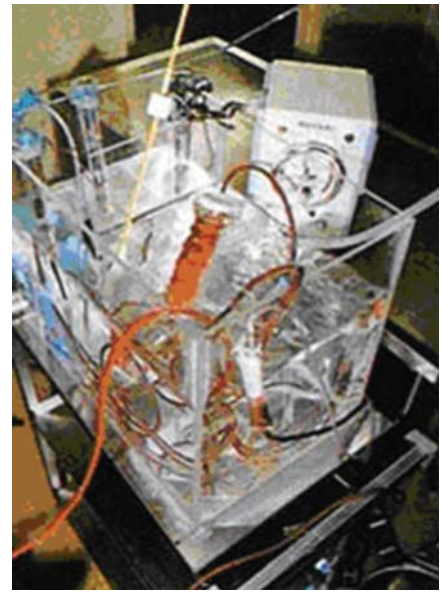

Figure 39.16. Equipment representing Matsumura bioartificial liver device (http://www.alinfoundation.com/Medical%20Research/Liver.htm). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

the blood in the same way as a natural liver. Disposable units can be used for a series of brief treatments, as with kidney dialysis.

Since then, following the same strategy, this area of research made great progress and although there are no bioartificial devices yet that are able to replace the organ, they are able to to keep the patient alive during the wait for an organ to be transplanted. Scientists at Berlin University's surgery and transplant unit developed a bioreactor containing a concentrated culture of metabolically-active pig liver cells, which are able to work as an "emergency liver" (43). The patient's plasma and blood cells are separated in an external circuit, with the plasma being directed to the bioreactor, which performs the normal liver functions in general and detoxification in particular. The plasma and blood cells are then recombined and reinjected into the patient. The main technological innovation of such bioartificial livers is in the organisation of the culture medium of pig liver cells in a three-dimensional structure (Fig. 39.17). This configuration allows cells to survive for several weeks by efficient oxygenation, properly supplying nutrients, and eliminating toxic waste.

By the end of January 1999, the system was used to support patients awaiting a transplant.

Bioartificial livers are exploited at clinical levels. Among other companies, Circe Biomedical Inc. developed a hollow fibre-based model with porcine hepatocytes–the HepatAssist™ liver support system. The Hybrid Organ GmbH Company, located in Germany, also developed a biohybrid liver system based on a hollow fiber design

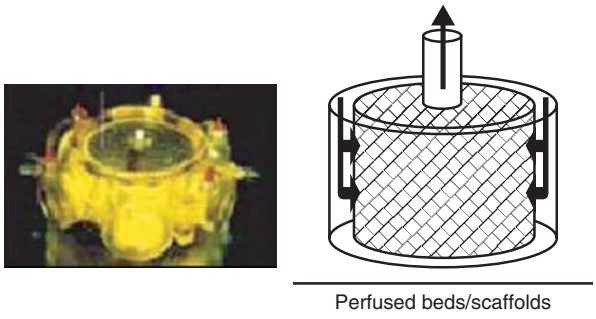

Figure 39.17. Three-dimensional structure of the bioartificial liver (picture from website: http://europa.eu.int/comm/research/rtdinf23/en/biotech.html). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

with porcine hepatocytes. In general, artifical liver devices containing pig cells can be used for about six to eight hours each day.

There has been much concern about exposing patients to animal cells, which may function slightly differently and harbor infectious agents. Devices that incorporate human rather than pig liver cells might be preferable as these may reduce risks and eventually function more like a normal human organ.

VitaGen Inc. of La Jolla, Califonia developed the first human-cell based bioartificial liver system designed to increase the liver's ability to regenerate and recover, the so-called Extracorporeal Liver Assist Device (ELAD®). The ELAD liver device is based on a hollow fiber bioreactor that uses human C3A hepatoblastoma cells. The device is designed to be used continuously for up to 10 days.

Cell-Loaded Membranes in Regenerative Medicine. There is currently great expectation over the possibility of replacing damaged body parts, through the new field of regenerative medicine. Potential strategies of regenerative medicine include stem cell transplantation, implantation of bioartificial tissues synthesized in the laboratory, and the induction of regeneration from the body's own cells by rendering the injury environment and/or the responding cells regeneration-competent.

The engineering aspects of regenerative medicine, such as membrane technology, scaffolds, and biointerface engineering, will play a key role in smart biomaterials, tailor-made surfaces, *in vitro* lymph nodes, bioreactors as assist devices, polymers for extracellular matrices, and biomimetic material development.

Currently, the only way to compensate for diseased or injured tissues is through bionic implants and organ transplants. Attempts to establish regenerative medicine have been ongoing for over two decades. The vast majority of work has been done with experimental animals, although human clinical trials to restore several types of tissues, such as islet cells of the pancreas to cure diabetes and dopaminergic neurons of the *substantia nigra* to cure Parkinson's disease have been conducted.

Three strategies have been used:

- cell transplants;
- the construction *in vitro* of implantable bioartificial tissues ("tissue engineering");
- the chemical induction of regeneration *in vivo* by controlled-release.

Cell transplants involve replacing the cells of a damaged tissue by transplanting aggregates of donor cells into the lesion. The transplanted cells can be differentiated cells, embryonic stem cells (ESCs) derivatives, or adult stem cells (ASCs).

The concept of bioartificial tissue construction (tissue engineering) is to seed cells into a biomaterial support (e.g. membranes and scaffold), then implant this construct into the body. The constructs can be open (biomimetic support moulded in the shape of the tissue, open to vascularization by the host) or closed (cells encapsulated in biomaterials and dependent on diffusion for survival). Ideally, substrates for tissue engineering should be highly biomimetic, not only providing the proper geometry and adhesive qualities to maximize cell migration, but also incorporating the biological cues and signals essential for proliferation and differentiation, as well as any factors for neutralization of molecules inhibitory to regeneration. They should also be biodegradable on a schedule that matches the growth and differentiation of the regenerating tissue. Widely used biomaterial supports are collagen I, alginate, ceramics, polylactic and polyglycolic acid meshes, and pig small intestine submucosa (SIS). No existing biomaterial meets all the criteria deemed necessary for good tissue regeneration, however, and research on new materials is of high priority.

39.5 OTHER MEMBRANE BIOREACTOR APPLICATIONS

39.5.1 Submerged Membrane Bioreactors in Wastewater Treatment

In the last decade membrane bioreactors have increasingly gained attention in the field of wastewater technology. The combination of bioreactors and membrane technology enables an innovative and effective cleaning process both in municipal and industrial wastewater technology. This is particularly important in view of the reduced inflows of drinking and rain water expected in the future.

A submerged membrane bioreactor combines biological treatment with membrane separation. The treated water is separated from the purifying bacteria (active sludge) by a

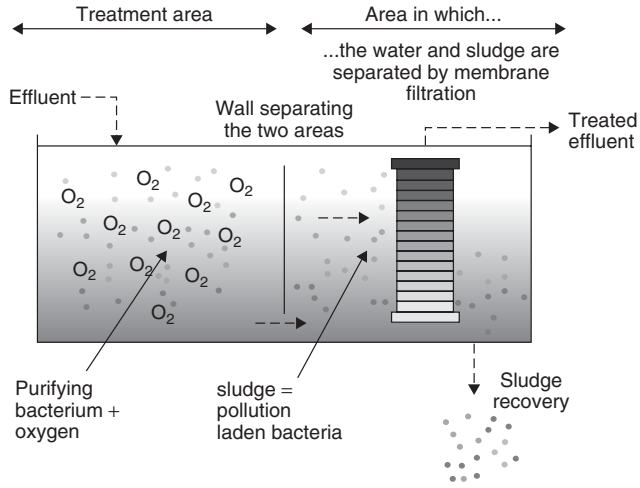

Figure 39.18. Schematic of a membrane bioreactor for wastewater.

process of membrane filtration rather than in a settling tank as in conventional systems. Only the treated effluent passes through the membrane. It is then pumped out. The sludge is recovered and dewatered (Fig. 39.18).

Large wastewater volumes characterize conventional wastewater technology. That means that municipal wastewater treatment plants have to treat high volume flows with relatively low contaminated dirty water. In order to ensure the purification performance of the plant even on days with more wastewater, caused for example by rainfall, large basin volumes are necessary in the area of the aeration tank and the final clarifier. These basins, which are usually open, are characterized by a large surface requirement and a long hydraulic retention time of the wastewater flows on dry days.

Compared with conventional wastewater technology, membrane bioreactors have a short hydraulic retention time and high biomass concentrations. Additionally, because of the compact way in which they are constructed, membrane bioreactors have a relatively low surface area requirement.

The sedimentation in the final clarifier is generally replaced by the implementation of membrane filtration. Using membrane technology, not only the biomass is separated from the water but also the quality of the purified wastewater is considerably improved. The use of microfiltration membranes with pore sizes usually between 0.1 and 0.4 μm ensures the complete retention of suspended matter and leads to a considerable reduction of the amount of bacteria in the outflow of the sewage plant.

The major benefits of the technology are: final effluent quality suitable for reuse; small ecological footprint <50% of a conventional plant; easy to control, can be monitored remotely; less sludge production, (generally 40% less).

In 1998, the US Environmental Protection Agency (EPA) promulgated final effluent limitation guidelines and standards in the Clean Water Act (CWA) for four subcategories of the pharmaceutical industry: (A) Fermentation; (B) Extraction; (C) Chemical Synthesis; (D) Mixing, Compounding, and Formulating. The regulations specifically identify "advanced biological treatment" as the basic technology for Best Practicable Control Technology (BPT) for Subcategory A, B, C, and D facilities; Best Available Control Technology (BAT) for Subcategory A, B, C, and D facilities; and New Source Performance Standard (NSPS) for Subcategory A, B, C, and D facilities. Membrane bioreactors fit as advanced biotreatment, and have been field-tested to provide reliable, cost-effective removal of chemicals from wastewater. The technology can treat many of the compounds listed in the regulations, including alcohols, aldehydes, alkanes, amides, amines, aromatics, chlorinated alkanes, esters, ethers, ketones, and miscellaneous compound groups.

Various companies are active in developing membrane bioreactors for wastewater treatment. Some of the most active ones are summarized in Table 39.7, while the membrane properties of some of the commercial modules are reported in Table 39.8.

Zenon, one of the leaders in membrane bioreactor technology worldwide, began by specializing in wastewater treatment over 20 years ago. The company has been selected to supply King County in the state of Washington with the largest membrane bioreactor in the world. The ZeeWeed MBR will treat an average day-flow of approximately 144,000 m^3 of municipal sewage or 38 million gallons per day (MGD) with peak flows up to 204,000 m^3 or 54 MGD, serving over 100,000 households [http://www.ecologicinvestor.com/news/printready.asp?ID=643].

Kubota process dominates the Japanese membrane wastewater treatment market. It provides the largest

Kubota	Flat Sheet	PEZ	0.4

number of membrane bioreactors, with more than 2140 plants installed worldwide. Most of them are of small or medium size, with flows of less than 200 m^3 perday with a membrane operation time of more than 11 years. Large plants are also installed, for example, a plant with an area of 97,320 m^2 allowing a flow of 75,000 m^3 per day was installed in Oman, in June 2006.

Most of the submerged membrane bioreactor applications are used in Asia (Japan, Korea and China), Europe (United Kingdom, Germany and Spain), and USA. Their overall geographical distribution for wastewater applications is illustrated in Fig. 39.19.

Major drivers for SMBRs implementation include more stringent legislation; local water scarcity; state incentives to encourage improvements in wastewater technology; decreasing investment costs; increasing confidence in and acceptance of SMBRs technology; and public concern.

The cost of membranes has decreased in the last 15 years from about US \$400 m^{-2} to about \$50 m^{-2}. Representative costs for life cycle for a membrane system are illustrated in Fig. 39.20. They only represent about 8% of the overall costs.

Drivers for membrane cost decrease include improvements in process design; improved operation and

maintenance schedules, and greater membrane life. Additional cost reductions can be expected upon standardization of element dimensions.

In conclusion, SMBRs are regarded by the water industry as "new" technology, although they are over 15 years old now. They provide lower ecological footprint, higher product quality, lower waste discharge, and meet more stringent regulation requirements.

SMBRs are expected to become more and more easily available due to the increasing number of investors (particularly from Asia), stakeholders, decision makers, technological innovation, and improved knowledge-base, for example with reference to membrane life, module design, operation mode.

Further reading on SMBRs can be found in Refs 1, 44–48.

39.6 CONCLUSIONS

In the last few years, biocatalytic membrane reactors have increased their potentiality in the rationalization of productive systems. Their intrinsic characteristics of efficiency, operational simplicity and flexibility, relatively high selectivity and permeability for the bioconversion and transport of specific components, low energy requirements, good stability, environmental compatibility, easy control and scale-up has been confirmed in various applications. As shown in Fig. 39.21, membrane bioreactors are already at a developing-maturing stage with respect to submerged membrane bioreactor configurations for wastewater treatment, and at an emerging-exploratory stage when considering the sidestream configurations for production systems. In the latter case, the real potentiality of the technology is still underestimated. Further demonstration over a long-term operation time is needed to prove the robustness of the technology in order to increase investor confidence and stakeholder acceptance.

Moreover, this new membrane bioreactor technology is very consistent with the strategy of process intensification, which today represents the most realistic answer to the demands of sustainable industrial growth.

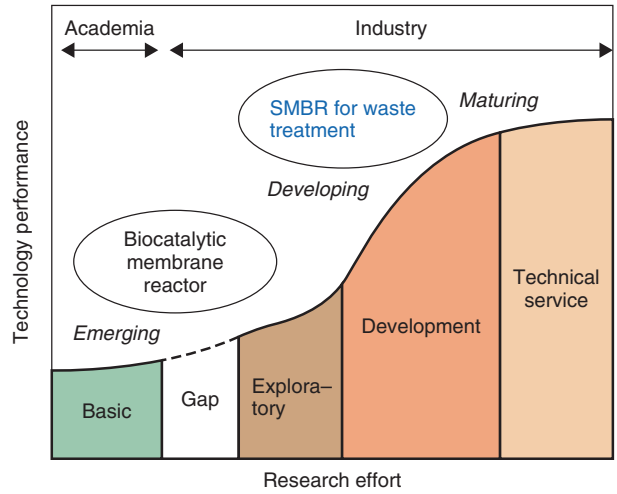

Figure 39.21. Membrane bioreactors' technology performance as a function of research effort. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Developments in membrane engineering, reactor design and control, genetically engineered biocatalysts and biomass, consumer demand of natural-like products, public concern and governmental regulations about environment, will fuel a renaissance of biocatalytic membrane reactors, and in particular their use in integrated systems. The field is expected to progress and contribute to innovative production, processing, and treatment strategies beyond the current technological solutions in various sectors including the fields of biotechnology, pharmaceutical, biomedical, agro-food, fine chemicals, water, fuel, and energy. To move from incremental progress to breakthrough advances, a holistic and interdisciplinary approach is mandatory considering that "the whole is more than the sum of its parts". It is therefore necessary to take into the account the sustainability of the entire life cycle of integrated systems, from development to operation, to disposal. There is no doubt that biocatalytic membrane reactors are among the best available technologies and they can certainly play a major role in facing the challenges of promoting sustainable processes.

BIOREACTOR SCALE-DOWN

Laura A. Palomares

Ideally, a bioreactor should operate under controlled and homogeneous conditions. However, concentration gradients due to deficient mixing can develop in inhomogeneous systems, such as hollow fibers, packed beds and microcarrier reactors, and also in the so-called homogeneous systems such as stirred-tanks, airlifts and bubble columns. Environmental heterogeneities are the result of bioreactor design and operating conditions, and in general, lead to poor process performance. Diverse environmental heterogeneities have been documented for suspended cultures of animal and plant cells, including gradients in carbon dioxide, pH, microcarrier concentration, and culture segregation due to formation of cell aggregates and clumps. Gradients in pH, dissolved oxygen or substrate concentration can also occur in large-scale animal and plant cell culture as predicted from analysis of the characteristic times of a particular process/bioreactor combination. In turn, gradients and heterogeneities occur in a variety of conditions during microbial cultures, such as pellet formation in mycelial fermentation, development of biofilms in chemostats and waste water systems, in culture broths with complex rheology, in solid-state fermentation, or during fermentations at very high cell densities. Here, scale-down is described as a method of approaching the problem of heterogeneity in large-scale cultures.

The classical approach for scaling-up a fermentation process on the basis of geometrical similarity basis has the long recognized drawback that only one fundamental variable can be maintained constant, whereas the rest will vary as the process is translated to the larger scale. Constant power input per unit volume, constant volumetric oxygen transfer coefficient, or constant speed at the impeller tip are among the most commonly used scale-up criteria. However, as seen in Table 40.1 (1), using any of these criteria will result in a lower agitation rate in the large-scale vessel compared to the small-scale bioreactor. Lower agitation rates will, in turn, favor the development of a nonuniform environment for fast bioreaction rates. If the desired scale-up goal is to maintain the same homogeneity as in the small-scale bioreactor, then the mixing time should be maintained constant. Nonetheless, this would require a substantial increase in agitation rate on the larger scale, a task that is usually not possible due to equipment limitations and/or the fragile nature of most animal cell, filamentous fungi, and other shear sensitive cultures. Increasing agitation speed also poses economical considerations due to elevated power

consumption in the large scale. Accordingly, the well-mixed condition obtained in laboratory-scale vessels cannot be maintained on larger scales. This is evidenced in Fig. 40.1 (2), where it can be seen that the mean circulation time (t_c) of Newtonian and pseudoplastic fluids increases with reactor volume.

Circulation time is defined as the time necessary for a fluid element to return to a fixed reference position after circulating through a stirred tank. As a rule of thumb, circulation time (t_c) is (3):

$$t_c = t_M/4 \tag{40.1}$$

where t_M is mixing time.

Several correlations exist to estimate t_c, some of which are listed here. However, correct estimation of t_c demands a case by case analysis. Circulation time is considered to be the total tank volume divided by the impeller pumping capacity (Q_p) (4,5). The impeller pumping capacity is defined as:

$$Q_p = KND^3 \tag{40.2}$$

where K is the discharge coefficient, N is the impeller speed and D is the impeller diameter. The discharge coefficient is a function of tank and impeller geometries. Some discharge coefficients for baffled tanks with standard configuration are listed in Table 40.2. Accordingly, the general form of t_c is:

$$t_c = \frac{V}{KND^3} \tag{40.3}$$

Tank geometry is explicitly included in other correlations for calculating t_c for example, (3):

$$t_c = \frac{V}{2HN\pi^2 T_v^2} \tag{40.4}$$

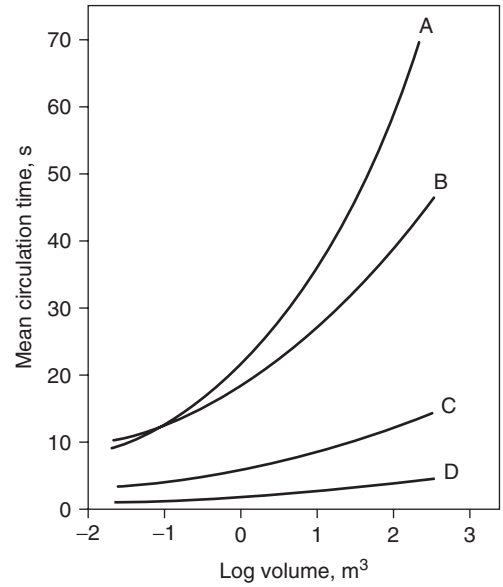

Figure 40.1. Variation of mean circulation time with vessel volume. Tank configuration $H/t_v = 1$, single disc turbine $D/t_v = 0.33$, power 1.67 kW/m^3. A, pseudoplastic fluid. B, Newtonian fluid (1 Pa s). C, Newtonian fluid (0.1 Pa s). D, Newtonian fluid (0.01 Pa s). (Reprinted from Ref. 2).

where H is liquid height and T_v is tank diameter.

In a culture where concentration gradients are present, a cell will be exposed to a fluctuating environment during its circulation through the bioreactor. If severe gradients develop, then localized zones differing from bulk conditions will exist in the bioreactor that can adversely affect the culture. For instance, dissolved oxygen (DO) or substrate can be limiting in stagnant zones, whereas in point-of-addition zones, the cells can be inhibited by high substrate or acid/base concentrations, resulting in pH gradients. Special attention should also be placed on shear stress gradients, particularly with fragile cells that will be exposed to deleterious shear stresses on a frequency determined by the circulation time.

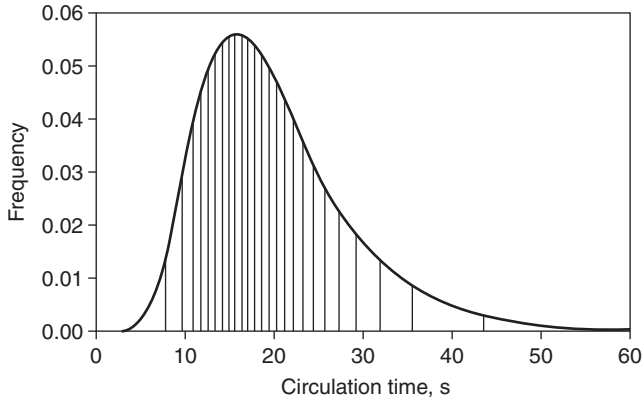

Figure 40.2. Frequency of circulation times for a lognormal distribution. (Reprinted from Ref. 6).

Circulation time is a fundamental parameter in scale-down studies because it determines the time spent by a cell in the various bioreactor regions and provides the framework for scaling the fluctuations in a large-scale fermenter into a test system (6). As indicated by Yegneswaran *et al*. (6), actual circulation times in large fermenters are distributed over a range of values, which can be described by a lognormal probability distribution (Fig. 40.2). Therefore, using a circulation time distribution rather than a mean circulation time should better mimic the real situation. As seen in Fig. 40.1, mean circulation times for typical microbial pilot and small-scale fermenters (less than 100 L) do not exceeded 10 s. In 10,000 L fermenters, t_c can range from 5 to 30 s for Newtonian fluids, and can be as high as 40 s for pseudoplastic fluids. In comparison, t_c for animal and plant-cell cultures are several-fold higher than those for microbial fermentations at equivalent scales. As reviewed in detail by Lara *et al*. (7), mixing times for typical large-scale stirred-tank cell culture vessels can range between 40 to 360 s, whereas for airlift and bubble column bioreactors for cell culture, t_M can range between 200 to 1000 s. Accordingly, circulation times for large animal and plant cell cultures will be between 10 to 250 s. In the case of industrial microbial fermentations, the reported t_M for stirred-tank reactors are in the range of 10–110 s (7), and as high as 1000 s for a 150-m^3 bubble column.

40.1 THE SCALE-DOWN APPROACH

Scale-down is a semiempirical method, based on regime analysis, which consists of reproducing on a small scale the conditions prevailing (or those that will be possible to attain) on the large scale (3,8). Scaling-down can be applied to two general situations. It can be used as a method for scaling a new process or operation to new larger scale equipment or installation. Alternatively, scale-down can be used for diagnosing problems (poor yields, cell death, etc.) and predicting the outcome of modifications to existing large-scale processes or equipment (changes in cell line, media composition, operation conditions or bioreactor fittings). In practice, the second general situation is most commonly encountered (3). In both cases, small-scale experiments are designed from knowledge of the fundamental parameters limiting the process at the large scale. The experimental results can then be used to optimize and predict the performance of the new (or modified) process or operation on the large scale. An underlying value of down scaling experiments is generating data under conditions resembling real conditions but without actual experimentation on the real scale, a task that is impractical and economically unfeasible. A schematic representation of the scale-down method is presented in Fig. 40.3, which shows that it consists of four main steps (9,10): regime analysis, simulation, optimization, and application. A more detailed review of the scale-down method can be found in Ref. 10.

40.2 REGIME ANALYSIS

Regime analysis is based on identifying the limiting mechanisms that determine the bioprocess on a large scale (11). This is achieved by obtaining the characteristic times (also called *relaxation times* or *time constants*) of the subprocesses conforming the system (3). Characteristic time is defined as capacity divided by flow of the particular subprocess (10,11). Three types of information are needed for determining characteristic times: the bioreactor configuration, physical models (for instance, models that describe mixing, heat, and mass transfer), and bioreaction models (for instance, models that describe the relationship between production rate and growth rate or between growth rate and substrate concentration or pH) (12). Any model has inherent limitations and thus, must be used with caution. Accordingly, analysis of subprocesses should be based only on comparison of the order of magnitude of the various characteristic times (12). When characteristic times of intracellular mechanism are of the same order of magnitude as those of changes in the extracellular microenvironment

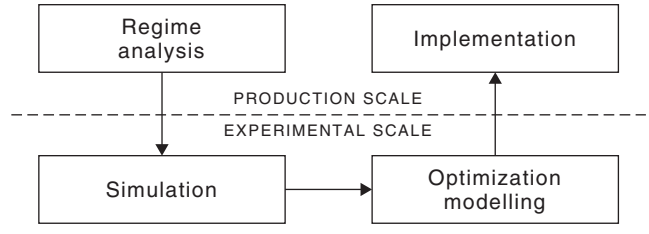

Figure 40.3. Scale-down procedure. Adapted from Refs 9,10.

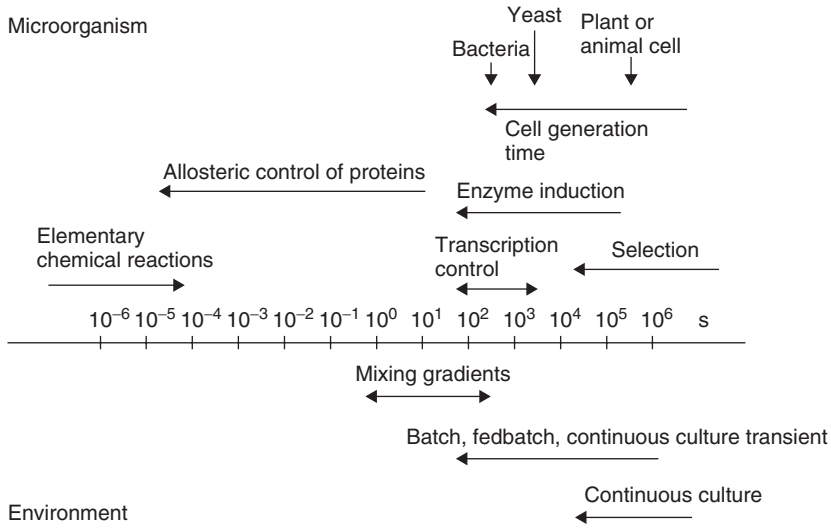

Figure 40.4. Characteristic times of important cellular and environmental processes. (Adapted from Refs 3,13).

(such as mixing and mass transfer), then both subprocesses will interact and will affect the behavior of the cell (3). In Fig. 40.4 (13), the relative magnitudes of characteristic times of important cellular and environmental processes are compared. Characteristic times of various subprocesses relevant to cell culture and microbial fermentations are summarized in Table 40.3. A more detailed discussion of characteristic times, including some examples and their derivation, as well as indications for selecting significant subprocesses can be found in Refs 3,8 and 10.

Small characteristic times are indicative of a fast process. In contrast, a slow process is distinguished by a large characteristic time and will be the potentially limiting step (14). For instance, Nienow *et al*. (14) reported oxygen uptake, mass transfer, and mixing characteristic times for recombinant CHO cells and NS0 cells in an 8-m^3 agitated bioreactor (Fig. 40.5). As seen in Fig. 40.5, oxygen uptake characteristic time for CHO cells is larger than the mass transfer and mixing characteristic times at all energy dissipation rates studied. Thus, it can be anticipated that no oxygen limitation or dissolved oxygen gradients will form under these conditions. In contrast, for higher cell concentrations and/or specific oxygen uptake rates, as is the case for the NS0

TABLE 40.3. Characteristic Times

Process	Formula
Mixing	t_M (experimentally determined)
Oxygen mass transfer	$t_{mt} = \frac{1}{k_L a}$
Circulation	$t_c = \frac{t_M}{4}$
Growth	$t_\mu = \frac{1}{\mu}$
Heat transfer	$t_{ht} = \frac{V\rho Cp}{UA}$
Difussion	$t_{\text{diff}} = \frac{\lambda_k^2}{D_{o/w}}$
Oxygen uptake	$t_{rxn} = \frac{c}{q_{O_2} X}$

Adapted From (12).

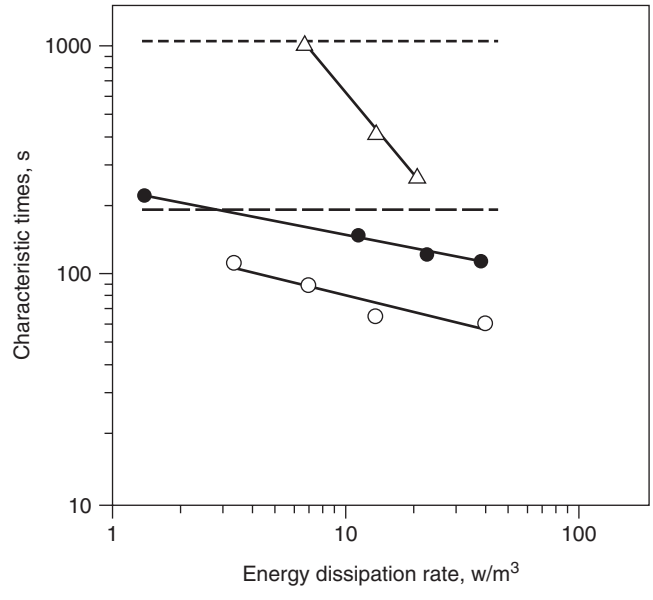

Figure 40.5. Characteristic times in an agitated tank at the 8-m^3 scale with 2/9 t_v Rushton turbine. Mass transfer time (open triangle) and t_M (open circle) at a superficial gas velocity of 2×10^{-4} m/s. t_M (closed circle) without aeration. Short dashed line indicates reaction time for 4×10^5 CHO 320 cells/mL. Long dashed line indicates reaction time for 2×10^6 NS0 cells/mL. (Reprinted from Ref. 14).

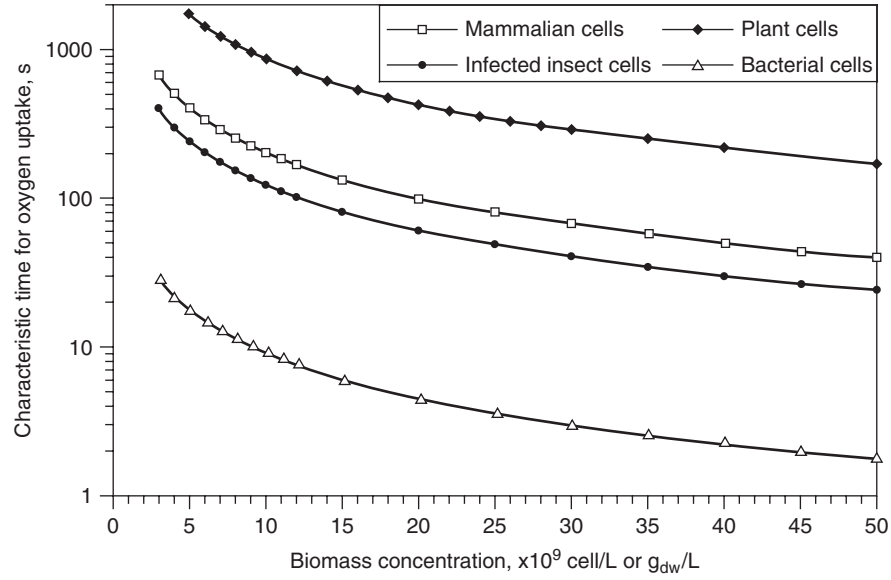

Figure 40.6. Characteristic time for oxygen uptake t_{rxn} (calculated after Table 40.3) of bacterial, animal, and plant cell cultures at different biomass concentrations. The q_{O2} utilized for calculations were 2.8 μmol/g_{dcw}/s, 0.031 μmol/g_{dcw}/s for plant cells, 0.111 μmol/10^9 s for mammalian cells, and 0.225 μmol/10^9 s for infected insect cells. Concentration of bacterial and plant cells in g_{dcw}/L, of mammalian and insect cells in 10^9 cell/L. The initial value for dissolved oxygen concentration (DO) was 50% of air saturation. (Reprinted by permission from Ref. 7).

cells, characteristic time for mass transfer will be longer than for oxygen uptake. Accordingly, it can be predicted that oxygen supply will be insufficient. Figure 40.6 shows the t_{rxn} (or oxygen consumption time) for plant, animal, and microbial cells as function of the cell concentration of a culture (7). A simple comparison of t_{rxn}, illustrated in Fig. 40.6, with the previously mentioned t_M for large-scale bioreactors reveals that there will be a variety of conditions where t_{rxn} is shorter than t_M. Therefore, dissolved oxygen gradients can easily occur in large-scale bioreactors.

40.3 SIMULATION

In this step, the rate limiting mechanism (or mechanisms), identified from regime analysis of the production scale, is simulated on a laboratory scale. It is not necessary to maintain geometric similarity during scaling-down in order to have conditions representative of the full scale. What is important is to maintain constant the relevant characteristic times between both scales (8). A fundamental difference between large and laboratory-scale bioreactors is that the latter are inherently well mixed. Because phenomena resulting from mixing deficiencies at large-scale are among the most common problems analyzed during scaling-down, ingenious experimental setups have to be designed for creating a nonuniform environment during laboratory-scale simulations. Furthermore, spatial gradients (i.e. those that are a function of the location in the reactor and that originate from mixing deficiencies) can result in fluctuating phenomena of low characteristic times (in the order of seconds to minutes). Therefore, spatial gradients can be difficult to simulate since very fast fluctuations will be usually required in the downscaled experiments (15). In contrast, temporal gradients (those that depend on process time) are associated to high characteristic time (in the order of minutes to hours) and are relatively simple to simulate (15). The commonly employed experimental configurations for scale-down studies are described in detail later.

40.4 OPTIMIZATION AND MODELING

After the limiting mechanisms on the large scale have been identified and reliable methods have been established to simulate them in a laboratory bioreactor, then an optimization study can be pursued. A broad range of conditions can be readily tested in scale-down experiments, including the effect of period, amplitude, and axis of oscillations of a particular culture variable on cell physiology and metabolism. The period, amplitude, and oscillation axis will correspond to circulation time, magnitude of gradients, and mean bulk condition, respectively, present on the full scale. In this way, the influence of changes in physical subprocesses on cellular subprocesses can be assessed. Unfortunately, very little information exists on bioprocess

optimization with respect to gradients (15). Furthermore, equipment, economic or operation constraints at the large scale can prevent the implementation of some possible optimization results (3). For instance, an optimization result can dictate the best configuration for distributing an ideal number of base addition or substrate feeding ports in a fed-batch or perfusion operation, as well as the best concentration of the corresponding feeding solutions. However, on the full scale, it may be impractical to implement the exact results of such optimization exercise due to concerns of contamination risks and/or increased operating and equipment complexity. In any case, the optimization results should consider only the attainable regimes in the full scale. An alternative approach is the modification of the cellular metabolism to develop cells with a reduced sensitivity to environmental fluctuations. This will be described later in this chapter.

The results of the optimization step can be used to generate improved microbiological models. This is important because the vast majority of microbiological models are based on balanced growth (pseudo), steady-state phenomena, or temporal gradients. Although there have been significant advances in modeling, the metabolic response of microbial cells to environmental perturbations (16,17), almost no models exist describing cell metabolism and physiology under transient oscillatory conditions resulting from spatial gradients (3,15). Furthermore, computational fluid dynamics (CFD) can be a powerful tool for complementing the simulation and optimization studies through estimations of concentration, fluid velocity, and shear rate profiles. In particular, CFD can yield important information on the maximum and minimum values of relevant variables such as pH, shear stress, temperature, and concentration of substrate, dissolved oxygen, carbon dioxide, and by-products. In addition, the fraction of culture volume exposed to a particular detrimental condition (information that is necessary for representative downscaling experiments) can be derived from CFD. Progress in CFD studies, including bioreaction, mass transfer, and fluid mixing in fungal fermentation, has been reported (18,19). A recent study by Lapin *et al*. (20) described the behavior of a heterogeneous population in a 900-L fed-batch culture of *Escherichia coli*. This study coupled the effects of nonideal mixing with previous knowledge on changes of metabolite concentrations as a result of environmental perturbations. The numerical simulation showed oscillations of key glycolytic metabolites as a function of the exposure to glucose gradients. Also, differences in intracellular concentration of pyruvate and phosphoenol pyruvate of the cells as function of the spatial position in the bioreactor were described. In contrast to these relatively advanced studies for microbial fermentations, only limited studies of CFD for plant or animal-cell cultures exist (21). However, the scarce knowledge of the impact of fluid dynamics and environmental gradients in biological systems makes difficult to verify the results of CFD predictions, especially in the case of cyclic exposures to environmental gradients.

40.5 APPLICATION

The final step in the downscaling method is translating the laboratory experimental results to the production scale (Fig. 40.3). The traditional scale-down approach considers the implementation of process or equipment modification based on the laboratory-scale experiments. Here again, quantitative published information is very scarce for the general area of microbial fermentations and is almost nonexistent for the area of animal and plant cell culture. An interesting case study is reported by Geraats (22) for the production of a lipase by *Pseudomonas alcaligenes*. In such study, a 65% reduction in maximum lipase concentration occurred when the process was scaled-up from 10 L to an existing 100-m^3 fermenter. To investigate the possible causes of the production loss, downscaling experiments at 10 L and 100 L were performed. The aspects studied included gradients of soy oil, pH, and oxygen, raw materials, medium preparation, and sterilization and inoculation procedures, dissolved carbon dioxide concentration, and shear and air-broth interfaces. Through such an approach, dissolved carbon dioxide was identified as the main cause of scaling-up problems. By increasing the ventilation rate and decreasing the head pressure combined with a lower pH, lipase production at full scale finally reached the values obtained on the 10-L scale.

A different strategy for improving process performance through scale-down studies has been reported by Lara *et al*. (23,24). These authors performed studies to investigate the physiological responses of a recombinant *E. coli* strain, expressing green fluorescence protein (GFP), to DO gradients simulated in a two-compartment scaled-down system, at a mean t_c of 50 s. Within the experimental setup used, the cells spent about 33 s under anaerobiosis, followed by about 17 s under aerobic conditions on a cyclic fashion (23). The production of GFP was 19% lower in the scaled-down cultures in comparison to fully aerobic cultures. The DO gradients also reduced the specific growth rate, and resulted in accumulation of all the metabolites from mixed-acid fermentation pathways. Transcriptional response to DO gradients was also analyzed. A generalized increase of up to sixfold on the transcriptional level of anaerobic genes, relative to transcription level of cultures at constant DO concentration was observed. Also, differential transcriptional level of genes from the tricarboxilic acids cycle and cytochromes in downscaled cultures was reported. This is an important observation because, as

illustrated in Fig. 40.4, the characteristic time for mixing gradients, transcription control, and enzyme induction can be of the same order of magnitude. Consequently, data of fermentation metabolites accumulation during the downscaled cultures is not enough to elucidate if the activation of fermentation pathways occurs at the level of enzymatic induction or gene expression. Based on the transcriptional and kinetic data, Lara *et al*. (24) inactivated genes involved in the production of acetate, formate, and lactate, which were the most importantly accumulated by-products in the downscaled cultures. Compared to the parental strain, a triple mutant *E. coli* strain only produced low amounts of acetate and did not produce formate or lactate when cultured under simulated DO gradients. More importantly, the specific growth rate and GFP production of the mutant strain was only slightly affected by DO gradients. This approach represents a valuable tool for process improvement because, as explained before, it is not always possible to implement in the larger scale equipment the results of scale-down studies.

It should be noted that culture parameters on a larger scale will not necessarily be inferior to those on a smaller scale. For instance, although antibody production by CHO cells was worst in a 1000 L production tank compared to a 2-L bioreactor, cell growth in the larger vessel was almost doubled (25). In this case, analysis of the hydrodynamic parameters for the two vessels revealed that cell damage due to disengagement of small bubbles was more important than mechanical stresses. Therefore, cell death was higher in the smaller bioreactor because superficial gas velocity was also higher compared to the larger vessel. Furthermore, if scale-down studies reveal an absence of detrimental effects caused by environmental gradients, there could be situations where an oscillatory operation could be beneficial on the large scale. For instance, when a cell culture is insensitive to particular dissolved oxygen gradients, then energy savings and reduction of deleterious shear stresses could be achieved by an intermittent mixing and/or gassing operation. Examples of the beneficial effects of an oscillatory environment can be found for various microbial fermentations (26–28).

A different approach for the scaling-down of industrial cultures has been recently applied to microbial and animal-cell processes. This approach is not necessarily based on regime analysis, but relies on matching the same performance in the large and small-scales, using the same power input values, superficial gas velocities, and oxygen transfer characteristics among others. This approach emerged from the need for faster screening of strains or cell lines, development, and optimization of culture processes. During recent years, the design and evaluation of bioreactors at mL and even at μL-scale have been under intense research. For instance, Bocazzi *et al*. (29), reported the design of a multiplexed bioreactor with a working volume of 50 μL. Global gene expression profiles of *E. coli* cultures carried out in the micro-bioreactor and cultures at 500 mL-scale were similar, which demonstrate the potential of the miniaturized systems for process development. The application of miniaturized bioreactors has allowed reproducing the performance of microbial fed-batch cultures (30). The utility of miniaturized bioreactors for the scale-up of microbial and cell culture has also been tested. For example, shaken microtiter cultures of *E. coli* and hybridoma cells have been scaled-up to 1.4 L- and 100 mL-scale cultures. In the case of *E. coli* cultures, a constant k_La allowed matching the results at both scales, whereas for hybridoma cells, keeping the mean energy dissipation rate constant yielded reproducibility at both scales (31). Islam *et al*. (32), scaled-up an *E. coli* culture from microwell plates scale to a 7.5 L STR by matching a constant k_La, with good results. The success of miniaturized bioreactors in the near future will rely on effective pH and DO control, and the capacity to emulate typical production conditions, like fed-batch mode.

40.5.1 Scale-Down Studies in Cell Culture

The development of improved operating strategies, aimed at attaining higher cell concentrations than in conventional cultures, will result in increased oxygen consumption and heat and carbon dioxide evolution. Moreover, a move toward the use of highly concentrated feeding solutions should be expected in improved fed-batch and perfusion strategies. Undoubtedly, all of this will worsen the problems of bioreactor heterogeneity observed until now. Diverse culture heterogeneities and problems due to scale-up or transient environmental changes have been reported for plant- and animal-cell culture (described in Refs 25 and 33). For instance, culture segregation due to cell clumping is common in plant cell culture, changes in protein glycosylation patterns can be caused by transient periods of glucose excess, heat shock proteins are induced by transient changes in temperature, and protein structural changes can occur during scale-up. A detailed description of other environmental heterogeneities and their adverse effects in cell culture is presented by Lara *et al*. (7). Nonetheless, scale-down has scarcely been used as a tool for simulating gradients or predicting their effect in cell culture. The reports by Slater (25), discussed previously, and by Nienow *et al*. (14), are among the very few available studies of scale-down in cell culture. In the latter study, Nienow *et al*. (14) used scaled-down vessels to simulate the mixing times of an 8-m^3 animal-cell bioreactor, and concluded that severe pH gradients are likely to develop in the full-scale system. Rhiel and Murhammer (34) assessed the effect of oxygen oscillations in animal-cell culture, specifically on the physiology of

insect cells. They reported an adverse effect of dissolved oxygen oscillations between 0 and 15% in cell growth and recombinant protein production. In their study, the cultures remained at each DO concentration for 30 min, and it took from 6 to 7 min to shift between both DO set-points. Serrato *et al*. (35) reported the effects of DO oscillations in the production and glycosylation pattern of a monoclonal antibody (MAb) produced in hybridoma cultures. By manipulating the composition of the inlet gas, sinusoidal DO oscillations were simulated in a one-compartment scale-down system at oscillation periods ranging from 800, 1600, 6400, and 12,800 s. As shown in Fig. 40.7, DO oscillations reduced the viable cell concentration and the specific growth rate in about 38 and 35% respectively. In contrast, the amount of MAb produced was only slightly affected. Despite this, the glycosylation pattern of the MAb produced under the highest DO oscillating period presented a higher amount of trigalactosylated and sialylated glycans, which can have a strong influence on the therapeutic function of the antibody. In the previous two studies, the oscillation frequencies tested were well above the t_c reported for large-scale bioreactors for cell culture. However, the reported results are very relevant due to the limited information available of scale-down studies for cell culture processes.

The impact of pH gradients is also a relevant problem in cell culture. The pH value in the medium usually tends to decrease during a culture, often as a result of metabolic activity. The addition of a base concentrated solution in a given point of the bioreactor, and the large t_c of the large-scale bioreactor operated for cell cultures can potentially lead to important pH gradients. For instance, it has been reported the existence of pH gradients of up to 1 unit between the alkali addition zone and the bulk liquid in an 8-m^3 stirred-tank bioreactor designed for mammalian-cell culture (36). Culture aggregation, nutrient gradients, and the use of inherently inhomogeneous bioreactors like packed beds or other systems with immobilized cells can also cause pH gradients (37). Exposure of cells to pH gradients may result in reduction of viability or cell lysis. Ozturk (38) reported cell lysis as a consequence of high pH values in the point of base addition. In another study (39), it was shown that although NS0 cells were robust with respect to a single pH perturbation (a transient step increase from 7.2 to 8), submitting the cell to cyclic perturbation of different frequency and duration (by adding 2 M NaOH pulses), importantly decreased their viability.

The scarcity of scaling-down studies can be a consequence of the relatively small scale at which plant- and animal-cell cultures have been commonly performed, as well as their high metabolic characteristic times, compared

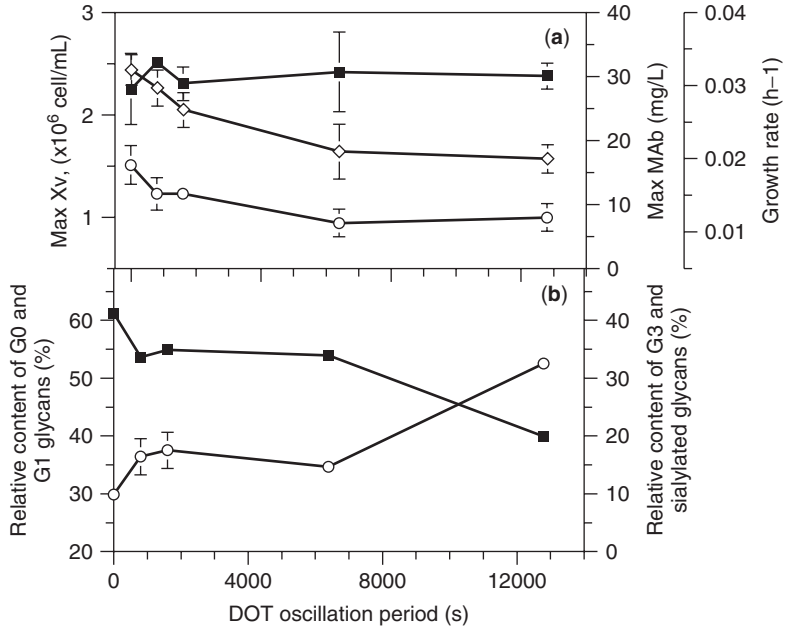

Figure 40.7. Dissolved oxygen tension (DOT) oscillations change the glycosylation profile of a monoclonal antibody produced by hybridoma cells. (a) Maximum viable cell concentration (open circles), maximum monoclonal antibody concentration (closed squares) and specific growth rate (open diamonds). (b) Relative content of glycans *N*-linked to the monoclonal antibody. Ungalactosylated and monogalactosylated glycans (closed squares), trigalactosylated and sialylated glycans (open circles). (Adapted from Serrato *et al*. Ref. 35).

to microbial cultures. However, it can be expected that, as operation of high cell density large-scale cultures increases, the application of downscaling experiments will increase. The characteristics of animal and plant cells and their culture systems will demand the design of novel experimental configurations to adequately simulate large-scale conditions in laboratories. However, there is a lack of published information of systems expressly designed for cell cultures. Accordingly, the description of experimental configurations for scale-down studies, presented in the next sections, is based on information generated from the microbial fermentations area. Most of the experimental configurations described in the next sections can be readily applied to animal and plant cells, and only particular attention must be placed on the fact that circulation times and shear sensitivity of cell cultures are several-fold higher than those of microbial fermentation.

40.6 SCALE-DOWN STUDIES IN MICROBIAL FERMENTATIONS

The vast majority of published scale-down studies have dealt with microbial fermentations. Several biological models have been the subject of study, such as the bacteria *E. coli*, *Bacillus subtilis*, and *Corynebacterium glutamicum*, the yeasts *Saccharomyces cerevisiae* and *Kluyveromyces marxianus*, and the fungi *Penicillium chrysogenum*, *Streptomyces clavuligerus*, and *Aspergillus niger*. Different environmental fluctuations have been studied, such as pH, DO, and substrate oscillations. Also, most of the different scale-down systems have been developed for the purpose of studying microbial fermentations. For instance, Sandoval *et al*. (40) reported the effect of DO gradients, simulated in a two-compartment scale-down system, on the production of recombinant human proinsulin (Fig. 40.8). Such study is relevant as it assessed the direct effect of DO gradients, independent from other environmental parameters variations, in a t_c range (20–180 s) similar to that present on large-scale bioreactors. Lara *et al*. (7) recently published a detailed review of available scale-down studies.

Scale-down studies of microbial fermentations have generally focused only on macrokinetic effects, whereas only two studies have characterized the expression of several genes of *E. coli* as a result of fluctuating environments (23,41). Such reports are valuable for establishing rational scale-up criteria and developing improved bioprocess monitoring. Furthermore, validation of industrial processes through scale-down studies is an important activity when producing therapeutic molecules, as it is necessary to ensure the consistency of product quality. For instance, Bylund *et al*. (42) analyzed the effect of scaling-up an *E. coli* culture on the degradation pattern of recombinant human growth

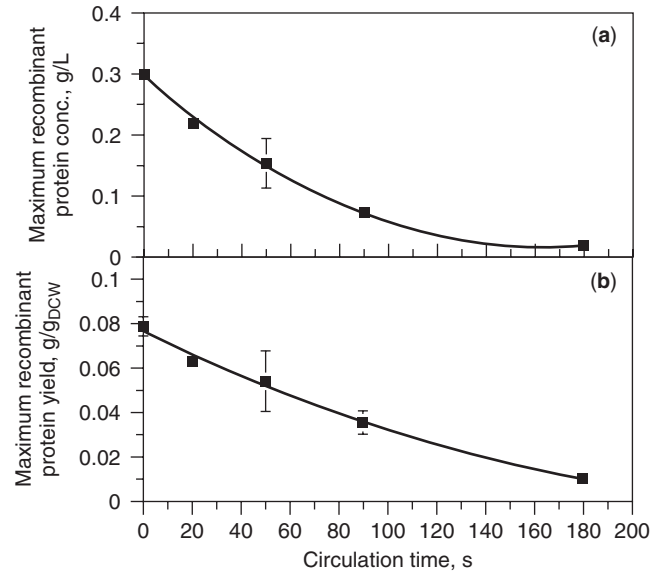

Figure 40.8. Effect of circulation time on: (a) maximum recombinant protein concentration; (b) recombinant protein yield on biomass, in cultures of *E. coli* producing recombinant human proinuslin under DO gradients simulated in a two-compartment scale-down system. Data points at t_c of 0 sec represent values obtained from control cultures maintained at constant 10% DO. (Reprinted by permission from Ref. 34).

hormone. Although the recombinant protein produced at the industrial-scale (3-m^3 fermenter) was 35% lower than at laboratory-scale (15-L fermenter), the fraction of degraded human growth hormone was similar on both scales. Despite the relatively large number of scale-down studies involving microorganisms, it is evident that more information is needed to understand the molecular mechanisms involved in the complex responses of microbial cells to fluctuating environments. Besides, the effects of temperature, pH and dissolved CO_2 oscillations on microbial cultures have been scarcely studied. Moreover, the available information on the effect of gradients on the production of recombinant proteins or plasmid DNA for therapeutic purposes is still very limited (7) and of crucial importance for developing commercial processes for such products.

40.7 EXPERIMENTAL CONFIGURATIONS FOR SCALE-DOWN STUDIES

Special experimental configurations are needed for simulating in laboratory the oscillatory environment to which a cell is exposed when spatial gradients are formed in a large-scale vessel. Scale-down systems can be classified in two general groups depending on the component studied: those for simulating gradients in dissolved oxygen or carbon

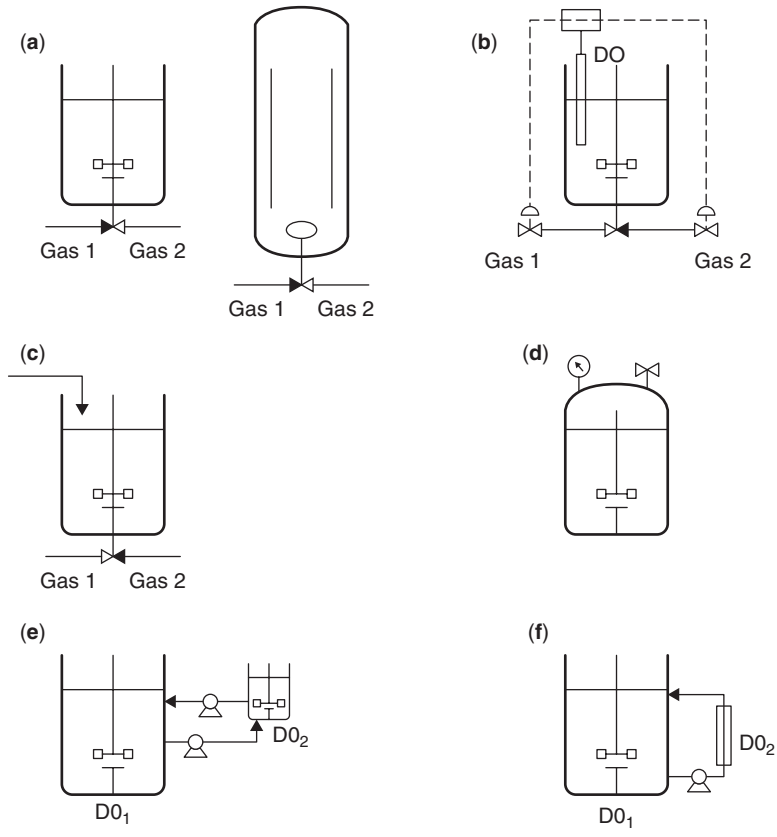

Figure 40.9. Experimental configurations for simulating dissolved oxygen or carbon dioxide gradients. One-compartment systems: (a) batch stirred and airlift bioreactors with open-loop gas control; (b) with closed-loop gas control; (c) chemostat; (d) pressure manipulated reactor. Two-compartment systems: (e) combination of STR with different oxygen concentrations; (f) STR and plug-flow reactor (PFR) combination. DO_1 and DO_2 refer to different dissolved oxygen or carbon dioxide concentrations, DO refers to a dissolved oxygen electrode.

dioxide, and those for simulating substrate or pH gradients. A detailed description of these two general scale-down systems and comparison of advantages and disadvantages of the various configurations in cell culture and microbial fermentation applications follow. Design of novel experimental configurations, not discussed here, will be necessary for simulating gradients of other variables such as temperature and shear stress, as well as gradients in inhomogeneous systems. Recent developments on miniaturized bioreactors (43) can help design multicompartment scale-down systems where each compartment can be independently controlled and interact with others by circulating culture broth between them. Such systems should be able to better represent the excursion of cells through the various regions that present different environmental conditions in a large-scale bioreactor. Important advances have also been achieved on the monitoring of miniaturized bioreactors (44,45), which will help to precisely monitor the physiological response of cell to environmental perturbation in very short time exposures to changing environments.

40.7.1 Simulation of Dissolved Oxygen or Carbon Dioxide Gradients

The most commonly used experimental arrangements for oscillating the concentration of a dissolved gas are schematically summarized in Fig. 40.9. Such general designs have been applied to oscillating DO but can also be readily applied for oscillating dissolved carbon dioxide concentration, which is of particular importance in cell culture. These designs can be divided into two general groups: one- (Fig. 40.9: a, b, c, and d) and two-compartment (Fig. 40.9: e and f) systems.

In one-compartment systems, the cells are maintained in a single vessel and the dissolved gas concentration is oscillated by various means (6,28,34,46,47). In the simplest arrangement (Fig. 40.9a), two different gas streams are intermittently sparged (or alternatively transferred through a membrane or liquid surface) to a stirred-tank, airlift or bubble column bioreactor. Various combinations of gas streams can be used, such as carbon dioxide and air, air and nitrogen, oxygen-enriched air and air, or on/off

aeration. Cyclic shifts between the two gases are generated by following a predetermined pattern that is independent of the actual DO of the culture (i.e. open-loop control). By assigning unequal sparging times to each gas, it is possible to simulate different culture volume fractions subjected to different conditions (for instance, the volumes of stagnant and well-mixed zones). In this way, the time spent by a cell in each condition can be simulated. Likewise, switching frequency can also be manipulated to simulate the circulation time. A mean constant circulation time can be manipulated by choosing a constant switching frequency. However, as described before, a real situation is better represented by a circulation time distribution (Fig. 40.2), which can also be simulated by establishing a random switching frequency. For instance, in a laboratory-scale reactor Yegneswaran *et al*. (6) utilized the Monte Carlo method to control random on/off cycles of aeration to reproduce the lognormal distribution of circulation times shown in Fig. 40.2. A simulation of the expected DO profile using such random method, compared to a constant switching frequency, is shown in Fig. 40.10. It can be seen that the Monte Carlo strategy, compared to constant oscillations, resulted in occasional longer periods of low DO which could have caused the reported reduction in antibiotic productivity. These results clearly indicate that the strategy chosen for simulating spatial gradients can strongly affect the experimental outcome.

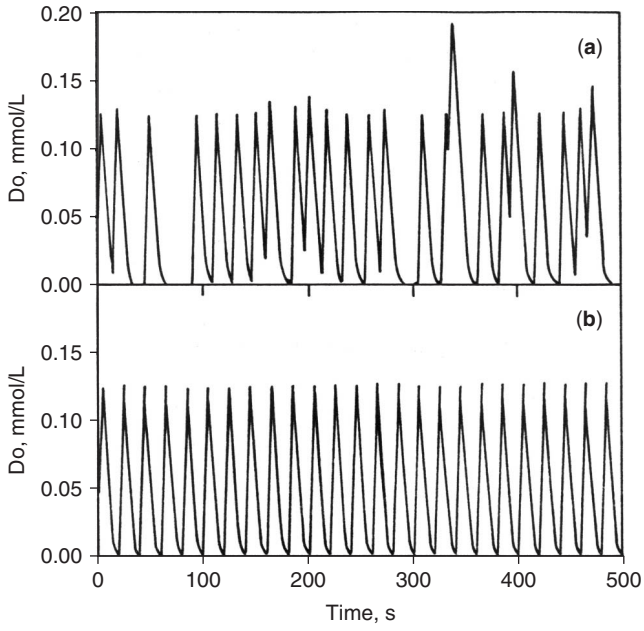

Figure 40.10. Simulated dissolved oxygen profiles for Monte Carlo and periodic aeration experiments in bacterial cultures. Aeration was on for 5 s and off for 15 s on average. (Reprinted from Ref. 6).

Single-compartment systems with open-loop control, as those described previously (Fig. 40.9a), have the advantages of simple operation and reduced equipment and instrumentation requirements. However, actual control of DO (or dissolved carbon dioxide) cannot be attained in such systems. In the case of DO, this problem can be overcome if the flows of the various gases used are controlled through a closed-loop algorithm based on the signal of a DO electrode (Fig. 40.9b). For instance, a closed-loop proportional-integral-derivative (PID) control, where oxygen partial pressure was varied according to the difference between DO measurements and a square-type oscillating DO set point, is shown in Fig. 40.11 (26). In this case, it was possible to obtain periodic sinusoidal DO profiles of predetermined periods, amplitudes, and oscillation axes, in actual fermentations (26). Only other few closed-loop algorithms for oscillating DO have been reported (23,28,35,40,46). A disadvantage of the closed-loop systems, besides their complexity, is the need for fast response electrodes when short oscillation periods are required.

Many experimental scale-down systems are based on batch operation, and thus, spatial gradients are simulated along with temporal gradients. In some instances, it is desirable to discriminate between the effects of both types of gradients and/or assess the effect of gradients under steady-state conditions. This can be achieved in experimental arrangements similar to those described above, but where a continuous or perfusion operation mode is established (Fig. 40.9c). An example of this configuration was reported by Buse *et al*.(47). A fluctuating dissolved gas concentration can also be attained in one-compartment configurations simply by oscillating the total pressure of the system (Fig. 40.9d). This system was used by Serrato *et al*. (48) for simultaneously simulating dissolved

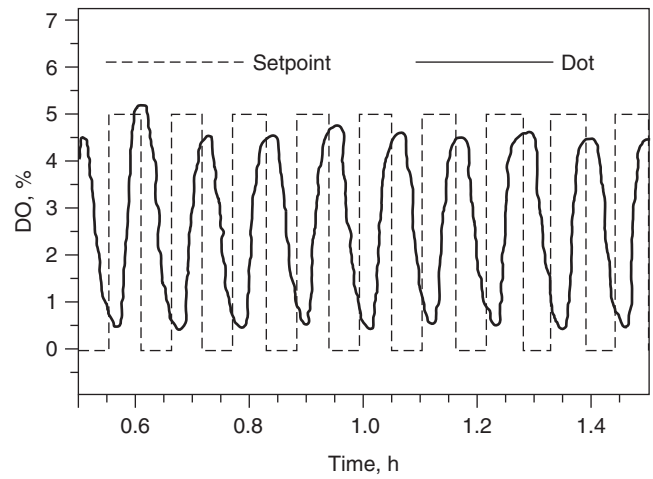

Figure 40.11. Closed-loop control strategy for oscillating dissolved oxygen at a predetermined frequency, amplitude, and oscillation axis. (Reprinted from Ref. 26).

CO_2 and pH oscillations on the production of a MAb by hybridoma. An advantage of these configurations is that pressure gradients, which can occur in large-scale vessels, can also be simulated (46). Nonetheless, special pressure-proof vessels are required and foaming problems can originate during decompression.

A general disadvantage of single-compartment (open-loop and closed-loop) systems is their slow dynamic response. This is a drawback when short oscillation periods are desired, but can be partially solved by increasing agitation and gassing rates, if shear sensitive cultures are not damaged. A questionable aspect of single-compartment systems is that all cells are simultaneously exposed to the same condition, potentially inducing a synchronization phenomenon, especially on yeast and animal-cell cultures, something that is unlikely to occur in a real large-scale culture. Some limitations of the experimental arrangements described above can be overcome by two-compartment systems.

The most commonly used two-compartment configurations are composed of two interconnected stirred-tank bioreactors, each maintained at a different dissolved gas concentration, and where culture broth is circulated between them via a pump system (Fig. 40.9e) (23,24,40,49,50). In this case, mean circulation time will be equal to the total volume of the two vessels divided by the circulation flow rate (49). A large-scale vessel can be considered to be composed of two main zones, a small well-mixed zone at the impeller vicinity, and a poorly mixed region in the rest of the tank. Thus, vessels of different sizes are commonly used to simulate these two different culture volume fractions (49). Accordingly, for the case of DO, the large vessel maintained at a low DO will simulate the large poorly mixed zone, whereas the small vessel maintained at a high DO will represent the well-mixed zone. The residence time distribution in each compartment will simulate the circulation time distribution in the large scale by manipulating the pumping rates in the scale-down system. An advantage of these systems is that the residence time distribution in each vessel will naturally simulate the circulation time distribution present in a large-scale culture. In addition, algorithms for controlling dissolved gas concentration in each vessel will be simpler than for one-vessel configurations, because complex dynamic behavior of mass transfer and electrode response is not involved. Furthermore, short oscillation periods can be attained in these systems simply by increasing the flow rate between the two vessels, as reported by Sandoval *et al*. (40). Nonetheless, shear stresses at the pumps will limit their use for fragile cells. Disadvantages of two-vessel configurations also include the need for duplicate equipment, increased contamination risk and operation failure at the circulation loops/pumps. It could also be questionable that cells in the two stirred-tank configuration will experience a step change between two different dissolved gas concentrations, contrary to what happens in a real situation where cells gradually move between both conditions. This sudden step change can be prevented if a two-compartment configuration, as shown in Fig. 40.9f, is used. In this case, cells are circulated from a stirred vessel to a PFR, where a gradual change in dissolved gas concentration due to cell metabolism occurs (51). Such types of systems have been successfully used for microbial cultures with high metabolic demands (23,24,40), but might result inadequate for animal and plant cells with relatively lower metabolic demands. Finally, it is interesting to note that for cultures where pH is controlled by a carbonate buffer system, as in most mammalian-cell cultures, the configuration shown in Fig. 40.9e can also be used to simulate pH gradients simply by maintaining a different dissolved carbon dioxide concentration in each vessel.

40.8 SIMULATION OF SUBSTRATE OR pH GRADIENTS

Substrate gradients can occur in large-scale cultures at feeding points during fed-batch and perfusion operation modes, and pH gradients can occur at acid/base addition zones. In both cases, cells will be transiently exposed to potentially deleterious high substrate or acid/base concentrations. Simulating gradients in a small-scale bioreactor can be a challenge because, in contrast to the experimental designs discussed in the previous section, recovery of the basal condition after pH or substrate pulses will strongly depend on metabolic activity. A notable exception is the case mentioned before for generating pH oscillations by fluctuations of dissolved carbon dioxide concentration. Various experimental configurations for simulating substrate concentration or pH gradients are schematically summarized in Fig. 40.12. It should be noted that only very few reports exist describing these experimental arrangements, even for microbial fermentation systems (52,53). Accordingly, their utility in animal- and plant-cell culture, which present much lower metabolic demands than microbial fermentations, remains to be proven.

The simplest experimental design for simulating substrate or pH gradients consists of a chemostat with pulsed additions of substrate or acid/base solutions (Fig. 40.12a) (54). In this case, the circulation time is simulated by the frequency of the pulses, whereas the magnitude of the gradient is simulated by the concentration of the pulse. Alternatively, two-compartment systems have also been proposed for simulating nutrient (55,56) and pH gradients (52,53). These usually consist of a stirred tank and a PFR connected in parallel in which medium is circulated between the two compartments via a pump system (Fig. 40.12b, c). The stirred-tank reactor represents the well-mixed zone of a large bioreactor, whereas the PFR represents the stagnant

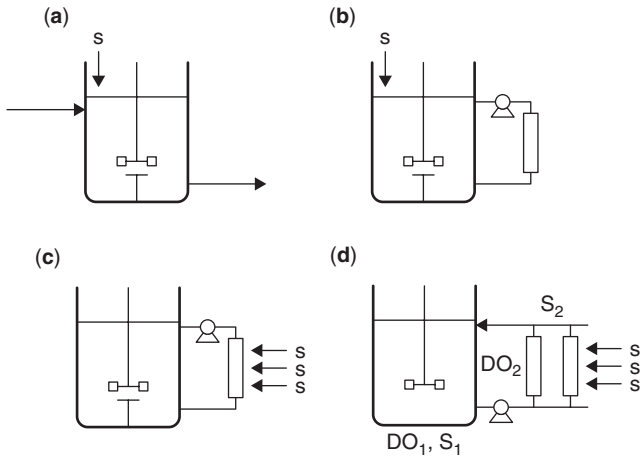

Figure 40.12. Experimental configurations for simulating substrate or pH gradients. (a) chemostat. (b) STR and PFR. Substrate added to the STR to simulate substrate limited regions. (c) STR and PFR. Substrate added to the PFR to simulate high substrate concentration zones. (d) Combination of a stirred-tank with two PFR for simultaneous simulation of substrate and oxygen gradients. S, S_1, and S_2 refer to substrate, acid, or base feeding solutions.

or feed injection zone (57). Depending on where substrate is added, zones of low or high nutrient concentration or pH can be simulated. If substrate is added in the stirred-tank reactor, as shown in Fig. 40.12b, then zones of low substrate concentration will develop in the PFR. Likewise, zones of high substrate concentration will develop in the PFR if the addition is performed directly into it. In this case, t_c will be represented by the residence time in each reactor, as already discussed in the previous section. The addition of substrate in the PFR often leads to oxygen depletion. Although it is commonly accepted that this occurs in the PFR, no direct measurement of dissolved oxygen profiles in the PFR have been reported. Finally, experimental arrangements shown in Fig. 40.12d can be designed for simulating simultaneously gradients of dissolved gas concentration and pH or substrate concentration (27). It should be stressed that the practical feasibility of applying such experimental designs in animal- and plant-cell culture still needs to be demonstrated. In particular, it should be tested if simulation of real cell culture circulation times can be attained under practical operation conditions.

40.9 SIMULATION OF SIMULTANEOUS ENVIRONMENTAL GRADIENTS

Although most scale-down studies have addressed the simulation of environmental gradients of one parameter, the existence of gradients on several physical parameters simultaneously is the most probable situation. This can be exemplified in the case of glucose-limited fed-batch cultures. The addition of glucose causes a gradient in substrate concentration, as usually the bulk of the reactor is kept at concentrations close to zero, whereas the zone close to the addition point will have a higher concentration. When cells transit from a glucose-depleted to a glucose-rich region, glucose uptake and hence the respiratory activity will be triggered. This may in turn lead to the production of acidic by-products and local depletion of the DO. The accumulation of acidic by-products can cause an acid region in the bioreactor. The combined effect of glucose gradients and DO depletion in *E. coli* cultures has been simulated using a STR–PFR configuration [for instance, see (53,58,59). Accumulation and reassimilation of lactate and formate in addition to acetate, showed the existence of dissolved oxygen gradients additionally to glucose gradients in the scale-down system. The STR-PFR system has been extensively used to simulate combined gradients. Recent work has included the evaluation of pH gradients by adding alkali to the PFR and combining this with the glucose and (potentially) DO gradients. Using such experimental design, the effect of pH, DO, and glucose heterogeneities was evaluated in *E. coli* cultures (60). Cultures at 5-L and 20-m^3 scale were compared to the cultures in the scale-down model. Although the biomass concentration reached in the 5-L fermentation was around 64% higher than in the 20-m^3 culture, the viability was about 18% higher in the large-scale than in the laboratory-scale culture. These results at large scale were better mimicked when pH, glucose, and DO (this latter not shown) gradients in the *E. coli* cultures were simulated and the cells spent 50 s in the PFR.

One limitation of the previously mentioned experiments is that no dissolved oxygen profiles in the zone of glucose addition (usually the PFR) have been shown. Consequently, the direct effect of glucose gradients from the DO depletion has not been completely dissected, which makes difficult the interpretation of the effects of combined gradients. More refined scale-down models can help to evaluate these conditions. For instance, a mini PFR has been connected to a STR to simulate a glucose gradient under both, fully aerobic or fully anaerobic conditions (61,62). The design of the mini-PFR (63) allowed controlling and monitoring of the DO levels during the glucose pulse, and sampling 11 different exposure times to the environmental gradients. It was found that *E. coli* accumulated acetate and formate as early as 5 s after the exposure to the glucose gradient even during fully aerobic conditions (62). Also, fully anaerobic conditions were generated during exposure to a glucose gradient, which triggered the mixed-acid fermentation metabolism in less than 5 s. The information generated in this short time frame, under properly controlled environmental conditions can help to improve the scale-down studies and to perform metabolic modifications in the cells that can lead to a better performance under industrially relevant conditions.

NOMENCLATURE

A	Area
C_p	Heat capacity
D	Impeller diameter
$D_{O/W}$	Diffusion coefficient of oxygen in water
DO	Dissolved oxygen concentration
DOT	Dissolved oxygen tension
H	Liquid height
K	Discharge coefficient
N	Impeller speed
P	Power
Q	Specific production rate
Q_p	Pumping capacity
STR	Stirred-tank reactor
t_c	Circulation time
t_M	Mixing time
t_{mt}	Time constant for mass transfer
t_{rxn}	Time constant for oxygen consumption
t_v	Vessel diameter
U	Overall heat transfer coefficient
V	Liquid volume
VVM	Volume of air per volume of liquid per minute
λ_k	Size of the smallest turbulence generated eddy
μ	Specific growth rate
ρ	Liquid density

BIOREACTOR SCALE-UP*

Laura A. Palomares and Octavio T. Ramírez
Departamento de Medicina Molecular y Bioprocesos, Instituto de Biotecnología, Universidad Nacional Autónoma de México, Cuernavaca, México

41.1 INTRODUCTION

Bioprocess and bioreactor scale-up are clearly activities that strictly depend on the substance being produced. For many biotechnology products, such as antibiotics, alcohols, organic acids, amino acids, and enzymes, a commercially viable process is attained only if a final fermenter scale on the order of hundreds of thousands of liters is reached. Such large volumes are needed to satisfy markets requiring very large amounts (10^2 to 10^7 t/year) of products with very low added value (10^{-1} to 10^3 \$/kg). In contrast, products derived from animal and plant cell culture are, in general, costly therapeutics or fine chemicals whose price can be as high as 10^4 to 10^9 \$/kg, but their worldwide demand is only 10^{-1} to 10^3 kg/year. Such a behavior is depicted in Fig. 41.1 where an inverse logarithmic relationship between product costs and market size exists (1). Accordingly, for the production of many substances derived from tissue or cell culture, at most only hundreds to thousands of liters per year are required to satisfy the demand, and, thus, the largest bioreactors needed hardly come close to the scales of other biotechnology products. This can be exemplified by two extreme cases, human erythropoietin (EPO) and taxol. EPO has the largest market for any therapeutic recombinant protein produced by mammalian cell culture. At an EPO selling price of \$0.013/U (130,000 U/mg), the total 2006 demand (\$11,500 $\times$ 10^6/yr) could be satisfied with only ca 7 kg/yr. Such production could be generated through a modest hypothetical bioprocess (batch operation, overall yield 500 U/mL cycle, 10-day cycles) in six bioreactors of less than 10,000 L. Similarly, the estimated world requirements of taxol (200 kg/yr at a bulk price of \$500,000/kg) could be satisfied by a single 70,000 L plant cell bioreactor yielding 0.25 g/L of product and operated in 15-day cycles (assuming a 50% purification yield) (1,2). These examples assume that a single manufacturer using a single vessel, which is a very improbable scenario, satisfies the market. Furthermore, the development of improved cell lines and bioreactor operation modes, such as perfusion culture, has resulted in substantial increases in cell and product concentrations, which would further reduce the bioreactor volumes calculated above.

In general, while the largest homogeneous cultures of suspended animal cells range between 4000 and 20,000 L, heterogeneous systems (microcarrier, packed beds, etc.) for anchorage-dependent animal cells usually do not exceed the 1000 L scale. Problems such as mass transfer limitations and concentration gradients, inherent to heterogenous systems, can explain their lower scales. Published data on the industrial production of products derived from cell culture is limited. Nonetheless, some of the largest cultures reported in the literature are summarized in Table 41.1. For example, the foot-and-mouth disease vaccine, obtained from baby hamster kidney (BHK-21) cells, has been produced by Wellcome for almost 30 years in a 1000 L reactor, and more recently at a 10,000 L scale (3). Cells from human origin (lymphoblastoid Namalwa cells) have

been cultured for interferon production up to 8000 L (4), and hybridomas for Mab production have been cultured in 2000-L airlift bioreactors (5). Recombinant antibodies are nowadays routinely produced in bioreactors of 10,000 L. Some of the largest reported scales for microcarrier cultures, packed beds, and ceramic cartridges are 7000, 100 and 240 L, respectively (6,7). Compared to animal cells, the scales of plant cell cultures tend to be larger. For instance, tobacco plant cells have been cultured in 20,000-L reactors (3), while a 75,000-L bioreactor is in operation for taxol production (2). Nevertheless, despite these successful experiences, large-scale culture of higher eukaryotic cellsis still a challenge, particularly for anchorage-dependent cell lines or very fragile cells, such as insect cells.

The first step to translate a cell culture process to a commercial scale is to define the product requirements and the overall production and downstream processing economics. A decision has to be taken whether a single large-scale batch reactor or smaller multiple continuous reactors are used. This decision can only be made after considering the whole process, operation and capital costs, available facilities, and even assessment of the consequences of a possible contamination during the culture. From a technical standpoint, one of the major issues for scaling up a cell culture bioreactor is the oxygen transfer problem. In general, the fragile nature of most higher eukaryotic cells and foaming associated problems due to the proteinaceous composition of many medium formulations limit the use of high power inputs and intense submerged aeration. As a process is scaled up, bioreactors must be more reliable, safe, cheap, and comply with regulations. In particular, the tight regulation imposed on the production of cell culture-derived therapeutics has significantly constrained the free development of improved and novel bioprocesses at a commercial scale. The dogma that the "process determines the product," mostly hatched from our analytical limitations to fully characterize cell culture products, has resulted in a costly and treacherous path for any company trying to modify its approved process. Thus, many therapeutics are produced by suboptimal processes and scales; however, this should change as regulation moves toward placing its attention on the characterization of products rather than on the bioprocess.

TABLE 41.1. Some of the Largest Scale Cultures Reported

Cell Line	Scale (L)	Reactor	Product	Reference
Taxus sp.	75, 000	Agitated tank	Taxol	2
Tobacco cells	20, 000	Agitated tank	Nicotine	3
BHK-21[a]	10, 000	Agitated tank	Foot-and-mouth disease vaccine	8
CHO[b]	10, 000	Agitated tank	tPA	6
Namalwa cells	8, 000	Agitated tank	Lymphoblastoid interferon	4
Bowes melanoma	7, 000	Agitated tank/microcarriers	tPA	6
Murine hybridomas	2, 000	Airlift	Mab	5
Vero cells	1, 000	Agitated tank/microcarriers	Killed polio virus vaccine	7
Murine hybridomas	1, 000	Stirred tank	Mab vs cell surface antigens of adenocarcinomas	9
BHK cells	500	Agitated tank/perfusion	Factor VIII	10
Microorganisms	400, 000	Bubble column	—	11
Microorganisms	400, 000	Airlift	—	11
Yeast	1, 500, 000	Bubble column	Baker's yeast	12

41.2 ASPECT RATIO, HOMOGENEITY, AND GRADIENTS

41.2.1 Stirred Tanks

The purpose of a bioreactor is to provide proper environmental conditions required for optimal growth and/or product production under a contained system. Ideally, the culture environment should also be homogeneous and controlled. These conditions can be better accomplished in agitated tanks, which are the preferred design for scaling up anchorage-independent cells. Stirred-tank bioreactors for cell culture are cylindrical vessels with an aspect ratio (liquid height-to-diameter ratio) usually in the range of 1:1–3:1 (3,8). Nonetheless, the aspect ratio should be kept under 2:1 and impellers should be spaced properly (1.0–1.5 impeller diameters apart) to avoid top-to-bottom heterogeneity (13). Furthermore, oxygen transfer from the liquid surface, which is particularly important for animal cell culture, can be improved by keeping the aspect ratio close to unity. Special attention should be placed to the headspace dimensions if foaming problems are anticipated. In general, foam and liquid height increase from gas holdup are handled by leaving 20–30% of the vessel empty (13). A common feature of stirred-tank bioreactors is a hemispherical bottom, which prevents stagnant zones even under mild agitation rates. Nonetheless, as pointed out by Charles and Wilson (13), the cost of a hemispherical bottom vessel can increase by as much as 50%; yet, no clear evidence of its superior performance over a standard dished-bottom vessel exists. Probably the most distinguishing feature between different stirred-tank bioreactor designs is the impeller configuration. Many different types of impellers have been used for the culture of animal and plant cells in stirred tanks, including marine propellers, sails, pitched blades, Vibromixers (perforated discs placed on a vertically reciprocating shaft), anchors, paddles, helical screws, cell lift, and centrifugal impellers. Typical geometric characteristics of commonly used impellers are shown in Fig. 41.2. Many of such impellers have been designed with the objective of preventing mechanical damage to the fragile cells, but still maintaining a homogeneous environment and high oxygen transfer rates (OTR). Likewise, excluding baffles, and minimizing other inserts, while placing the impeller shaft eccentrically to avoid vortex formation, can reduce mechanical damage to the cells. Finally, vessel design should optimize the use of available materials; however, excessive costs are usually reduced by simply selecting a vessel among reactors already available from specialized vendors.

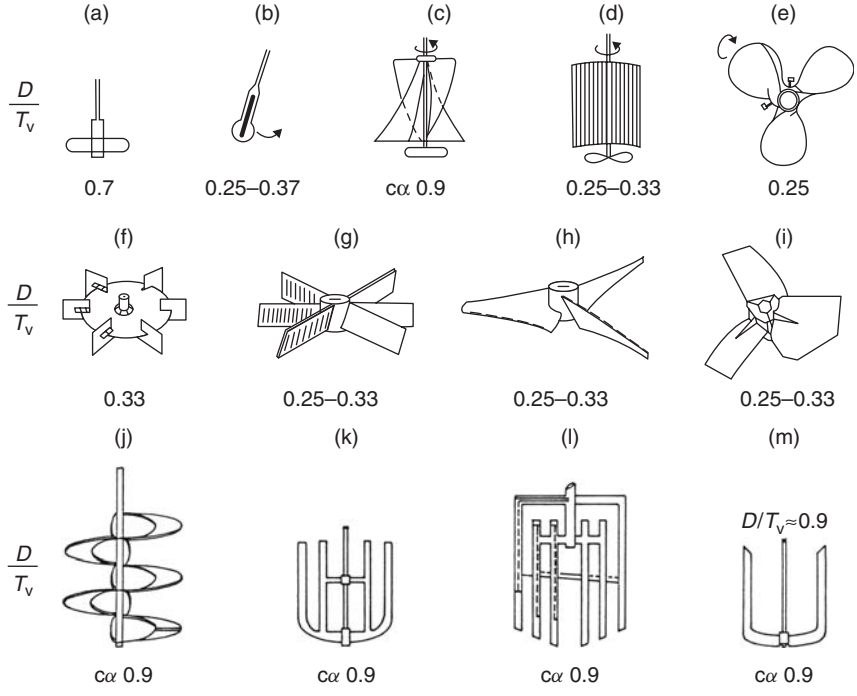

Figure 41.2. Commonly used impellers, and their geometric characteristics, used in animal and plant cell culture. D = impeller diameter, T_v = vessel diameter. (a) Suspended magnetic bar, (b) spherical rotating flex stirrer, (c) sail impeller, (d) membrane basket agitator, (e) marine propeller, (f) disc turbine, (g) angled blade, (h) and (i) profiled impellers, (j) helical ribbon impeller, (k) gate-anchor impeller, (l) gate impeller, and (m) anchor impeller. [Adapted from Refs. 14–16.]

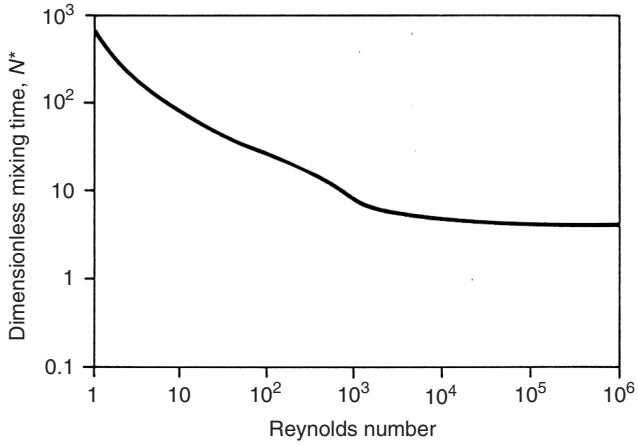

Figure 41.3. Dimensionless mixing time as a function of Reynolds number for turbine impellers in baffled vessels as determined from pH tracer experiments. [Reprinted with permission from Ref. 18.]

Tank geometry must be carefully selected as it influences the homogeneity of the bioreactor, especially as scale increases. Furthermore, heat and mass transfer are directly influenced by mixing, which in turn depends on operating variables and geometric characteristics of the bioreactor. For instance, the mixing time (time required for the system to reach a specified degree of uniformity) for a nonaerated Newtonian fluid in a baffled stirred tank with a flat-blade turbine impeller can be obtained from Fig. 41.3 and Equation 41.1 (15,17,18).

$$N^* = N t_M \left(\frac{g}{N^2 D}\right)^{1/6} \frac{D^2}{T_v^{1.5} H^{0.5}} \qquad (41.1)$$

where N^* is dimensionless mixing time, N is impeller speed, t_M is mixing time, g is gravitational acceleration, D is impeller diameter, T_v is vessel diameter, and H is liquid height.

Mixing times of different culture systems have been summarized elsewhere (19). Only very scarce information exists of homogenization and concentration gradients in large-scale animal or plant cell bioreactors. Among such studies, Langheinrich *et al*. (20) obtained mixing time data for typical operation conditions (maximum agitation speed of 1 s^{-1}, maximum air sparging rate of 0.005 VVM (volume of air per volume of liquid per minute), superficial air velocity of 2×10^{-4} m/s) of an 8000-L stirred-tank bioreactor (Rushton turbine $D = 2/9T_v$) used for animal cell culture at Glaxo Wellcome Research and Development. As a draw-and-fill operation is employed during production, aspect ratios of 0.3, 1.0, and 1.3 were studied. It was shown that mixing time, obtained from pH tracer and decolorization experiments, could be correlated with the total energy dissipation rate, ε_T (Figs 41.4 and 41.5), defined by Equation 41.2:

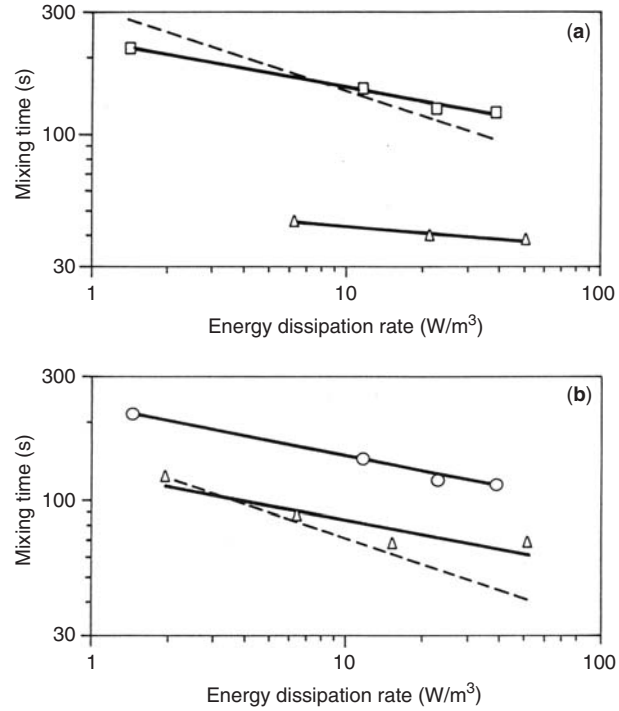

Figure 41.4. Effect of specific energy dissipation rate from agitation on mixing time. Determinations based on pH tracer experiments for various aspect ratios in an unaerated large-scale bioreactor. (a) $H = 0.3\ T_v$ (open triangle), $H = 1.3\ T_v$ (open square), dashed line = prediction by Cooke *et al*. (22) and (b) $H = T_v$ (open triangle), $H = 1.3\ T_v$ (open circle), dashed line—prediction by Ruszkowski *et al*. (21). [Reprinted with permission from Ref. 20.]

$$\varepsilon_T = \frac{P_0 \rho N^3 D^5}{V} + u_G g \rho \qquad (41.2)$$

where P_o is power number (Eq. 41.27), ρ is liquid density, V is liquid volume, and u_G is superficial gas velocity. The first term on the right hand side of Equation 41.2 is the contribution from agitation, whereas the second term is from aeration. Interestingly, experimental data of Langheinrich *et al*. (20) fitted well literature correlations (Eqs 41.3 and 41.4) obtained under agitation and aeration conditions two orders of magnitude above those studied in the animal cell culture bioreactor.

$$t_M N P_0^{1/3} = 5.3 \left(\frac{T_v}{D}\right)^2 \qquad (41.3)$$

for aspect ratios of 1 (21), and

$$t_M N P_0^{1/3} = 3.3 \left(\frac{H}{D}\right)^{2.43} \qquad (41.4)$$

for aspect ratios of 1–3 (22).

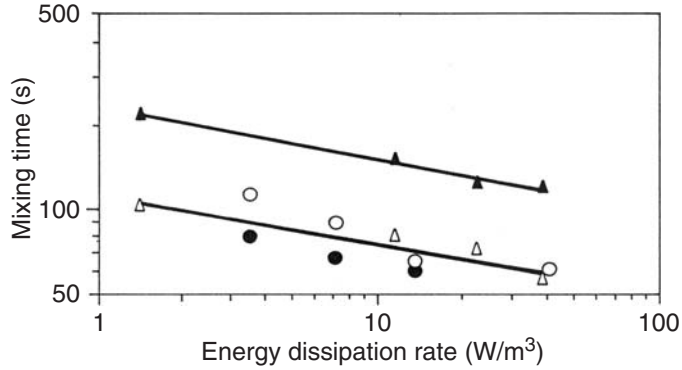

Figure 41.5. Effect of specific energy dissipation rate from agitation and aeration on mixing time. Determinations based on pH tracer experiments for various aspect ratios in a large-scale bioreactor. Closed symbols, determinations at the liquid surface and open symbols, determinations at the end of impeller discharge stream. Unaerated (triangles) and aerated (circles) at $u_G = 2 \times 10^{-4}$ m/s. [Adapted and reprinted with permission from Ref. 20.]

Several important conclusions, for the particular system used, are drawn from the study of Langheinrich *et al*. (20). First, gradients in pH and dissolved oxygen can potentially occur in large-scale animal cell culture since high mixing times, in the range of 40–200 s, were obtained under typical operation conditions. Computational fluid dynamics (CFD) has been used to predict gradients in microbial cultures (23,24). Secondly, homogenization is dramatically affected by geometric characteristics, as a fourfold increase in mixing times can occur as aspect ratios increase from 0.3 to 1.3 (Fig. 41.4). And finally, sparging substantially enhances mixing, particularly in the upper parts of the vessel and at aspect ratios greater than 1 (Fig. 41.5).

Poor mixing in stirred-tank reactors has been reported to cause significant problems in *Escherichia coli*, other microbial cultures, myeloma, hybridoma, Chinese hamster ovary (CHO), and insect cell cultures at high cell density (25–30). Undesirable carbon dioxide accumulation has been found to occur in 110–1000-L reactors as a result of low mass transfer characteristics of the systems (31,32). Furthermore, heterogeneities in microcarrier concentration and pH gradients have been found in large-scale stirred vessels (33–35). For instance, severe localized cell lysis problems at the point of base addition, allegedly caused by high mixing times, were observed in a 15-L reactor with cell retention (30). Another problem aggravated by deficient mixing is culture segregation, which originates from the formation of cell aggregates and clumps during high cell density cultures (30). Problems related to mixing can negatively affect overall culture performance. However, due to the fragile nature of animal cells, increasing agitation intensity cannot solve such problems. Therefore, other solutions must be found. For instance, pH gradients can be eliminated by adding base through multiple points properly localized in the reactor (30), while carbon dioxide removal can be enhanced by manipulation of air bubble size through proper design of the sparging system (29).

41.2.2 Disposable Bioreactors

Disposable bioreactors represent a novel development that is increasingly employed (36,37), particularly within the pharmaceutical area. This new paradigm in bioprocess technology has been motivated by several advantages that disposable bioreactors have over traditional stainless steel systems. Regulatory aspects impose important constraints in the pharmaceutical industry; among them, the most important is the need to guarantee that all bioprocess equipment in contact with the product has been perfectly cleaned between operation runs. This requirement substantially increases capital investment in a stainless steel-based facility since costly and sophisticated equipment such as steam-in-place and clean-in-place systems, as well as those needed for associated services such as clean steam generators, must be considered in the manufacturing plant. In addition, the initial cost of a stainless steel bioreactor can be several-fold higher than that of a disposable system of equivalent volume. Altogether, capital costs for a plant based on stainless steel bioreactors can be between three- and fourfold higher than an equivalent one based on disposable systems (38). In addition, operating costs for disposables are lower than for stainless steel bioreactors, as the former systems do not require labor-intensive procedures such as cleaning and sterilization validation, and shorter turnaround times between lots can be attained. Furthermore, stainless steel bioreactors require laborious specification and purchasing procedures, long times for design, construction and delivery, long times and

high costs of installation and qualification, and precious facility space is occupied by hard pipe installations and ancillary equipment. Accordingly, in addition to the higher capital and operating costs, a facility based on stainless steel bioreactors has limited flexibility, and compared to disposables, has higher risks of contamination and longer start-up times. Such issues are important for multipurpose plants and new start-up companies, as well as for rapid development, scale-up, and manufacture of new drug substances or drug candidates. Criteria and analysis tools for aiding in the decision process for selecting between disposable and stainless steel systems can be found elsewhere (39).

Disposable bioreactors consist of γ-irradiated presterilized multilayered bags formed by films of polyester, polyethylene, ethylene vinyl alcohol polymer, and other US Pharmacopoeia (USP) class VI materials with low or negligible leaching of extractable compounds. Bags are placed in various types of containers for conferring them structural rigidity. Various types of ports and accessories are attached to the bags, such as exhaust gas filters and aseptic rapid-type connectors. Different designs exist to attain homogeneity and to transfer gases to the liquid medium, the most common being those consisting of bags placed on rocking platforms that create a wave-like liquid movement (40), reciprocating bellows, and bags integrated to various types of molded polyethylene impellers and impeller shafts that are then placed into cylindrical containers (38,41). The latter systems allow the design of bioreactors with conventional geometric ratios, although unlike traditional stainless steel equipment, the bottom of the vessels is flat. Different design challenges exist; in particular, the need for mechanically agitated shafts and impellers contained within a closed presterilized bag. This has been solved by different means, including bottom-driven magnetically levitated impellers or impellers connected to sheaths for inserting an external top-driven shaft. Another challenge is placement of sensors, such as pH and dissolved oxygen, which has been solved using disposable probes based on optical sensor technology or alternatively using traditional probes sterilized in disposable bellows that are inserted through quick-connectors to the sterile bag. Liquid transfer, inoculation, and sampling from and to the bags are usually performed through sterile tubing welding equipment, and in some systems aeration is performed through porous patch membranes, open-end tubing, or jet nozzle diffusers. Disposable bioreactor systems are available in volumes ranging form 100 mL to 1000 L. Some companies are developing bioreactors of 2000 L, which could be the highest volume attainable for disposable technology.

In addition to bioreactors, there is a growing trend for designing and developing other disposable process equipment for extending the advantages of disposable bioreactors to other bioprocess operations. At present, there is a widespread use of disposable bags for buffer preparation and media containers. Likewise, disposable cartridges for microfiltration and ultrafiltration are commonly employed in manufacturing facilities. Also, there is a growing interest for developing disposable downstream processing equipment, such as chromatography media and columns (36). In particular, disposable bags have been designed for use in special continuous centrifuges. Such equipment, placed in series to disposable bioreactors, offer important advantages for separating cells during perfusion culture mode in a complete sterile and disposable operation.

In spite of the convenient features of disposable bioreactors, there still exist important disadvantages that limit their application in fields other than production of certain pharmaceuticals. In general, operation is limited to low agitation rates (<200 rpm), low aeration rates (<0.02 VVM), and low total pressure (<0.5 psig). Accordingly, the maximum volumetric oxygen transfer coefficients and OTR that can be attained are below 18 h^{-1} and 15 mmol/L h, respectively. Such constraints usually restrict the application of disposable bioreactors to animal and plant cell cultures operated at low or medium cell concentrations, although applications in microbial cultures are starting to appear (42). In addition, the maximum bioreactor volume available to date (1000 L) implies that multiple systems operated simultaneously will be required for manufacturing products requiring production outputs above 100 kg/yr. Finally, disposable bags are expensive and disposing the used bags and accessories must be considered under environmentally sustainable practices. Risk of puncture during operation must also be considered. Qualification of extractables and leachables must be necessary for particular processes that have not been previously validated by the bag vendors.

41.2.3 Airlift and Bubble Column Bioreactors

Airlift and bubble columns are also commonly used bioreactor configurations for the culture of suspended cells (typical geometric characteristics are shown in Fig. 41.6). These bioreactors are useful for culture broths with Newtonian behavior. They have higher energy efficiency than stirred tanks. Also, they have no moving parts, which can decrease maintenance time and costs, and in general they provide low shear. However, foaming can be a major problem, while bubble coalescence can reduce their performance (43). The height-to-diameter ratio of these reactors can range between 6:1 and as high as 12:1, but is typically 10:1. Nonetheless, airlift reactors with aspect ratios even below 2 have been reported for animal and plant cell cultures. As in stirred-tank vessels, geometric characteristic directly influence homogeneity, mass, and heat transfer in airlift and bubble column bioreactors. For instance, the relationship

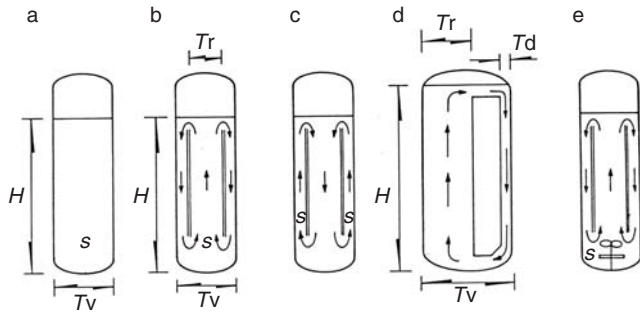

Figure 41.6. Typical geometric characteristics of common airlift and bubble column bioreactors used for cell culture. For all vessels shown, $H/T_v > 2$. For internal-loop airlifts, $T_r/T_v > 0.6$. For external-loop airlifts, $T_r/T_d \approx 2$. (a) bubble column, (b) and (c) internal-loop airlifts, (d) external-loop airlift, and (e) airlift with impeller. Arrows indicate direction of liquid flow and "s" indicates sparger position. [Adapted from Ref. 14.]

between geometric characteristics and mixing time is shown in Equations 41.5 and 41.6 (15,44):

$$t_M = Bt_c \left(\frac{A_d}{A_r}\right)^{0.5} \tag{41.5}$$

where B is a constant equal to 3.5 and 5.2 for internal- and external-loop airlift reactors, respectively, A_d and A_r are the downcomer and riser cross-sectional areas, respectively, and t_c is the circulation time or time taken for a liquid element to complete a circulation cycle in the reactor. Circulation time of airlift reactors (either internal loop or external loop with short horizontal top and bottom sections) can be determined from the superficial liquid velocity and geometric parameters according to

$$t_c = \frac{H_r}{u_{Lr}} + \frac{H_d A_d}{u_{Lr} A_r} \tag{41.6}$$

where H_r and H_d are the riser and downcomer heights, respectively, and u_{Lr} is the superficial liquid velocity in the riser. u_{Lr} is affected, among other variables, by liquid density, gas holdups, frictional loss coefficients, and frictional pressure drops, in riser and downcomer, through complex relationships usually solved by iterative algorithms. However, simplified correlations between u_{Lr} and geometric characteristics and operation parameters have been developed for particular conditions. For instance, Popovic and Robinson (45) proposed the following equation for a pseudoplastic fluid in an external-loop airlift ($u_{Gr} \geq 0.04$ m/s, $H = 1.88$ m, and A_d/A_r of 0.111, 0.25 and 0.44):

$$u_{Lr} = 0.23 u_{Gr}^{0.32} \left(\frac{A_d}{A_r}\right)^{0.97} \mu_{app}^{-0.39} \tag{41.7}$$

where u_{Gr} is superficial gas velocity in the riser and μ_{app} is the apparent viscosity (Pa s), this last variable being important only in some plant cell cultures.

Using Equations 41.1, 41.5, 41.6, and 7, Doran (15) compared the time constants of hypothetical 10,000-L stirred tank and external-loop airlift plant cell reactors of typical dimensions [details of geometric characteristics given in Doran (15)]. From the results of such simulation, shown in Fig. 41.7, several conclusions can be drawn. First, under typical operation conditions, the mixing time for a large-scale airlift can be substantially longer than that for a stirred vessel of the same volume. For instance, while mixing times from 200 to as high as 1000 s were predicted for the airlift, the range of mixing times for the stirred vessel was only between 20 and 200 s. A similar conclusion was reported by Bello *et al*. (44) where the mixing time per unit volume of stirred tanks was three to five times shorter than that of airlifts (either internal- or external loop) at the same total power input per unit volume. It is interesting to note that the calculations shown in Fig. 41.7 are in close agreement with experimental determinations by Langheinrich *et al*. (20), discussed in the previous section, for an animal cell stirred-tank reactor of similar size. Doran (15) also calculated the time constants for oxygen consumption, t_{rxn} (ratio of equilibrium oxygen concentration in the culture liquid to the volumetric oxygen consumption rate), and for mass transfer, t_{mt} (inverse of the volumetric mass transfer coefficient), while Lara *et al*. (19) calculated the time constants for oxygen consumption of different organisms and compared them with reported t_{mt}. Mixing problems will be encountered if $t_M > t_{rxn}$, while oxygen limitation will occur if $t_{mt} > t_{rxn}$. Accordingly, it was concluded that even for the long mixing times of the airlift, neither oxygen limitation nor dissolved oxygen gradients will occur at low plant cell concentrations (5 kg/m^3, Fig. 41.7a). Nonetheless, as cell concentration increases to 30 kg/m^3, mixing becomes limiting in the airlift reactor at gas velocities below 0.5 m/s and, thus, oxygen gradients will develop (Fig. 41.7c). Furthermore, for the high cell concentration case, oxygen limitation will occur in the airlift below gas velocities of 0.1 m/s and in the stirred tank below an agitation rate of 6 s^{-1} (Fig. 41.7c and d). Note that, due to cell fragility, most bioreactors are operated at a gas velocity and agitation rates well below 0.5 m/s and 6 s^{-1}, respectively.

Mixing problems in airlift vessels have been documented experimentally (46). As for stirred-tank vessels, the fragile nature of most higher eukaryotic cells limits the options for improving homogeneity in airlift and bubble column reactors. Accordingly, some solutions to mixing problems, such as addition of impellers to the draft tube of airlifts, have not been widely applied and appear to contradict the design essence of an airlift. Proper design of reactor geometry can be an efficient alternative to

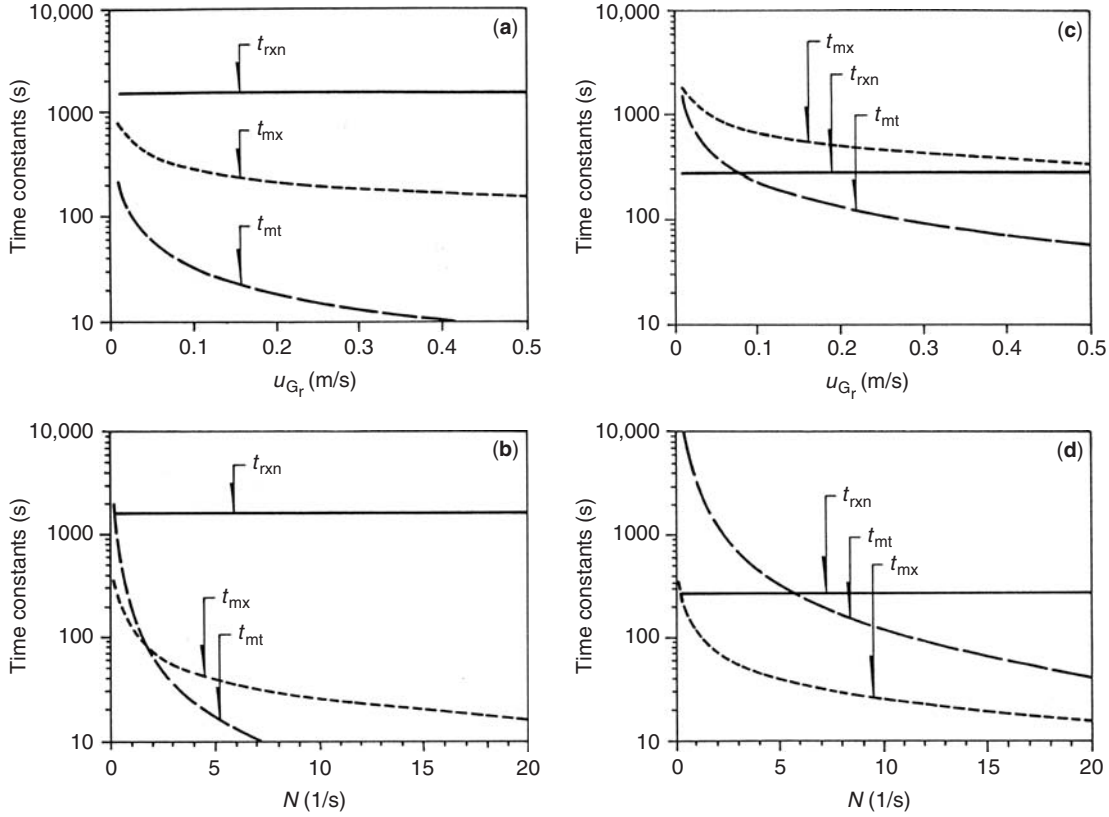

Figure 41.7. Comparison of time constants for 10,000-L hypothetical plant cell bioreactors. (a) External-loop airlift reactor: cell concentration 5 kg/m^3 dry weight. (b) Stirred-tank reactor: cell concentration 5 kg/m^3 dry weight. (c) External-loop airlift reactor: cell concentration 30 kg/m^3 dry weight. (d) Stirred-tank reactor: cell concentration 30 kg/m^3 dry weight. [Reprinted with permission from Ref. 15.]

improve homogeneity. For instance, minimal mixing times of internal-loop airlift reactors have been observed for riser-to-column diameter ratios (T_r/T_v) above 0.6 (15). Accordingly, a riser-to-downcomer cross-sectional area equal to unity ($T_r/T_v = 0.71$) has been proposed as a good design criterion (47). Other geometric characteristics that can considerably affect homogeneity of airlift reactors are the draft tube and sparger positions, the draft tube to liquid height ratio, and the curvature of the bottom sections.

In the case of bubble columns, two types of flow regimes have been described, homogeneous and heterogeneous (48). Homogeneous flow regime, characterized by the absence of a circulatory flow, occurs at low gas superficial velocities (<0.04 m/s) and when the sparger holes are uniformly distributed on the bottom of the vessel. In typical conditions, mostly all bubble columns operate under heterogeneous flow regimen where circulatory flow is present as a result of uneven distribution of sparger holes or high superficial gas velocities. Mixing time has been correlated with geometric characteristics and operation parameters for bubble columns under heterogeneous flow regime according to (48):

$$t_M = 11\frac{H}{T_v} + \left(g u_{Gs} T_v^{-2}\right)^{-0.33} \tag{41.8}$$

where u_{Gs} is the superficial gas velocity corrected for local pressure.

A comparison of calculated mixing times for airlift and bubble column bioreactors has been presented by van't Riet and Tramper (48). Such comparison revealed that for low superficial gas velocities (0.001 m/s), mixing times of bubble columns were shorter than that for airlifts, and the opposite occurs for gas velocities above 0.001 m/s. Nonetheless, for all conditions calculated and an aspect ratio of 10, differences in mixing times between both reactors were small and never exceeded 30%. Furthermore, such differences were even smaller as the reactor volume increased. Accordingly, the behavior of large-scale airlift and bubble column reactors in terms of homogeneity and presence of concentration gradients should be relatively similar.

Although high superficial velocities improve homogeneity and prevent formation of concentration gradients in airlift and bubble column reactors, foaming problems and bubble-associated cell damage limit the use of high aeration rates. Tramper *et al*. (49) have proposed a killing volume hypothesis, where cells are killed within a hypothetical volume associated with each air bubble. The specific death rate constant, k_d, was then correlated with operation and geometric characteristics of bubble columns according to

$$k_d = \frac{24 F_g V_k}{\pi^2 d_b^3 T_v^2 H} \tag{41.9}$$

where F_g is gas flow rate, d_b is bubble diameter, and V_k is killing volume, which is constant for a particular system and can be experimentally determined. Equation 41.9 shows that the aspect ratio of bubble column bioreactors can have important consequences on animal cell survival. For instance, a decrease in aspect ratio will result in an increase in the death rate constant for a given reactor volume and superficial gas velocity. Thus, a high aspect ratio should be the design criterion. However, Meier *et al*. (50) showed that cell damage increases with liquid height. As liquid height is increased, a higher number of cells attach to bubbles, due to their longer ascension time. Cell attachment to bubbles is reduced by the addition of Pluronic F68 or other shear protectants to culture medium.

41.2.4 Heterogeneous Bioreactors

Heterogeneous systems can be defined as those where cells grow either attached to or entrapped by a solid substratum arranged within a particular device or bioreactor configuration. Many different types of substrata and geometric configurations exist; however, heterogeneous systems can be simply classified according to Table 41.2 (51). In almost all heterogeneous systems, oxygen transfer will be the limiting factor, and, thus, as discussed below, dissolved oxygen concentration gradients will be present. Accordingly, predicting dissolved oxygen profiles constitutes the basis for a rational design of many heterogeneous systems. The simplest designs include static units, such as dishes, flasks, and trays, where oxygen is transferred through the liquid surface only by diffusional mechanisms. As described by Murdin *et al*. (52), the dissolved oxygen profile can then be predicted from a steady state mass balance according to:

$$c = \frac{\mathrm{OUR}}{2D_{o/w}} \left[\left(\frac{2D_{o/w} c_m}{\mathrm{OUR}} \right)^{0.5} - y \right]^2 \tag{41.10}$$

where c and c_m are dissolved oxygen concentration in the liquid and at saturation, respectively, OUR is oxygen uptake rate, y is liquid depth, and $D_{o/w}$ is the diffusion coefficient of oxygen in water (2.6×10^{-5} cm^2/s). For a typical maximum cell concentration (3×10^6 cell/mL) and typical specific oxygen consumption rate (4×10^{-10} mmol/cell h), Equation 41.10 predicts that medium height must be maintained below 2 mm in order to avoid oxygen limitation. This result indicates that very high superficial area to culture volume ratios (A/V), usually in the range of 2.5–5 cm^{-1}, are required. That is, two to three orders of magnitude higher than that of large-scale homogeneous bioreactors. A modest increase (two- to threefold) in substratum area, without a corresponding increase in A/V ratios, can be achieved by circulating medium through multistacked static units or by rotating vessels and flasks containing multiple internal surfaces. Scalability of high A/V culture units is limited, since their cumbersome configurations require labor-intensive operations; yet, volumes as large as 200 L have been reported (51). Very high substratum areas to culture volume ratios, and concomitantly very high cell concentrations ($>1 \times 10^8$ cell/mL), can be attained in some heterogeneous bioreactors, such as packed beds (4–100 cm^{-1}) and hollow fiber (HF) (30–200 cm^{-1}). High gas/liquid areas needed for oxygen transfer are eliminated by perfusing oxygen-saturated medium. This results in very compact bioreactor designs, as well as in the possibility of culturing anchorage-independent cells in perfusion mode, at very low shear stresses, and close to *in vivo* cell concentrations.

In spite of the fact that heterogeneous systems are extensively used in lab-scale applications and commercial size operations, a strictly controlled and uniform environment cannot be maintained. Thus, undesirable heterogeneities and existence of concentration gradients will inevitably occur during scale-up. Accordingly, heterogeneous systems are usually scaled up by increasing the number of small-scale units, rather than increasing the size of the equipment. Many disadvantages exist for such an approach, including higher capital and operation costs, poorly controlled and monitored operation, and unit-to-unit variability. Therefore, the challenge is to design heterogeneous bioreactors that approach a more uniform environment. This can be

TABLE 41.2. Classification of Heterogeneous Systems

Plate devices	
Static	T-flasks, plate units, trays, multiwell plates, petri dishes
Dynamic	Plate units, roller bottles
Films	Bags, spiral wound
Tubes	Macroforms, hollow fibers
Packed beds	Ceramic, glass spheres, helixes, springs, diatomeceous earth, polystyrene jacks, sponges

achieved through proper design of geometric characteristics and operation conditions. Since many different types of heterogeneous systems exist, each case deserves a unique analysis. Nonetheless, geometric and homogeneity considerations of microcarrier systems, HF, and packed-bed reactors are analyzed below, since these are among the most important systems for a commercial scale operation.

41.2.4.1 Hollow Fiber Reactors. Conventional HF reactors are composed by a bundle of HF sealed into an outer casing, forming a shell and tube configuration of 3.2–9 cm in diameter and 6–30 cm in length. HF are anisotropic structures composed of a thin (0.1–2.0 μm) inner or "active" skin and a thick (50–85 μm) spongy support layer. The internal fiber diameter commonly ranges from 40 to 200 μm and the molecular weight (MW) cutoffs (MW of species retained) vary from 300 to 300,000 Da. Medium is perfused from the lumen side and transported through the porous membrane to the shell side, where the cells are immobilized. As illustrated in Fig. 41.8, there are three common operation modes (open shell, closed shell, and crossflow), each resulting in a different pressure distribution throughout the HF cartridge (53). The axial pressure drop inside the fibers can be expressed, to a good approximation, by Equation 41.11, obtained from the Hagen–Poiseuille equation for flow in a pipe (54):

$$\frac{dp_c}{dz} = -\frac{8\mu_b}{r_c^2}\overline{u_c} \tag{41.11}$$

where p_c, and $\overline{u_c}$ are pressure and average axial velocity inside the capillary, respectively, z is axial position, and r_c is the inside capillary radius. The transmembrane flux depends on the pressure difference between the shell and lumen sides of the fiber. For the open and closed shell operation modes, the pressure gradient, and thus medium flux, decreases along the axial direction, causing undesirable concentration gradients. The result is a higher cell concentration at the inlet section and only negligible growth after a certain cartridge length. Most commercial HF devices operate on the closed mode, resulting in a reversed flux at the downstream section of the reactor. Thus, while fresh medium is supplied to the cells in the inlet section, exhausted medium and toxic wastes are removed in the outlet segment, creating severe environmental heterogeneities. Accordingly, scale-up of HF reactors in the axial direction is limited and explains the short length of commercially available devices. In conventional HF reactors, only diffusional transport exists on the shell side. Thus, fibers must be tightly packed to avoid nutrient limitation and/or by-products accumulation at the interstitial zones. Even so, necrosis usually occurs since distance from the interstices to the inner capillary skin is, at best, 150 μm. Necrotic zones will still occur even if convective transport is forced through the shell side, as the tissue-like cell concentrations prevent a uniform flow distribution. Accordingly, severe radial gradients are also present in many HF reactors. Concentration polarization and fouling of the inner lumen surface are additional problems that can lead to reactor heterogeneities. Experimental determinations of axial and radial heterogeneities are well documented (53,55–57).

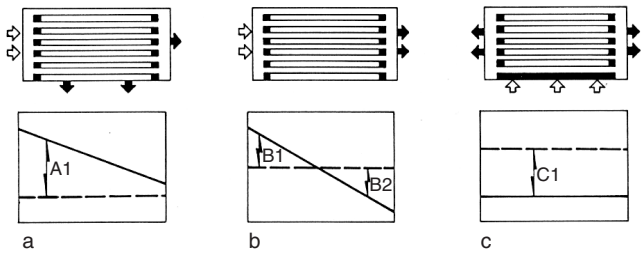

Figure 41.8. Schematic representation of common operation modes and pressure distribution in hollow fiber reactors. Open arrows indicate feed inlet and closed arrows indicate effluent streams. The tube-side pressure is represented by a solid line and shell-side pressure by a dashed line. (a) Open shell ultrafiltration and transmembrane pressure difference, A1. (b) Closed shell ultrafiltration and transmembrane pressure difference, B1 and B2. (c) Crossflow ultrafiltration and transmembrane pressure difference, C1. [Reprinted with permission from Ref. 53.]

Many solutions have been proposed for improving homogeneity and preventing nutrient limitation and by-products buildup in HF reactors, most of them on the basis of modifying geometric characteristics and operation conditions (55–57). For instance, combination of fibers and membranes in flat-bed HF arrangements; introduction of porous distribution tubes to perfuse either fresh medium or oxygen; mixing aeration and medium supply fibers; combination of different fiber types; selection of MW cutoffs; flow alternation between shell and lumen sides; and flow reversal at different interval times. Still, scale-up of HF reactors is primarily performed by increasing the number of devices in a modular fashion. Predicting dissolved oxygen profiles in the radial direction can help design more efficient HF reactors (fiber size, distance between fibers, etc.). A simplified approach is to perform a steady state mass balance around a cylindrical capillary where only diffusion is considered. Dissolved oxygen profiles can then be obtained, as detailed by Murdin *et al*. (52), from the following equation:

$$c = c_m + \frac{\mathrm{OUR}}{4D_{o/w}}\left[r^2 - r_c^2 - 2r_0^2 \log\frac{r}{r_c}\right] \tag{41.12}$$

where r is radius and r_0 is radius at which oxygen concentration falls to zero.

41.2.4.2 Packed-Bed Reactors. Packed-bed reactors are also widely used for the culture of anchorage-dependent and independent cells (58). In general, an aspect ratio of 3 is suitable for packed beds. As shown in Table 41.2, many different materials have been used as packing matrix. The diameter of the various matrix particles commonly range from 0.1 to 5 mm, resulting in typical void fractions of 0.3–0.6. Depending on the packing material used, very high substratum area to culture volume ratios can be reached (see above), which approximate those of HF reactors. However, in contrast to HF, properly designed packed-bed reactors should not present radial gradients, and, thus, a straightforward scale-up in this direction is possible. Still, axial concentration gradients are inherently present and will limit reactor length. Again, dissolved oxygen is almost always the limiting substrate and its concentration profile along the axial direction can be determined using a macroscopic mass balance (59):

$$c = c_0 - \left(\frac{\text{OUR}}{u_\text{L}}\right) z \tag{41.13}$$

where c_0 is inlet dissolved oxygen concentration and u_L is superficial liquid velocity based on empty bed. Concentration gradients will decrease as u_L increases (Eq. 41.13). Nonetheless, maximum u_L will be limited by permissible maximum pressure drop, which can be determined from the Ergun equation (60):

$$\Delta_\text{p} = \frac{150 z \mu_\text{b} (1-\varepsilon)^2 u_\text{L}}{T_\text{p}^2 \varepsilon^3} + \frac{1.75 z \rho u_\text{L}^2 (1-\varepsilon)}{T_\text{p} \varepsilon^3} \tag{41.14}$$

where ε is void fraction, T_p is particle diameter, and μ_b is culture medium viscosity. Maximum shear stresses in the bed must also be considered for determining the maximum allowable u_L.

41.2.4.3 Microcarriers. Stirred vessels and airlifts are the reactor configurations used for cultivation of cells attached to microcarriers. Furthermore, the density of microcarriers is only slightly above that of culture medium (1.03–1.05 g/mL). Thus, geometric considerations and homogeneity characteristics of the bulk liquid phase will be the same as for homogeneous systems. Nonetheless, concentration gradients within porous microcarriers (typical diameter range between 100 and 500 μm) can still exist. Dissolved oxygen profiles within porous microcarriers can be modeled from a steady state mass balance of oxygen diffusion into a sphere, as has been described by Murdin *et al*. (52). Alternatively, mass transfer limitations, and, thus, formation of undesirable gradients within a porous microcarrier can be determined from plots of the observable module (obtained from the Thiele modulus), Φ, versus the effectiveness factor, η, shown in Fig. 41.9 (61). For spherical particles and OUR being the rate of interest, Φ and η are defined as

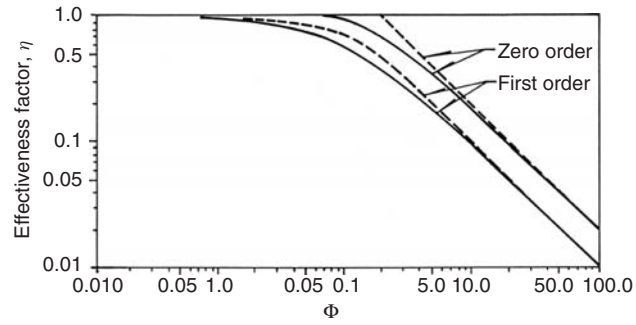

Figure 41.9. Effectiveness factor as a function of the observable modulus. Michaelis–Menten kinetics. Continuous line, spherical geometry and dashed line, slab geometry. [Reprinted with permission from Ref. 61.]

$$\eta = \frac{\text{Observed OUR}}{\text{OUR without diffusional limitation}} \tag{41.15}$$

$$\Phi = \frac{\text{OUR}_\text{o}}{D_\text{e} c_\text{m}} \left(\frac{V_\text{p}}{A_\text{p}}\right)^2 \tag{41.16}$$

where A_p and V_p are the external surface area and volume of a microcarrier, respectively, and OUR_o is the observed OUR. D_e is effective diffusion coefficient, which in turn is a function of the microcarrier porosity and tortuosity factor. From Fig. 41.9 and Equations 41.15 and 41.16, it can be seen that oxygen limitation will occur at an observable module above 0.3. Accordingly, oxygen limitation can be avoided ($\Phi < 0.3$) through proper design of microcarrier geometry (Fig. 41.9 and Eqs 41.15 and 41.16). This approach can also be applied to other immobilized systems such as HF and microencapsulation.

41.3 HEATING AND COOLING

Maintenance of a constant and homogeneous temperature is an essential requirement in cell culture. Temperature variations of 1°C can reduce cell growth, viability, and/or product production (62). Temperature has also been reported to affect cell cycle phases, metabolism, and cell resistance to shear (63), while its control is particularly relevant when temperature inducible genes are used for recombinant protein production (64). High temperatures may also increase proteolytic activity and alter protein posttranslational modifications (63). Moreover, culture susceptibility to viral infection can be modified by temperature (65). Although for some processes, viral infection is an undesirable event, in others, such as virus

[a]Optimum temperature should be determined for each recombinant protein produced.

production for vaccines or bioinsecticides, viral progeny is the desired product. As shown in Table 41.3, there exists a wide range of optimum temperatures for tissue culture. Mammalian cell lines are usually cultured at or near 37°C, while cells from other origins, such as insect, amphibian, fish, or plant, require lower temperatures, usually between 10 and 30°C. Optimum temperature for growth is not always the best for product production. In an attempt to provide the most favorable conditions for growth and product production, several groups have proposed production strategies that demand a fine control of temperature (63,66). Moreover, temperature monitoring has been proposed as a tool for designing control strategies (63,67). Altogether, it is clear that optimum temperature control and monitoring are imperative, especially when applications of cell culture are scaled up to a commercial level.

For fermentations of lower eukaryotes or prokaryotes, heat transfer becomes increasingly problematic as the fermenter is scaled up. This is due to the high cell concentrations reached, the high heat generated from metabolic activity, and the very large volumes of fermenters employed. The importance of heat transfer in such processes can be illustrated by the production of single-cell protein, where operating costs from heat removal can be higher, or at least equal, than that from oxygen transfer (14). A particular problem that occurs at very large scales is that heat transfer from the vessel walls is severely limited since reactor volume increases to the cube while reactor area increases only to the square. A contrasting situation exists for cell culture, where heat transfer is not considered an important problem and has been widely overlooked, while other aspects such as oxygen transfer have received much more attention. The reasons for this are the lower cell concentrations, smaller power inputs, lower size of commercial reactors, and lower generation of metabolic heat of animal and plant cell culture compared to microbial fermentations. Nonetheless, careful attention must still be placed on the design of the heat transfer and temperature control systems of large-scale cell cultures, particularly if temperatures near ambient are required. Heat transfer can become an important issue as higher cell density cultures are developed and larger reactor volumes are needed. Also, particular operation strategies can result in temperature gradients. Druoin *et al*. (74) observed transient temperature increases when CHO cells were circulated through a sonic separator in perfusion cultures. Temperature increases in animal and microbial cell cultures trigger heat shock responses, which have various effects on metabolism and productivity (75,76). Moreover, the fragile nature of most animal cells limits the use of highly turbulent mixing, necessary if high heat transfer rates are needed. Accordingly, heat transfer phenomena must be considered during the design of a large-scale cell culture and microbial process.

Effective heat transfer is required not only for maintaining a constant temperature in the bioreactor, but also for sterilizing and cooling the vessel, the latter being important for assuring product stability at the end of the culture. In this section, a general introduction to heat transfer in bioreactors is given, with special emphasis to cell culture. Only the maintenance of a desired temperature during the culture phase is discussed, as sterilization and product recovery are discussed elsewhere. Finally, the relevance of heat transfer is evaluated from calculations for hypothetical large-scale cultures.

41.3.1 Heat Transfer in Bioreactors: The Basics

The main heat flows in a stirred-tank bioreactor are shown in Fig. 41.10. The heat accumulation rate in such a reactor,

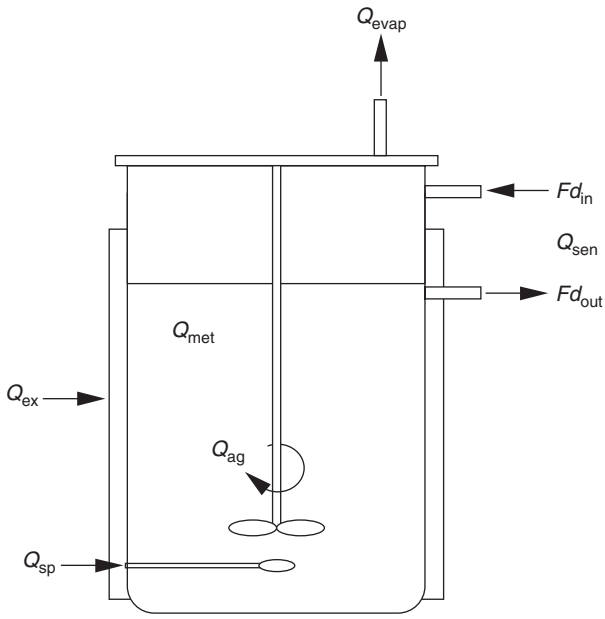

Figure 41.10. Main heat flows in a stirred-tank bioreactor.

for constant pressure, is given as follows:

$$Q_{acc} = Q_{met} - Q_{sen} + Q_{sp} + Q_{ag} - Q_{evap} + Q_{ex} \tag{41.17}$$

where Q_{met} is heat produced by metabolism of the cells, Q_{sen} is sensible enthalpy gain by flow streams (outlet–inlet), Q_{ag} is heat generated by power input from agitation, Q_{sp} is heat generated by sparging, Q_{evap} is heat removed by evaporation, and Q_{ex} is heat transferred by the heat exchanger. Heat transferred between the environment and the reactor can be important for small-scale vessels, but becomes negligible as volume increases. Heat transferred from the environment can be included in Q_{ex}. If temperature of the reactor is maintained constant, then

$$Q_{acc} = 0 \tag{41.18}$$

Each of the terms in Equation 41.17 is individually analyzed below.

41.3.1.1 Metabolic Activity. Heat generated by metabolic activity depends, among other things, on the type of cell, growth phase, type and concentration of substrates, concentration of by-products, shear and osmotic stresses, and physicochemical properties of the culture medium (77). This has been extensively analyzed for cultures of prokaryotes or lower eukaryotes, but only very scarce information exists for animal and plant cell cultures. Heat generated from aerobic growth can be calculated from the oxygen consumption using the oxycaloric equivalent, which is defined as the heat yield from oxygen consumed. For any cell type, fully aerobic metabolism, and all biologically useful organic substrates, the oxycaloric equivalent has been determined to be −450 (±5%) kJ/mol O_2 (77). However, compared to *in vivo*, the oxycaloric equivalent is always more negative for cells grown *in vitro*. This is caused by nutritional deficiencies present in the *in vitro* environment, which must be fulfilled by rapidly growing cells through anaerobic processes (77). Under such conditions, use of the oxycaloric equivalent to calculate the heat produced from cell metabolism can lead to an underestimation of almost 40%. Heat flow rates for several biological models have been determined under controlled pH and dissolved oxygen using microcalorimeters or bench-scale calorimeters (67,77,78). Heat fluxes (heat flow rate per cell) for some mammalian cell lines are shown in Table 41.4. However, caution should be taken when using such values, as the heat generated by metabolism is affected by the various parameters mentioned above.

If metabolic pathways are lumped into one global reaction, then heat produced by cellular metabolism can also be calculated from the standard enthalpies of substrates, biomass, and products. Again, caution should be taken as metabolic reactions are very variable, and depend on the particular system studied, including substrate availability, physicochemical conditions, and toxicity of by-products.

TABLE 41.4. Specific Heat Flux for Some Cell Types

Cell Type	Heat flux (pW/cell)
Human erythrocytes	0.01
Human platelets	0.06
Bovine sperm	1.3 ± 0.1
Human neutrophils	2.5 ± 0.3
Human lymphocytes	5
Horse lymphocytes	8
Human T-lymphoma	8 ± 1
3T3 mouse fibroblasts	17
Chinese hamster ovary 320 (recombinant)	~23
kB	25
Vero	27 ± 2
Mouse lymphocyte hybridoma	30–50
HeLa-53G	31.2
Mouse macrophage hybridoma, 2C11-12	32 ± 2
Chinese hamster ovary K1	38
Human foreskin fibroblast	40 ± 10
Rat white adipocytes	40
Human white adipocytes	49 ± 15
Human melanoma, H1477	80
Human keratinocytes	83 ± 12
Hamster brown adipocytes	110
SV-K14 (transformed) keratinocytes	134 ± 35
Rat hepatocytes	329 ± 13
Kluyveromyces fragilis	1.2[a]

[a] In grams per liter, calculated from data of Ref. 78.

Even when catabolism of higher eukaryotic cells is very complex, Kemp and Guan (77) have concluded that, for heat balance considerations, the metabolic processes of animal cells can be described essentially by glycolysis, oxidative phosphorylation, the pentose phosphate pathway, and glutaminolysis. Accordingly, they summarized animal cell growth and product production as follows:

$$\text{Glucose} + \text{Glutamine} + O_2 \rightarrow \text{Biomass} + \text{Product} + \text{Lactate} + CO_2 + NH_3 + H_2O \quad (41.19)$$

Q_{met} can then be calculated from the standard enthalpies of formation of each compound, if reaction stoichiometry is known, according to (14)

$$Q_{\text{met}} = \sum_{i=1}^{m} b_i H_{\text{p},i} - \sum_{j=1}^{n} a_j H_{\text{s}j} \quad (41.20)$$

where m and n are the number of products and substrates, respectively; b_i and a_j are the stoichiometric coefficients of product i and substrate j, respectively; and $H_{\text{p},i}$ and $H_{\text{s},j}$ are the enthalpies of product i and substrate j, respectively. It should be noted that the contribution of anabolism to heat generation is generally negligible (67). Some standard enthalpies of formation for common cell culture substrates and by-products are shown in Table 41.5. von Stockar and Marison (78) have determined that neither temperature nor the thermodynamic state of compounds is significant for energy balance calculations of aerobic (or mainly aerobic) cell growth. Therefore, values shown in Table 41.5 can be utilized for energy balances for culture temperatures different at 25°C without any further corrections.

TABLE 41.5. Standard Formation Enthalpies of Various Compounds (25°C, 1 atm)

Compound	Formula	$\Delta H^0{}_f$ (kcal/mol)
Acetic acid	$C_2H_4O_2$(aq)	−94.5
Acetate ion	$C_2H_3O_2{}^-$ (aq)	−116.1
Alanine	$C_3H_7O_2N$(s)	−88.9
Ammonia	NH_3(g)	−41.4
	NH_3(aq)	−19.4
Ammonium chloride	NH_4Cl(s)	−75.4
Ammonium ion	$NH_4{}^+$(aq)	−31.8
Bicarbonate ion	$HCO_3{}^+$(aq)	−165.5
Biomass	$CH_{1.8}O_{0.5}N_{0.2}$(aq)	−21.9
Carbon dioxide	CO_2(g)	−94.0
	CO_2(l)	−98.9
Carbonic acid	H_2CO_3	−167.2
Ethanol	C_2H_5OH(l)	−66.3
Formic acid	CH_2O_2(aq)	−85.1
$\alpha - \beta$-D-Glucose	$C_6H_{12}O_6$(aq)	−302.0

41.3.1.2 Inlet and Outlet Flows. The heat flow contributed by substances fed to or eliminated from the reactor, Q_{sen}, if no phase change occurs and if inlet and outlet flows are equal, is given as follows:

$$Q_{\text{sen}} = F_{\text{fd}} C_{\text{p}} (T_{\text{out}} - T_{\text{in}}) \quad (41.21)$$

where F_{fd} is flow rate, C_{p} the heat capacity of the stream, and T_{out} and T_{in} are the temperature of the outlet and inlet flows, respectively. Heat generation can also originate from the temperature difference between the gas and the culture broth. For instance, if gases are compressed adiabatically, their temperature can be higher than the liquid, particularly for cultures controlled at low temperatures (48). Accordingly, the sensible enthalpy gain by the gaseous stream is given as

$$Q_{\text{sen}_{\text{g}}} = F_{\text{g}} C_{\text{p}_{\text{g}}} \rho_{\text{g}} \left(T_{\text{g}} - T_{\text{b}}\right) \quad (41.22)$$

where T_{b} is the temperature of the culture broth, ρ_{g} is gas density, and the subindex g refers to the gas phase.

Other reactions occurring in the system simultaneously to cell growth, such as neutralization of buffers in culture media, also contribute to the energy balance (80). The enthalpies of neutralization of physiological buffers are shown in Table 41.6, which are usually exothermic in culture conditions (80).

41.3.1.3 Power Input by Agitation and Sparging. An important source of heat in a bioreactor is the power input from agitation and sparging. The power transferred to the reactor from sparging, P_g, can be calculated from the following equation (14,81):

$$P_{\text{g}} = \rho_{\text{g}} F_{\text{g}} \left[\frac{R T_{\text{b}}}{\text{MW}} \ln \frac{p_1}{p_2} + \alpha \frac{u_{\text{G}_{\text{o}}}^2}{2} \right] \quad (41.23)$$

TABLE 41.6. Enthalpies of Neutralization of Physiological Buffer Systems for the Reaction $A^- + H^+ \rightarrow AH$

Buffer System	T(°C)	$\Delta\ _bH_H+$ (kcal/mol) H^+	pk_a
Bicarbonate	25	−2 to −1.8	6.4
HCO_3/CO_2(aq)	37	−1.2	6.3

where R is the gas constant, MW is the gas molecular weight, p_1 is pressure at the sparger, p_2 is pressure at the top of the vessel, α is the fraction of gas kinetic energy transferred to the liquid (typically 0.06) and u_{G_o} is the gas velocity at the sparger orifice. For well-designed spargers, the term $\alpha\frac{u_{G_o}^2}{2}$, which represents the jet kinetic energy developed at the sparger holes, is small and can be neglected (14). Equation 41.23 can be used to calculate power dissipation due to sparging into stirred tanks, bubble columns, and airlift bioreactors. Notice that, Equation 41.23, neglecting the jet kinetic energy at the sparger holes, corresponds to the term of energy dissipation rate from aeration of Equation 41.2. This is obtained by substituting in Equation 41.23 the molar gas flow rate and pressure difference between the sparger and top of the vessel, given by Equations 41.24 and 41.25, respectively:

$$\dot{n} = \frac{F_g\,(p_1 - p_2)}{\ln\left(\frac{p_1}{p_2}\right) RT_b} \tag{41.24}$$

$$(p_1 - p_2) = \rho_g H \tag{41.25}$$

where $\dot{n}$ is the molar gas flow rate.

The power, P, transferred to a Newtonian fluid by agitation depends on the fluid density, viscosity, agitation speed, impeller type, impeller diameter, vessel diameter, liquid height, and other geometric characteristics and parameters of the system (18). Then, using dimensional analysis, the energy dissipated to the liquid by agitation is a function of

$$\frac{P}{\rho N^3 D^5} = fn\left\{\frac{\rho N D^2}{\mu_b}, \frac{N^2 D}{g}, \frac{T}{D}, \frac{W}{D}, \frac{H}{D}, \text{etc.}\right\} \tag{41.26}$$

where W is impeller width. P_0, Re, and Fr are the power, Reynolds, and Froude numbers, respectively, defined as

$$P_0 = \frac{P}{\rho N^3 D^5} \tag{41.27}$$

$$Re = \frac{\rho N D^2}{\mu_b} \tag{41.28}$$

$$Fr = \frac{N^2 D}{g} \tag{41.29}$$

Fr is important only if gross vortexing exists in the reactor. If vortexing is prevented by baffling or off-center stirring, then the power number will be only a function of Re and geometrical ratios (18). As shown in Fig. 41.11, this is true for the laminar flow regime ($Re < 3 \times 10^5$), where P_0 is related to Re through the proportionality constant, K_p, which only depends on the system geometry:

$$P_o = \frac{K_p}{Re} \tag{41.30}$$

In turbulent flow regime the power input is independent of Re. Figure 41.11 can be used to predict P_0 for various system geometries. For other geometries, P_0 must be determined experimentally. For vessels equipped with multiple

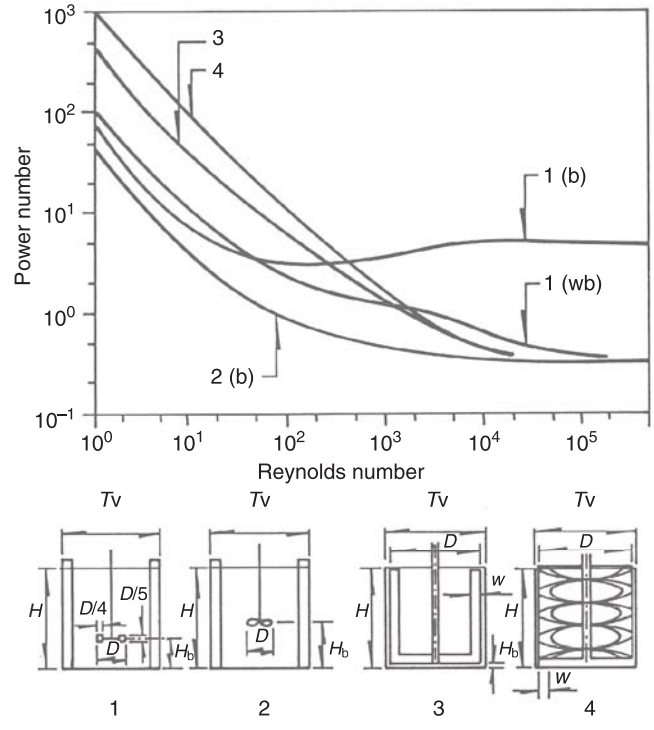

Figure 41.11. Power number as a function of Reynolds number. (1) Turbine stirrer, $T_v/D = 3.33$, $H_b/D = 1$, wb = without baffles, b = with baffles. (2) Marine propeller, angle 25°, $T_v/D = 3.33$, $H_b/D = 1.5$. (3) Anchor impeller, $T_v/D = 1.02$, $H_b/D = 0.01$, $W/D = 0.1$. (4) Helical ribbon impeller, $T_v/D = 1.02$, $H_b/D = 0.1$, $W/D = 0.1$. [Reprinted with permission from Ref. 48.]

impellers, the interaction between them is not significant if the distance between impellers exceeds their diameter (48). Power consumed will then be the addition of the power consumed by each impeller. Furthermore, if an agitated vessel is also aerated, then power input from agitation will decrease with respect to the unaerated case. van't Riet and Tramper (48) recommend the correlation by Hughmark for turbine stirrers in water for calculating aerated power inputs P_a:

$$\frac{P_a}{P} = 0.10\left(\frac{F_g}{NV}\right)^{-0.25}\left(\frac{N^2D^4}{gWV^{2/3}}\right)^{-0.20} \tag{41.31}$$

41.3.1.4 Evaporation. If the inlet gas is at a lower temperature than the bioreactor, heat loss due to evaporation can be significant. Furthermore, evaporation can contribute to substantial water loss in the fermenter, which has to be replaced or avoided through the use of effective condensers. As the gas temperature increases, the water content of saturated air increases. The latent heat of evaporation for water, λ, is 41 kJ/mol, and the heat loss due to evaporation can be calculated as (14)

$$Q_{evap} \approx \lambda F'_g(w_{out} - w_{in}) \tag{41.32}$$

where F'_g is dry air flow and w_{out} and w_{in} are the water contents of the inlet and outlet flows, respectively. Water contents can be calculated from psychrometric charts.

41.3.1.5 Heat Exchangers. Heat exchangers have to be included in vessels for controlling the culture temperature. Vessels can be jacketed, have internal or external coils, and even an external heat exchanger can be used. Jacketed vessels are used in low-scale reactors, but as scale increases, the heat transfer area per unit volume decreases, and internal or external coils may be required for efficient control of temperatures. As illustrated in the practical cases shown below, a jacket is more than enough for transferring the necessary heat in typical large-scale cell cultures. Furthermore, shear damage of cells in pumps and risk of contamination limit the use of external heat exchangers.

In order to maintain a constant culture temperature, the heat generated (or removed) by all the processes analyzed previously must equal the heat transferred by the exchanger. Heat transfer depends on the overall heat flow resistance, R', and the temperature gradient, ΔT, between the exchanger and the culture broth:

$$Q_{ex} = \frac{\Delta T}{R\prime} \tag{41.33}$$

Calculation of ΔT depends on the system geometry and on the direction of motion of the fluids. For heat transfer from jackets in agitated-tank reactors, ΔT is given by the log-mean temperature difference (LMTD):

$$\text{LMTD} = \frac{(T_i - T_o)}{\ln\left(\frac{T_b - T_o}{T_b - T_i}\right)} \tag{41.34}$$

where T_i and T_o are the temperatures of the coolant entering and leaving the reactor, respectively. T_b is constant if a perfectly mixed vessel is assumed. In turn, R' is defined as

$$R\prime = \frac{1}{UA} \tag{41.35}$$

where A is the area for heat transfer and U is the overall heat transfer coefficient. U depends on the nature of the material across which heat is transferred, the system geometry, and the nature of the fluid flows involved. As a rule of thumb, U for a clean vessel usually ranges between 280 and 1137 W/m^2 °C (13). However, a wider range exists for various practical situations (82). Lower values correspond to very viscous non-Newtonian fluids, while larger values correspond to nonviscous Newtonian fluids. The overall heat transfer resistance is the sum of the individual resistances in series in the path of heat transfer. Therefore, for the jacket of thin-walled vessels, where the area normal to the direction of heat transfer can be considered constant, U is given by the following expression:

$$\frac{1}{U} = \frac{1}{h_i} + \frac{t}{k_m} + \frac{1}{h_o} + \frac{1}{h_{f_i}} + \frac{1}{h_{f_o}} \tag{41.36}$$

where h_i and h_o are the broth and coolant side heat transfer coefficients, respectively; t is vessel wall thickness; k_m is the metal thermal conductivity; and h_{f_i} and h_{f_o} are the inside and outside fouling heat transfer coefficients, respectively. Fouling factors are caused by deposits (microbial film, scale, dirt, etc.), which depend on operating conditions and should be kept to a minimum by maintaining vessels and jackets or coils clean. Fouling resistances for various systems can be found elsewhere (82). Individual heat transfer coefficients depend on the fluid properties, geometric characteristics, and operation conditions of the system through complex relations. Thus, from a practical standpoint, individual heat transfer coefficients are obtained from empirical correlations, some provided by vessel vendors, relating the Nusselt number, Nu, with the Reynolds and Prandtl, Pr, numbers. For instance, h_i for stirred vessels can be determined as:

$$Nu = aRe^b Pr^c \left(\frac{\mu_b}{\mu_w}\right)^d \tag{41.37}$$

TABLE 41.7. Values of Constants in Equation 37 for Jacketed Vessels

Impeller	*a*	*b*	*c*	*d*	*Re*
Jacketed vessels					
Paddle	0.36	0.66	0.33	0.21	300 to 3×10^5
Pitched-blade turbine	0.53	0.66	0.33	0.24	80–200
Disk flat-blade turbine	0.54	0.66	0.33	0.14	40 to 3×10^5
Propeller	0.54	0.66	0.33	0.14	2×10^3
Anchor	1	0.5	0.33	0.18	10–300
Anchor	0.36	0.66	0.33	0.18	300–40,000
Helical ribbon	0.63	0.5	0.33	0.18	$8–10^5$
Helical coils					
Paddle	0.87	0.62	0.33	0.14	300 to 4×10^5

Adapted from Ref. 82.

where a, b, c, and d are constants (listed in Table 41.7 for various reactor configuration), μ_w is broth viscosity at the wall temperature, and Nu and Pr are defined as

$$Nu = \frac{h_i T_v}{k} \tag{41.38}$$

$$Pr = \frac{C_p \mu_b}{k} \tag{41.39}$$

where k is broth thermal conductivity. Equation 41.37 is acceptable for unaerated fluids; however, no correlations have been published for aerated conditions (13). Depending on stirring speed and flooding phenomena, aeration can improve or deteriorate h_i. Nonetheless, the influence of gassing is minor in relation to other variables (48).

Liquid circulation in bubble columns is determined by the gas flow rate, and, thus, h_i can be determined as (48)

$$h_i = 9391 \left(u_{G_s}\right)^{0.25} \left(\frac{\mu_{wt}}{\mu_b}\right)^{0.35} \tag{41.40}$$

where μ_{wt} is the water viscosity and μ_b is broth viscosity. Equation 41.40 is applicable for vessels with diameters ranging from 0.1 to 1 m and for broths viscosities between 10^{-3} and 5×10^{-2} N s/m^2.

The liquid velocity has to be known in order to perform heat transfer calculations in airlift bioreactors. This is rather complex and, as exemplified by van't Riet and Tramper (48), an average liquid velocity can be estimated only from numerical simulations. Alternatively, simplified correlations, such as the one shown in Equation 41.7, exist. However, liquid velocity gradients are present, and, thus, a single value for heat transfer cannot be given. Flow in the downcomer can be considered as a single phase. Thus, h_i can be determined from correlations of turbulent flow in pipes (48):

$$\frac{h_i T_d}{k} = 0.027 \left(\frac{\rho \overline{u_{L_d}} T_d}{\mu_b}\right)^{0.8} Pr^{0.33} \tag{41.41}$$

where $\overline{u_{L_d}}$ is average superficial liquid velocity in the downcomer and T_d is diameter of the downcomer. The flow regime in the riser can be described in the same manner as in a bubble column; that is, either homogeneous or heterogeneous flow (see previous section) (48). The flow regime is determined mainly by the total hydrodynamic resistance of the bioreactor. If the riser acts as a bubble column in the heterogeneous flow regime, Equation 41.40 can be used for calculating the heat transfer coefficient. For a "true" airlift flow (homogeneous flow), Equation 41.41 can be used.

For packed-bed reactors, the heat transfer coefficient between the inner container surface and the fluid stream can be calculated from the following correlation (82):

$$Nu = b_1 b T_v^{0.17} \left(\frac{T_p G}{\mu_b}\right)^{0.83} Pr \tag{41.42}$$

where T_p is particle diameter, G is superficial mass velocity, k and C_p are used to calculate Pr (refer to the liquid phase), b is a coefficient dependent on T_p/T_v (Fig. 41.12), and b_1 is equal to 1.22 (SI) or 1 (US customary).

Heat transfer coefficients for other heterogeneous systems, such as HFs and fluidized beds, have to be evaluated for each individual case, as the packing, liquid velocity, and the aspect ratio have to be considered. Various correlations for such systems can be found elsewhere (82). Finally, once all the terms of Equation 41.36 are known, the heat transferred by the exchanger can be calculated by combining

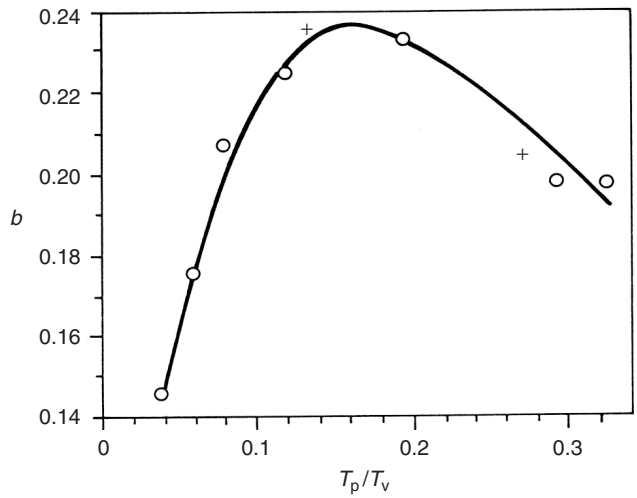

Figure 41.12. Coefficient b of Equation 41.42, T_p/T_v in inches per foot. [Reprinted with permission from Ref. 82.]

Equations 33, 34, and 35:

$$Q_{ex} = UA\left(\frac{T_i - T_o}{\ln\left[\frac{T_b - T_o}{T_b - T_i}\right]}\right) \tag{41.43}$$

and the cooling water flow rate, F_w, can be calculated from

$$F_w = \frac{Q_{ex}}{C_p\,(T_o - T_i)} \tag{41.44}$$

Many industrial operations still rely on simply multiplying the number of small-scale units (such as T-flasks or roller bottles) and placing them in contained suites. For such cases, a very different approach for solving heat transfer problems must be taken. These are usually solved through proper design of the HVAC (heating, ventilation, and air conditioning) systems. A "mega roll" industrial unit has been described by Panina (83). This unit has a capacity of 7200 roller bottles of 1 L in cylindrical wire racks. Racks are positioned in an incubator of 269.8 m^3 heated with electric heaters that generate 14 kW. Heat is uniformly distributed by forced air circulation and temperature is controlled by a heat exchanger fed with cold water.

41.3.2 Practical Cases

In order to assess the magnitude of the various heat flows, and thereby the importance of heat transfer in a cell culture process, heat balances for a hybridoma culture in a hypothetical 10,000-L water-jacketed stirred-tank reactor are presented. Comparison is made with a hypothetical baculovirus-infected insect cell culture in the same vessel. The behavior of the large-scale hybridoma culture is assumed to follow real kinetic data obtained from a 1-L agitated batch reactor under the experimental conditions described by Higareda *et al*. (84). Such an assumption is valid since the data at the 1-L scale, shown in Fig. 41.13, are very similar to data reported by Backer *et al*. (9) at the 1000-L scale. The calculations are performed for a hypothetical vessel, detailed in Table 41.8, which closely resembles the reactor used for CHO cell culture at Glaxo Wellcome and described by Nienow *et al*. (85).

Viable cell concentration and OUR are shown in Fig. 41.13a. The horizontal line represents the time of glutamine depletion that corresponds to the onset of respiration cessation and the end of exponential growth. A similar behavior has been described by Higareda *et al*. (84). Heat flow during the lag and exponential growth phases was calculated using 50 pW/cell, which corresponds to the highest heat flux reported for a mouse hybridoma (Table 41.4). By choosing such a high value, the calculated results should yield the worst case scenario in terms of heat generation. Guan *et al*. (67) showed

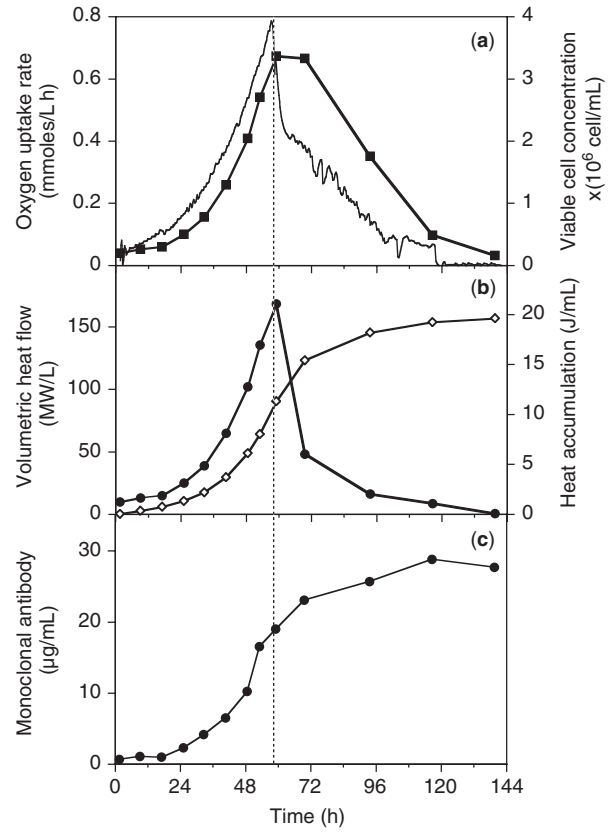

Figure 41.13. Kinetic data of a hybridoma batch culture in a 1-L stirred-tank reactor. (a) Oxygen uptake rate (–) and viable cell concentration (closed squares). (b) Heat flow (closed circles) and heat accumulation (open diamonds). (c) Monoclonal antibody. Dotted-line represents the time of Gln depletion.

that as metabolic activity of a culture decreases, the heat generated approaches the oxycaloric equivalent. Accordingly, during the stationary and death phases, the heat flow was calculated using the oxycaloric equivalent, 450 J/mmol O_2. The calculated profiles of volumetric heat flow and accumulated heat (integral of heat flow with time) are shown in Fig. 41.13b. It can be seen that volumetric heat flow and accumulated heat will have a maximum of 0.17 W/L and 20 J/mL. Thus, for the 10,000-L reactor (8000 L working volume), a maximum heat flow of 1.36 kW will be expected. In comparison, maximum heat flows of 7.4 W/L and 26 W/L have been reported for typical aerobic growth of yeast (at a relatively low maximum biomass concentration of 6.2 g/L) and unicellular protein production in a 2.3×10^6-L reactor, respectively (78). That is, heat generated from metabolism of the hypothetical hybridoma culture will be between 1 and 2 orders of magnitude lower than that for other microbial fermentations.

To satisfy the oxygen requirements of the culture shown in Fig. 41.13, OTR must equal OUR. In this example,

TABLE 41.8. Details of the Hypothetical 10,000-L Bioreactor

Working volume	8000 L
Aspect ratio	1.3
Liquid height	2.54 m
Tank diameter	2 m
Vessel wall thickness	6×10^{-3} m
Baffles	4
Turbine	1 Rushton
Turbine diameter	0.44 m
Distance of turbine from vessel bottom	2/9 T_v
Heat exchanger	Water jacket
Area of water jacket	12 m^2
Aeration	Superficial and submerged
Superficial gas velocity	2×10^{-4} m/s
Temperature	37°C
Dissolved oxygen concentration	20% wrt air saturation
Metal conductivity	80 W/m^2°C

Some values are based on Ref. 85.

maximum OUR was 0.8 mmol/L h. Thus, an oxygen transfer coefficient, k_La, of at least 5.47 h^{-1} is required. As determined by Nienow *et al*. (85), such a k_La can be obtained if 50 W/m^3 are supplied to the reactor by agitation and sparging. Total heat dissipated by the reactor would then be 1.76 kW. Interestingly, under such situations, 80% of the heat flux will originate from cellular metabolism, whereas only 23% from aeration and agitation. For a superficial gas velocity of 2×10^{-4} m/s (Table 41.8) and using Equations 41.23 or 41.2, the power supplied by sparging will be 1.96 W/m^3. Thus, 48.04 W/m^3 is needed for agitation. An impeller speed of 1.67 s^{-1} can be calculated from Equation 41.27 if a power number of 5 is assumed for the reactor (85). This results in a fully turbulent flow regime with a Reynolds number of 323,312 (assuming that culture broth behaves like water), but where shear damage is not expected. A broth side heat transfer coefficient of 1694 W/m^2°C can then be calculated using Equation 41.37. Finally, if no fouling layers in the tank or jacket are formed, and if the heat transfer coefficient on the coolant side is negligible, an overall heat transfer coefficient of 1503 W/m^2°C results from Equation 41.36 and data from Table 41.8 (vessel wall thickness and metal thermal conductivity). This value agrees with overall heat transfer coefficients of jacketed vessels using brine as coolant and water as fluid in vessel, which range from 230 to 2625 W/m^2°C (82).

In order to maintain the temperature of the reactor constant, heat generated from cellular metabolism, agitation, and sparging has to be removed by the water jacket, dissipating to the environment, and evaporation. Again, for the worst case scenario, maximum heat removal from the exchanger can be determined if heat losses to the environment and from evaporation are neglected. This is possible if the reactor is well insulated and a water saturated gas stream at the culture temperature is used for aeration. Accordingly, solving Equation 41.43 for a jacket area of 12 m^2 yields an LMTD of 0.09°C. Multiple combinations of inlet and outlet water temperatures below 37°C, but above 36°C, can satisfy the calculated LMTD. For instance, water entering the jacket at a temperature of 36°C and a flow rate of 22 L/min (Eq. 41.44) would be necessary for maintaining the culture temperature at 37°C. Interestingly, such a result indicates that for the hypothetical hybridoma culture, the heat transfer problem actually becomes a heating task, as jacket inlet water is required at a temperature above ambient.

A different situation will result for another model culture, for instance, protein production by the insect cell baculovirus expression vector system (69,86,87). An insect cell culture, typically maintained at 27°C, can reach a concentration of 8×10^6 cell/mL and an OUR of 17 mmol/L h during infection with a baculovirus. Using the oxycaloric equivalent, a heat flow from metabolic activity of 17.2 kW will result for the same hypothetical vessel described above, that is, about 13 times higher than that for the hybridoma culture. For comparison purposes, the same agitation and aeration rates used for the hybridoma culture are also used in this case. Since OUR is several-fold higher, it is assumed that OTR can be increased by oxygen enrichment, additional membrane aeration and/or pressure increase, or other means. It should be cautioned that for a real situation, the practical utility of such alternatives must be carefully evaluated. The fragile nature of insect cells also rules out the use of higher agitation and aeration rates. Accordingly, the total heat generated will be 17.6 kW. Following the same procedure as before, an LMTD of 0.98°C can be calculated. Such an LMTD could be satisfied, at least theoretically, for inlet water temperatures ranging from 6 to 26°C. Thus, more options exist than that for the hybridoma culture, for designing the heat transfer system. In conclusion, the cases illustrated show that jacketed vessels are more than enough to satisfy heat transfer requirements for cell culture at the typical largest scales performed to date. Moreover, compared to microbial systems or oxygen transfer requirements in cell culture, the heat transfer problem is not a major challenge, but cannot be overlooked.

NOMENCLATURE

A	area
A_d	downcomer cross-sectional area
a_j	stoichiometric coefficient of substrate j

A_p	area of microcarrier
A_r	riser cross-sectional area
b_i	stoichiometric coefficient of product i
c	dissolved oxygen concentration
c_m	dissolved oxygen concentration at saturation
c_0	inlet dissolved oxygen concentration
C_p	heat capacity
D	impeller diameter
d_b	bubble diameter
D_e	effective diffusion coefficient
$D_{o/w}$	diffusion coefficient of oxygen in water
F_g	gas flow rate
F'_g	dry gas flow rate
F_{fd}	flow rate (feed)
Fr	Froude number
F_w	cooling water flow rate
g	gravitational acceleration
G	superficial mass velocity
H	liquid height
H_b	height of stirrer above vessel bottom
H_d	downcomer height
h_{f_i}	inside fouling heat transfer coefficient
h_{f_o}	outside fouling heat transfer coefficient
h_i	broth side heat transfer coefficient
h_o	coolant side heat transfer coefficient
$H_{p,i}$	enthalpy of product i
H_r	riser height
$H_{s,j}$	enthalpy of substrate j
k	thermal conductivity
k_d	specific death rate constant
k_m	metal thermal conductivity
K_p	proportionality constant
LMTD	log-mean temperature difference
m	number of products
Mab	monoclonal antibody
MW	molecular weight
n	number of substrates
$\dot{n}$	molar gas flow rate
N	impeller speed
N^*	dimensionless mixing time
Nu	Nusselt number
OUR	oxygen uptake rate
P	power
p_1	pressure at the sparger
p_2	pressure at top of vessel
P_a	aerated power input
p_c	pressure in capillary
P_g	power transferred to liquid from sparging
P_o	power number
Pr	Prandtl number
q	specific production rate
Q_{acc}	heat accumulation rate
Q_{ag}	heat produced by agitation
Q_{evap}	heat removed by evaporation
Q_{ex}	heat transferred by the heat exchangers
Q_{met}	heat produced by metabolism
Q_{sen}	sensible enthalpy gain by flow streams
Q_{seng}	sensible enthalpy gain by gas stream
Q_{sp}	heat produced by sparging
R	gas constant
R'	resistance to heat flow
R	radius
r_0	radius at which oxygen concentration falls to zero
r_c	capillary radius
Re	Reynolds number
t	vessel wall thickness or time
T	temperature
T_b	broth temperature
t_c	circulation time
T_d	downcomer diameter
T_g	temperature of gas
T_i	jacket fluid inlet temperature
T_{in}	temperature of the inlet flow
t_M	mixing time
t_{mt}	time constant for mass transfer
T_o	jacket fluid outlet temperature
T_{out}	temperature of the outlet flow
T_p	diameter of particle
T_r	riser diameter
t_{rxn}	time constant for oxygen consumption
T_v	vessel diameter
U	overall heat transfer coefficient
$\overline{u_c}$	average axial velocity inside capillary
u_G	superficial gas velocity
u_{G_o}	gas velocity at the sparger orifice
u_{G_r}	superficial gas velocity in the riser
u_{G_s}	pressure corrected gas velocity
u_L	superficial liquid velocity
u_{Lr}	superficial liquid velocity in the riser
$\overline{u_{L_d}}$	average superficial liquid velocity in downcomer
V	liquid volume
V_k	killing volume

V_p	volume of a microcarrier
VVM	volume of air per volume of liquid per minute
W	width of impeller
w_{in}	water content of inlet gas stream
w_{out}	water content of outlet gas stream
X_t	total cell concentration
y	liquid depth
z	axial position
α	fraction of gas kinetic energy transferred to the liquid
Δp	pressure drop
ε	void fraction
ε_T	total energy dissipation rate
Φ	observable module
η	effectiveness factor
λ	latent heat of evaporation of water
μ	viscosity
μ_{app}	apparent viscosity
μ_b	broth viscosity
μ_w	broth viscosity at the wall temperature
μ_{wt}	water viscosity
ρ	liquid density
ρ_g	gas density

BIOREACTORS: AIRLIFT REACTORS

J.C. Merchuk
Ben-Gurion University of the Negev, Beer-Sheva, Israel
F. Garcia Camacho
Universidad de Almeria, Almeria, Spain

42.1 INTRODUCTION

42.1.1 Airlift Reactors

An airlift reactor (ALR) is a gas–liquid or gas–liquid–solid pneumatic contacting device that is characterized by fluid circulation in a defined cyclic pattern through channels built specifically for this purpose. In ALRs, the content is pneumatically agitated by a stream of air or by other gases. In these cases, the name *gas lift reactors* has been used. In addition to agitation, the gas stream has the important function of facilitating exchange of material between the gas phase and the medium; oxygen is usually transferred to the liquid, and in some cases, reaction products are removed through exchange with the gas phase.

The main difference between ALRs and bubble columns (BCs, also pneumatically agitated) lies in the type of fluid flow, which depends not only on the gas input but also on the geometry of the system. The BC is a simple vessel into which gas is injected, usually at the bottom, and random mixing is produced by the ascending bubbles. In the ALR, the major patterns of fluid circulation are determined by the design of the reactor, which has a channel for gas–liquid upflow—*the riser*—and a separate channel for the downflow (Fig. 42.1). The two channels are linked at the bottom and at the top to form a closed loop. The gas is usually injected near the bottom of the riser. The extent to which the gas disengages at the top, in the section termed the *gas separator*, is determined by the design of this section and by the operating conditions. The fraction of the gas that does not disengage, but is instead entrapped by the descending liquid and taken into the downcomer, has a significant influence on the fluid dynamics in the reactor and hence on the overall reactor performance.

42.1.2 Reactor Morphology

ALRs can be divided into two main types on the basis of their structure (Fig. 42.1): (i) external loop vessels, in which circulation takes place through separate and distinct conduits, and (ii) baffled (or internal loop) vessels, in which baffles placed strategically in a single vessel create the channels required for the circulation. All ALRs comprise four distinct sections with different flow characteristics:

1. *Riser:* The gas is injected at the bottom of this section, and the flow of gas and liquid is predominantly upward.
2. *Downcomer:* This section, which is parallel to the riser, is connected to the riser at the bottom and at the top. The flow of gas and liquid is predominantly downward. The driving force for recirculation is the difference in mean fluid density between the downcomer and the riser; this difference generates the pressure gradient necessary for liquid recirculation.
3. *Gas separator:* This section at the top of the reactor connects the riser to the downcomer, facilitating liquid recirculation and gas disengagement. Designs that allow for a gas residence time in the separator

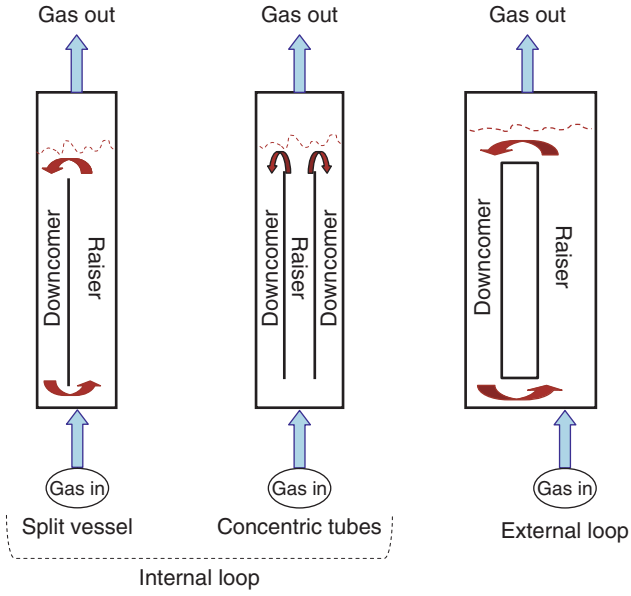

Figure 42.1. Different configurations of ALRs. In all cases clearly directional circulation of the liquid results from the gas input to the system.

that is substantially longer than the time required for the bubbles to disengage will minimize the fraction of gas recirculating through the downcomer (1,2).

4. *Base:* In the vast majority of airlift designs, the bottom connection zone between the riser and downcomer is very simple. The design of this section may sometimes influence gas holdup, liquid velocity, and solid phase flow (3,4).

Momentum, mass transfer, and heat transfer will be different in each section, but the design of each section may influence the performance and characteristics of each of the other sections, because the four regions are interconnected.

42.1.3 Advantages

ALRs are superior to traditional stirred-tank fermenters (STRs) for many processes based on biomass growth, despite the fact that the conventional fermenters provide the major requirements for culturing microorganisms: large gas–medium interface for the supply of oxygen and the removal of waste gases; good agitation to ensure proper nutrient distribution and to minimize damage, resulting from local addition of concentrated acid or base (for pH control); means of heat transfer (for temperature control); and a contamination-free environment. The reason for the more successful growth reported in ALRs (5–14) appears to lie in the difference in the fluid dynamics of ALRs and STRs. In conventional STRs, the energy required for the movement of the fluids is introduced focally at a single point in the reactor, via a stirrer. Energy dissipation is very high in the immediate surroundings of the stirrer and decreases away from it toward the walls. Similarly, shear will be greatest near the stirrer (15,16), because the momentum is transferred directly to the fluid in that region (17), which, in turn, transfers this energy to the slower moving, more distant elements of the fluid. This results in a wide variation of shear forces; for example, the maximum shear gradient in a STR with a flat-blade turbine has been reported to be approximately 14 times the mean shear gradient (18). An even more dramatic difference is found following the calculation methods recommended by Henzler (19), leading to a ratio of the maximum and mean energy dissipation rate in a stirred reactor of the order of 30 for standard operation conditions.

Cells in culture may thus be exposed to very different environments in a mechanically stirred vessel, either to minimal shear forces that may generate potentially undesirable gradients in temperature and in substrate, metabolite, and electrolyte concentrations. Alternatively, cells will be exposed to highly turbulent zones, with no problems of heat or mass transfer, but with very high shear gradients that may endanger cell integrity or exert some influence on cell morphology and metabolism (17). Changes in the morphology of microorganisms associated with high shear forces in the medium have frequently been observed (20–22). In the case of plant cell cultures, it has been shown that high shear conditions may also lead to changes in the production rate and yield of secondary metabolites (23,24). The nature of the relationship between such morphological changes and the rates of growth and metabolite production is still not properly understood, although it may be of great importance in the design and scale-up of bioreactors.

In ALRs, as in BCs, the gas is injected at a single point, but in ALRs, the direct contribution of gas injection to the dynamics of the system is small; circulation of liquid and gas is facilitated by the difference in gas holdup between the riser and the downcomer, which creates a pressure difference at the bottom of the equipment.

$$\Delta P_b = \rho_L g h(\varphi_r - \varphi_d) \tag{42.1}$$

where ΔP_b is the pressure difference, ρ_L is the density of the liquid (the density of the gas being considered negligible), g is the gravitation constant, and ϕ_r and ϕ_d are the fractional gas holdup of the riser and downcomer, respectively. This pressure difference forces the fluid from the bottom of the downcomer toward the riser, generating the circulation in the ALR. As ϕ_r and ϕ_d are both average values, integrated along the height of the reactor, it follows that no focal points of energy input exist and shear distribution is homogeneous throughout the ALR. This creates a relatively constant environment, minimizing sharp changes in the mechanical forces acting on suspended cells. One of

the most critical points is the bottom, where a sharp 180° turn takes place (3,25).

It has been reported (26) that the driving force in Equation 42.1 is important only for lower values of gas flow rate, because at higher values, the circulation velocity is governed by friction in the reactor vessel. While this is essentially true, and frictional loss control that may be found in small ALRs used in laboratory trials and especially in draught tubes devices with small gaps in the annulus, the usual range of operation of medium and large-scale ALR in bioprocesses assures that ΔP_b indeed controls the circulation in the system.

Shear-sensitive mammalian and plant cells in culture should benefit from ALRs as bioreactors for these cells need to minimize shear-related damage (17–19,24–39). Mammalian and plant cells in culture are more susceptible than microorganisms to the flow conditions in the reactor. Dinoflagellata are another example of cells extremely sensitive to shear damage (27–29). Mammalian cells, which lack the rigid cell wall of microorganisms, have a larger size than microorganisms and are very sensitive to mechanical stress. Plant cells have a rigid cellulose wall, but they are also much larger than microorganisms (usually by about an order of magnitude) and are therefore also sensitive to reactor conditions. Kolmogoroff's model of isotropic turbulence (30) indicates that serious damage may occur at relatively large values of the length scale. The last length is a parameter of the model and indicates the size of the eddy where energy starts to be dissipated by viscous resistance. It has been observed that plant cells, in spite of their rigid wall, are shear sensitive, and growth problems have been found in stirred-tank cultures, especially in large-scale systems. Although high agitation rates may be detrimental to cell growth, low agitation rates lead to an increase in the number and size of cell aggregates—also an undesirable phenomenon. The aggregates are formed as a result of daughter cells failing to separate after division and as a consequence of the stickiness of the polysaccharides excreted by the cells, especially at the end of the growth phase. An optimal shear rate between these two extremes must be found for each culture.

It has been shown experimentally that velocity fluctuations related to turbulent shear are relatively homogeneously distributed in an ALR (31–34). Measurements of fluctuating velocity made show that the liquid turbulence in ALRs is homogeneously distributed in both the riser and the downcomer (31). It thus seems reasonable to assume that the homogeneity of the stress forces is the main advantage offered by ALRs and that this homogeneity is responsible for the success of shear-sensitive cultures in the ALR type of fermenter (5,14,35–40). Another advantage of the ALR is the mechanical simplicity of the device. The absence of a shaft and of the associated sealing, which is always a weak element from the point of view of sterility, confers on the ALR an obvious advantage over agitated tanks. This consideration is especially important in processes involving slow-growing cultures, such as animal and plant cells, for which the risk of contamination is large.

ALRs may also be used for processes involving low value products, in which case efficiency of energy use may well become the key point for design, as in wastewater treatment (41). The superiority of ALRs over mechanically agitated contactors in terms of mass transfer rates for a given energy input has been demonstrated (42). Comparison of the efficiency of oxygen transfer, that is, the mass of oxygen absorbed per unit energy invested and unit time, showed that the efficiency of the ALR is among the highest in agitated systems (41). The ALRs are particularly suited to processes with changing oxygen requirements because aeration efficiency and performance are relatively insensitive to changes in operating conditions. Performance decreases markedly in mechanically stirred systems as the energy input [or oxygen transfer rate (OTR)] increases, but it is quite constant in ALRs (43). The introduction of mechanical agitation in an ALR increases, as expected, the rate of oxygen absorption from the gas, but leads to a decrease in the efficiency of mass transfer (44,45).

The efficiency of ALRs decreases only slowly as the energy input per unit volume of reactor is increased as shown in Fig. 42.2, for a split vessel airlift reactor (SV-ALR) of rectangular section with different configurations in the gas separation section. In contrast, the mass transfer rate can be easily enhanced in STR by increasing the power input, but this improvement is achieved at the expense of a considerable decrease in the efficiency of oxygen transfer. This decrease may constitute a crucial disadvantage in a bioprocess such as wastewater treatment, where the energy input is an important element in the cost, and flexibility of operating conditions is required because of changing feed composition and flow rate.

Energy economy in the ALR may be improved by placing a second sparger in the upper part of the downcomer (1,41). If the liquid velocity is greater than the free-rising velocity of the bubbles generated, the gas is carried down, resulting in a longer contact time between the bubble and the liquid. This diminishes the energy requirements, because part of the gas is injected against a lower hydrostatic pressure This principle has been used in processes developed for CO_2 removal from flue gas (46,47).

The advantages described earlier counterbalance the obvious disadvantage of ALRs, which is the requirement for a minimum liquid volume for proper operation. Indeed, the changes in liquid volume in these reactors are limited to the region of the gas separator, because the liquid height must always be sufficient to allow liquid recirculation in

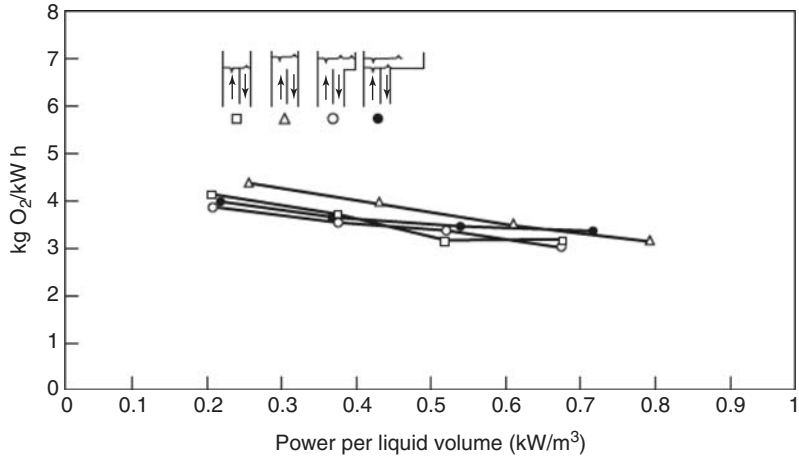

Figure 42.2. Aeration efficiency as a function of pneumatic power of gas input per unit volume in a straight baffle ALR. The level indicated corresponds to no-aeration conditions. Adapted from Ref. 41.

the reactor and must therefore be above the separation between the riser and the downcomer.

42.2 FLUID DYNAMICS

The interconnections between the design variables, the operating variables, and the observable hydrodynamic variables in an ALR are presented diagrammatically in Fig. 42.3 (48). The design variables are the reactor height, the riser-to-downcomer area ratio, the geometrical design of the gas separator, and the bottom clearance [in draft tube airlift reactor (DT-ALR) C_b is the distance between the bottom of the reactor and the lower end of the draft tube. In general, it is the free area for flow in the bottom, and accounts for the resistance to flow in this part of the reactor]. The main operating variables are primarily the gas input rate and the top clearance (C_t, the distance between the upper part of the draft tube and the surface of the nonaerated liquid). These two independent variables set the conditions that determine the liquid velocity in the ALR via the mutual influences of pressure drops and holdups (Fig. 42.3) (48). Viscosity is not shown in the figure as an independent variable because in the case of gas–liquid mixtures, it is a function of the gas holdup (and of liquid velocity in the case of non-Newtonian liquids), and because in a real process, it will change with time due the changes in the composition of the liquid.

42.2.1 Flow Configuration

42.2.1.1 Riser. In the riser, the gas and the liquid flow upward, and the gas velocity is usually larger than that of the liquid. The only exception is homogeneous flow, in which case both phases rise at the same velocity. This can happen only with very small bubbles, in which case the free-rising velocity of the bubbles is negligible with respect to the liquid velocity. Although about a dozen different gas–liquid flow configurations have been described (49), only two of them are of interest in ALRs (50):

1. homogeneous bubbly flow regime, in which the bubbles are relatively small and uniform in diameter and turbulence is low
2. churn-turbulent regime, in which a wide range of bubble sizes coexist within a very turbulent liquid.

The churn-turbulent regime can be reached from homogeneous bubbly flow by increasing the gas flow rate or by starting from slug-flow and increasing the liquid turbulence, by increasing either the flow rate or the diameter of the reactor (Fig. 42.4) (51). The slug-flow is to be avoided because large bubbles offer very poor capacity for mass transfer. In small diameter tubes (<0.1-m diameter) slugs may bridge the entire cross section.

Comparison of flow configurations described for BCs to those appearing in ALR shows that the transitions due to increases in the gas superficial velocity are delayed in the ALR till higher gas flow rates, due to the high circulation velocity and its directionality (53,54). Figure 42.5 shows graphically such a comparison of the flow configuration transitions in a stirred tank, an ALR, and a BC. In the case of the ALR, the configurations in the downcomer are indicated (55).

42.2.1.2 Downcomer. In the downcomer, the liquid flows downward and may carry bubbles down with it. For bubbles to be entrapped and flow downward, the liquid velocity must be greater than the free-rise velocity of the bubbles.

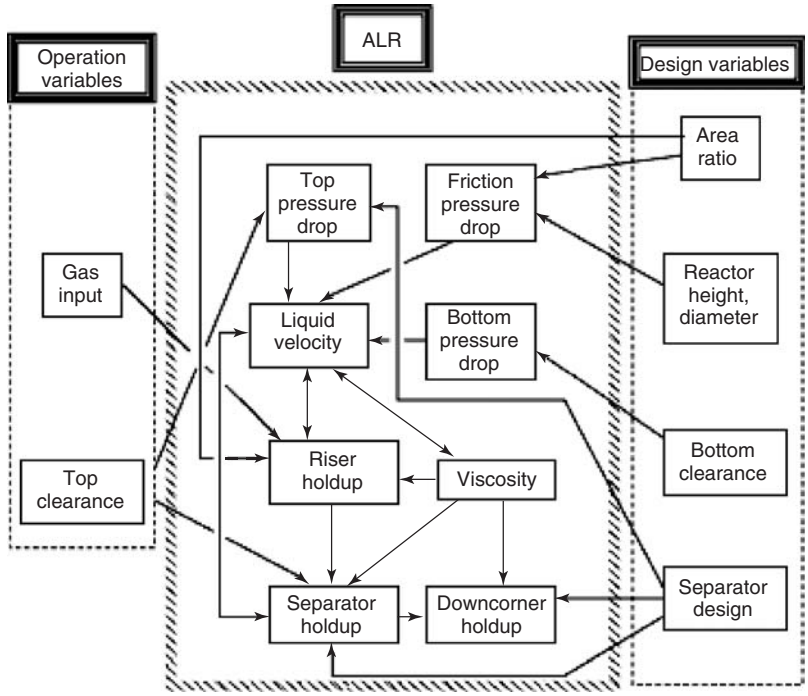

Figure 42.3. Interaction between design and operation variables in an ALR. Adapted from Ref. 48.

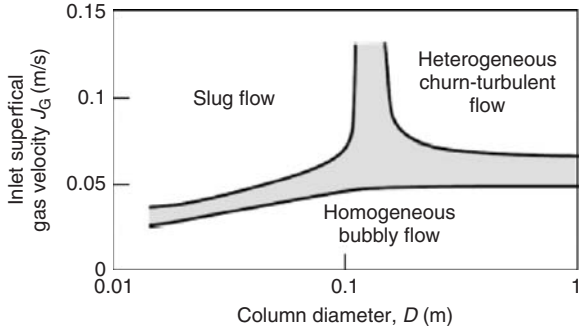

Figure 42.4. Map of flow configurations for gas–liquid concurrent flow in a vertical tube, as a function of the superficial gas velocity, J_G and the diameter of the tube D adapted from Ref. 52, with permission.

At very low gas flow input, the liquid superficial velocity is low, practically all the bubbles disengage, and clear liquid circulates in the downcomer. As the gas input and concomitantly the gas holdup in the riser increase, the liquid velocity becomes sufficiently high to entrap the smallest bubbles. On further increase in liquid velocity, larger bubbles are also entrapped. Under these conditions, the presence of bubbles reduces the cross section available for liquid flow, and the liquid velocity increases in this section. Bubbles are thus entrapped and carried downward, until the number of bubbles in the cross section decreases, the liquid velocity diminishes, and the drag forces are not sufficient to overcome the buoyancy. This feedback loop in the downcomer causes stratification of the bubbles, which is evident as a front of static bubbles, from which smaller bubbles occasionally escape downward and larger bubbles, produced by coalescence, escape upward. The bubble front descends, as the gas input to the system is increased, until the bubbles eventually reach the bottom and recirculate to the riser. When this point is reached, the bubble distribution in the downcomer becomes much more uniform. This is the most desirable flow configuration in the downcomer, unless a single pass of gas is required. The correct choice of cross-sectional area ratio of the riser to the downcomer will determine the type of flow.

The operation of a reactor under the condition of stratified static bubbles in the downcomer described earlier has attracted the attention of researchers (55–57), because it allows the detailed observation of a rising (and, nevertheless, static to the observer's eye) bubble or swarm of bubbles. The practical use of this flow configuration in an actual industrial setting is, however, doubtful. The static bubbles become very soon depleted of, or saturated with, the component that is being transferred and become an inert volume. In general, the only interest in this flow configuration are the limits of operation conditions (55,58) that lead to a situation that is to be avoided.

42.2.1.3 Gas Separator. The gas separator is often overlooked in descriptions of experimental ALR devices, although it has considerable influence on the fluid dynamics of the reactors. The geometric design of the gas separator will determine the extent of disengagement

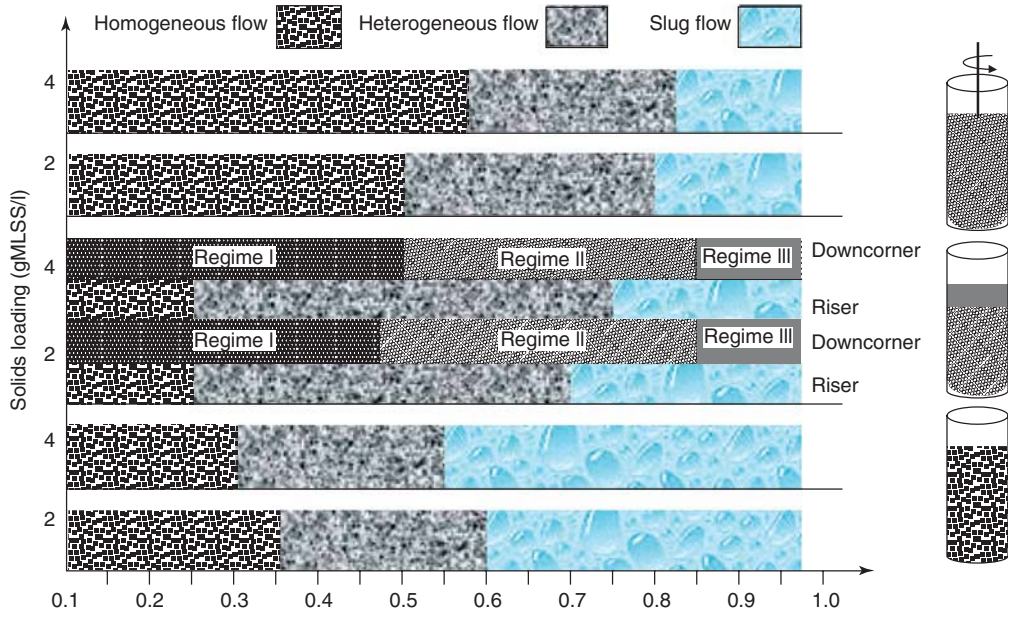

Figure 42.5. Comparison of flow configuration transitions in a stirred vessel, an ALR, and a BC. From Ref. 54, with permission.

of the bubbles entering from the riser (17,59,60). In the case of complete disengagement, clear liquid will be the only phase entering the downcomer. In the general case, a certain fraction of the gas will be entrapped and recirculated. It is quite common to enlarge the separator section to reduce the liquid velocity and to facilitate better disengagement of spent bubbles. Experiments have been reported in which the liquid level in the gas separator was high enough to be represented as two mixed vessels in series (51,61). Fresh gas may also be entrapped from the headspace if the fluid is very turbulent near the interface. This entrapment may influence gas holdup and liquid velocity in the whole reactor.

42.2.2 Gas Holdup

Gas holdup is the volumetric fraction of the gas in the total volume of a gas–liquid–solid dispersion:

$$\varphi_i = \left(\frac{V_G}{V_G + V_L + V_S} \right)_i \qquad (42.2)$$

where the subindexes L, G, and S indicate liquid, gas, and solid, and i indicates the region in which the holdup is considered, that is, the gas separator (s) the riser (r), the downcomer (d), or the total reactor (T).

The importance of the holdup is twofold: (i) the value of the holdup gives an indication of the potential for mass transfer, because for a given system, a larger gas holdup indicates a larger gas–liquid interfacial area, and (ii) the difference in holdup between the riser and the downcomer generates the driving force for liquid circulation (strictly true for gas–liquid systems: if other dispersed phases are present as well their holdup differences will count as well, but the gas will always be the main factor). It should be stressed, however, that when referring to gas holdup as the driving force for liquid circulation, only the total volume of the gas is relevant. This is not the case for mass transfer phenomena. In this case, the interfacial area is of paramount importance, and therefore, some information on bubble size distribution is required for a complete understanding of the process.

Gas holdup values will vary within a reactor. Average values, referring to the whole volume of the reactor, and more frequently to one of its zones (defined in Fig. 42.1) such as the riser or the downcomer are usually reported. These types of data are most valuable because they provide a basis for determining liquid velocity and mixing. While total holdup in a reactor is measured quite accurately from the change in height of the gas–liquid dispersion with and without gas injection, the measurement of local gas holdups requires more sophisticated methods. The measurement of pressures along the tube is the most common technique and assumes that the hydrostatic pressure is dominant. If the frictional losses are considerable, they should be taken into account (62), or more sophisticated methods should be used, as electrodes that measure the gas content in a small volume of the liquid (63–67).

The geometric design of the ALR has a significant influence on the gas holdup. Changes in the ratio A_d/A_r, the cross-sectional areas of the downcomer and the riser, respectively, and in the bottom clearance will change the

liquid and gas residence time in each part of the reactor and hence their contributions to the overall holdup.

42.2.2.1 Internal Loop ALRs. The factors that influence the performance of ALRs (Fig. 42.3) would be expected to be present in any expression representing or correlating gas holdup, liquid velocity, or mass transfer data. However, usually only some of those variables are considered in the form:

$$\varphi_r = a(J_G)^{\alpha}\left(\frac{A_d}{A_r}\right)^{\beta}(\mu_{ap})^{\gamma} \qquad (42.3)$$

where J_G is the superficial gas velocity (gas volumetric flow rate per unit of cross-sectional area), μ_{ap} is the effective viscosity of the liquid, and $\alpha\beta\gamma$ and a are constants that depend on the geometry of the reactor and the properties of the liquid. This expression has been justified by fundamental fluid dynamic considerations (68) and can be used to predict the holdup in a system that is being designed or simulated as a function of the operating variables, the geometry of the system, or the liquid properties. Such correlations are effective for fitting data for the same type of reactor (e.g. a SV reactor) with different area ratios or even different liquid viscosities, but they are mostly reactor-type specific (69–76). For example, Equation 42.3 does not consider any effects of changes in variation of the diameter or of the height of the reactor.

Some of the most published correlations are shown in Table 42.1. Only in few cases, the correlations show the influence of all the variables, both those of design and those of operation. As shown in Koide's correlations, variations in

[b] Refers to A_r.

the performance of an internal loop airlift reactor (IL-ALR) are expected weather the gas is introduced in the annulus or in the draught tube (which is the most usual design). Some of the correlations have been formulated using usual dimensionless groups. Koide's correlation in Table 42.1 considers the frothing characteristics of the liquid, using the Marrucci's group (77). Coalescence is a very important property in ALRs, because it affects by means of bubble diameter, the gas holdup, liquid dynamics, and mass transfer rate. Zahradnik et al. (78) studied the influence of addition of electrolytes and alcohols and gave a correlation for their data on the transition concentrations, which indicate a sudden increase in coalescence inhibition. In most cases, the experimental data are not wide enough to justify the use of dimensional groups. Figure 42.6 shows the gas holdup following some of the correlations shown in Table 42.1. The figure was drawn taking the ratio of areas $A_d/A_r = 1$, the bottom clearance $C_b = 0.4$, the top clearance $C_t = 1$, a diameter of the separator equal to that of the reactor, and the physical properties of pure water. Another point that is extremely important to the user of those correlations is that special care should be taken inspecting how the gas superficial velocity was defined by the authors. This may be clear in the case of external loop airlift reactors (EL-ALRs), where the following definition is followed:

$$J_{Gr} = \frac{Q_{Gr}}{A_r} \tag{42.4}$$

where Q_{Gr} is the gas flow rate in the riser. In the case of IL-ALRs, this is not so clear. Many researchers have used the following definition

$$J_{Gr} = \frac{Q_{Gr}}{A_T} \tag{42.5}$$

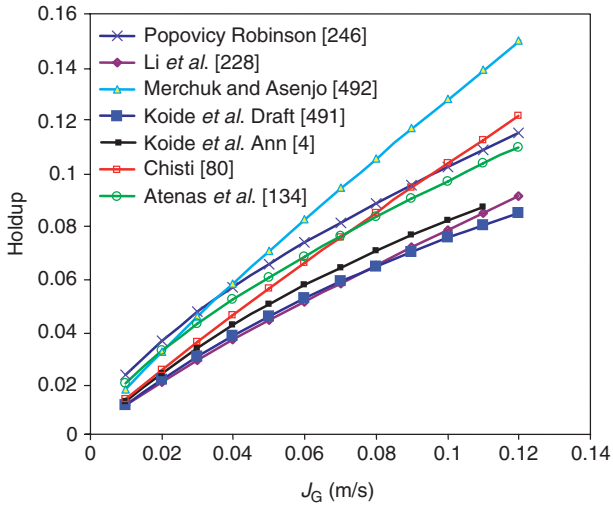

Figure 42.6. Gas holdup in IL-ALRs. Correlations are shown in Table 42.1.

probably because of their intention of comparing the performance of the ALR to a BC, where definition (42.5) applies. In Table 42.1, the definition used for J_G is indicated either with an R (riser) or with a C (column), indicating which cross-sectional area was used by the authors of the correlation. As the influence of only one variable is shown, the main point in this figure is the consensus respect the general form of the dependency of ϕ_i >on the $J_{Gi,Li}$.

The cyclic flow in the ALR complicates the analysis of the system. The riser gas holdup depends strongly on the geometric configuration of the gas–liquid separator and the water level in the gas separator. This has been shown experimentally in a rectangular SV-ALR (17), but the premise can essentially be extended to any IL-ALR. Analysis of the system revealed that these factors influence the gas disengagement and hence the gas recirculation in the downcomer. When this influence is taken into account and the holdup is plotted against the true gas superficial velocity, $J_{Gr,true}$, which is defined as the sum of the gas superficial velocity of the freshly injected gas, Q_{in}, and the recirculated gas, Q_{out}, that is,

$$J_{Gr,true} = \left(\frac{Q_{in} + Q_{out}}{A_r}\right) \tag{42.6}$$

then all the data for the different gas separators may be represented by a single relationship. In other words, if the actual gas flow is known, the influence of gas recirculation (which depends on A_d/A_r and the design of the gas separator) is taken into account and does not need to be considered again. Nevertheless, this simple approach has a drawback in that the true gas superficial velocity is difficult to measure because the gas recirculation rate is usually not known. A method for evaluation of the extent of the maximum gas recirculation has been proposed (78).

The safest procedure for the prediction of the gas holdup in an ALR under design is to take data provided by researchers who have made the measurements in that particular type of reactor with similar physicochemical properties of the system. Using a correlation from the literature without studying in depth the equipment used and the experimental conditions may be a very dangerous exercise for the designer. Only if such type of data is not available, correlations in Table 42.1 are recommended for prediction of the gas holdup in the riser. More sophisticated models, including those using computational fluid dynamics (CFD) methods, will be mentioned latter on.

Gas holdup in the downcomer is lower than that in the riser. The extent of this difference depends mainly on the design of the gas separator (86). The simplification proposed by Chisti and Moo-Young (68), which assumes that the ratio of the gas holdups in downcomer and riser is constant, has been widely used. This is an approximation that

seems to be close to reality in two-phase systems. In the case of three-phase flow, the point becomes more complicated. A liquid balance at the top results in

$$\varphi_d = \left(\frac{U_{Lr}A_r}{U_{Ld}A_d}\right)\varphi_r - \left(\frac{U_{Lr}A_r}{U_{Ld}A_d}\right)(1-\varphi_{sr}) + (1-\varphi_{sd}) = \alpha\varphi_r + \beta \quad (42.7)$$

and the range over which α and β can be considered constants is still an open question (87).

Many empirical expressions showing linearity, or almost linear relationship between gas holdup in the riser and the downcomer have been published (83,87,88). At low liquid flow rates, ϕ_d is usually negligible, because most of the bubbles have enough time to disengage from the liquid in the gas separator. This usually happens at the low gas flow rates frequently used for animal cell cultures.

The gas holdup in the separator is very close to the mean gas holdup in the whole reactor (61), as long as the top clearance C_t is relatively small (one or two diameters). For larger top clearances, the behavior of the gas separator begins to resemble that of a BC, and the overall performance of the reactor is influenced by this change.

42.2.2.2 External Loop ALRs. From the point of view of fluid dynamics, neither the external configuration (shape and architecture) nor the fact that both riser and downcomer are easily accessible is the most important difference between external and internal loop reactors. The most important point is that the gas separator of the EL-ALR is buil t in such a way that gas disengagement is usually much more effective in this type of reactor. In DT-ALRs or SV-ALRs, the shortest path that a bubble has to cover from the riser to the downcomer is a straight line across the baffle that separates the two sections. In the case of EL-ALRs, there is usually a minimum horizontal distance to be covered, which increases the chances of disengagement of the bubbles. In this case, it is worth pointing out that if gas does appear in the downcomer, then most of it will be fresh air entrained in the reactor because of interfacial turbulence or vortices that appear in the gas separator above the entrance to the downcomer. In many of the studies reported in the literature on holdup in EL-ALRs, total disengagement is attained. No such data are available for the concentric tubes of SV-ALRs, because total disengagement is possible only at very low gas flow rates.

Several authors (48,88–106) have presented their results of gas holdup as the gas velocity versus the superficial mixture velocity, based on the drift flux model of Zuber and Findlay (89). These authors derived general expressions for prediction of the gas holdup and for interpretation of experimental data applicable to nonuniform radial distributions of liquid velocity and gas fraction. The drift velocity is defined as the difference between the velocity of the particular phase (U) and the volumetric flux density of the mixture (J), where

$$J = J_G + J_L \quad (42.8)$$

The drift velocities of the gas and liquid phases may thus be expressed as

$$J_G = U_G - J \quad (42.9)$$

$$J_L = U_L - J \quad (42.10)$$

Zuber and Findlay (89) derived the relationship (9), which has been shown to be adequate to provide a correlation of gas holdup measurements in tower reactors with high liquid velocities, such as ALRs (90):

$$U_G = \frac{J_G}{\varphi} = C_o J + \frac{\frac{1}{A}\int_A \varphi(U_G - J)dA}{\frac{1}{A}\int_A \varphi dA} \quad (42.11)$$

The value of C_o depends mainly on the radial profile of the gas holdup. Zuber and Findlay (89) calculated $C_o = 1$ for a flat profile and $C_o = 1.5$ for a parabolic profile. Experimental values have been reported in the range of 1.03–1.2 for upflow (90–96) and 1.0–1.16 for downflow (92,94,97) and others reported higher values, approaching 2, for transition regime, that is, between homogeneous to heterogeneous bubbling (97,98). This is consistent with the physical meaning of C_o, because it is known that the transition zone is characterized by the existence of macrocirculation patterns that disappear as a fully heterogeneous regime is established (Fig. 42.7) (97). The opening percentage shown indicates the position of a valve located in the downcomer to control the liquid velocity. The authors report that in spite of the changes in the value of J at which the flow regime transition occurs, the J_G was approximately the same in all cases, indicating that the transition depends mainly on the gas superficial velocity. Guet et al. (96) studied the effects of bubble size on the parameters of the drift flux model and presented models that allow the consideration of bubble size in the calculations; however, for biological reactors, the gas flow rates used will be modest, and the transition and heterogeneous regimes are not relevant. For a bioreactor that is being designed in absence of specific data, $C_o = 1$ would be a solid choice.

The last term in the right-hand side of Equation 42.11 is the weighted mean value of the drift velocity. Zuber and Findlay (89) recommend the following expression:

$$U_{GJ} = 1.53\left(\frac{\sigma g \Delta\rho}{\rho_L}\right)^{1/4}(1-\varphi)^{3/2} \quad (42.12)$$

It has been shown (93) that a plot of U_G versus J gives a straight line, suggesting that a constant value of the drift

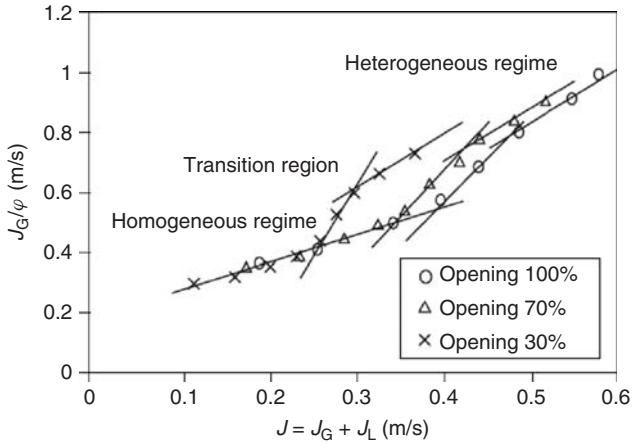

Figure 42.7. Experimental determination of C_o in the draft tube of an external tube ALR. The opening percentage shown indicates the position of a valve located in the downcomer, which controlled the liquid velocity. From Ref. 97, with permission.

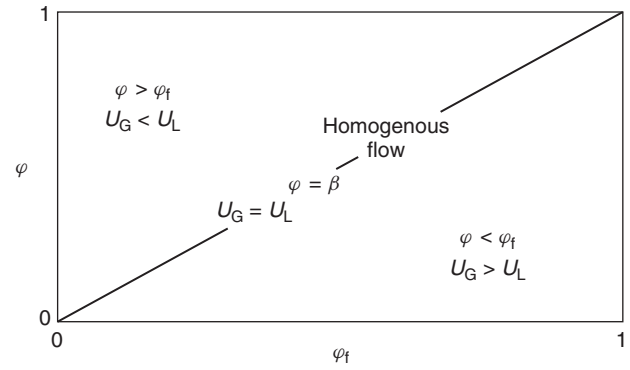

Figure 42.8. Gas holdup φ versus flowing volumetric concentration φ_f. The different zones in the plane $\varphi - \varphi_f$ correspond to different flow configurations. Adapted from Ref. 107.

velocity satisfactorily represents the two-phase flow in the riser of an EL-ALR. The distribution parameter was $C_o = 1.03$, and U_{GS}, the value of the slip velocity of a bubble, was taken as the mean drift velocity. Siegel et al. (1) applied the same model for the study of gas recirculation in a SV-ALR and obtained the values of $C_o = 1.11$. The slip velocity that they obtained fitting their data to Equation 42.11 was 0.238 m/s. It has been suggested (90) that this simplification holds as long as coalescence is not a predominant factor in the process.

It is very important to stress the difference between holdup, ϕ, and the flowing volumetric concentration, ϕ_f, which is defined as

$$\varphi_f = \frac{Q_G}{Q_G + Q_L} = \frac{J_G}{J} \tag{42.13}$$

Zuber–Findlay's drift flux model allows us to derive the following equation, which establishes a connection between the gas holdup and ϕ_f:

$$\frac{\varphi_f}{\varphi} = C_o + \frac{U_{b\infty}}{J} \tag{42.14}$$

where $U_{b\infty}$ is the terminal bubble velocity. Figure 42.8 gives a representation of the $\phi - \phi_f$ plane. The 45° line indicates that $\phi = \phi_f$, an equality that is true only for non-slip flow, where the velocity of the gas is equal to the velocity of the liquid. Such a situation can be visualized for the case of very small bubbles in a relatively fast liquid. In this case, there is no influence of one phase on the motion of the other. As indicated in Fig. 42.8, all the points below the 45° line indicate operation situations in which the liquid is driven by the gas:

$$U_G > U; \varphi < \varphi_f \tag{42.15}$$

This happens in the riser of ALRs. For all points above the line, the opposite is true:

$$U_G < U; \varphi > \varphi_f \tag{42.16}$$

This latter condition reflects the operation of the downcomer.

A number of authors (90,95,99–102) have measured the local holdup profile along the riser of an EL-ALR. In general, it was found that the holdup increases with height. This finding concurs with the expected expansion of gas bubbles as regions of lower pressure are reached. This situation must be limited to a certain range; an increase in bubble size will enhance turbulence and result in an increase in bubble encounters, leading eventually to bubble coalescence. The larger bubbles will rise much faster, resulting in a decrease in holdup. Such a scenario was indeed observed (90) who reported the tendency to a maximum in the holdup profile for the case of a single-orifice gas distributor. For a multiple-orifice sparger, producing a more homogeneous bubble size distribution, straight lines were observed within the studied length of the riser, which was 4 m. Similar holdup distributions have been observed by others (97,101).

Literature data from different sources for gas holdup in the riser under conditions of little or no carryover of gas from the separator into the downcomer for different A_d/A_r and top clearance C_t may be represented by the simple exponential:

$$\varphi_r = \alpha J_G^{\beta} \tag{42.17}$$

where the constant α depends on the friction losses in the loop, and β is usually a value between 0.6 and 0.7 (Fig. 42.9) (103). The data correspond to various A_d/A_r. The fact that neither the area ratio (within certain limits) nor the top clearance affects the gas holdup demonstrates the role of the gas–liquid separator in determining the performance of the reactor in general. In the absence of gas

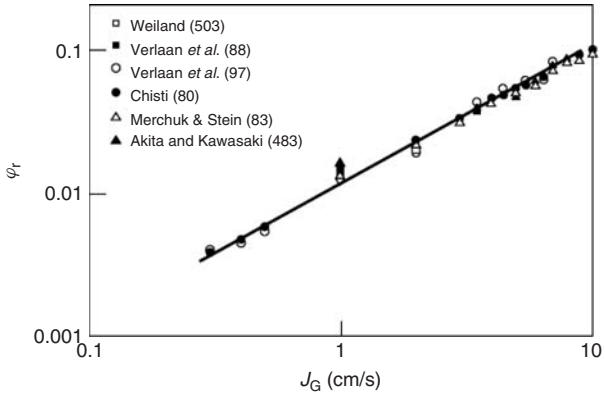

Figure 42.9. Gas holdup reported for the gas holdup φ_r under conditions of little or no gas recirculation.

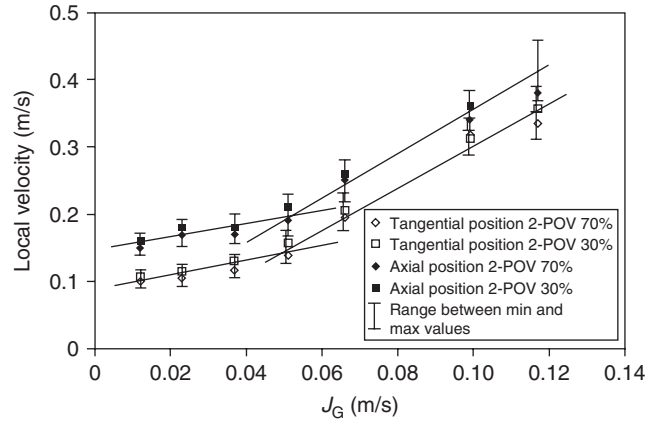

Figure 42.10. Local values of the axial and tangential velocity in the riser, with two different valve positions, 70% and 30% of aperture of a valve controlling the liquid recirculating velocity. From Ref. 97, with permission.

recirculation, there is no effect on these variables. Moreover, this means that under conditions of no gas entrainment from the separator to the downcomer, it is possible to predict the riser gas holdup as a function of the riser superficial gas velocity alone, which is of great importance for design purposes (79).

It is accepted that liquid velocity has a mild negative effect on gas holdup in the riser. This effect is usually studied by reducing the liquid flow; this is achieved by adding resistance to the liquid loop by means of a valve or other controlled obstruction (74,90,97,99,100,104,105) under conditions of low or nil gas recirculation. Such experiments, which are relatively simple in EL-ALRs, indicate that the holdup decreases as the liquid velocity is increased from zero (BC) to 0.3 m/s (which is close to the bubble free-rise velocity). For higher velocities, the effect of U_L is small. These findings add to our understanding of the fluid dynamics in the column. At liquid velocities that are smaller than the bubble free-rising velocity, the liquid transported in the wake of the bubbles, which must return downward to balance the mass flux, is the cause of the meandering and loops that typically appear in BC operation (53). As the overall liquid flux increases, the patterns straighten out, the bubbles begin to ascend in a straight pattern, and the holdup goes down. This is because the main component of bubble velocity is axial, and the decrease in holdup for further increases in liquid velocity is due solely to the change in the ratio of gas–liquid volumetric flow rates. Vial et al. (97) reported a very detailed study of the fluid dynamics in the riser of an external tube ALR, analyzing the influence of the liquid circulation rate by the method of generating a controlled pressure drop in the downcomer mentioned earlier, under conditions of complete gas disengagement. An important conclusion they arrive to is that while holdup and liquid mean velocity are mainly influenced by the geometric design variables, bubble-scale phenomena are almost independent of the geometry. The measurements shown in Fig. 42.10 display local values of the axial and tangential velocity in the riser, with two different valve positions, 70% and 30% of aperture. It can be seen that even in heterogeneous regime (the higher range of J_{Gr}), the axial velocity that depends on the gas holdup is predominant and higher than the tangential velocity, driven by bubble-scale phenomena. This is in fact the most important difference between flow characteristics of ALRs and BCs.

When there is gas recirculation, the area ratio A_d/A_r becomes an important variable affecting gas holdup. This effect starts in the region in which gas entrainment from the separator to the downcomer occurs. If it is assumed that the riser cross-sectional area A_r remains unchanged and the downcomer cross-sectional area A_d is increased, then it can be expected that the liquid velocity in the riser will increase as a result of the smaller resistance to flow in the loop, which in turn leads to a decrease in the riser gas holdup. An increase in A_d/A_r will result in a decrease in the liquid velocity in the downcomer, which leads to a decrease in the gas recirculation, because fewer bubbles are entrapped in the downcomer. The final outcome of increasing A_d/A_r is thus a decrease in the riser gas holdup. A similar argument can be applied in the discussion of the effect of reactor height on the riser gas holdup, that is, an increase in the height of the downcomer will result in a higher liquid velocity, which will in turn lead to a decrease in the holdup in the riser. In contrast, an increase in A_d/A_r will lead to an increase in the extent of bubble entrapment in the downcomer, which will serve to inject some additional gas into the riser. On the other hand, an increase in gas holdup in the downcomer diminishes the driving force for recirculation, as shown in Equation 42.1, and simultaneously reduces the free area for liquid circulation, and this will moderate the increase in liquid velocity generated.

TABLE 42.2. Some of the Published Correlations for Gas Holdup in EL-ALRs

Source	Correlation	
69	$\varphi_r = 0.76\left(1-\frac{A_d}{A_r}\right)^{-2} J_{Gr}^{0.8}$	
80	$\varphi_r = 0.02\left(1-\frac{A_d}{A_r}\right)^{-1.06} J_{Gr}^{0.65}\mu_{eff}^{-1.03}$	
108	$\varphi_r = 0.65\left(1-\frac{A_d}{A_r}\right)^{-0.258} J_{Gr}^{0.603+0.78C_s}$	
109	$\frac{\varphi_r}{1-\phi_r} = 2^{\frac{(3n+5)}{(n+1)}} n^{-\frac{(n+2)}{2(n+1)}}\left(1-\frac{A_d}{A_r}\right)^{-\frac{3(n+2)}{4(n+1)}} J_{Gr}^{\frac{(n+2)}{4(n+1)}}\left(\frac{\kappa}{\rho}\right)^{-\frac{1}{2(n+1)}} g^{-\frac{n}{2(n+1)}}$	
110	$\varphi_r = 0.203\frac{Fr^{0.31}}{Mo^{0.012}}\left(\frac{J_{Gr}A}{J_{Lr}A_d}\right)^{0.74}$	
111	$\varphi_r = 8.7^{*}10^{-4}\left(\frac{\rho J_{Gr}h}{\mu}\right)^{0.74}\left(1+\frac{A_d}{A_r}\right)^{1.32} F_f^{1.7}$	
112	$\varphi_r = \frac{J_{Gr}}{0.24+1.35(J_{Gr}+J_{Lr})^{0.93}}$

c	−0.05	−0.08

This feedback control of the liquid velocity is one of the characteristics particular to ALRs.

Table 42.2 shows several of the expressions published for the correlation of experimental data of ϕ_r obtained in EL-ALRs. Some of these expressions are presented in Fig. 42.11. The differences between the predictions obtained with the different correlations are probably due to the design of the gas separator. The equation given by Popovic and Robinson (106) seems to give an average of the proposed correlations. More general, simultaneous evaluations of several of the fluid dynamic parameters (gas holdups and velocities) can be obtained using mathematical models.

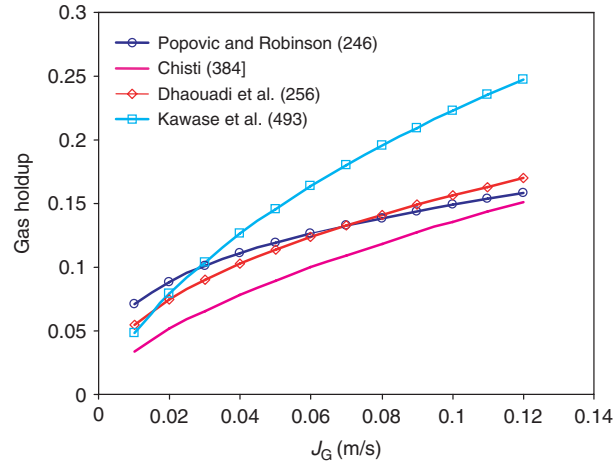

Figure 42.11. Correlations proposed for the gas holdup in the riser, φ_{Gr}, in EL-ALRs. The gas holdup in presented as a function of J_G only, for physical properties of water and $A_d/A_r = 1$.

42.2.2.3 Effects of Liquid Rheology. The effect of rheology on the reactor behavior and performance is of great interest because in most biotechnological processes, an increase in biomass provokes changes in the rheology of the fluid, especially in the case of mycelial growth. This effect is enhanced when in addition to the biomass growth, a product of the process is released into the medium in appreciable amounts (114), particularly the biosynthesis of polysaccharides, which cause an increase in the liquid viscosity (115,116). Klein et al. (117) reported measurements of liquid circulation velocity in an ALR with high cell density of an highly flocculating recombinant

strain of *Sacharomyces cerevisiae*. Their work showed the existence of a critical value of biomass concentration at which a dramatic deceleration of net liquid flow appeared with increasing biomass quantity. Rheological analysis revealed exponential increase in viscosity of the yeast flock suspension at the same biomass concentration. Thus, rheology changes during bioprocesses may influence the fluid dynamics in many aspects and should be considered.

The effect of viscosity on gas holdup in BCs has been studied and the main problem is non-Newtonian flow. If the viscosity changes with the shear rate (non-Newtonian systems), then the evaluation of shear rates becomes particularly relevant for the definition of the system. Nishikawa et al. (118) and Nakanoh and Yoshida (119) analyzed the problem of heat transfer in a BC with non-Newtonian liquids. They found a direct proportionality between the superficial gas velocity and the global shear rate:

$$\gamma = 5000 J_G,\ J_G > 0.04 \text{ m/s} \tag{42.18}$$

Moo-Young et al. (120) extended the expression to low the range of J_G, most common in bioprocesses, as follows:

$$\gamma = 1000 J_G^{0.5},\ J_G < 0.04/ \text{ ms} \tag{42.19}$$

This global shear rate can be used to calculate an effective or apparent viscosity:

$$\begin{aligned} \mu_{\text{eff}} &= \kappa (5000 J_{Gr})^{n-1} \\ \tau &= \kappa \gamma^n \end{aligned} \tag{42.20}$$

In shear-sensitive cultures, the global shear rate a is of great importance, because it predicts viability and productivity. Henzler (121), Kawase and Moo-Young (122), and Schumpe and Deckwer (123) have followed the approach of Nishikawa et al. (118) but have suggested different proportionality constants relating the global shear rate to the superficial gas velocity. This approach is, however, questionable from the rheological point of view because it will predict the same shear rate for a certain superficial gas velocity, no matter which liquid is used. El-Tamtamy et al. (124) introduced an improvement by calculating the shear rate from the bubble velocity divided by the bubble diameter. However, accurate evaluation of the latter two parameters is difficult. Henzler and Kauling (125) suggested relating the shear rate to power input based on dimensional analysis by expressing the shear rate as a function of the power input per unit volume, $[P/(V\rho\mu)]^{1/2}$. Their analysis gives different shear rates for liquids with different rheology. The above-described relationships predict different shear rates that vary up to three orders of magnitude.

In contrast to the influence of rheology on gas holdup in BCs, the data available for ALRs clearly show that the effect of liquid viscosity is less dramatic. Figure 42.12 shows the effects of the addition of carboxymethyl cellulose (CMC) (103). The change in CMC concentration had only a slight effect on the gas holdup for additions in the range 0.01–0.05% CMC. Only for solutions with concentrations higher than 0.5% CMC was an appreciable decrease in holdup seen (103). The viscosities corresponding to these solutions ranged from 4 to 14 mPa s. The addition of glycerol to water, that is, the change in viscosity keeping a Newtonian behavior of the liquid gave similar effects on the gas holdup. At low additions of the viscous fluid, a moderate increase in the gas holdup is evident, particularly in the downcomer and also in the riser. These increases are caused by the lower free-rise velocity of the bubbles, which increase the gas residence time. In addition, the entrapment of the bubbles into the downcomer is increased, and this is manifested mainly in ϕ_d. Further increases in viscosity, however, have a much smaller effect.

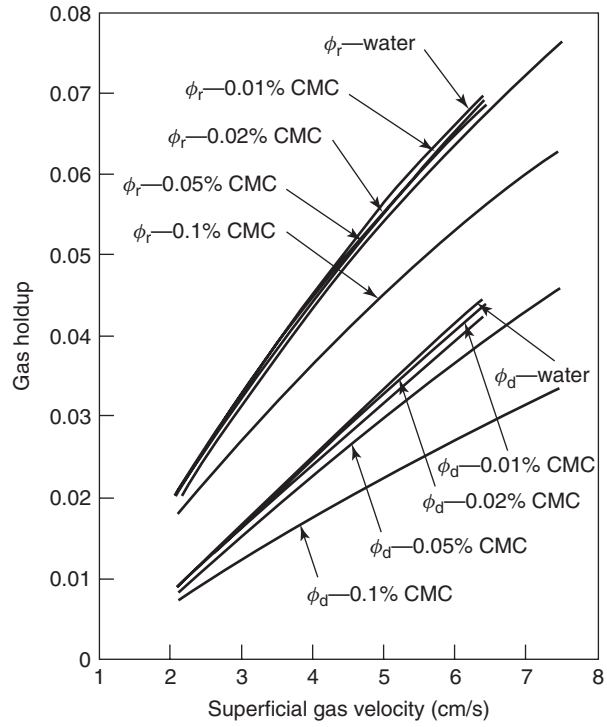

Figure 42.12. Effect of liquid rheology on the gas holdup of the riser and the downcomer of an IL-ALR. The apparent viscosity corresponding to the solutions used varied from 5 to 56 (mPa s). Adapted from Ref. 103, with permission.

42.2.2.4 Effect of Liquid Level. The influence of the liquid level C_t on the gas holdup is manifested as changes in the extent of disengagement of the bubbles in the gas separator. This influence is therefore dependent on the geometric design of this section. Whether a bubble will disengage or will be entrapped into the downcomer depends on the interrelationship of several parameters—the free-rising velocity

of the bubble $U_{b\infty}$ (a function of size and viscosity), the liquid velocity in the downcomer U_{Ld} (a function of the difference in gas holdup between the riser and the downcomer and frictional losses), and the residence time of the bubble in the gas separator (a function of geometric design and liquid height). For a given bubble size, if U_{Ld} is smaller than the $U_{b\infty}$ corresponding to the smallest bubble, there is no carryover. For smaller bubbles, the balance between the time required to cover the path from the end of the riser to the zone near the entrance of the downcomer and the time needed for disengagement will give the fraction of bubbles recirculated. It should, nevertheless, be kept in mind that this is a feedback process. A higher bubble disengagement rate leads to a lower gas holdup in the downcomer, which in turn increases the liquid velocity, enabling larger bubbles to be trapped, until the system eventually reaches a balance.

Due to the above-explained mechanism of control exerted by the geometric design, the influence of the liquid height is completely different in internal and EL-ALRs. In IL-ALRs, an increase in C_t increases the zone of the separator in which the gas holdup is higher, and as a result, the gas holdup increases. The extent of this increase depends, as said earlier, on the free-rise velocity of the bubbles. Figure 42.13 shows the gas holdup in the riser and downcomer of a 30-L ALR for two values of the top clearance, $C_t = 0.178$ m and $C_t = 0.308$ m, for two different liquids, water and a 0.5% CMC solution. It can be seen that although for water C_t has a small effect, this is not so for the more viscous solution. In the latter, the lower rising velocity of the bubbles causes a greater number of bubbles to be entrained and carried down by the liquid. Thus, the residence time in the disengagement section becomes very important in determining the fraction of bubbles that recirculate. A lower C_t will give

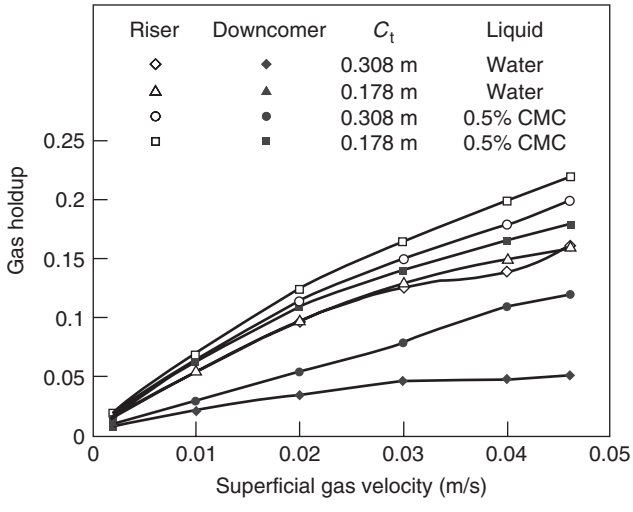

Figure 42.13. Riser and downcomer gas holdup in an IL-ALR for two different top clearances and two liquids. Adapted from Ref. 3.

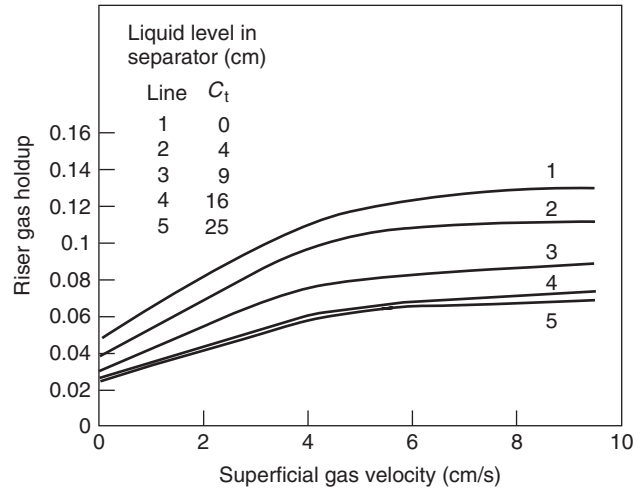

Figure 42.14. Gas holdup in the riser of an EL-ALR for several top clearances. Adapted from Ref. 103, with permission.

a shorter residence time in the separator, a larger bubble recirculation, and, hence, a larger gas holdup.

In EL-ALRs, the opposite effect is obtained, as may be seen in Fig. 42.14 (103). The data in Fig. 42.14, obtained for a 4-m high EL-ALR, show that the holdup in the riser decreases as C_t increases. This is due to the construction of these reactors, in which much of the gas that enters into the downcomer is trapped from the headspace due to the turbulence in this zone. An increase in the liquid height serves to reduce the amount of gas trapped, so that less gas circulates in the downcomer and the liquid velocity increases. The final result is a reduction in the gas holdup, both in the riser and the downcomer (103).

Although in general C_t is a fixed design characteristic, it may be used as an operation variable as well. Galindez-Meyer et al. (126) presented SV design with perforated baffle that allowed a variable-volume operation of the system. The behavior of ϕ and k_La observed were in essence similar to that described earlier.

The gas separation section also has a leading influence on the overall mixing in the reactor. Mehrnia et al. (2) studied the mixing and mass transfer characteristics of DT-ALRs for a water-in-kerosene microemulsion. Among the design variables studied, they included the gas separator design. They expressed the height of the liquid not as C_t, top clearance ratio, but as the ratio of volumes of separator to the rest of the reactor, defined as a "filling factor," F_f (127).

The top section of the airlift bioreactors is usually considered the best-mixed part of these bioreactors (61,86,128–131). Merchuk and Yunger (86) presented a model for airlift bioreactors in which the top section was considered to be perfectly mixed, while the riser and the downcomer were considered as two plug-flow sections.

Surprisingly, this simple model adequately represents quite adequately the effect of geometrical design factors on the mixing performance of an ALR.

42.2.3 Gas Recirculation

The degree to which gas flowing in the riser is entrapped and recirculated through the downcomer is an important variable, because it influences not only the flow configuration in the downcomer but also the performance of the ALR as a whole. The liquid velocity depends mainly on the difference in holdup between the riser and the downcomer, and it in turn influences the gas holdup in the riser. Despite the importance of recirculation, very little quantitative data are available on this phenomenon. Siegel et al. (1) evaluated the gas recirculation in a SV-ALR by an indirect method based on holdup measurements. From their results (Fig. 42.15), it may be seen that the recirculation rate is determined largely by the geometric configuration of the gas–liquid separator and the liquid level in the separator.

Three zones are evident in Fig. 42.15; they represent operating conditions giving oscillating, borderline, and straight bubble flow in the downcomer. Oscillating flow patterns produce much larger fractions of gas retained in the downcomer, but they are much more sensitive to J_G. At low superficial gas velocity, the recirculation increases very sharply with J_G. The bubbles exhibit an oscillating swirling flow pattern, with some larger bubbles escaping toward the top. The borderline condition is defined as oscillatory bubble flow at a low gas flow rate that shifts to straight bubble flow with increasing input gas flow rate. The straight flow operation zone is distinguished by bubble flow in a straight, well-defined flow pattern for all the input gas flow rates studied. If a straight bubble flow pattern is desired, the reactor should be operated at high riser gas flow rates, at which the reactor will shift toward stable operation.

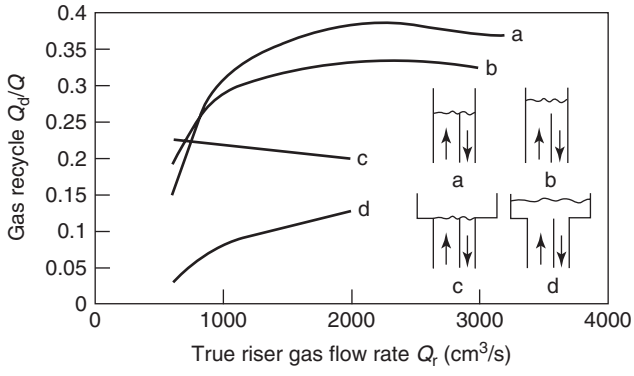

Figure 42.15. Gas recirculation in a SV-ALR. The liquid level in the separator schematically indicated corresponds to no-aeration conditions. Adapted from Ref. 1, with permission.

Lubbert et al. (132) attempted to evaluate the recirculation of gas during the cultivation of yeast (*S. cerevisiae*) on waste from a starch factory in a 4-m^3 pilot plant. They used microprocessor-aided pseudostochastic tracer input and cross-correlation techniques, which made possible the use of very reduced tracer feeds due to a high signal-to-noise ratio. The response to a pulse of helium was measured directly at the surface of the liquid in the separator by a quadruple mass spectrometer. The peak obtained showed pronounced shoulders, which could be interpreted as superimposition of a second peak that represents the helium tracer one loop after. The fitting of such a model to the experimental data suggested recirculation of 25% of the gas. This figure is in the range of the recirculation rates presented by Siegel et al. (1), considering the differences in the coalescing properties of the liquids used in these two works and the corresponding differences in the downcomer holdup. Burris et al. (133) evaluated the recirculation of bubbles in a full-scale ALR, and concluded that the recirculation varied from 0% to 50% of the gas, depending on the operation conditions.

Merchuk and Berzin (107) developed a mathematical model based on the application of the first law of the thermodynamics to each of the regions of an ALR. This model facilitates the evaluation of the maximum liquid recirculation possible in the system. The calculation is based on the premise that the gas recirculated must be compressed from the pressure at the top of the downcomer to the pressure at its bottom. The mathematical expression that gives this maximal gas recirculation is

$$Q_{Gd} = \frac{Q_L(P_2 - P_3) + Q_L \rho_L g h - \frac{1}{2} r_L C_d A_d (1 - \varphi_d) U_L^2}{P_4 \ln\left(\frac{P_3}{P_2}\right)} \tag{42.21}$$

where Q_{Gd} is the gas flow rate in the downcomer, Q_L is the liquid circulation flow rate, P_i is pressure at point i of the reactor (1 is top of the riser, 2 is top of the downcomer, 3 is bottom of the downcomer, and 4 is bottom of the riser), h is dispersion height, and C_d is the hydraulic resistance coefficient. The calculation of Q_d thus requires knowledge of the liquid flow rate, the pressures, and the geometry of the reactor. This equation represents the maximum recycling of gas in the downcomer, which will take place only if all the energy dissipated in the downcomer is invested in gas compression.

42.2.4 Liquid Velocity

The liquid velocity is one of the most important parameters in the design of ALRs. It affects the gas holdup in the riser and downcomer, the mixing time, the mean residence time of the gas phase, the interfacial area, and the mass and heat transfer coefficients.

Circulation in ALRs is induced by the difference in hydrostatic pressure between the riser and the downcomer as a consequence of a difference in gas holdup. Liquid velocity—like gas holdup—is not an independent variable, because (Fig. 42.3) the gas flow rate is the only variable that can be manipulated. As shown in Fig. 42.3, the geometric design of the reactor will also influence the liquid velocity, but it will usually remain constant during operation. Experiments have been carried out in devices specially designed to artificially change the resistance to flow, with the aim of studying the effect of the velocity at a fixed rate of aeration (90,95,97,100,105). The information from these experiments indicates that an increase in the liquid velocity leads to a decrease in the mean residence time of bubbles in the riser and hence of the gas holdup in the riser. In practice, when the gas flow rate is increased, the higher liquid velocity increases the carryover of bubbles from the gas separator into the downcomer; the carryover dampens the liquid flow by reducing the hydrostatic driving force. As a result, the overall change in liquid velocity is tempered.

42.2.4.1 Liquid Velocity Measurement. Several different methods can be used for measuring the liquid velocity. The most reliable ones are based on the use of tracers in the liquid. If a tracer is injected and two probes are installed in a section of the tube, the velocity of the liquid traveling the distance between probes can be taken directly from the recorded peaks, as the quotient of the distance between the two electrodes and the time required by the tracer to travel from one to the other. The latter is obtained as the difference between the first moments of the two peaks. The tracer may be an electrolyte that can be followed by conductometry (57,97) or with a pH meter (57). The tracer may also be a particle with high magnetic permeability followed with a magnetic metal locator (60) or, in special cases, with image analysis (134). Those tracer methods can also be used to calculate the mean liquid velocity (U_L), from the circulation time (t_c) and holdup (ϕ) as

$$\overline{U}_L = \frac{V_L}{t_c \overline{A}(1-\varphi_T)} \tag{42.22}$$

where $\overline{A}$ is the mean cross-sectional area. In this case, only one electrode is necessary, and the circulation time is obtained from two successive peaks recorded by the electrode. This is a velocity that is representative of the flow in a general way and does not necessarily correspond to the actual velocity in any of the regions of the ALR.

A more sophisticated method that has also been used is laser Doppler velocimetry (LDV) (97,135–137). Operation in the backscatter mode allows liquid-phase analysis, while forward mode gives access to gas-phase properties (138,139). LDV makes possible to obtain multiple local velocity readings, and its limits of applicability have been studied (136).

42.2.4.2 Liquid Flow from Energy Balances. Two main methods have been used for the modeling of two-phase flow in ALRs—energy balances and momentum balances. Chakrabarty et al. (79) used the energy balance approach to obtain a relationship between superficial gas velocity, holdup, and liquid velocity. Lee et al. (140) calculated U_L by a similar type of model for a series of data for DT-ALRs and EL-ALRs and from their own results for SV-ALR. In both the above-mentioned models, constants accounting for friction losses were obtained by adjusting the models to the experimental data. Jones (141), on the other hand, managed to express the results of his energy balance [based on previous work of Nicklin (142) and Freedman and Davidson (94)] in a relationship free of empirical constants. His results, however, fit the experimental data only qualitatively, and the fit is satisfactory only for very small diameters. An improvement of this method was suggested by Clark and Jones (143), who took into account the radial distribution of the gas holdup through the drift flux model. However, the values of the distribution coefficient C_o needed for satisfactory fitting of the experimental data for lager diameters is far from the range usual in this type of flow.

Chisti and Moo-Young (144) extended a model originally proposed by Bello (145), based on an energy balance over the airlift loop. Their expression for the average superficial liquid velocity in the riser is

$$U_{Lr} = \frac{2gh_D(\varphi_r - \varphi_d)}{\frac{K_t}{(1-\varphi_r)^2} + K_b\left(\frac{A_r}{A_d}\right)^2 \frac{1}{(1-\varphi_d)^2}} \tag{42.23}$$

where h_d is the downcomer height and K_b and K_t are the hydraulic pressure loss coefficients.

By choosing suitable values for the friction coefficients in each case, the authors showed that much of the published data on liquid velocity for the different types of ALRs could be satisfactorily correlated by Equation 42.23. Only one coefficient has to be adjusted, because the authors assume that K_t, the friction coefficient at the top of the loop, is negligible in DT-ALRs and that in EL-ALRs K_t can be taken as equal to K_b, the friction coefficient for the bottom of the loop. Equation 42.21 has thus been adopted by many scientists (85). Wachi et al. (146) claimed that their derivation of the same equation gives a clearer physical meaning to the adjustable parameters. Equation 42.22 can also be derived from a simple momentum balance (107). Chisti et al. (147) presented an empirical correlation for K_b obtained by comparison of results obtained from several sources:

$$K_b = 11.402\left(\frac{A_d}{A_b}\right)^{0.789} \tag{42.24}$$

where A_b is the minimal cross section at the bottom of the ALR. Equation 42.21, as most of the expressions derived

from energy balances, has the particularity that the gas flow rate, which is the main, and often the only manipulable variable in the operation, is not present directly but exerts its influence through the gas holdup. Therefore, either experimental data or a valid mathematical expression for the gas holdup in both the riser and the downcomer are required, in contrast with the empirical correlations where the arguments are known.

Chisti and Moo-Young (144) extended this model (Eq. 42.23) further to facilitate the prediction of liquid circulation in ALRs operating with pseudoplastic fluids, such as mould suspensions. This improvement is very important, because many commercial fermentation processes involve such non-Newtonian liquids. Kemblowski et al. (110) presented a method for the prediction of gas holdup and liquid circulation in EL-ALRs. In their experiments, there was almost no gas recirculation, because of the large size of the gas separators used.

García-Calvo (148) presented an ingenious model based on energy balances and on an idea originally proposed by Richardson and Higson (149), and García-Calvo and Leton (150) extended the model to BCs. The model is based on the assumption that the superficial gas velocity (J_G) in any region can be considered to be the sum of two streams (J' and J'') as follows. The J' stream has a velocity equal to that of the liquid and can therefore be treated by the laws of homogeneous two-phase flow (no slip between the bubbles and the liquid). The second stream (J'') is considered to be responsible for all the energy losses at the gas–liquid interface. The concept in itself is simple and elegant, and it is possible to envisage its application even to the flow in the downcomer, where $U_G < U_L$. In such a case, they would divide the gas flow rate into two parts as follows: One part would be larger than the actual flow rate, that is, it would have the same velocity as the liquid. To arrive at the actual gas flow rate, the second flow rate must have the reverse direction. This type of gas flow can actually be seen under certain conditions, such as when there is coalescence of bubbles and larger bubbles ascend along the walls of the downcomer.

An alternative technique used by several researchers to predict liquid velocity is the momentum balance of the ALR. This method has been used by Blenke (151) in jet-loop reactors and by Hsu and Dudukovic (152), Kubota et al. (153), Bello (145), Koide et al. (154), and Merchuk and Stein (90). Merchuk and Stein presented a simple model for the prediction of the liquid velocity as a function of the gas input in an ALR. They assumed that the pressure drop between the bottom and the top of their external loop reactor return (top, downcomer, and bottom) could be expressed as a continuation of the downcomer, using an equivalent length L_{eq}. This length was set as an adjustable parameter describing the pressure loss in the loop. Kubota et al. (153) used a similar approach for the analysis of Imperial Chemical Industries' deep-shaft reactor. They were able to simulate the operation of the reactor and to predict the minimum air supply required to prevent flow reversal.

Verlaan et al. (95) used a similar model, in combination with the expression of Zuber and Findlay (89), to calculate the friction coefficients from experimental data reported by several authors for a wide range of reactor volumes. Koide et al. (154) presented an analysis of the liquid flow in a concentric tube ALR that was also based on a momentum balance. The main difference between this model and that used by Merchuk and Stein (90) was that Koide et al. (154) used a convergence–divergence flow model for the bottom and the top of the loop. At the bottom, the effect of flow reversal on the pressure drop was included in the effective width of the gas–liquid flow path under the lower end of the draft tube, which was smaller than the actual gap. Miyahara et al. (155), who studied both the bubble size distribution in an IL-ALR and the pressure drop at the top and the bottom of the draft tube, also presented a model facilitating the prediction of the liquid velocity.

Other models use the drift flux model (122) presented in Equations 42.5–42.7, as

$$U_{Lr} = \frac{J_{Gr}(\frac{1}{\varphi_r} - C_o) - U_{GJ}}{(1 - \varphi_r)C_o} \tag{42.25}$$

For the range of flow rates usual in bioreactors, U_{GJ} can be taken from Equation 42.12. The range of variation of C_o is rather narrow, as shown in the previous section, and therefore, it is not difficult to make a judicious guess as to the value of C_o in an unknown system. The drift flux model has also been used together with energy balances (156) or with the momentum balance (157).

Some studies on liquid flow present the results in the form of empirical correlations (61,69,158). The usefulness of these correlations (Table 42.3 and Fig. 42.16) depends on the amount of data and the number of parameters taken into account. In general, the superficial liquid velocity increases with an increase in the superficial gas velocity, but its rate of increase is much lower at high superficial gas velocities. The A_d/A_r area ratio and the reactor height are the main parameters that affect the superficial liquid velocity at constant superficial gas velocity. The superficial liquid velocity increases with an increase in A_d/A_r.

The effects of the properties of the liquid, such as viscosity, surface tension, and ionic strength, on the superficial liquid velocity are much milder in ALR than in BC (162). Increasing the liquid viscosity will decrease the liquid velocity because of frictional losses, but this will increase the gas holdup in the riser and consequently increase the driving force for liquid recirculation. These two effects balance each other partially and result in a milder effect on the superficial liquid velocity. The effects

TABLE 42.3. Gas Correlations of Liquid Velocity in ALRs

of the surface tension and the ionic strength are also exerted via their influence on the gas holdup, as analyzed earlier.

As a rule, it can be recommended that the Zuber–Findlay expression (Eq. 42.25) be used when the holdup is known and the liquid circulation velocity is high. For low liquid velocity, a correlation obtained in a piece of equipment as similar as possible to the one under design should be used.

42.2.5 Liquid Mixing

A thorough knowledge of mixing behavior is necessary for the design, modeling, and operation of ALRs. This is of particular importance during the process of scale-up from laboratory- to industrial-scale reactors. The optimum growth rate of a microorganism or the optimum production rate of a specific secondary metabolite usually relates to well-defined environmental conditions, such as pH range, temperature, substrate level, limiting factors, dissolved oxygen, and inhibitor concentration in a specific well-mixed laboratory-scale vessel. Because of the compromises made during scale-up, it is difficult to keep the same hydrodynamic conditions established in the laboratory; mixing on an industrial scale may not be as good as mixing on a laboratory scale (16). In smaller scale reactors, it is easier to maintain the optimal conditions of pH, temperature, and

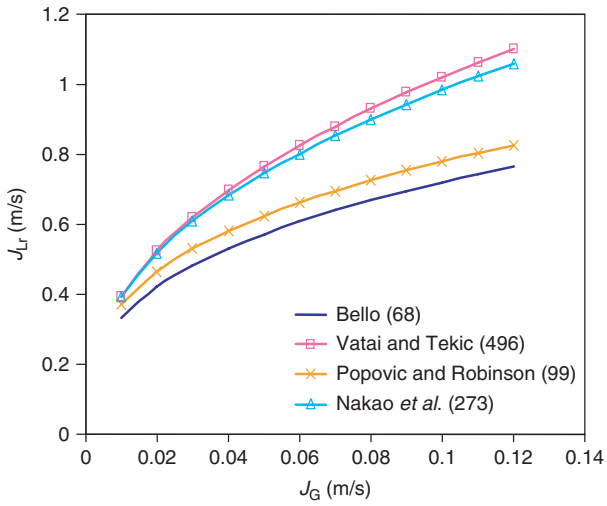

Figure 42.16. Liquid velocity predicted by some of the proposed correlations.

substrate concentration required for maximum productivity of metabolites in a fermenter.

Furthermore, in fermentation systems, efficient mixing is required to keep the pH within the limited range, giving maximum growth rates or maximum production of the microorganism during addition of acid or alkali for pH control. Mixing time—or the degree of homogeneity—is also very important in fed-batch fermentation, where a required component, supplied either continuously or intermittently, inhibits the microorganisms or must be kept within a particular concentration range (163,164). A large number of commercially important biological systems are operated in batch or fed-batch mode. In this operation mode, fast distribution of the incoming fluid is required, and the necessity for understanding the dynamics of mixing behavior in these vessels is obvious. Even for batch systems, good control of the operating conditions, such as pH, temperature, and dissolved oxygen, require prior estimation of mixing so that the addition rates can be suitably adjusted. Deviation of the pH or temperature from the permitted range may cause damage to the microorganism, in addition to its effect on the growth and production rates. Moreover, a knowledge of the mixing characteristics is required for modeling and interpreting mass and heat transfer data.

A parameter used frequently to represent mixing in reactors is the mixing time (t_m). It has the disadvantage that it is specific to the reactor design and scale, but it is easy to measure and understand. Mixing time is defined as the time required to achieve the desired degree of homogeneity (usually 90–95%) after the injection of an inert tracer pulse into the reactor. The so-called degree of homogeneity (I) is given by

$$I = \frac{C - C_m}{C_m} \tag{42.26}$$

where C is the maximum local concentration and C_m is the mean concentration of tracer at complete mixing.

A more comprehensive way of analyzing mixing, applicable to continuous systems, is a study of the residence time distribution (RTD). Although ALRs are usually operated in a batchwise manner, at least in the laboratory, advantage is taken of the fact that the liquid circulates on a definite path to characterize the mixing in the reactor. Hence, a single-pass RTD through the whole reactor or through a specific section is usually measured. On the basis of the observed RTD, several models have been proposed. These models have the advantage of reducing the information of the RTD to a small number of parameters, which can later be used in design and scale-up.

The axial dispersion model, which has the advantage of having a single parameter, is widely accepted for the representation of tower reactors. This model is based on visualization of the mixing process in the tower reactor as a random, diffusion-like eddy movement superimposed on a plug-flow. The axial dispersion coefficient D_z is the only parameter in the formulation:

$$\frac{\partial C}{\partial t} = D_z \frac{\partial^2 C}{\partial z^2} + U_L \frac{\partial C}{\partial z} \tag{42.27}$$

where C is the concentration of a tracer. The boundary conditions depend on the specific type of tower reactor. This model is attractive, because it has a single parameter, the Bodenstein number (Bo), which is used to describe the mixing in the reactor:

$$Bo = \frac{U_L L}{D_z} \tag{42.28}$$

where L is the characteristic length (distance between tracer injection and detection points). When the Bo number tends to infinity, the mixing conditions are similar to those of a plug-flow reactor, and the reactor can be considered as well mixed for low Bo numbers.

The alternative approach of Buffham and Mason (165) states that the mixing characteristics of a piece of equipment should be expressed as the variance σ^2 of the distribution obtained by injection of a pulse of tracer without adopting any mechanistic model (165). The relationship between Bo and σ^2 depends on the reactor configuration (166). The approach of Buffham and Mason facilitates the presentation of mixing characteristics free of any modeling assumptions. The variance σ^2 is the second moment of the distribution and carries information on the spread of the distribution around the mean value (first moment). Nevertheless, most of the data on mixing in bioreactors have been presented either as t_m or as overall Bo numbers, which can be obtained by relatively simple experiments of pulse injection.

Single-pass mixing in the ALR is due to mixing in the individual and interrelated sections of the reactor riser, separator, downcomer, and bottom. Repeated passage mixing is the sum of the mixing in the subsequent passages. The latter is usually reported as the mixing time (t_m), the former as *Bo* or σ^2. Indeed, these parameters are interrelated, and knowledge of *Bo* or t_m is sufficient for calculating, theoretically, the mixing time (122,132) based on the deviation of the envelope of the maxima in the response curve to a pulse, which is a measure of the degree of in homogeneity. Verlaan et al. (104) and Lin et al. (167) correlated their results as follows:

$$t_m = M Bo \tag{42.29}$$

where M is a constant equal to 0.093 (104) or 0.089 (167). The coefficient M given by Verlaan et al. (104) is in exact agreement with the theoretical relationship derived by Murakami et al. (168) for $Bo > 50$ and a degree of inhomogeneity, $I = 0.05$. The results obtained lately by Sánchez Mirón et al. (169) confirm this form of the dependency of t_m on *Bo*.

Equation 42.28 shows that the circulation path, which enters in the definition of *Bo*, has a linear effect on the mixing time. If the mean circulation time and the axial dispersion coefficients are known, it is possible to estimate theoretically the mixing time using Equation 42.27. Experimental details must, however, be carefully planned to avoid complications. Note that to simplify data processing, it is important to inject the signal and to measure the response at exactly the same point (170) (in some reports, the position of the injection point is not specified despite its effect on the mixing time). In a study of the effect of the injection point on the dynamics of the mixing time, Schügerl (171) concluded that the gas–liquid separator is the best choice for tracer injection for short mixing times. Fields and Slater (163) reported a marked dependence of the respiratory quotients on the injection point of methanol during unlimited fed-batch growth of *Methylophilus methylotropus* in a DT-ALR. Assuming that this is due to poor mixing of the substrate, this would be an indication of the importance of the injection point for the mixing process.

Figure 42.17 shows experimental data for *Bo* reported for different types of ALR in which the reactor is considered as a single unit. Because of the definition of the overall *Bo*, the values are specific to the reactor for which they were obtained and can be used only as indication of trends and orders of magnitude. The sources are provided in Table 42.4.

An alternative way of correlating mixing in ALRs was proposed by Sánchez Mirón et al. (169), using the velocity of the gas phase instead of that of the liquid:

$$Bo_{LG} = \frac{J_G D}{D_z} \tag{42.30}$$

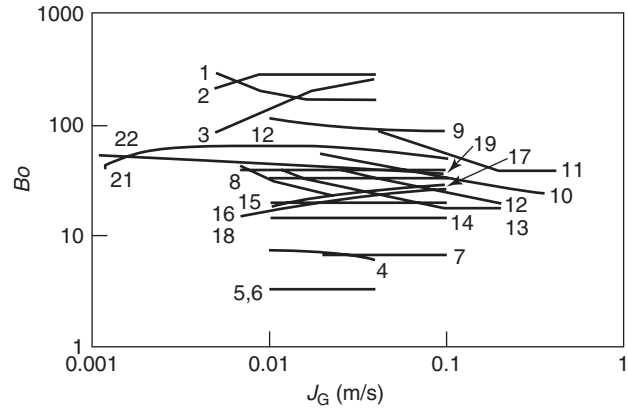

Figure 42.17. Global Bodenstein numbers reported for ALRs. See references in Table 42.4.

and managed to correlate successfully the experimental data of overall mixing obtained in both DT-ALRs and SV-ALRs with expressions of the following form:

$$Bo_{LG} = \beta \left(Fr^{\frac{1}{3}} \right)^{\lambda} \tag{42.31}$$

As explained earlier, the ALR is, in fact, a combination of several regions having quite different fluid dynamic characteristics. The overall mixing is the result of the contributions of each of them, and the overall *Bo* represents this combination for a particular reactor. This value thus has some limitations for extrapolation to other configurations or scales. Because each section has different mixing characteristics (it may have a different cross section, flow configuration, etc.), from a strictly engineering point of view, the mixing in each of the sections of the ALR should be defined and considered separately.

One way of obtaining information on the mixing characteristics of each of the regions of the ALR is the simultaneous measurement of the response in the ALR at several points, so that after one single pulse injection, the response of each section in the loop can be obtained (48,104,176). This method of measurement has the advantage that multiple measurements are made for the same tracer injection experiment. This enables us to check the consistency of the liquid velocity results obtained, because independent measurements can be obtained in the same run, as can be seen in Fig. 42.18.

The results for *Bo* obtained by Verlaan et al. (104) in an EL-ALR are shown in Fig. 42.19 (the much higher *Bo* in the downcomer was explained by the fact that the data were obtained under conditions of complete gas disengagement). The results indicated that most of the mixing took place in the gas separator, and both riser and downcomer could be considered as plug-flow conduits. The same conclusions were drawn for IL-ALRs by Merchuk et al. (48)

by analysis of mixing times: the shift in results for mixing times obtained with different probes in response to the same impulse perturbation indicated that the riser and the downcomer were introducing a pure delay in the response, that is, they behaved as plug-flow sections.

The simplest model of an ALR, from the point of view of fluid dynamics, is a combination of two plug-flow reactors, representing the riser and the downcomer, and a perfectly stirred tank, representing the gas (86,177). The validity of using this simple model as a first approximation is supported by experimental evidence that shows that the mixing time decreases when the separator volume increases (38,129). When the volume of the separator is increased substantially without changing the reactor diameter, the gas separator becomes tall and slender and may depart from total mixing behavior. It has been reported that under such conditions the circulation time measured from two successive peaks of a probe is not influenced by changes in the top clearance (61,178). This indicates that the gas separator acts as two interconnected well-mixed regions, one of them being the link between riser and downcomer.

The extent of mixing in the gas separator of IL-ALRs can probably be compared with that in a BC of the same dimensions. In the case of EL-ALRs, the extent of mixing depends on the geometric design. In designs such as the channel-loop reactor (179), a different approach must be taken. However, in general, consider that all the mixing takes place in the gas separator, and calculate the degree of mixing in it using data for BCs. Godboole and Shah (180) recommend the use of the correlation proposed by Deckwer et al. (181):

$$D_z = 0.678 d^{1.4} J_G^{0.3} \tag{42.32}$$

where d is the column diameter, or the relationship proposed by Joshi et al. (182):

$$D_z = 0.33(U_c + J_L)d \tag{42.33}$$

where J_L is the superficial liquid velocity and U_c is the cell circulation velocity given by

$$U_c = 1.31\left[gd\left(J_G - \frac{\varphi_s}{1-\varphi}J_L - \varphi U_{b\infty}\right)\right] \tag{42.34}$$

where $U_{b\infty}$ is the terminal bubble velocity. The liquid superficial velocity (J_L) can be easily calculated for EL-ALRs, and for IL-ALRs, J_L may be taken as half the liquid velocity in the riser. The viscosity may also play a role in the rate of mixing. An increase in liquid viscosity will increase the energy dissipation in the loop and result in an increase in mixing time and Bo. In non-Newtonian fluids, however, the behavior may be different (Fig. 42.20). In the case of the addition of polymers that confer pseudoplastic behavior to the liquid, low concentrations produce a decrease in the mixing time (183,184). This can be explained in terms of the drag reduction due to the presence of polymers in the boundary layer near the walls. Fields and Slater (184) found that the mixing time increased for xanthan gum, above the critical concentration. (The critical concentration is a theoretically

calculated value at which appreciable overlapping of polymer molecules occurs and which marks the onset of a rapid increase in the apparent viscosity).

Gavrilescu et al. (185) presented a model based on two-phase theory and takes into account all the basic

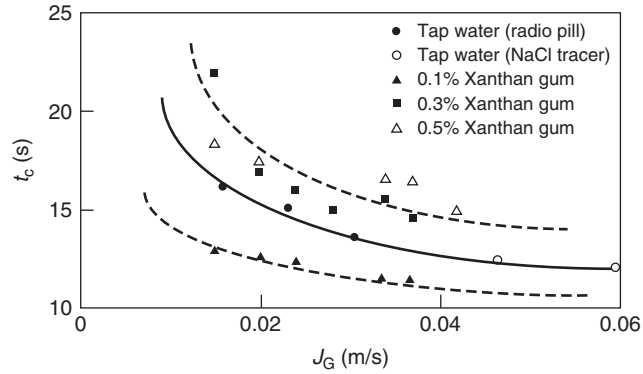

Figure 42.20. Variation of mean circulation times with J_G for several solutions. Adapted with permission from Ref. 184.

parameters that characterize an ALR, as area ratio, gas and liquid superficial velocities, and holdup. Hari and Tan (186) present an alternative way of analyzing the cyclic flow in ALRs. Their approach is based on concepts rooted in the dynamical system theory, not very usual in chemical engineering practice, and claim good prediction of mixing time.

The use of CFD for the calculation of mixing characteristics in ALRs has also been extremely successful.

42.2.6 Mixing in the Gas Phase

For all practical purposes, the gas in the riser of an ALR exhibits plug-flow behavior. Only for extremely high J_G or hindered liquid circulation will the axial dispersion of the bubbles have some effect on the gas RTD. In the downcomer, the gas flow is almost plug-flow when the bubble recirculation is fully developed. But at the stage at which a stationary phase of suspended bubbles appears at the top of the downcomer, appreciable dispersion will occur. This zone has a large degree of mixing due to coalescence and consequent rise of larger bubbles amid smaller ones, with repeated events of breakup and coalescence. However, this type of operation has no relevance to practical applications as it is an operation mode to be avoided. No data on mixing under these conditions have been reported. The main question related to the mixing of the gas phase is related to gas recirculation. When a particular gas flow has developed in the downcomer, part of the gas is being recirculated. A pulse of gas tracer at the inlet would produce, as a response, a series of pulses, separated one from the other by the gas circulation time. In practice, not many of these pulses would be detected, due to dilution and disengagement of the tracer in each pass through the separator.

Fröhlich et al. (187) reported on gas-phase mixing in an ALR. The distribution of the gas residence times in two reactors, one of $0.08\,m^3$ and the other of $4\,m^3$, was measured using pseudostochastic tracer signals and a mass

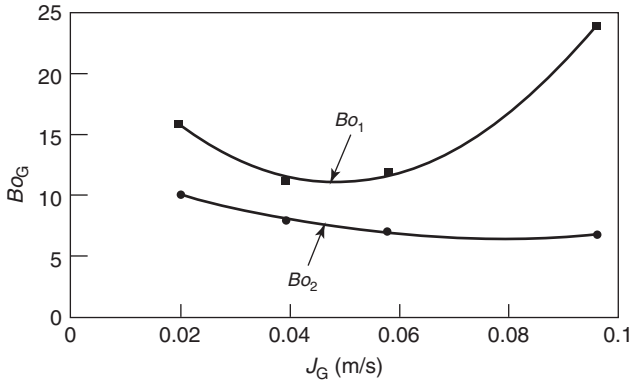

Figure 42.21. Bodenstein numbers for the gas-phase dispersion calculated from first (Bo_1) and second peak (Bo_2) of the RTD after pulse injection in a 80-L IL-ALR. From Ref. 187, with permission.

spectrometer. The values of Bo_G were calculated from the first and second peaks, indicating the main gas stream and the recirculation. Figure 42.21 shows the Bo_G obtained for a laboratory-scale ALR. The values obtained in a pilot plant were of the same order.

An interesting method for the study of the dynamics of the gas phase in pneumatically agitated reactors (ARs) is the "dynamic gas disengagement" (188), which consists in studying the rate of bubble disengagement following the height of the dispersion, or the concomitant changes in pressure. The interpretation of this type of data considering the effect of the internal liquid circulation was presented by Deshpande et al. (189). Thus, the dynamic gas holdup during gas disengagement can be used to provide new insights into the fundamentals of BC behavior. In this way, it becomes possible in principle to interrelate macroscopic properties such surface area, gas-phase residence tune distribution, and intensity of mixing in the liquid phase, even in opaque industrial reactor systems (190,191). Toye et al. (191) used this method coupling pressure probes to electric resistance tomography (ERT), producing images that show the difference between Newtonian and non-Newtonian liquids. In the latter, the range of existence of homogeneous bubbling is reduced, probably because of increased coalescence (Fig. 42.22).

42.2.7 Energy Dissipation and Shear Rate

ALRs are being increasingly used in processes involving shear-sensitive cells (mammalian, insect, plant cell, and microalgae) (5,17,22,39,192–201). This has created the need for considering shear stress as one of the relevant parameters in reactor design. Although the evaluation of shear rates is a matter that has been studied for many years in STRs, information on this subject is scanty for pneumatically stirred reactors. The first approach made in this direction in pneumatically agitated vessels was that of Clark et al. (92), who were interested in the problem of heat transfer to a non-Newtonian liquid in a BC. This study was extended to mass transfer by Nishikawa et al. (118), who proposed the expression (17).

This expression has been widely accepted despite the criticism sometimes leveled at it (86,177,202–204). Some modifications have thus been proposed (123,125,205), which, like the original approach, were based on data for BC performance and therefore have limited application for ALRs. A method facilitating the prediction of the distribution of the energy dissipated in an ALR, based on a simple thermodynamic approach, has been developed (107). Energy dissipation was considered to occur in the ALR by two main mechanisms: wall friction and bubble-associated dissipation (ideal gas behavior was assumed). The work done by the gas on the liquid (and vice versa) was expressed assuming isothermal expansion of the bubbles. The energy dissipation inside the gas phase was considered negligible. The general energy balance (206) was written as

$$\Delta(PQ) + \Delta E_p + E_D = W_s \tag{42.35}$$

In this equation, the first term represents the flow work lost by the system under consideration, E_D is the energy dissipated per unit of time, and W_s is the shaft work done by the surroundings on the system under consideration. The schematic representation of the DT-ALR in Fig. 42.23 indicates the different points in the reactor considered in the mathematical expressions. The expressions found for the energy dissipated in each zone were the following: *Riser:*

$$(E_D)_r = Q_L(P_4 - P) - Q_L\rho gh - Q_{Gr}P_4 \ln\left(\frac{P_5}{P_4}\right) \tag{42.36}$$

Gas separator:

$$(E_D)_s = Q_L(P_5 - P_2) - Q_{Gin}P_4 \ln\left(\frac{P_1}{P_5}\right) - Q_{Gd}P_4 \ln\left(\frac{P_{21}}{P_5}\right) \tag{42.37}$$

Downcomer:

$$(E_D)_d = Q_L(P_2 - P_3) - Q_L\rho gh - Q_{Gd}P_4 \ln\left(\frac{P_3}{P_2}\right) \tag{42.38}$$

Bottom:

$$(E_D)_b = Q_L(P_2 - P_4) - Q_{Gd}P_4 \ln\left(\frac{P_4}{P_3}\right) \tag{42.39}$$

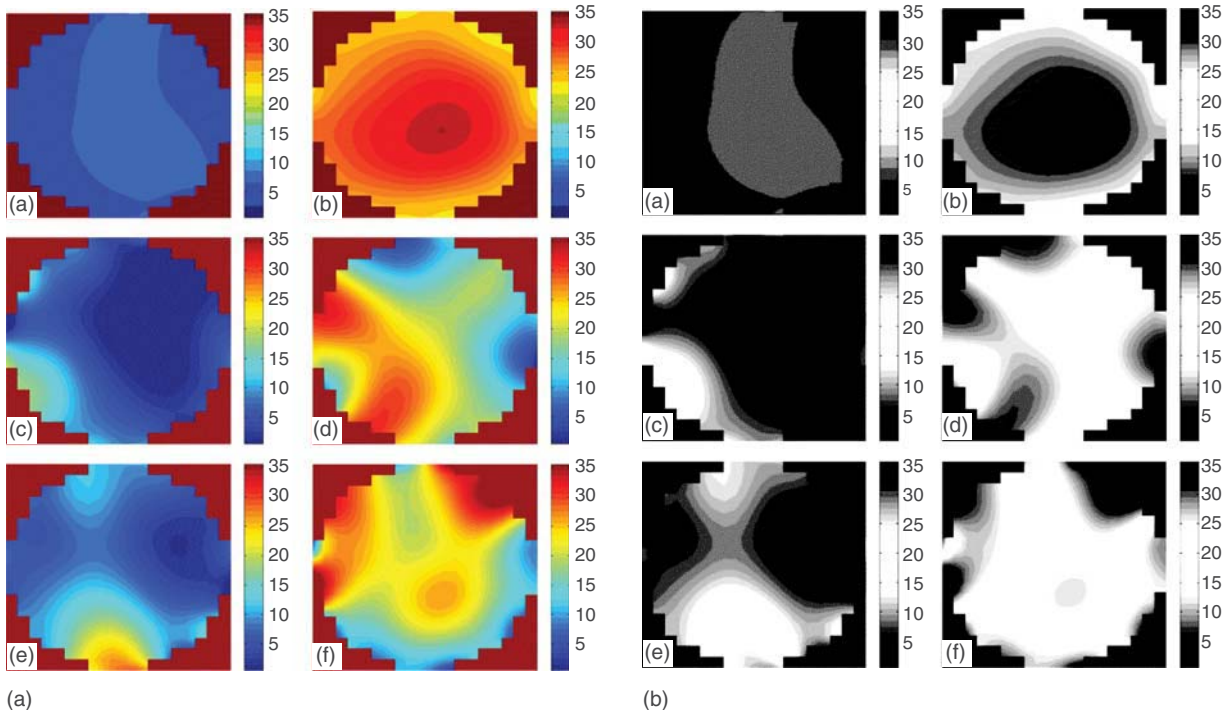

Figure 42.22. Reconstructed images of the gas holdup distribution obtained by ERT: (a) water, $J_G = 0.02$ m/s; (b) water, $J_G = 0.11$ m/s; (c) 3 g/L xanthan, $J_G = 0.02$ m/s; (d) 3 g/L xanthan, $J_G = 0.11$ m/s; (e) 5 g/L xanthan, $J_G = 0.02$ m/s; (f) in 5 g/L xanthan, $J_G = 0.11$ m/s. From Ref. 191, with permission.

Results of this model of an ALR can also be used to estimate the energy dissipation in each region of the reactor. Some approaches have been published on the relationship between dissipation and shear rate have been proposed.

42.2.7.1 Cell Damages due to Bubbles in ALRs. While shear rate in reactors is usually related to macroscopic flow, in the case of suspensions of cells and of some enzymes, the gas bubbles themselves are associated to shear damages that are independent of the bulk flow of the liquid. This damage may become a limitation that must be considered in reactor design for production of therapeutic proteins, vaccines, and antibodies in animal cells (207–209) and in plant cell cultures (210–212), because bubbling is an essential element in ALR operation. The effects of bubbles may range from changes in metabolite production to cell lyses and depend strongly on cell type and bubble size. Models have been offered describing a microenvironment in the surroundings of a bubble, associated with the turbulent wake generated. The "killing volume" defined by Tramper et al. (192,213) allows the mechanistic formulation of a cell death kinetic that is first order on biomass concentration, which agrees with the common knowledge on cellular lyses. The kinetic constant in this model is inversely proportional to bubble volume or the cube of bubble diameter. Wang (214) proposed a model where the damage rate would be inversely proportional rather to the interfacial area or the square of bubble diameter. These models agree in principle with the recognized fact (192,215–218) that small bubbles (<2-mm diameter) are much more damaging than larger ones (>10-mm diameter). Several researchers found, however, that the source of damage is not the mere presence of bubbles, but the fluid dynamic events happening during their disengagement of the liquid (219–222). When a bubble emerges through a free surface, its upper part remains enclosed by a thin liquid film that eventually ruptures, starting at the highest point where the film is thinner. The rupture of the thin liquid film liberates an amount of energy that is relatively larger for smaller bubbles. As the film retracts, a "crown" is generated and small jets of liquid are ejected at very high velocities. In addition, a central jet is also generated. This process is highly damaging for the cells caught in the liquid jets, and also for those in the immediate surrounding, because of the rapid velocity fluctuations in the liquid, which follow the jet ejection.

The indications that the main source of damage is the burst of the bubble rather than its passage through the reactor led to a corresponding design strategy in column reactors for fragile cells. It seems practical to maximize the mass transferred by each bubble before bursting, using a longer residence time that is obtained using higher columns

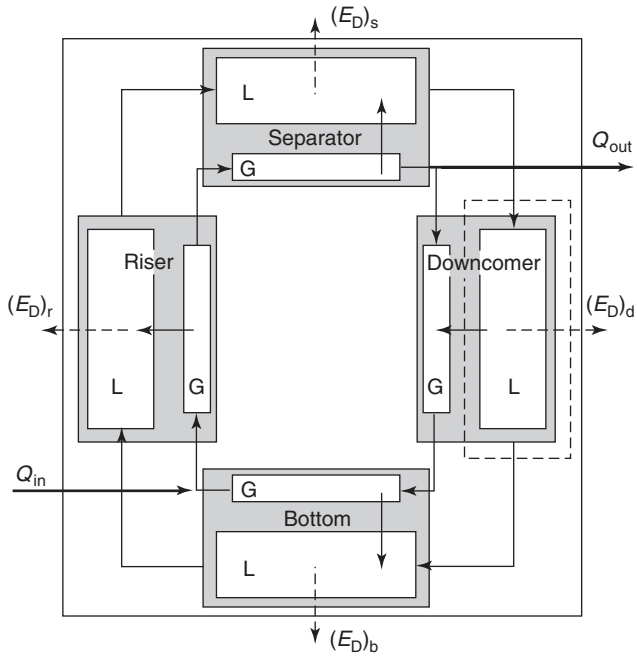

Figure 42.23. Schematic description of the energy fluxes in the thermodynamic model of an ALR, from Ref. 107, with permission.

(192,201,213,216,223–225). This mechanism of the cell damages also indicates the convenience of minimizing the amount of cells in the surroundings of the bubble at bursting time. This may be achieved by a stable foam layer maintained at the top of the reactor. The relatively long time spent by each bubble queuing before bursting increases the draining of the liquid and the thinning of the film where cells are usually in a higher concentration than in the bulk.

On the other hand, this mechanism of cell damage explains the effects of many of the additives used for cell protection, as serum and Pluronic F68. Those molecules change the surface properties of the liquid, as surface tension, diminishing the crown and jet effects, and therefore the intensity of the microscopic fluctuations at bubble burst. A review of the use of those additives for animal cell bioreactors can be found in Ref. 209.

The bubble-burst central position in the cell-damaging phenomena in bioreactors is, however, still a polemic subject. Ma et al. (226) have recently reported that indeed the number of cells attached to bubbles decreases as the concentration of Pluronic F68 increases. At low PF-68 concentrations (0.001 g/L), cells had a very high affinity for bubbles in those experiments, indicating a more than 10-fold increase in cell concentration in the foam layer liquid versus the bulk liquid. At high PF-68 concentrations (<3 g/L), however, the cell concentration in the foam layer liquid was only $< 40\%$ of that in the bulk cell suspension. On the other hand, they reported that most of the cell damage took place in processes other than cell burst. In any case, the number of cells damaged by each bubble increased with decreasing PF-68 concentration and increasing bulk cell concentration. It can be concluded that bubble damage to suspended cells is an open question. There are no doubts on its great relevance to bioreactor design, but the quantitative aspects of the mechanistic explanations and the solutions proposed to solve it should be carefully studied for each particular case.

42.3 MASS TRANSFER

The volumetric mass transfer coefficient k_La is the rate of transfer across the gas–liquid interface, per unit of driving force (the driving force is the gradient of concentration between the liquid and gas phases). The mass transfer coefficient k_La can be seen as the product of two terms: the mass transfer coefficient k_L and the specific interfacial area, a. They both depend on variables that can be grouped into three categories: (i) static properties of the liquid such a density, diffusivity, and surface tension; (ii) dynamic properties of the liquid (related to liquid flow), such as the rheologic parameters; and (iii) parameters that depend on liquid dynamics. In general, the variables in group 1 do not change very drastically. The variables in groups 2 and 3 span over quite wide ranges.

42.3.1 Mass Transfer Rate Measurement

The methods for determination of k_La in a reactor can be classified as steady- and unsteady-state methods. In the steady-state methods, the rates of oxygen uptake in steady-state operation are evaluated, be it by measurement of inlet and outlet rates of oxygen or from known consumption rates. One of the problems of measuring inlet and outlet gas amounts is that the changes in oxygen concentration in the gas streams are usually small, and the errors of measurement are important. An example of the direct analysis of a compound that reacts with the oxygen is the case of the sulfite method. In this case, the experiment can be run for enough time to obtain a reliable reading of the concentration of sulfite, which reacts catalytically with the oxygen. However, when a chemical is added to the system as part of the k_La evaluation procedure, the question arises of whether the addition has not provoked changes in the physicochemical properties of the liquid, changing the bubble size distribution of the original system.

Transient methods follow the response of the dissolved oxygen concentration in the system after a step change in oxygen concentration in the inlet stream of gas. They have the advantage that no addition of any alien material is required and that a single concentration is followed. The correct use of this method has been analyzed in depth by Linek et al. (227).

One important point to take into account is the dynamics of the oxygen electrode. The lag in the response of the oxygen electrode makes it necessary to discern between the electrode response and the real oxygen concentration, especially when close to a sharp change in concentration. A correct analysis should also include the model of the dynamic behavior of the electrode. To simplify the procedures, approximations based on the truncation of parts of the response curve have been proposed (204,228). These methods are based on truncating the first part of the electrode response obtained in a transient experiment. Once the error admitted in the value of k_La is set, the extent of truncation is fixed, allowing simplification in the analysis of the remainder of the recorded concentration curve. It should be kept in mind that this simplification implies the loss of part of the information, and due care should be given to statistical analysis of the results.

The dynamic gassing out technique (229) is a very simple and ingenious method for studying bubble dispersions (8,230–239). Variations of the dynamic method have been proposed to minimize disturbances in the system, by introduction of step variations of agitation or pressure (227,240). In this way, the method can be applied bioreactors during real operation of the system.

One problem in the measurement of mass transfer rates, especially when viscous liquids are used, is related to the presence of very small bubbles that are depleted from oxygen very rapidly, but do not disengage in the gas separator, becoming an inert volume of gas in the reactor (205). Kawase and Moo-Young (241) analyzed the use of transient absorption of CO_2 for the determination of k_La and concluded that the error due to small bubble retention was much smaller than that in the case of using O_2.

Whatever the method used for the determination of k_La, the process of data elaboration is basically the same as that shown in Fig. 42.24 (242). The measured variable (usually oxygen concentration) is compared with the value that a mathematical model of the process predicts. The model includes k_La as a parameter. The value of k_La that minimizes the difference between the two outputs is chosen.

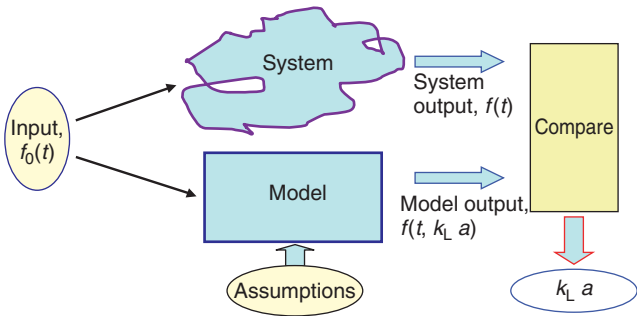

Figure 42.24. Steps in the determination of the mass transfer coefficient k_La.

This stresses that the choice of the model is very important and poor assumptions on flow characteristics of the gas or the liquid phases may lead to errors and deviations from the true values (243). All models are a simplified (to make them amenable to mathematical treatment) description of the system. It should be kept in mind, therefore, that k_La is not a property of the system, but a parameter of the model adopted. If, for example, total mixing is assumed in the model adopted, the mass transfer coefficient obtained will be limited consequently. Regrettably, assumption of complete mixing is so common in practice that many reports do not even specify explicitly that this was done, and in many texts, it can be found that the equation

$$\text{OTR} = k_La(C^* - C) \tag{42.40}$$

is taken as the definition of the mass transfer coefficient k_La, forgetting to state that this equation is valid only for perfectly mixed systems. The question that naturally emerges here is whether the liquid in an ALR can be considered as perfectly mixed.

Strictly, in ALRs, the different sections (riser, downcomer, and gas separator) have different flow characteristics, and the mass transfer coefficient may thus be expected to differ from one region to another. Some (69) have assumed that the contribution of the downcomer to the overall mass transfer is negligible and have reported values of k_La that are, in fact, the whole of the mass transfer divided by the fractional volume of the riser. The fact that the values of the mass transfer coefficient are calculated and reported in different ways introduces some ambiguity into the data; special care should therefore be taken when comparing data or using published mass transfer coefficients for design purposes.

The assumption of perfect mixing in the liquid phase may be questionable in the case of tall reactors. One very simple method to verify this assumption is the simultaneous measurement of the response of the concentration in different points of the reactor to a step change in the inlet. In a perfectly mixed system, the location of the probe should be irrelevant. It was shown (179) that the criterion originally proposed by Andre et al. (244) may be used for ALRs. This criterion compares the circulation time in the reactor with the characteristic time for mass transfer, which is the inverse of the mass transfer coefficient:

$$t_c k_L a < 0.5 \tag{42.41}$$

If this condition is not fulfilled, the bioreactor cannot be considered as a perfectly mixed volume, and more sophisticated ways of analysis are required. The mathematical model and consequently the analysis of the experimental data become much more complicated in this case. Nevertheless, this approach has been used (81,129,245,246), and

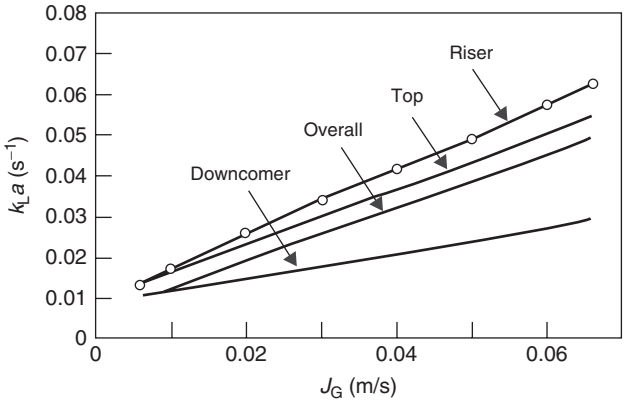

Figure 42.25. Local values of k_La in the different regions of an ALR. Adapted from Ref. 246, with permission.

the mass transfer experiments render in this case the k_La for each of the regions of the ALR. Figure 42.25 shows the results reported by Hwang and Lu (246) in an IL-ALR. The graph shows that the mass transfer takes place at the highest rate in the riser. The downcomer shows 50% lower values, and the gas separator is between them. The overall mass transfer rate is the result of the balance of the respective volumes and rates in the three sections.

The gas composition should also be carefully considered. While in a short equipment the oxygen concentration may change very little, and many times can be considered as constant, this is not so in taller columns, especially at low J_G, when the gas stream depletion is greater. Distributions of gas composition have been modeled and presented and can be of use to the designer (247–249).

In addition, the value of the volumetric OTR determined for a microbial system can differ substantially from that obtained for oxygen absorption in nonreacting solutions with an invariable composition of the liquid media with time. Hence, it is preferable that k_La be determined in bioreactors, which involve the actual media and microbial population (250,251). Figure 42.26a shows the k_La variation with the superficial gas velocity in the riser for absorption in water. Figure 42.26b shows the evolution of k_La through an actual fermentation course employing two different nitrogen sources, at $J_G = 0.05$ (m/s). The k_La decreases and reaches a minimum value at about 24 h. After this time, the k_La starts to increase, and after 48 h of fermentation, it reaches a more or less constant value, which remains until the end of the process. This behavior is similar irrespective of the nitrogen source and is related to changes in rheology.

Various design modifications proposed for ALRs imply changes in mass transfer characteristics. The addition of plates or other internals that reduce the liquid velocity, and in some cases, produce a redistribution of the gas phase as it ascends in the riser, also affects the mass transfer rate.

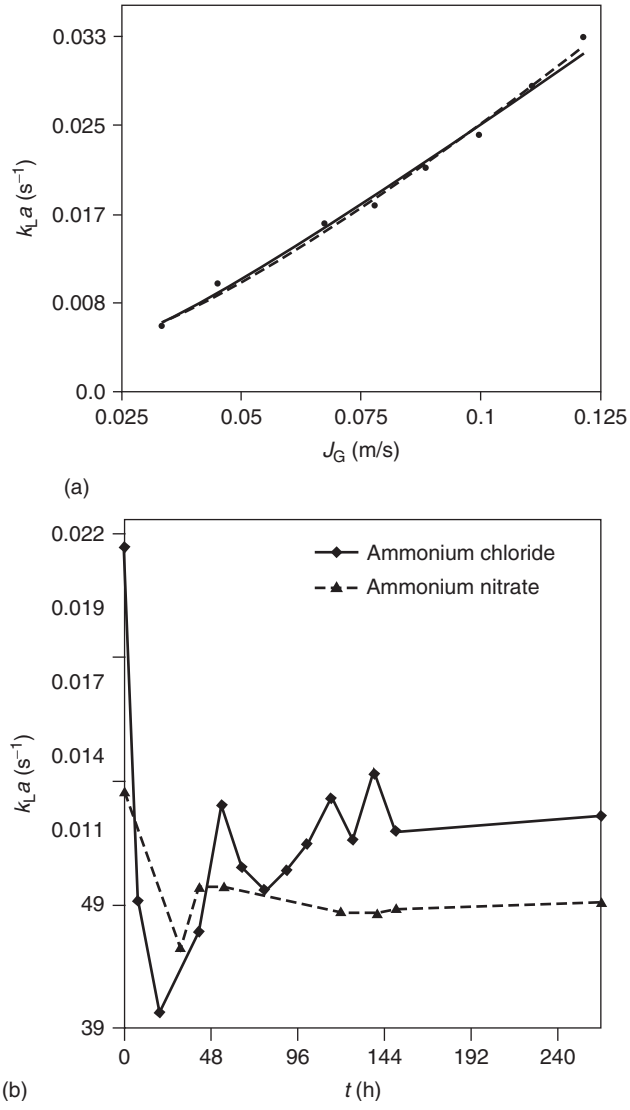

Figure 42.26. Oxygen absorption during growth of *Gibberella fujikuroi* in an airlift bioreactor. (a) k_La variation with the superficial gas velocity in the riser in water. (b) Evolution of k_La through an actual fermentation with two different nitrogen sources (producing different viscosities), at $J_G = 0.05$ m/s. From Ref. 251, with permission.

Nikakhtari and Hill (252) reported an increase in the absorption of volatile organic chemical (VOC) in an EL-ALR due to the addition of internals. The same was observed using a wire mesh made using a draught tube (253). The addition of a stirrer to the ALR to increase liquid circulation, as reported by Chisti et al. (44), improved mixing and mass transfer rate, but strongly reduced the efficiency of oxygen transfer. While the mass transfer rate, as well as other characteristics of the reactors, are expected to have trends similar to those described for ALRs in general, the actual value of the coefficients must be carefully evaluated in each case.

Another point of interest is the question of the enhancement of the mass transfer rate due to the biochemical reaction. This old controversial issue (254) has been lately revived by García-Ochoa et al. (232,255,256), claiming there is a measurable enhancement in the absorption of oxygen during the growth of aerobic cultures.

42.3.2 Bubble Size and Interfacial Area

The interfacial area per unit volume is an important component of the volumetric mass transfer coefficient. In fact, it is the part of $k_L a$ that is more susceptible to changes. The mass transfer coefficient k_L varies only within a limited range (257). The interfacial area is mainly responsible for the changes in mass transfer rate due to variations in turbulence, initial bubble size, and liquid properties:

$$a = \frac{6\varphi}{d_{32}} \tag{42.42}$$

where the Sauter mean diameter (d_{32}) is given by

$$d_{32} = \frac{\sum n_i d_i^3}{\sum n_i d_i^2} \tag{42.43}$$

where n_i is the number of bubbles with diameter d_i. For the riser, the correlation presented by Miyahara et al. (155) for the volumetric mean diameter of the bubbles in the riser of a concentric tube ALR can be used. They proposed

$$\overline{d}^{=} f(N_W) \tag{42.44}$$

where d_o is the diameter of the sparger orifice and ρ the surface tension,

$$N_W = \frac{We}{Fr^{0.5}} \tag{42.45}$$

and the function $f(N_W)$ is different for each range of N_W:

$$\begin{aligned} f(N_W) &= 2.9 N_W < 1 \\ f(N_W) &= 2.9 N_W^{-0.188}, \quad 1 < N_W < 2 \\ f(N_W) &= 2.9 N_W^{-0.188}, \quad 2 < N_W < 4 \\ f(N_W) &= 3.64 < N_W \end{aligned} \tag{42.46}$$

Data on bubble size in the downcomer of an ALR were published by Popovic and Robinson (106).

Bubble size results from an equilibrium between bubble beak up and bubble coalescence. Bubble break up phenomenon was shown by Bhavaraju et al. (258) to be related to liquid turbulence in the vessel rather than gas turbulence in the orifice. Procedures were developed by the authors through a simple liquid circulation model to obtain a criterion for the onset of bubble breakup. The optimal design of a sparger for sparging air into a liquid of given properties (ρ, σ, μ) was studied. They correlated the bubble size for the equilibrium between physicochemical and hydrodynamic forces in a gas–liquid dispersion under a certain energy input.

Bubble coalescence may happen on bubble collision in the core of a liquid. Collision phenomenon implies that the liquid between the two bubbles is reduced to a thin film, which may break producing a larger single bubble or may not withstand the process leaving the two bubbles as they were. Marrucci (259) studied this point and presented criteria that allow to predict the breaking of the film, presenting the group (Crk^2/σ) This group has been used to correlate bubble dispersion properties, as holdup (4), and it is called the *Marrucci group* (Ma).

42.3.3 Data Correlation for Mass Transfer Rate

There are two ways of correlating experimental data from ALRs. First, a hydrodynamic point of view suggests that the movement of the fluid in the reactor determines its overall behavior, and the gas superficial velocity is therefore the more appropriate independent variable. Second, a thermodynamic point of view would suggest considering energy balance—a more global approach to the system. This will lead to correlation of the phenomena in the system as a function of the energy input. Indeed, it is easier to compare mass transfer coefficients in ALRs with those in conventional reactors where the data are presented as a function of the total power input (both mechanical and pneumatic) per unit volume of the medium (43,44). Figure 42.27 shows data of mass transfer coefficients as a function of specific power input (177,260).

4	EL	8.50	0.100	0.25	99
5a	DT	1.70	0.117	0.19	262
5b	DT	1.70	0.176	0.26	262
6	EL	1.80	0.15	0.69	263
7	DT	3.21	0.755	1.27	44

Selected correlations proposed for the prediction of mass transfer coefficients are shown in Tables 42.6 and 42.7, for internal and EL-ALRs, respectively (the warning on the applicability of correlations obtained in different experimental setups must be kept in mind). Among the internal loop reactors, two correlations presented for reactors with rectangular cross section are shown (41,264). For EL-ALRs, the correlation by Popovic and Robinson (80) is recommended. In the case of IL-ALRs, most of the correlations predict similar values. The correlation by Merchuk et al. (48) can be recommended on the basis that more geometrical parameters have been taken into account, and this gives more generality.

42.4 HEAT TRANSFER

Because of the relatively low reaction rates of processes involving microorganisms and cells, heat effect problems related to local variations of temperature are not common in bioreactors. Even in the case when polymeric products are released to the medium and a very high viscosity is attained, heat transfer is not the controlling step, because such viscous media will also hinder the mass transfer and the heat generation will consequently be limited. The case of reactions catalyzed by immobilized enzymes, on the other hand, may require another sort of considerations, because of the higher reaction rates.

Data on heat transfer in BCs are much more frequent than that in ALRs, and some of the basic observations are valid for both. The heat transfer rate in BCs is much larger than the one expected from single-phase flow (270). This is caused by the bubble-driven turbulence and liquid recirculation, which are characteristic of the flow in BCs.

Several correlations have been proposed for the prediction of the heat transfer coefficient in bioreactors (271) based on the surface renewal model and Kolmogorov's theory of isotropic turbulence:

$$St = 0.1(\mathrm{Re}FrPr^2)^{-0.25} \tag{42.47}$$

Kawase and Moo-Young (202) presented an expression that fits satisfactorily most of the published data for non-Newtonian systems. The model is based on Levich's (272) three-zone concept and Kolmogoroff's (273) isotropic turbulence theory and has no empirical adjustable parameters. For Newtonian systems, the resulting equation is

$$Nu = 0.134^{1/3}(Pr)^{1/3}Fr^{-1/4}(\mathrm{Re})^{3/4} \tag{42.48}$$

Roy et al. (274) reviewed data of heat transfer and concluded that the correlation proposed by Joshi et al.(182) fits all of them within 8% error:

$$Nu = 0.087\left(\frac{d^{1.33}g^{1.33}(U_G - \phi_T U_{b\infty})^{0.33}\rho_L}{\mu}\right)^{0.8} Pr^{0.33}\left(\frac{\mu_E}{\mu_w}\right)^{0.14} \tag{42.49}$$

This expression is therefore quite general, but requires knowledge on actual gas holdup in the system, which can be calculated from the corresponding correlations or models.

Because, as noted by Roy et al. (274), the heat transfer process is governed by the flow pattern and thermal diffusivity, the use of CFD with correct velocity and holdup profiles and correct eddy diffusivity should lead to correct predictions of the heat transfer coefficients (274,275).

An interesting question is the effect of suspended microorganisms on the rate of heat transfer. Blakebrough et al. (276,277) studied the heat transfer rates in an external loop airlift fermenter. They reported an enhancement of this rate due to the presence of microorganisms in the case of laminar flow. In their studies, carried out with mycelial suspensions of *Aspergillus niger*, they conclude that this enhancement can be explained by two mechanisms: disturbances of the liquid layer near the surface at low microbial concentrations and a "scraped surface" type of heat transfer at high concentrations or when the microorganism grows in the form of pellets. While this interpretation may be questioned on the grounds that most of the researchers have agreed that boundary layers are irrelevant in BC liquid flow, which is mainly controlled by bubble-scale dynamics, the reported enhancement possibility should be considered.

For the case of denser solids, Dhaouadi et al. (113) have used glass beads in their experiments and found opposite

results (Fig. 42.28). An addition of solids up to 3% in volume produced a reduction in the heat transfer coefficient (Fig. 42.29). This effect may be associated with the difference introduced by the presence of the solids on the bubble size distribution, indicated by the change in the frequency spectra reported. This concurs with the fact that in bubbly flow, the heat transfer to the walls is related to bubble-scale phenomena.

While the most common heat exchange surface is the wall of the reactor, some processes require the presence of heat exchangers in the bulk, bringing into question the nonhomogeneity of heat transfer. Special probes for measurement of heat transfer coefficients have been developed and used (278–280). In general, and as expected from the radial distribution of bubbles and of liquid velocities, the values of the heat transfer coefficient at the center are of the

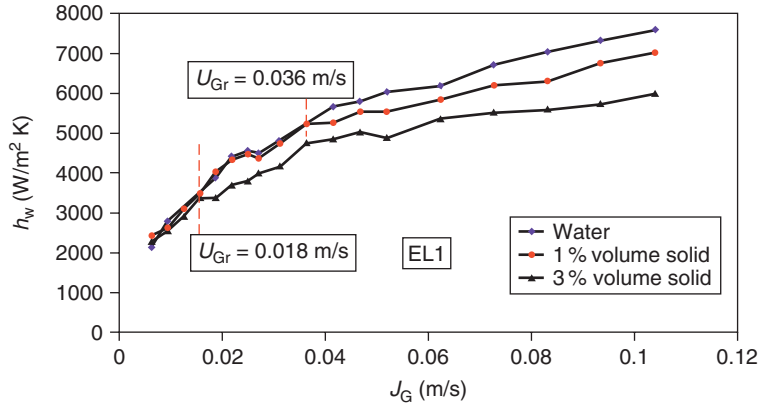

Figure 42.28. . Heat transfer coefficient to the wall of an EL-ALR, with three concentrations of 90-μm diameter glass beads. From Ref. 113, with permission
