

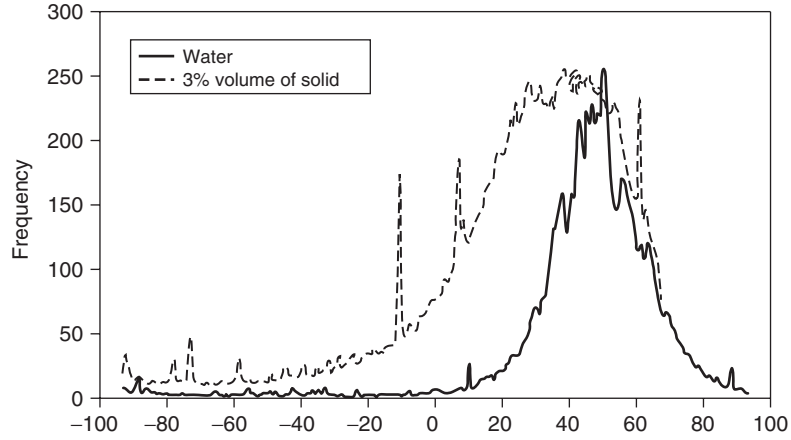

Figure 42.29. Effect of solids concentration (90-mm glass beads) on the measured frequency spectra. The wider spectra indicate a larger bubble size distribution. From Ref. 113, with permission.

order of 10% higher than that at the walls. High pressure produces a decrease in these coefficients (281).

42.5 MULTIPHASE AIRLIFT BIOREACTORS

The special qualities of the ALR stem, as stated before, from its fluid dynamic characteristics. One such characteristic is the directionality of the liquid flow. Independently of superimposed fluctuations, a clear net flow is present in the reactor, with exception of the gas separator in internal loop designs. Therefore, it is to be expected that the fluidization capacity of the ALR will be markedly superior to that of a BC.

42.5.1 Three-Phase ALRs

The most used combinations of phases in ALR have been gas–liquid–solid, but more complex systems have as well been used. Many studies have been conducted on the suspension of solids in ALRs, particularly on the use of this type of device for catalytic processes in the chemical industry (282–287). A very important point is the minimum gas superficial velocity that leads to complete solid fluidization (161,282,285,287–293). Hysteresis has been observed in some cases (294,295); once total fluidization has been attained, the superficial velocity can be reduced to values lower than that required to reach this state. This is due to the high pressure drop related to passage of liquid through a bed of solids, before fluidization, as compared with the drag forces required to maintain the solid in suspension after all the solids are suspended.

Contradictory data on the effect of the suspended solids on the reactor performance have been reported. Fan et al. (296) claimed that the overall gas holdup increased due to the presence of the solids, whereas Koide et al. (77,297) showed the opposite effect on the gas holdup and reported

a small decrease in $k_L a$ as well. It is possible that these discrepancies are due to the use of different solids. One of the properties of solids that is often overlooked is wettability (298). Small bubbles may adhere on wettable solids, leading to a change in the apparent density of the particle and thus changing their solid circulation velocity. Some authors use activators or dispersants to increase the wettability to distribute them evenly and stabilize the solids (299), but the contribution of these additives to the hydrodynamics and mass transfer properties has not been studied.

In the case of suspended solids that take an active part in the process, the mass transfer rate from the liquid to the solid may become the limiting step. The dependence of particle size on the mass transfer to the suspended solids has been studied (35,300,301).

All the comments made above relate to heavy solids. This situation is not very frequent in biological processes, with the exception of biolixiviation (302) or the special case of microbial desulfuration of coal (303). In most of the biological processes that may take place in an ALR, the solids are either cells, clumps of cells, or supports that are not much denser than the medium. Therefore, neither fluidization nor the distribution of solids in the reactor constitutes a problem. Assa and Bar (304) found very small variations in the axial distribution of animal and plant cells suspended in an IL-ALR. This is due to the small free-falling velocity of the solids, which is the reason for the difference in loading between the riser and the downcomer when heavy particles are used (284,285,305). Because of the small difference between solid and medium density, the movement of the particles usually present in biological processes is not as dependent on gravity forces as on liquid and bubble movement. In this case, the transport of liquid in the wake of the bubbles may be considered to be the prevailing transport mechanism (306). Snape and Thomas (307) proposed a Monte Carlo algorithm for modeling particle movement by this mechanism in bubbly flow to predict distribution of circulation times in the reactor. Koide et al. (77) conducted a broad study of gas holdup and mass transfer rates in an IL-ALR containing Ca-alginate beads, which are often used for cell immobilization. The authors found that solid loading had a negative effect on both parameters, but the particle diameter had no influence in the range studied ($1.8\,\text{mm} < d_p < 3.98\,\text{mm}$). Chang et al. (38) studied the influence of suspended pellets (cylindrical pellets of immobilized penicillin acylase) on the mixing time in an IL-ALR. They found that mixing time increased when the solid volumetric concentration was raised up to 15%. For higher concentrations, the trend inverted, and the mixing time decreased. No such effects were observed with heavier solids. Increases in gas superficial velocity and in top clearance both led to decreases in mixing time in all cases.

The use of light particles whose density is smaller than that of water is more and more frequent. The energy necessary to maintain them suspended and in motion is lower than with heavier particles. Their roughness and porosity is also an important parameter in the growth of attached microorganisms. Couvert et al. (308) characterized the hydrodynamic behavior and the oxygen mass transfer characteristics of a three-phase ALR, under the influence of two types of plastic materials less dense than water, a regular smooth one (P1) and a rough one (P4), both used in bioprocesses. The addition of solid at the assayed percentages (10–40% of P1 particles and 10–70% of P4 particles) had little impact on the mixing parameters. Neither did the solids affect the hydrodynamic parameters, except for the gas holdup if the solid concentration is below 16% and high gas velocities are used. The material P4 distribution and hydrodynamic parameters were more homogeneous in the reactor than for P1. The quantity of solid not only had influence on the mass transfer, but also the nature of the solid particles (shape, size, porosity, etc.). Although P1 seemed to increase $k_L a$, the presence of P4 caused a decrease in $k_L a$. Nevertheless, below a solid holdup of 16%, both types of solids did not alter the volumetric mass transfer coefficient in the reactor.

A special type of gas–liquid–solid three-phase bioreactors are the particle-based biofilm reactors (PPBRs). In them, cell aggregates are formed spontaneously as large dense granules or attached to suspended carriers to improve gravity separation. PPBRs are extensively used in environmental biotechnology because they can be operated at high biomass concentrations to treat the large volumes of dilute aqueous solutions that are typical of industrial and municipal wastewaters without the need for separating the biomass and the treated effluent.

Lately, an extensive review of the latest generation of PPBRs was presented (309). Two of them based on gas lift pumps outstand: biofilm airlift suspension reactors (BASRs) and internal circulation reactors (ICRs) (Fig. 42.30a and 42.30b). The main difference of BASR with the conventional ALR is the three-phase separator on the top. The ICR is a more novel and original adaptation of airlift pumping system. In essence, it consists of two reactor compartments situated on top of each other, one highly loaded and the other scarcely loaded. The biogas produced in the first compartment is collected by the lower level phase separator and is used to generate a gas lift pumping system. Several full-scale IC and BAS systems are presently in operation in Europe.

42.5.2 Four-Phase ALRs

Secondary metabolites from cell cultures are either stored within the cells and/or excreted into the medium (they may also appear in the medium due to cell lysis). In cases where the yield of bioproduct of interest is low due to

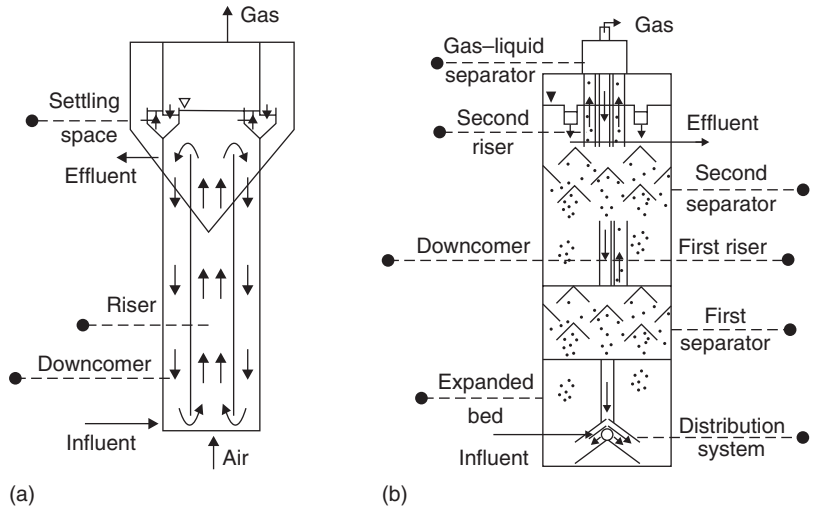

Figure 42.30. Particle-based biofilm reactors (PPBRs) based on gas lift pumps. (a) Biofilm airlift suspension reactor (BASR) and (b) internal circulation reactors (ICRs). Reprinted with permission from Nicolella et al. (309).

cellular-mediated regulation of the ratio between intracellular and extracellular bioproduct concentrations, extractive fermentation seems to provide excellent results, particularly for metabolites produced by plant cell cultures (310). This process increases the net production by reducing the concentration of the secondary metabolites in the culture medium. The same approach can be used for removing substances from culture broth either to avoid their degradation or to increase the biosynthetic rates by reducing feedback inhibition of biosynthesis.

In extractive fermentations, the addition of the solvent directly to the bioreactor is the simplest operation way, but it can lead to the formation of stable emulsions of organic phase in the aqueous medium due to high shear rates required for solvent dispersion. Therefore, the bioreactor design is extremely important. In this sense, ALRs are serious candidates because shear is lower and they are more uniform, eliminating the formation of very small solvent drops. Sajć and Vunjak-Novakovic (311) presented a very interesting extractive bioconversion in a four-phase external loop airlift bioreactor. The aim was the extractive bioconversion of anthroquinones by plant cells. The cells were immobilized in alginate beads suspended in an aqueous medium. In the riser, a gas and a solvent (silicone oil or *n*-hexadecane) were injected. The gas bubbles provided the energy for the circulation of the system and the solvent drops extracted the anthroquinones produced. Both gas and solvent were completely separated at the top and only the aqueous medium and the suspended alginate beads circulated (Fig. 42.31).

Previously, Sajc et al. (312) performed a exhaustive study in which the influence of gas, solvent, calcium alginate particles, and culture medium composition on gas and

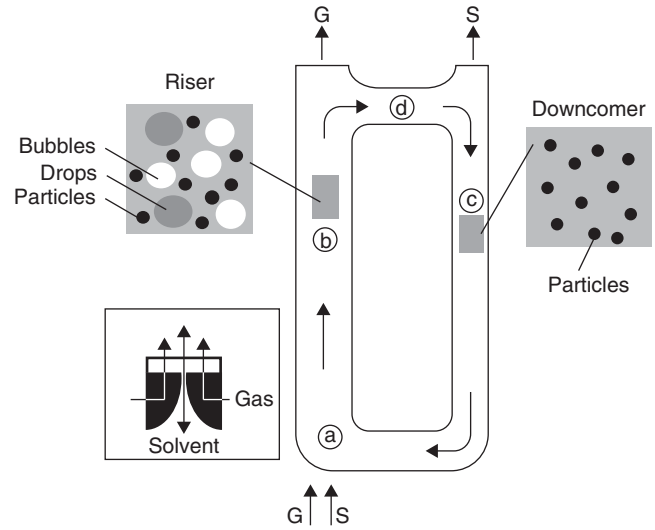

Figure 42.31. Extractive bioconversion in a four-phase external loop airlift bioreactor. In the riser, gas and a solvent are injected. Both gas and solvent are completely separated at the top and only the aqueous medium and the suspended alginate beads circulate. From Ref. 311, with permission.

solvent holdup, liquid circulation velocity, mixing in aqueous liquid phase, and mass transfer coefficients of oxygen and plant cell product was analyzed. They showed that the gas holdup is the principal variable determining the properties of the four-phase system, and a unified correlation for the gas holdup, derived from drift flux flow in a three-phase system (313), was proposed to the four-phase system. No differences under bubbly flow regime were observed in the bubble size and size distribution when water or culture

medium was used as aqueous phase. Consequently, hydrodynamic parameters for the four-phase system such as gas holdup, liquid circulation velocity, oxygen mass transfer coefficient, and axial liquid dispersion were similar for both aqueous phases tested.

In spite of interest of this four-phase EL-ALR, the authors did not study the impact of dispersed solvent liquid phase on fluid dynamics compared with the same system without it. Although with a different purpose, Mehrnia et al. (2,266,314) studied hydrodynamics and mass transfer in airlift bioreactors containing water-in-oil microemulsions as models of the biocatalytic desulfurization of petroleum. Several configurations of gas separator and draft tube heights were tested. The rate of gas recirculation and consequently the rate of liquid circulation were influenced by the small bubble sizes generated with the microemulsion. In general, gas holdup and volumetric gas–liquid oxygen transfer coefficient for water-in-oil systems were significantly higher than those for the distilled water system. For all assayed microemulsions with kinematic viscosities up to about 8×10^{-6} m^2/s, the bubbly flow regime prevailed. However, an increase in kinematic viscosity up to around 32×10^{-6} m^2/s, either through changing the oil base or the water-to-oil phase volume ratio of the microemulsion, resulted in the onset of churn-turbulent regime at most of the air rates employed. A concomitant decrease in the gas holdup and k_La values was also observed.

42.6 SELECTION AND DESIGN

42.6.1 Scale-Up

The methods available for scale-up of bioreactors have been reviewed by Oosterhuis (315), Kossen and Oosterhuis (316), Sweere et al. (317), Sola and Godia (318), and Zlokarnik (319), among others. Unfortunately, there are still no exact and well-established rules ensuring an accurate transition from one scale to another, particularly for scale-up of ALRs.

42.6.1.1 Integrated Kinetics and Fluid Dynamics. In general, design from first principles cannot be undertaken because of the lack of basic knowledge on the hydrodynamics of the bioreactors. One possible solution is the semifundamental method, which comprises simple approximate models for fluid dynamics integrating them with basic known kinetics and heat and mass transfer rates. For example, Sikula et al. (320) have modeled the biotransformation of glucose to gluconic acid by *A. niger*, performed in IL-ALRs of different scale (12, 40, and 200 L), using a tank in series model. Kinetic parameters were estimated from data obtained in the smallest reactor. Hydrodynamic parameters (i.e. gas holdups, circulation velocities of the liquid and the gas, and the volumetric mass transfer coefficient of oxygen) were predicted from semiempirical correlations reported in the literature. The end of the fermentation process was reasonably predicted with an error of about 10%; this error was mainly associated to the strong dependence of the results on the initial concentration of the biomass in the reactor. An improved simulation may have been achieved incorporating the physiological state of inoculum to the model (e.g. morphology, internal nutrient pool, and growth phase).

Recently, Boyadjiev (321) also used integrated modeling to tackle the problem of scale effect associated to the radial nonuniformity of the velocity distribution in column reactors (the scale effect has been erroneously regarded as an increase in the longitudinal dispersion in many works). He developed an elegant model based on velocities and concentrations averaged over a cross section of an airlift three-phase catalytic reactor. The model includes radius-dependent parameters determined using average concentrations, which is easier than parameter determination involving measurement of local concentration.

42.6.1.2 Rules of Thumb. It does not happen very often that all the information relative to integrated modeling is available with a degree of certainty that allows safe design of a large system. Thus, the designer must usually resort to dimensional analysis. The method implies the description of the problem by a complete set of pi-numbers, and knowing initially all relevant physical quantities that describe the problem. As prerequisite, a thorough and critical knowledge of the process in question is needed. In fact, Zlokarnik (319) established degrees of applicability of dimensional analysis, depending on the knowledge available.

A simplified version of this method is to limit the number of variables to one or two and to follow rules of thumb (322), which, depending on the specific case, may be kept constant alone or combined with each other (P/V, k_La, N, Re, t_m, etc.). Figure 42.32 shows some typical examples carried out in STRs.

More recently, Liu et al. (324) have successfully scaled-up L-lactic acid production by *Rhizopus* sp. MK-1196-96 from 0.003 to 5 m^3 ALR using OTR as the scale-up criterion. The correlation between OTR and L-lactic acid production in the 0.003, 0.1, and 5 m^3 ALRs is plotted in Fig. 42.33, suggesting that OTR can be used as a scale-up criterion for this fermentation process.

The literature shows, however, many cases of inconsistency for this method. For example, design of a scaled-up bioreactor in which the OTR is kept constant can lead to a better performance than expected (325) or worse than expected (326).

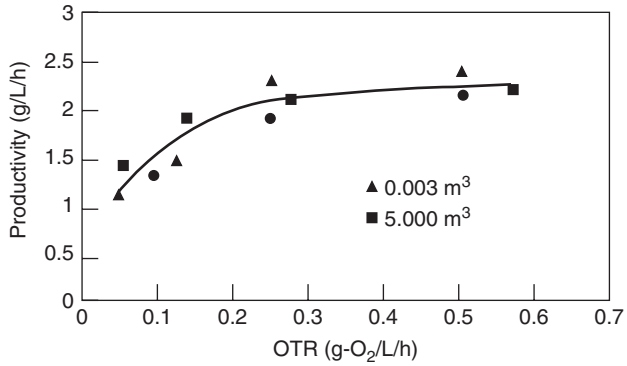

Figure 42.33. Correlations between OTR and L-lactic acid production in ALRs. Adapted from Ref. 324.

42.6.1.3 Regime Analysis and Scale-Down. The method of regime analysis and scale-down (315,316,327) combines two tools to overcome the problem posed by the complexity of biochemical reactors. Their method is based on considering the regime of the full-scale process as the objective and planning the strategy of process development from this point on. This method is therefore applicable only to conventional and well-studied bioreactors that are to be used in a new bioprocess.

Regime analysis is based on the consideration that, generally, biochemical processes involve a series of steps, some being mass or heat transfer by convection, some being diffusive mechanisms (activated or not), and others being chemical reaction steps. In the latter case, a mass transfer mechanism is superimposed, because molecules must encounter one another to react, and usually a heat effect will accompany the reaction. Therefore, regime analysis involves the identification of the time and length scales for the phenomena of particular interest (Figs. 42.34 and 42.35).

Depending on whether these steps take place in parallel or in series and on the relaxation time for each step (328), the rate of the total process is often given as the rate of one single step. But the equilibrium between all the individual rates can be (and usually is) upset by a change in scale. This is to be expected, because a change in scale will not bring a change in the physicochemical or kinetic parameters (scale-insensitive variables) but will affect the overall convective mass and heat rates (scale-sensitive variables). A new equilibrium will be established, and the interplay of all the parameters of the system may lead to a regime in which a different step becomes the step controlling the process rate.

The method of Kossen and Oosterhuis (316) starts with an analysis of the operation of the large-scale system. Once the regime is clarified, a small-scale system is designed in such a way that it simulates the operation regime of the larger one. Optimization studies can be done on the smaller model, and conclusions will then be extrapolated to the full-scale process (Fig. 42.36). An example is given by Oosterhuis (315), in which a large-scale STR is simulated on a laboratory scale by two interconnected vessels; one

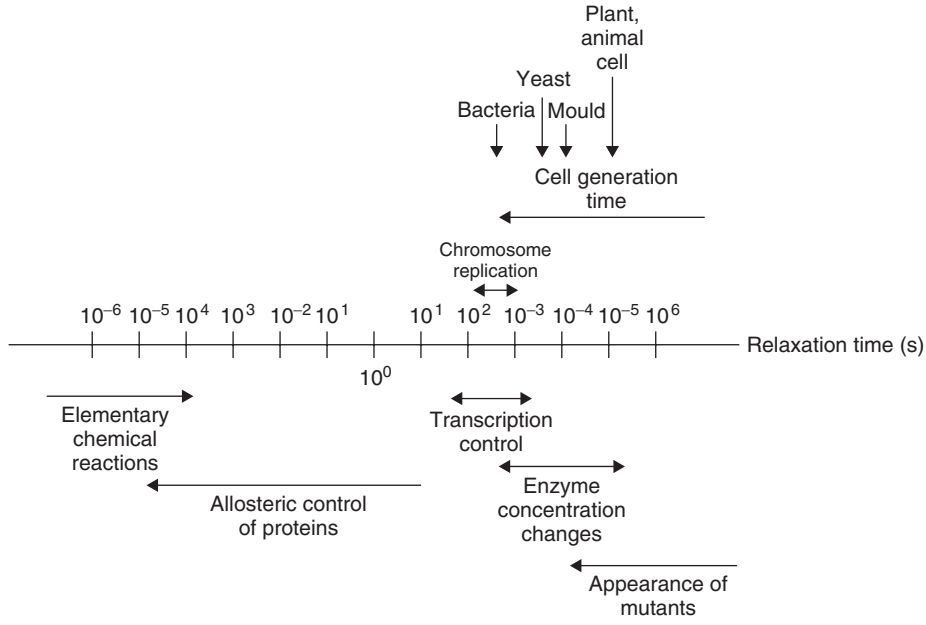

Figure 42.34. Characteristic times for biological responses important in bioreactor engineering. From Ref. 229, with permission.

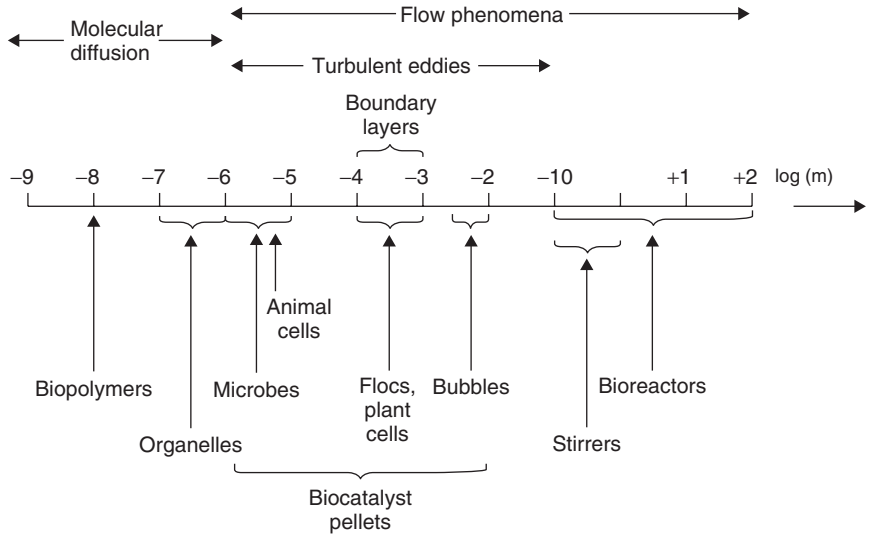

Figure 42.35. Characteristic length scales encountered in bioreactor design and analysis. From Ref. 229, with permission.

with a small liquid volume, high agitation rate, and high rate of oxygen supply (representing the zone near the impeller sparger in the reactor), and a second vessel with a much larger liquid volume, oxygen consumption (simulated by nitrogen sparging), and gentle agitation. The success of this model suggests that large vessels must be carefully analyzed and their internal structure studied for proper modeling and design to be performed. The analysis starts with the definition of the characteristic time constants of the system.

An analysis of the time constants required for the design of an ALR for plant cell culture was presented by Doran (40). Figure 42.37 shows the reported values of the time constants calculated for an EL-ALR for mixing, mass transfer, and oxygen consumption at two different cell concentrations: 5 and 30 kg/m^3. These graphs exemplify the changes in the controlling mechanism that may take place as the physical properties of the broth change in the course of the bioprocess.

A complete example of how to use this methodology of regime analysis and scale-down for scaling-up the continuous production of isopropanol–butanol mixtures by immobilized *Clostridium* sp. was presented by Schoutens et al. (329). Two reactor types were studied: a fluidized bed reactor (FBR) with liquid recycling and an EL-ALR. Initially, a regime analysis, by evaluating time constants associated to flow, mixing, and conversion, was conducted in 50–65 m^3 large-scale bioreactors to identify the reigning regime. Next, two representative model reactors were developed using scale-down approach: a 10-L FBR and a 15-L EL-ALR. For both reactors, the hydrodynamic behavior and the total reactor performance were exhaustively studied.

In an innovative work, Papagianni et al. (330) designed a bioreactor as a tool for scale-up/scale-down studies. It consisted of an EL-ALR that simulated circulation loops experienced in conventional STRs; the circulation time was a measure of reactor size. The ALR was tested using the citric acid fermentation by *A. niger* as a model system. Citric acid production and fungal morphology were used successfully as the response variables for evaluation. The relationship between product concentration and circulation time is given in Fig. 42.38. High circulation times in the EL-ALR correspond to inadequate mixing in larger STRs. Because other parameters such as number of impellers, baffles, and power input may also influence the above-mentioned relationship, a correlation for each parameter should be obtained.

42.6.1.4 Computational Fluid Dynamics. CFD tools have been published showing the capability of handling the complex problem of multiphase flow in ALRs (97,133,274,331–344). CFD gives much more detailed information, reaching the level of local velocities and local holdup (Fig. 42.39) (339). Local gas holdup and axial liquid velocity along the radius of a column (345)

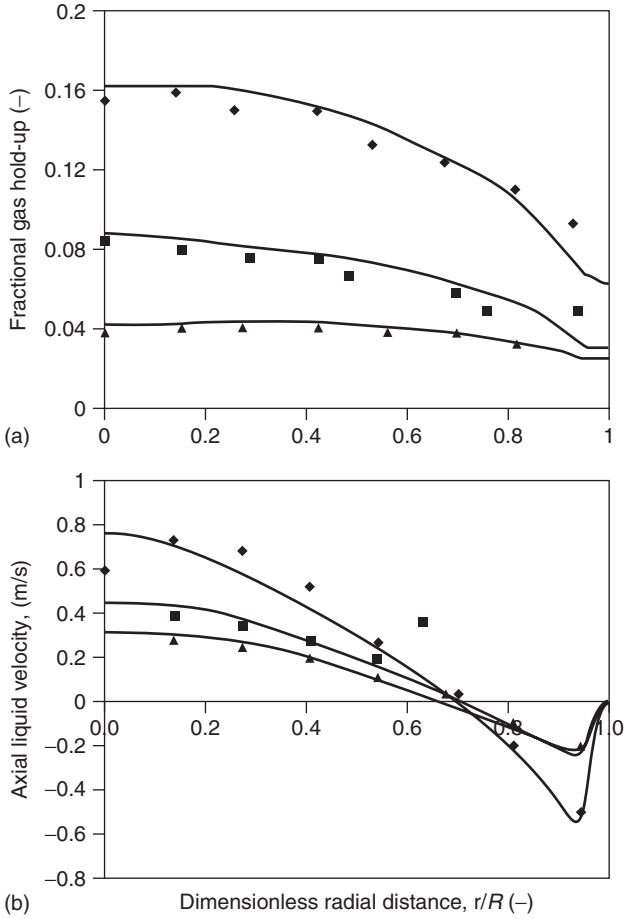

Figure 42.39. Gas holdup and liquid velocity radial distribution as calculated using CDF. Comparison with experimental data of Menzel et al. (345). Liquid velocity: ▲$J_G = 0.012$ m/s; ■$J_G = 0.024$ m/s; ♦$J_G = 0.048$ m/s. From Ref. 339, with permission.

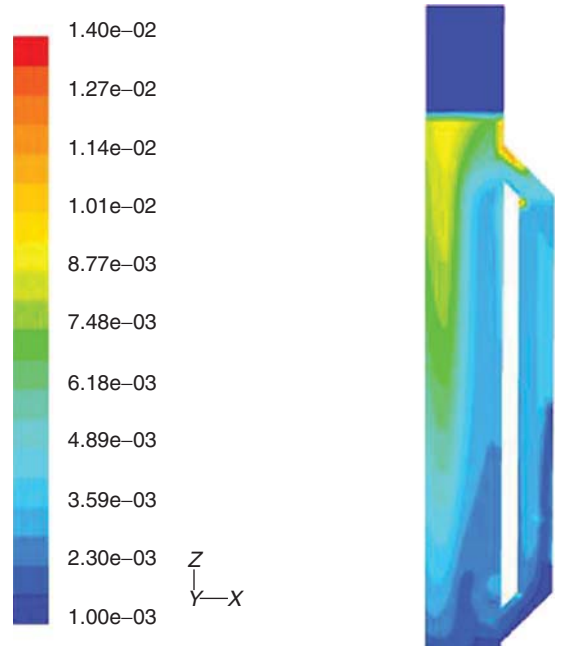

Figure 42.40. Contours of the Sauter mean diameter in millimeters along symmetry plane for superficial velocity of 0.03 m/s. With permission from Ref. 346.

can be predicted with a remarkable precision, and CFD results were validated. This tool also allows the prediction of mixing times and axial dispersion coefficients (339). One of the most difficult obstacles in the simulation of a multiphase system as those that we are analyzing is the behavior of the gas dispersion (346), most of the literature does not account for the dynamic breakage and coalescence of bubbles. These phenomena affect the bubble size distribution, a key factor that influences OTR in aerobic fermentation systems, because it modifies the interfacial area. Dhanasekharan et al. (346) proposed a modeling approach in which these effects are included by solving a population balance model with bubble breakage and coalescence. The population balance model was coupled to multiphase flow equations and solved using a commercial computational fluid mechanics code, FLUENT 6. Predicted values of gas holdup and volumetric mass transfer coefficients for different superficial velocities were validated with experimental data from Kawase and Hashimoto (347). Figure 42.40 shows a contour plot of the Sauter mean bubble diameter in an ALR. In Fig. 42.41, examples of CFD predictions are displayed. The results of modeling showed good agreement with the experiments. In this case, the use of CFD seems to overcome the need for correlations whose application is restricted to certain geometric configurations and flow conditions.

Feng et al. (348) have recently developed a coupled CFD model to simulate the phenol biodegradation by yeast *Candida tropicalis* in an IL-ALR. The model combines hydrodynamics with biochemical reactions, without accounting for the dynamic breakage and coalescence of bubbles. The local instantaneous flow and phenol biodegradation features, gas holdup, gas velocity, liquid velocity, cell concentration, and phenol concentration inside the ALR were successfully predicted by the proposed model (Fig. 42.42). In a previous work conducted with BCs, Feng et al. (349) reported similar results. The predictions of the hydrodynamic characteristics and phenol biodegradation behavior were accomplished in a virtual BC bioreactor, but the results were not validated experimentally.

It therefore seems that in the near future, with the improvement of CFD, this technique will progressively replace the use of empirical correlations for the prediction of gas and liquid velocity, gas and solids holdup, and mixing parameters and will also provide evaluations of shear rate and energy dissipation. It should be kept in mind that CFD should always be validated with experimental data.

42.6.1.5 Artificial Neural Networks. It is clear that there is a great need of correlations for predicting the hydrodynamics and mass transfer parameters in ALRs, which should be system-independent and could further be used for proper design and scale-up of industrial bioprocesses. In general, the available literature correlations for predicting hydrodynamics and mass transfer in ALRs are based on dimensionless numbers and specific mixing power input, supposedly independent of the gas–liquid system. However, they often provide large deviations when compared with experimental data. Artificial neural networks (ANNs) are emerging as a powerful tool for predicting the hydrodynamic parameters in aerated and ARs (350).

Al-Masry (351) applied basic principles of ANNs to analyze the effects of changing the volume of the liquid in the gas–liquid separators on the hydrodynamics of EL-ALRs.

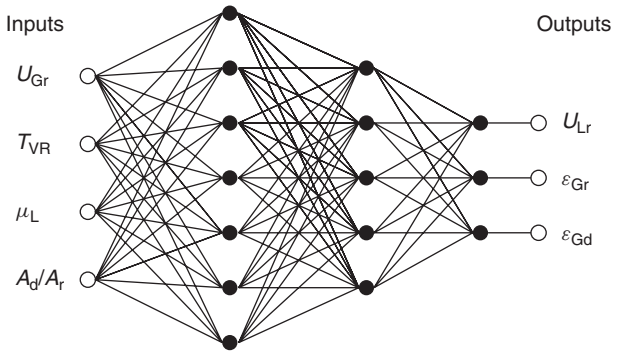

Figure 42.43. Three-layer feed-forward neural network with four inputs and three outputs. Adapted from Ref. 351.

The used neural network was very simple and consisted of four inputs and three outputs with two hidden layers. The inputs were superficial gas velocity J_{Gr}, volume ratio T_{VR}, liquid viscosity μ_L, and scale-up factor A_d/A_r, while the outputs were liquid circulation velocity J_{Lr}, riser gas holdup ε_{Gr} and downcomer gas holdup ϕ_{Gd} (Fig. 42.43). The network was trained on 60% of the data and then used to predict 40% of the data that had never been seen by the network. The training was successfully accomplished because the neural network noticeably improved the predictions of the hydrodynamics variables in relation to those calculated from correlations reported by Al-Masry (98).

The correlations for gas holdup usually have a validity over a limited range of J_G. Shaikh and Al-Dahhan (352) developed a unified correlation for gas holdup using a combination of dimensional analysis and ANN modeling. A databank of around 3500 measurements was collected from 60 sources (Table 42.8). Authors identified four relevant dimensionless groups (Re_g, Fr_g, Eo/Mo, and ρ_g/ρ_L) to predict overall gas holdup. A comparison with selected correlations in the literature showed that the developed ANN correlation noticeably improved prediction of overall gas holdup. The developed correlation also shows better prediction over a wide range of operating conditions, physical properties, and column diameters, and it predicts properly the trend of the effect of the operating and design parameters on overall gas holdup. The developed ANN correlation should be useful in the scale-up of BC reactors.

Lemoine and Morsi (238) developed empirical and back-propagation neural network (BPNN) correlations to predict the hydrodynamic and mass transfer parameters in gas–liquid ARs. They also used a large number of experimental data points (7374) obtained from their laboratory, as well as from the literature, covering wide ranges of reactor geometry, impeller diameter, physicochemical properties, and operating variables. One of the reactors included in this study was a DT-ALR. Correlations were employed to construct a simple algorithm for predicting the gas holdup (ϕ_G), volumetric mass transfer coefficients (k_La), Sauter mean bubble diameter (d_{32}), gas–liquid interfacial area (a), and liquid-side mass transfer coefficient (k_L) in different ARs under industrial conditions. The developed algorithm based on the BPNN correlations was used to predict the effects of liquid-phase viscosity and composition of the gaseous feed to the reactor on the hydrodynamic and mass transfer parameters in a soybean oil hydrogenation carried out in a large-scale gas-sparging AR (2.5-m inside diameter and 5-m height).

TABLE 42.8. Range of the Key Variables and Physical Properties, and Type of Spargers Included in the Collected Databank

Variable	Range
Column diameter	0.045–5.5 m
Liquid density	684–2965 kg/m^3
Liquid viscosity	0.41–2.95 cP
Surface tension	20–72 m N/m
Gas density	0.083–1.2 MPa
Superficial gas velocity	0.005–0.75 m/s
Superficial liquid velocity	0 (bath liquid)
Overall gas holdup	0.05–0.685

Source: Adapted from Ref. 352.
Gases: Air, N_2, CO_2, He, Ar, mixture of N_2, and H_2. Liquids: water, tetradecane, paraffin oil (A, B), soltrol-130, isopropanol, monoethylene glycol, *n*-heptane, isopar-G, and so on. Sparger types: perforated plates with different number of holes, geometry and hole sizes, single nozzle sparger, cross-sparger, sintered plate, and so on. Number of sources: 60 (1965–2000). Number of data points: 3500.

42.6.1.6 Global Strategy. Each case of scale-up has particularities that should be considered. For example, average shear rate is one of the more important parameters used in the design of bioreactors for culture shear-sensitive microorganisms. But, shear rates are unevenly distributed in the different zones of ALRs (353,354). Al-Masry (355) found that the wall shear rates developed in EL-ALRs with aerated non-Newtonian liquids can be significant: the ratio of wall shear rates to bulk shear rates ranged from 5% to 40%. More recently, Al-Masry (356) observed that wall shear rates could be strongly influenced by the scale and proposed a new empirical correlation for estimating them given by

$$\gamma_w = 4800 U_{Gr}^{1.86} \left(1 + \frac{A_d}{A_r}\right)^{-0.14} h^{0.48} \qquad (42.50)$$

The used working volume, A_d/A_r ratio, and height of dispersion (H_D) ranged from 40 to 700 L, from 0.1 to 1.0, and 1.2 to 6.2 m, respectively. Polymer solutions of xanthan gum and CMC were used to simulate non-Newtonian behavior of biological systems. Therefore, because frequency of passage of sensitive cells through these high shear regions may be determinant, wall shear rates should be kept in mind in any strategy of scale-up.

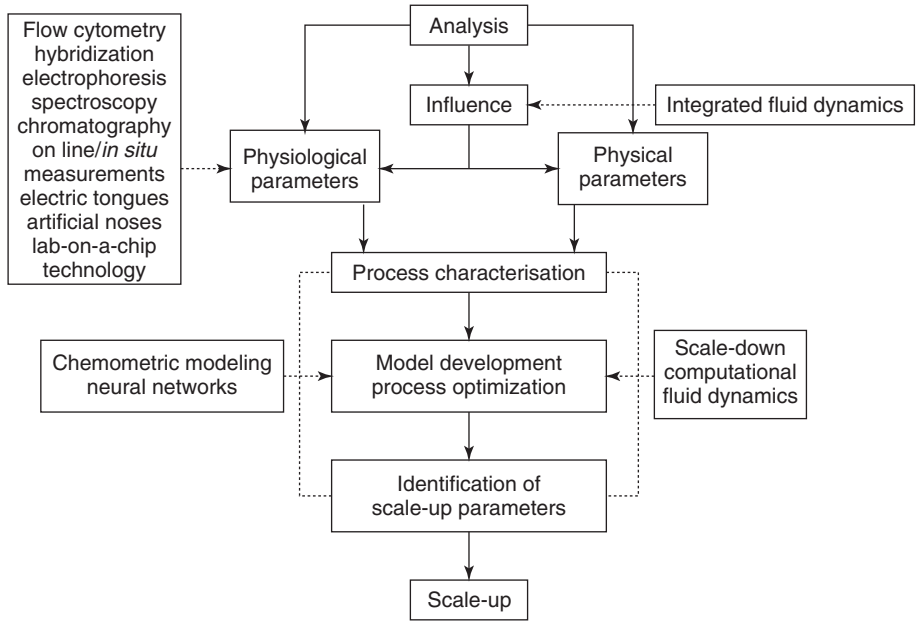

Figure 42.44. Conceptualization of a global strategy for scale-up of ALRs. Adapted from Ref. 357.

Unfortunately, despite the central role of the scale-up issue in bioprocess engineering, there is not a clear generally applicable strategy of scale-up in ALRs. For each individual bioproduct, microorganism, and type of ALR, a suitable strategy has to be elaborated. Schmidt (357), in a comprehensive review about optimization and scale-up of industrial fermentation processes, proposed a holistic scale-up strategy that may be adopted for ALRs. It consisted of a complete and detailed process characterization to identify key factors and parameters influencing product yield and quality, and of an appropriate process control and process design ensuring optimum mixing and bioreaction conditions, supported by appropriate knowledge and models as well as computational tools (Fig. 42.44).

Nonetheless, any approach and any model will always be based on approximations and will not completely reflect the highly complex interactions and relationships of the physical conditions governing the fermentation process. Successful scale-up will not be the result of a conclusive and straight-lined experimental strategy, but rather of an independent optimization on each scale, which highly depends on the experience, skill, and the intuition of the researcher (357).

42.6.2 Design Improvements

Several modifications to the classic ALR morphologies (Fig. 42.1) have been proposed. Figure 42.45 collects some of these designs aimed at the improvement of some of the characteristics of the equipment.

42.6.2.1 Multistage ALRs. One of the earliest modifications was the two-staged ALR (43). This design was inspired by the improvement observed in the performance obtained with multistage sieve trays over single-stage BCs. A substantially higher mass transfer coefficient and a better performance in terms of oxygen transferred per unit of energy invested were obtained.

A more complex version of multistage ALR was recently presented (358,359). Authors devised a novel multistage EL-ALR operating in three stages to remove trace pollutants from wastewater. The staging effect was achieved through hydrodynamically induced continuous bubble generation, breakup through rupture and coalescence (Fig. 42.46). The ALR was constructed with three vertical stages operating in a series. Bubbles were generated at the lowest part of the column below the first stage. At the beginning of the first stage, bubbles were ruptured and coalesced by imposing a flow disturbance using a disk with single central orifice (contraction disk). The G/L dispersion passing through the orifice was subjected to dynamic instabilities in the form of flow expansion followed by flow contraction. The flow expansion was achieved by positioning a mesh (expansion disk). Both types of disks were alternatively arranged along the riser. A screen positioned between two contraction disks was defined as one stage. At the end of each stage, bubbles lost their individual identity and new bubbles were generated at the beginning of each stage. The gas holdup achieved was higher than that in the single-stage system for the same superficial gas and liquid velocities. The values of a and $k_L a$ obtained at low power consumption were significantly higher than in other gas–liquid contactors. Maximum

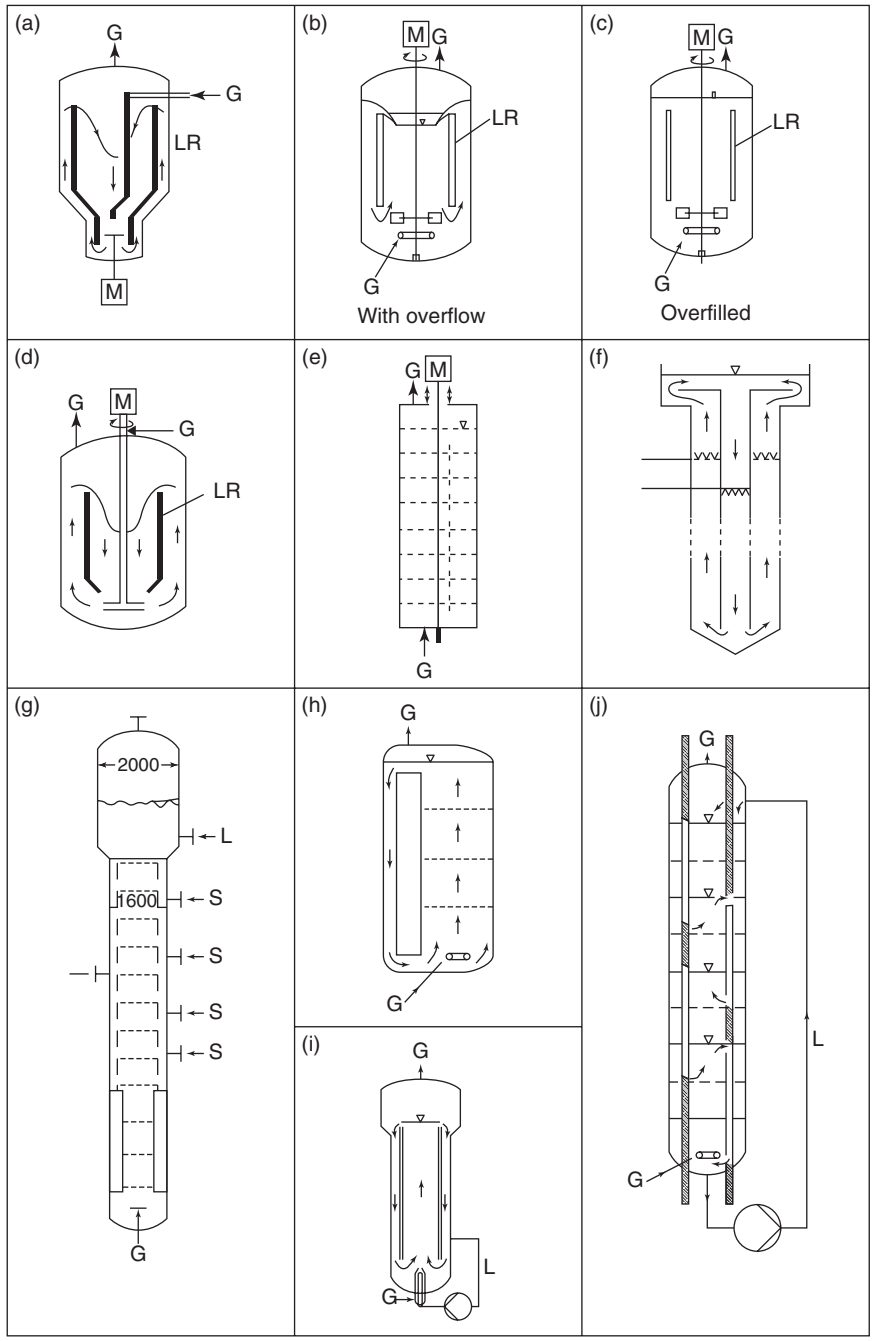

Figure 42.45. Some modifications from classic ALR morphologies. (a–e) configurations using mechanically moved internals for energy input, (f) downstream air ALR, (g) ALR with static mixer, (h) multistage EL-ALR, (i) nozzle loop ALR, and (j) multistage ALR. From Ref. 229, with permission.

mass transfer rate was found out through modifications in the riser-to-downcomer ratio.

42.6.2.2 ALRs Using Mechanically Moved Internals. The combination of a DT-ALR with a marine propeller (1000 rpm) was studied and compared with other column reactors (360) (Fig. 42.47). In this modification, the stirrer located near the bottom of the draft tube served to increase the circulation rate, which may be low for viscous liquids. This configuration showed enhanced oxygen transfer and more uniform distribution of the dissolved oxygen concentration throughout the reactor in comparison with

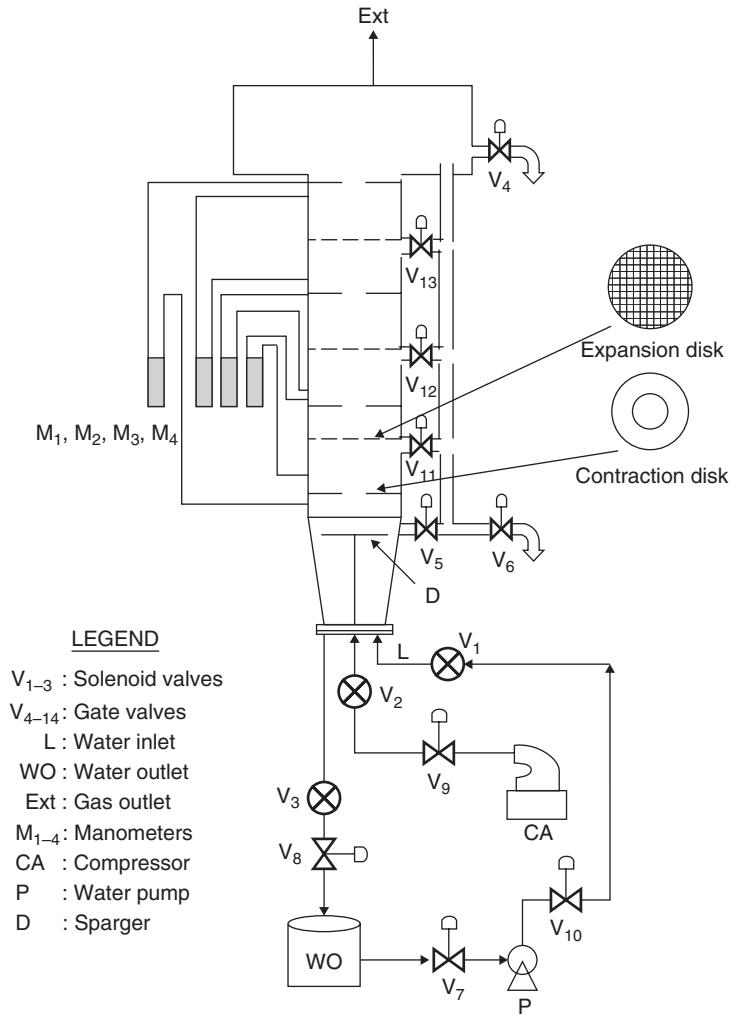

Figure 42.46. Schematic diagram of an experimental multistage EL-ALR. Disks of contraction and expansion were alternatively arranged along the riser. From Ref. 358, with permission.

that of the unmodified ALR. The liquid circulation was also intensified. However, the improvement was achieved at the cost of the introduction of a focus of energy input. As mentioned before, the absence of such a high shear region is one of the advantages of the ALR. It is interesting to note that a bakers' yeast culture (360) grown in the same type of modified reactor did not reveal any improvement. This may be related to the strong shear rate in the vicinity of the propeller.

42.6.2.3 ALRs with Static Mixers. Different types of static mixers, usually located in the riser, have also been used for enhancing the performance of ALRs. Potucek (361) studied the influence of static mixers on the gas holdup and interfacial gas–liquid area in a DT-ALR and found an improvement in interfacial area. Enhancement of $k_L a$ has also been obtained, especially in viscous liquids, as reported by Gaspillo and Goto (362) and Chisti et al. (363). Zhou et al. (364) showed better growth of *Cephalosporum acremonium* in an ALR with static mixers.

One of the advantages of the directionality of flow in ALRs is the improved fluidization capacity. The strengthening of this advantage was the aim of another modification, the helical flow promoter (HFP), proposed by Gluz and Merchuk (300). The HFP causes the fluid to flow down in the downcomer in a helical pattern (Fig. 42.48). The device comprises several fins or baffles, which have the effect of modifying the flow paths; instead of going in straight lines along the axis, the flow paths move along a helix. The baffles may be installed in a small section at almost any place along the riser or the downcomer, and the effect is perceived throughout the reactor. One of the best positions for the HFP is the top of the riser. A helical flow is then generated in the downcomer to produce a swirl at the bottom and a corkscrew-like path in the riser. This has a strong potential for the culture of photosynthetic microorganisms. The

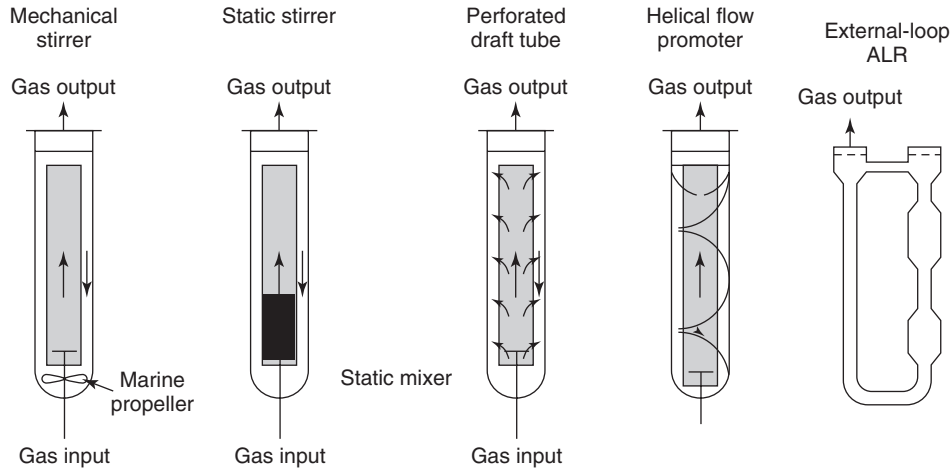

Figure 42.47. Modifications proposed in ALRs.

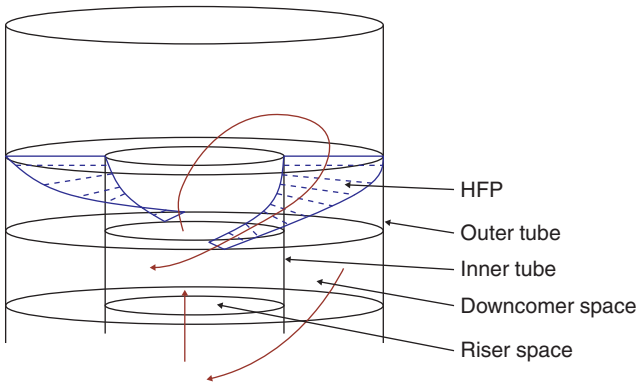

Figure 42.48. The helical flow promoters (HFPs) proposed for modification of the flow pattern in ALRs. From Refs (308) and (365).

helical movement causes secondary flow, which leads to enhanced radial mixing, and therefore more homogeneous distribution of light and heat among liquid elements and suspended particles. With the HFP, it is thus more likely that all the elements of the fluid get the same exposure to light and heat exchange.

One of the most important characteristics of the HFP is the enhanced capacity for fluidizing solid particles. This is due to the swirls that develop at the bottom of the reactor. Thus, this modification is especially suited to processes operating with cells immobilized on a solid. The minimal gas flow rate for complete fluidization of solids in an ALR may be reduced drastically by the use of a HFP (187). In addition, the mass transfer rate to suspended solids may be enhanced up to 50%, because of the higher relative velocity between the particles and solids.

Another interesting aspect of the performance of HFPs was highlighted by Schlotelburg et al. (366). Mass transfer coefficients obtained in a BC, an ALR, and an ALR with HFP were compared for water and two solutions of CMC: 0.2% and 0.04%. The corresponding effective viscosities for $\gamma = 50/\text{s}$ are 16 and 38 mPa s, respectively. It is clearly shown that although with water there is a consistent difference in favor of the BC, the differences diminish as the CMC concentration increases, and for the highest concentration tested, the difference is negligible. This implies that under these conditions, the disadvantage of the HFP in mass transfer vanishes, whereas all the advantages mentioned before subsist.

Vorapongsathorn et al. (367) studied the effect of cross-sectional baffles located in the riser of an ALR on hydrodynamics and mass transfer. Baffles reduced liquid circulation velocity (U_L) compared with the unbaffled configuration and significantly enhanced the gas holdup in the riser zone. However, because U_L was diminished, baffles caused a reduction in the gas holdup of the downcomer. Thus, the baffles had scarcely any influence on the overall gas holdup and on k_La. The authors highlighted as disadvantage the development of the stagnant regions beneath the baffles (Fig. 42.49). These regions could become contamination niches. This phenomenon and the risk of fouling are common among ALRs carrying static mixers.

42.6.2.4 External Loop and Draft Tube. As mentioned earlier, it has been shown repeatedly that the mass transfer rate in a BC is usually higher than that in the conventional ALR. It therefore makes sense to try to bring into the ALR some of the characteristics of BCs in a controlled fashion. This was done by several authors (368–375), who tested different perforated draft tubes in a DT-ALR. The perforations in the draft tube facilitated communication between the less-well aerated liquid in the downcomer and the better aerated riser. The reported improvements in mass transfer rates were undoubtedly obtained at the cost of a reduction

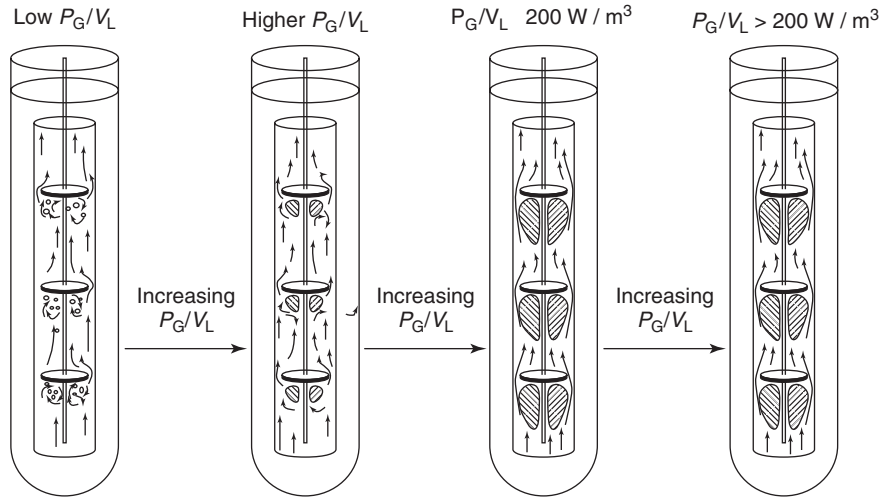

Figure 42.49. Development of stagnant regions in baffled ALRs as a function of specific power input. From Ref. 367, with permission.

in circulation velocity. Similar results were observed (253) in a modified ALR with rectangular wire mesh draft tubes. The draft tubes improved the liquid mixing and decreased the bubble coalescence in the ALR. The ALRs, in both the small and large scales, had the highest capabilities of liquid mixing and mass transfer in comparison with those of the conventional BC. By using the proposed reactor, the mixing time was reduced up to 30%, volumetric mass transfer coefficient and gas holdup increased up to 50% and 90%, respectively.

Another variant tested is the converging–diverging EL-ALR (376). The authors reported that the changes in cross section in the riser produced an increase in the gas holdup. An analogous study was accomplished by Wei et al. (377,378), but in an IL-ALR in which different convergence–divergence draft tubes were employed. The coalescence and distribution of bubbles were considerably affected and the gas holdup was much higher than that in a conventional draft tube ALR. The tested variation of structural parameters has scarce effect on gas holdup. At the same superficial gas velocity, the liquid circulation rate for ALR with different convergence–divergence draft tubes was lower than that for a conventional DT-ALR. However, the volumetric mass transfer coefficient was at least 10% higher than that of the conventional ALR.

A novel modified ALR with divided draft tubes was designed by Liu and Tay (379) for aerobic granulation. This configuration guaranteed the even discharging of the mixture of liquid and solids from the draft tube and from the downcomer compared with conventional DT-ALR, allowing the successful cultivation of aerobic granules and the stable operation of aerobic granular sludge in 5 months.

Futselaar et al. (380) have recently tested a new side-stream system for municipal wastewater treatment [NORIT Airlift membrane bioreactor (MBR) system]. It consists of an EL-ALR with filtration membranes positioned in the loop outside the bioreaction section. The membrane modules were arranged vertically and were aerated continuously at the bottom. This continuous aeration was the main driving force for the circulation of the activated sludge, while the feed pump was used to compensate the hydraulic losses. Permeation was controlled by a suction pump. A combination of forward flushing and periodic backflushing and/or relaxation intervals was used to control the cake layer formation inside the membrane tubes and to extend the intervals between maintenance cleanings. In industrial applications, this way of applying membranes in separation of water from sludge has lead to very compact units.

42.6.2.5 Split Baffle. Jajuee et al. (231) conceived a three-phase ALR in which a semipermeable membrane was used as split baffle between riser and downcomer (Fig. 42.50). The bioreactor was used for biodegradation of hydrocarbon compounds (381). The dividing membrane consisted of a rectangular sheet of nonwoven polyester textile that was supported by stainless steel mesh. The structure of textile membrane allowed the entrapment and immobilization of a wide range of solid particle sizes and microorganisms attached. The horizontal bulk motion due to hydrostatic pressure differences between the riser and downcomer was responsible for entrapment of suspended particles. This ALR provided higher mass transfer efficiency for lower superficial gas velocities where lower liquid circulation velocity and mixing rate could be compensated by horizontal flows through the porous membrane. In fact, higher biological degradation

rates compared with similar bioreactor systems reported in the literature were obtained.

42.6.2.6 Inverse Fluidization. Garnier et al. (382) proposed the internal loop inverse fluidized bed airlift reactor (IL-IALR). In essence, it consisted of DT-ALR where light particles, such as expanded polystyrene beads, were placed in the annulus, and the bed was expanded toward the bottom of the reactor by the resultant downward liquid flow, creating an inverse fluidized bed. The advantage of the setup is the decoupling of gas contact with the solid phase, thereby limiting shear damage to the microorganisms. However, this configuration still allowed gas entrainment in the downcomer and the adherence of the light particles to the bubbles and subsequent disengagement and bursting of the bubbles could result in some cellular damage.

This problem was circumvented by Guo et al. (268), who proposed the use of an external loop inverse fluidized airlift reactor (EL-IALR). The sparger was located in the middle of the riser, so that heavy particles were fluidized in the lower section of the riser. In this device, gas–liquid and solid–liquid contacts were also decoupled. Flow reversal occurred between the bottom bend and the injection point of gas. However, it was necessary to lengthen the riser to increase gas holdup and favor the fluidization. The downcomer had scarce functionality, except as part of the liquid circulation path.

In both IL-IALR and EL-IALR, the gas holdup was fixed for a given gas superficial velocity and a solids loading. Due to the importance of maintaining high dissolved oxygen concentration in the treatment of wastewater containing high phenol concentrations, Loh et al. (383,384) proposed a simple modification of an external loop fluidized bed airlift bioreactor (EIFBAB). The main characteristic of this ALR was the installation of a globe valve between the riser and the downcomer at the bottom. By varying the extent of the valve opening, gas holdup could be increased at a fixed gas velocity without the need to increase the solids loading. Under high phenol concentrations, where the degradation rate is oxygen limited, EIFBAB provided the advantage of increasing dissolved oxygen tension by adjusting the valve opening when operating at high gas velocities.

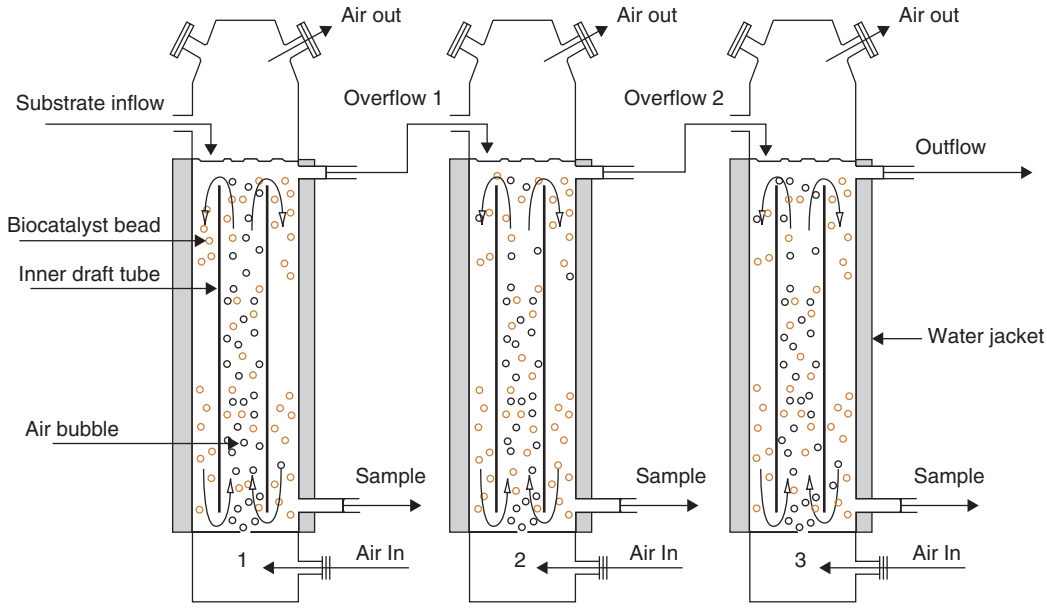

Figure 42.51. Cascade of three ALRs for producing a glycopeptide antibiotic from immobilized *A. teichomyceticus* cells. From Ref. 386, with permission.

42.6.2.7 Type of Contact. A novel integrated bioreaction–crystallization process bioprocess for the continuous production of calcium gluconate crystals has been proposed (385). The system consists of two EL-ALRs in a series, one being bioreactor and the other crystallizer. The concentrated calcium gluconate solution produced in the bioreactor is fed into the crystallizer in which the product is crystallized for its recovery. The mother liquid of the crystallizer is recycled to the bioreactor. Hence, the feed of solid glucose and calcium hydroxide to the bioreactor with simultaneous removal of calcium gluconate crystals from the crystallizer led to a continuous production of the crystals. The overall productivity in the proposed process was comparable to that of the batch fermentation process. However, the process advantages, reduced waste streams and simplicity, make it more attractive than the batch process.

Jovetic et al. (386) have recently proposed the culture of immobilized *Actinoplanes teichomyceticus* cells in three ALRs connected in a serial flow arrangement for continuous biotransformation of a glycopeptide antibiotic (Fig. 42.51). Distinct operational regimes were examined in independent laboratory-scale experimental trials. Very high final conversions of 95–99% combined with an extensive continuous operation time were achieved representing an advantage over the batch process.

42.6.2.8 Arrangement and Shape Modifications. The vast majority of ALRs reported in the literature have cylindrical geometry. However, many of them are being versioned in rectangular geometry because it provides good mixing and betters mass transfer performance (80,88,253,387–390). One of the interesting applications of rectangular shape is the microalgal mass culture because it could improve the efficiency of light utilization (391–395). For example, the new flat panel airlift bioreactor with a defined circulation path developed by Degen et al. (396) for culturing photosynthetic microalgae. The bioreactor exposes the cells to intermittent light to improve the efficiency of light utilization through the flashing light effect. A small downcomer zone was located on one side of the reactor (Fig. 42.52). The riser was

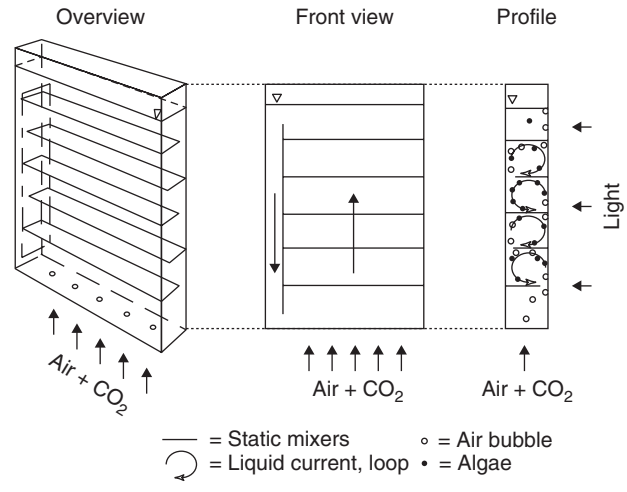

Figure 42.52. Flat panel airlift bioreactor to culture photosynthetic microorganisms. From Ref. 396, with permission.

subdivided into interconnected chambers by means of horizontal baffles. The baffles were attached alternately to the front and the back of the larger flat faces of the reactor. The fluid in the chambers circulated so that the cells regularly moved between the narrow illuminated zone and the deeper dark zone.

Chen et al. (397) compared a rectangular mesh baffle-plates ALR with conventional ALR and BC. Mesh baffle-plates improved mass transfer and mixing with the mass transfer coefficient of the proposed reactor being up to 12% higher than that in a conventional ALR under the same operating condition. The mixing time of the proposed reactor was 95% lower than that of the conventional ALR.

The effect of the bioreactor position in relation to a vertical plane has been barely studied. Lu et al. (398) observed a drastic change in hydrodynamic behavior of a rectangular BC when it was inclined up to 10° from the vertical. The liquid velocities in the inclined column were from 10- to 50-fold the superficial gas velocity. Further inclination of the column in the range of 10–45° had little effect on liquid velocity and mixing time. This observation was exploit by the same authors to efficiently culture murine hybridoma cells in a BC inclined 45° from vertical (399). This inclination allowed to separate the rising bubbles at the column upper surface, leaving the bulk of the liquid bubble-free. Liquid circulated due to the airlift effect. The adherence of cells to rising bubbles and the exposure of the cells to bursting bubbles on surface were minimized. This arrangement may be interesting to avoid cell damage by shear stresses associated to bubbling.

However, the more evident positive effects of tilting bioreactors have been observed in the field of microalgal biotechnology. The appropriate inclination of culture system facing the sun increases the irradiance level on photobioreactor surface and consequently improves the cell photosynthetic activity. Merchuk et al. (400) have recently presented a novel inclined tube ALR, which integrates the excellent hydrodynamic characteristics of ALRs and the benefices of a enhanced irradiance with inclination. The reactor consists of a tube with a flat baffle inserted in its bore, so as to generate two volumes that communicate at both ends of the tube, as shown in Fig. 42.53. Two gas streams are injected, one above the baffle (Q air top) and one below it (Q air bottom). The latter has the role of generating a cyclic, airlift-type flow in the device, while the gas injected above the baffle has the role of modifying the flow of the liquid going down to enhance radial mixing generating light/dark cycles, which are of fundamental importance in algal optimal growth. Those cycles can be seen in three experimentally measured trajectories (Fig. 42.54). The upper part of the tube acts as a downcomer and the lower part as a riser. There are no previous reports on this type of reactors. The feasibility of the algal culture in this type of reactor with actual flue gas was demonstrated

in a 4-week culture of *Dunaliella parva*. The experiments were carried out in a medium size device connected directly to the flue gas in a power plant.

42.6.2.9 Special Designs Based on Airlift Pump. The gas lift advanced dissolution (GLAD) is a method for sequestration of low purity CO_2 emitted by thermal power plants (402). The dissolution tube is approximately 200-m long, and the drainpipe reaches more than 1000 m in depth. In fact, this is not a gas lift reactor, because this is a once-through system, and recirculation, a basic characteristic of ALRs, does not exist. It is, therefore, a gas lift pump in which gas dissolution is especially important (Fig. 42.55).

Low dissolved oxygen concentrations in the hypolimnia of lakes or reservoirs can have a negative effect on environment and on water treatment processes. Hypolimnetic

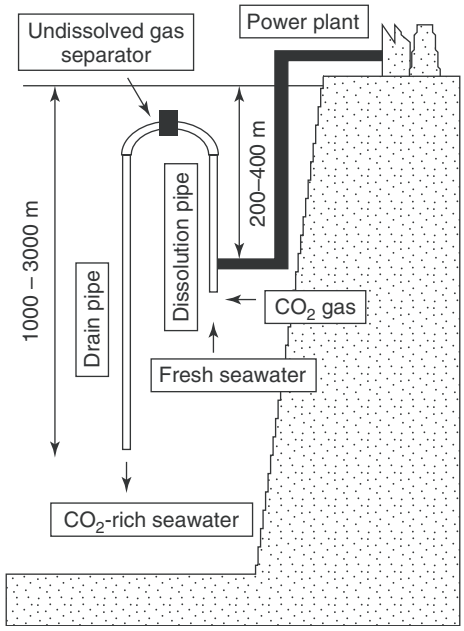

Figure 42.55. The gas lift advanced dissolution (GLAD), a method for sequestration of low purity $J_G = 0.024$ emitted by thermal power plants. From Ref. 402, with permission.

aeration and oxygenation are commonly used to add dissolved oxygen to water bodies while preserving stratification. Airlift devices have also been used for hypolimnetic aeration. They typically consist of a vertical riser tube, a diffuser inside the bottom of the riser tube, an air–water separation chamber at the top of the riser, and one or two return pipes (downcomers). Figure 42.56 displays a photograph of full-lift aerator. Compressed air is delivered to the aerator and bubbles freely from the diffuser. This creates a positively buoyant gas–water mixture that ascends the riser. At the top of the riser, bubbles are released to the atmosphere, and some may be entrained in the water that enters the downcomers. The oxygenated water descends the downcomers and is returned to the hypolimnion (403).

42.7 MODELS

A considerable number of researchers have tackled the task of describing the flow of liquids, gases, and solids in ALR and the mass transfer between those phases. Early models were mainly aimed at the description of liquid velocity as a function of the easily measured gas holdups and were based on energy balances (79,108) (Table 42.9). Some of them model gas/liquid systems, and eight attempt the representation of three-phase, gas/liquid/solid systems. Some overlapping exists, because several models are presented in a general form that fits both G/L and G/L/S systems.

The table shows that the liquid velocity and the gas holdup in the riser are seen as the main variables studied and appear in all the proposed models. Indeed, those variables are closely related, because the difference in gas holdup between riser and downcomer is the only driving force for liquid circulation in the system. This has been clearly stated by Heijnen et al. (420), who expressed the pressure difference per unit height required as

$$\frac{\Delta P}{gH} = (\varepsilon_{Gr} - \varepsilon_{Gd}) - (\varepsilon_{Sr} - \varepsilon_{Sd})(\rho_S - \rho_L) \qquad (42.51)$$

In closed reactors, or as long as the overall solid amount does not change, the last term is the product of two differences that always have the same sign, because if the density of the solid is larger than that of the liquid, its rising velocity will be smaller and the holdup of solids in the riser will be larger than that in the downcomer and vice versa. The presence of solids, therefore, will always diminish the driving force for circulation, independently of their density. The hydrodynamic model presented by Heijnen et al. (420) is one of the most interesting and offers a complete representation of the fluid dynamics in an ALR from a macroscopic point of view. The model is able to describe both two- and three-phase flow. The ingenuity of the model

consists in avoiding the need of dealing with four different variables (the holdups of gas and liquid in both riser and downcomer) by writing the difference in gas holdups $\phi_r - \phi_d$ as a function of the overall gas holdup ε_G, the gas superficial velocity, and the circulation liquid velocity. A similar procedure is followed with respect to solids holdup. The simplification proposed by Chisti (83) assumes that the ratio of the gas holdups in downcomer and riser is constant. This is an approximation that seems to be close to reality in two-phase systems, but strictly, it contradicts simple liquid mass balance.

Several of the models listed in Table 42.9 consider gas recirculation. As Heijnen et al.'s (420) model circumvents the need of knowing the gas holdup in riser and downcomer, in spite of handling the regime of gas recirculation, it does not provide an evaluation of the fraction of gas recirculated. The model presented by Freitas et al. (410) uses a pseudohomogeneous liquid approach and assumes that the concentration of solids is homogeneous all over the reactor. This is strictly valid only for solid density that is very close to the density of the liquid, $\rho_{sol} < \rho_L$. Indeed, they use alginate beads as solid carriers, with density close to that of water. Friction coefficients are calculated from one-phase correlations. The model confirms that an increase in solids produces a decrease in holdup. The gas holdup in the downcomer is calculated as in the model by Heijnen et al. (420), assuming a linear relationship between riser and downcomer holdups. For the external loop, they assume no gas recirculation. They optimize their parameters (four parameters) and get excellent fitting of their data.

Tall ALRs constitute a special type because of the high liquid velocities that can be reached. Not only can gas be entrapped into the downcomer, but it can also be directly injected in this section, with a considerable gain in gas-phase residence time and in energy required for gas injection. One of the most promising applications is the disposal of carbon dioxide from flue gas by injection into deep waters (402). Sanders et al. (416) have presented a model for the prediction of liquid velocity in such reactors. A basic analysis based on the Zuber and Findlay (89) two-phase flow approach seems to represent satisfactorily the trends of pressure drops and liquid velocities in a high recirculation ALR.

García-Calvo et al. (421) presented a thermodynamic model (based on the first principle), which is simply an extension of a previous two-phase model (148) to the three-phase airlift reactor (TPAL). The model requires knowledge of the bubble slip velocity. They show that it is possible to predict the transition from packed bed to fluidized bed and to circulating bed, as well as the hysteresis phenomenon that has been observed in these flow configurations (422), and good concurrence with experimentally observed transitions is reported. These transitions between flow configurations, classified taking the solid phase as reference, are different from the transitions between configurations based on the gas behavior (58).

Mousseau et al. (409) present a model for a rectangular section ALR with suspended solids of lower density than water, used for wastewater treatment: The model allowed the prediction of the changes in ammonia, dissolved oxygen, and biomass. They use the penetration model and the isotropic turbulence model for the description of the gas–liquid mass transfer.

In some of the papers in Table 42.9, the problem of gas/liquid mass transfer is addressed and is given more attention than fluid dynamics: Hwang and Lu (246), Tobajas et al. (412), and Camacho-Rubio et al. (423). Hwang and Lu (246) present an analysis of "gassing out" experiments, where a different value of the mass transfer coefficient k_La is considered in each of the three distinct regions: riser, downcomer, and separator. This is in fact an improved version of the original paper by Merchuk et al. (245), where this structured analysis of an ALR was first presented, structured means the zones of different fluid dynamic characteristics are recognized. This work was successfully extended to three-phase reactors by Wen et al. (57)

The model by Tobajas et al. (412) refers to a three-phase system, because it deals specifically with the biotreatment of marine sediment. A simple model is proposed combining Higbie's penetration model and Kolmogoroff's theory of isotropic turbulence and is used for prediction of mass transfer rates. No parameters are adjusted, and slip velocity, friction coefficients, equivalent length, and so on are taken from independent sources. Excellent match of experimental and predicted values was found for gas holdup in the riser, liquid velocity, and mass transfer rate.

Rubio et al. (423) deal with the axial profiles of oxygen in tall ALRs, which are frequently ignored. They show that, as a consequence of the hydrostatic pressure variation, steady-state axial dissolved oxygen concentration profiles exist even if no oxygen consumption exists. These axial inhomogeneties increase as the gas flow rate increases. It is obvious, therefore, that the conventional method of k_La determination, which is based on the assumption of perfect mixing in the reactor, is not valid in a tall bioreactor. The problem of inhomogeneity in dissolved oxygen concentration was also touched by Dhaouadi et al. (424) and Korpijarvi et al. (415), starting from the dynamic response of an ALR to sudden changes in inlet gas concentration. In all those cases, the main point of interest is the recognition that the so common assumption of perfect mixing may not hold in the case of tall reactors.

The fundamental and solid model presented by Young et al. (405) for an external ALR was upgraded (407), adding to the initial model the effect of gas buoyancy forces in the gas. Based only on the physical properties of the gas and liquid phases, the reactor dimensions, and the gas input,

the model predicts gas and liquid velocity and gas holdup along the riser for bubbly flow. Total disengagement of the gas at the top is assumed.

The seminal model by Ho et al. (404) has been an inspiration and a basis for much improved models that represent the ALR as a sequence of perfectly mixed cells (413,417,425). Those models are convenient for handling biological or chemical reactions. The simplification of the mathematical treatment may sometimes outweigh the unrealistic stepwise change in the variables along the reactor that is obtained. Steiff et al. (425) produced a considerable amount of experimental data that can be used to calibrate the model parameters. Of special interest, because these data are scarce in the literature, are the data of gas recirculation, measured following the technique proposed by Siegel et al. (1).

Shechter and Merchuk (426) presented a three-phase model for the fluid dynamic description of an airlift unit. The model is based on a momentum balance over riser and downcomer, and a series of macroscopic equations that describe the continuity of liquid and solid as it passes from the riser to the downcomer. Figure 42.57 shows the effect of solid density on the behavior of the system: while the gas holdup in the riser and the velocity of the solids in the riser remain almost constant when the density of the solid changes by 5% under and over the density of water, the solids holdup in the riser and downcomer are affected in opposite ways: while ε_{Sr} increases, ε_{Sd} decreases. The lines cross at a particle density equal to that of water. The difference between riser and downcomer solids holdup thus changes from negative to positive as ρ_s increases. The difference in absolute terms is smaller (approximately 0.03 vs 0.074) at higher particle density, and the predicted increase in liquid velocity, therefore, concurs with the general conclusions from Equation 42.1. This simulation refers to solids with density close to that of the liquid. When the density of the particle is substantially higher, the additional problem of complete fluidization appears. This is especially critical in systems with short draft tubes (427).

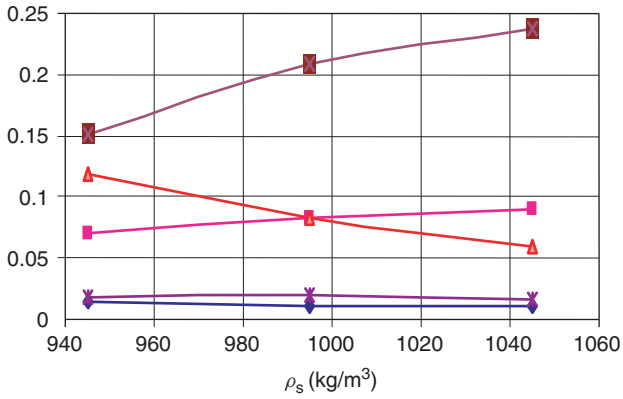

Figure 42.57. Influence of suspended solid density on the gas and solid holdup in an ALR for wastewater treatment. The legends for the vertical axis are: ♦, φ_{Gr}; ■, φ_{Sr}; ▲, φ_{Sd}; ×, U_{Lr}; *, U_{Sr} from Ref. 426, with permission.

Table 42.9 also lists models that deal with the application of CFD codes to the description of the flow in ALRs. Cockx et al. (406) presents a simulation based on one-dimensional two-fluid mass and momentum balances. Their results produce axial profiles of gas holdup in both riser and downcomer and a flow map of the liquid that includes radial profiles of velocity. Mudde and Van Den Akker (337) carried out two- and three-dimensional simulation of an airlift, trying to minimize the use of *ad hoc* closure terms. Surprisingly, they do not find clear advantage in the three-dimensional model, because both approaches coincide with experimental measurements of gas holdup. The two-dimensional model predicts a strong influence of the sparger geometry and seems to be better at low gas superficial velocities. Of special relevance is the model presented by Roy et al. (274). The model presented stems from an exhaustive analysis of the two-phase flow in an ALR. The input parameters are those related to energy dissipation in a three-dimensional two-phase flow, including the distribution parameter C_o because the Zuber and Findlay drift flux model is adopted for the description of the interaction between phases. With this input, a remarkable fit of previously published data was obtained. The calculated results of local values of fluid velocity, radial and axial distribution of gas holdup, and global parameters as mixing time and axial dispersion coefficient concurred with experimental results of other researchers. This excellent fit indicates that models making use of CFD are an alternative to the empirical correlations that are used today.

42.8 BIOPROCESSES

42.8.1 Drugs

ALRs may find successful applications in plant cell and roots suspension cultures (428–436). Airlift bioreactors are also used for the production of recombinant proteins and monoclonal antibodies from large-scale mammalian cell cultures (14,437–439) or to produce penicillin G from immobilized *Penicillium chrysogenum* in a DT-ALR, utilizing a magnetic field.

42.8.2 Biopolymers

The microbial exopolysaccharides (EPSs) are a class of highly valuable biopolymers with diverse biological activities. ALRs have been tested for production of biopolymers from fungi *Ganoderma applanatum* (440),

Tremella fuciformis (441), *Paecilomyces tenuipes* (442), *Grifola frondosa* (443), and *Sclerotium glucanicum* (444). κ-Carrageenan for the phycocolloid industry may also be obtained from *Kappaphycus alvarezii* calluses in a DT-ALR (445). The production of biodegradable thermoplastics from bacterial polyhydroxyalkanoates synthesized by *Ralstonia eutropha* in a membrane ALR (446) and a DT-ALR (447) has been examined. Obtaining of bacterial cellulose from cultures of *Acetobacter xylinum* in a DT-ALR has also been documented (448,449).

42.8.3 Exploitation of Lignocellulosic Wastes

Lignocellulosic biomass is a very important waste worldwide. The microbial biomass production from the hydrolysate of rice straw by yeast *Candida arborea* using a laboratory-scale EL-ALR has been recently evaluated (450). The influences of gas flow rate, initial liquid volume, hole diameter of gas sparger, and numbers of sieve plates on microbial biomass production were examined. The culture system was proved to be better than the conventional STR, opening the possibility of reducing the cost for microbial biomass production from this type of waste. Approximately 70% of municipal solid waste in industrialized countries consists of waste cellulosics, waste paper being the major component. A means of recycling is the conversion of cellulose to soluble sugars via enzymatic processes have been carried using an ultrasonic EL-ALR (293,451). In these works, the effects of paper size, sparging gas, humidity, and ultrasonic irradiation on the process kinetics and rate were studied.

42.8.4 Hydrocarbons in Groundwater

An immobilized cell ALR by Karamanev et al. (452,453) for the biodegradation of recalcitrant compounds has also been proposed for the aerobic bioremediation of simulated diesel fuel contaminated groundwater. It was tested with *p*-xylene and naphthalene in batch and continuous regimes. The culture system consists of two stages: an immobilized soil bioreactor where an efficient microbial consortium is developed from the indigenous microorganisms (which exists in diesel fuel contaminated soil) serves for inoculating another immobilized cell ALR in which microorganisms were immobilized on the fibers of a membrane (454).

42.8.5 Treatment of Waste Gas

Bioremediation rates of VOCs as air pollutants are limited by the mass transfer rates of oxygen and the low solubility of VOCs into the water phase. The EL-ALRs may provide a well-mixed environment appropriate for this purpose without the need for an impeller. Thus, it has been demonstrated that the use of a stainless steel mesh packing in the riser section of an EL-ALR can improve VOC mass transfer rates compared with an unpacked reactor and provide a large surface area for cell immobilization (252,455). In a recent work, the transient behavior of a DT-ALR for degradation of toluene in a waste gas stream was examined (456). The gas pollutant flowed into the ALR from the bottom, and it was then degraded by microorganisms suspended in the liquid phase. A mathematical integrated model was proposed to describe the dynamic behavior of toluene degradation. The biological removal of ethyl acetate in air streams was also feasible in a DT-ALR using microorganisms immobilized on activated charcoal particles (457,458).

42.8.6 Removing of Heavy Metals

The accumulation of heavy metals in the environment has received special attention because they carry a serious risk to public health and to the environment. The effectiveness of commonly used methods for the treatment of heavy metal-polluted wastes, such as chemical precipitation and ion exchange, remains limited because the large volumes of wastewater do not always meet regulatory standards. This limitation has encouraged the development of technologies to replace or complement conventional techniques. The utilization of microorganisms as biosorbents in ALRs to remove heavy metal ions from wastewaters offers a potential alternative for their detoxification and the recovery and reuse of toxic/precious metals [e.g. Cd(II)] removal from aqueous solution by immobilized waste brewery yeast (459), and hexavalent chromium (460), especially in dealing with large volumes of effluents with low concentrations of pollutants (Zn, Cu, Co, Fe, Al, Ag, Cr, As, and Se) (461).

42.8.7 Food Additives

Sotolone, a flavor widely used in the food and tobacco industries, and precursors may be produce in a meshed DT-ALR from *Trigonella foenum-graecum* root cultures (462). Production of betacyanins, red-violet pigments commercially important as natural dyes, was examined from roots of *Beta vulgaris* L. grown in different types of ALR (463). Vegetative cells of *Haematococcus pluviales* were cultured in a DT-ALR; this microalgal strain produces astaxanthin, a pigment with high antioxidant activity and extensively employed as a pigmentation inducer (464). It has also been demonstrated that ALRs of different configurations can be suitable to culture microalgae and fungi producers of highly valuable polyunsaturated fatty acids (392,465,466).

Commercial preparations of lipases produced from fungi and bacteria grown in ALRs have been proved to be feasible (467,468). Other microbial enzymes of great interest to food industry (e.g. proteinases, proteases, amylases, glucanases) may also be produced in ALRs (469–472).

42.8.8 Wastewater Treatment

As one of the recognized characteristics of ALRs is the potential for scaling-up and the relatively low power consumption for agitation and oxygenation, it is natural that many processes related to wastewater treatment use this type of reactor. Some applications of ALR included below have been reported in processes where the point of interest was simply that the process can be run using an ALR with savings in energy requirements.

42.8.8.1 Starch Processing Wastewater. Starch is a major rough material for the food industry, and starch processing wastewater (SPW) must be treated. Jin et al. (473) used an ALR in a pilot plant system for SPW reclamation by *Aspergilius orizae* and *Rhizopus oligosporus*. The efficient removal of COD, BOD, nitrogen, phosphorus, and suspended solids makes possible the use of reclaimed SPW for farm irrigation with production of α-amylase (<50 EU/mL), a value-added bioproduct. Fungal morphology was a function of ALR fluid dynamics. Free mycelial growth increases the viscosity, limiting the OTR from the gas to the culture. The solution that has been almost universally adopted for this problem—for production of citric and other organic acids and antibiotics—is to find the conditions under which the biomass forms pellets. The advantage in gas–liquid transfer rate, because of the decrease in viscosity, usually outweighs the added transfer resistance stemming from the intraparticle diffusion of oxygen. But the formation of pellets in optimal size and compactness is a very complex matter. Metz and Kossen (474) pointed out the multiplicity of variables and the difficulties of a priori prediction of the operation conditions required. Jin et al. (475) found empirically the optimal gas flow rate in a 4.5-L ALR and was able to scale-up these conditions to a pilot plant 160-L ALR.

42.8.8.2 Domestic Wastewater. The use of suspended solids as a support for a biofilm is gaining popularity in wastewater treatment. Lazarova et al. (476) studied experimentally the fluid dynamics and the performance of a SV-ALR with a rectangular section for wastewater treatment. They carefully studied the influence of suspended solids on gas holdup both in the riser and the downcomer, as well as the influence of the ratio of riser-to-downcomer cross-sectional areas on liquid velocity. Their measurements of mass transfer rate did not reveal important changes with respect to those obtained in water once the biofilm was developed. The main aspect stressed by the researchers was the capacity for nitrification observed in various stages. Bakker et al. (477) immobilized *Nitrobacter agilis* inside κ-carrageenan gel beads and used a cascade of two small-scale ALRs to study the oxidation of nitrite to nitrate. This is an important step in the nitrification process (i.e. the oxidation of ammonia to nitrate via nitrite, usually followed by a denitrification stage with reduction of nitrate to N_2). The use of two bioreactors in series presented some advantages that were attributed to the kinetics of the process (noncompetitive substrate and product inhibition). Because the density of the beads was close to unity, there was no problem in fluidizing of the beads in spite of the small scale. While the basic characteristics of an ALR indicate its advantages for aeration of large volumes of wastewater, the problem of ammonia removal calls for special handling. Two approaches have been presented incorporating the nitrification denitrification element into a basic airlift arrangement. The first one is the already mentioned BASR (58,478) (Fig. 42.30). The conventional airlift with its three phases is enclosed into an additional vessel (extension) that becomes the anaerobic volume. Part of the liquid and suspended biofilm-coated solids overflow the aerobic airlift core and enter the top of the extension, reentering at the bottom. The design allows the control of aerobic/anaerobic times for the biofilm-coated particles suspended in the system to improve the nitrification/denitrification of wastewater. The flow of liquid and suspended solids in the extension, which is the anaerobic volume, can be controlled manipulating the overpressure in the headspace of the reactor. A mathematical model was developed and used for the design of a pilot plant. The experimental results of gas and solid holdups concur satisfactorily with the model. Garrido et al. (479) showed that in the BASE (56) they could manipulate the system to obtain higher nitrite than nitrate, in the presence of both *Nitrosomonas* ($\rightarrow$nitrite) and *Nitrobacter* strains ($\rightarrow$nitrate). They presented a simple model based on diffusion in the biomass film, with homogeneous distribution of microorganisms. At low O_2 tensions, nitrification was improved. The model assumes zero-order reaction for *Nitrosomonas* and Blackman kinetics for *Nitrobacter*.

Zhou et al. and de Kreuk et al. (480,481) evaluated a BASR filled with ceramic materials as biocarriers with different diameters for treatment of domestic wastewater. A mathematical model was proposed to describe the internal liquid circulation. Froude number and superficial gas velocity at different biocarrier concentrations were correlated. The internal liquid circulation velocity was function on the square root of the reactor height and the superficial gas velocity. Because the internal liquid circulation flow rate was much higher than influent flow rate, the BASR showed a great resistance to significant changes in influent organic matter concentration. Resistance increased with the height of a BASR. In comparison with the conventional activated sludge process, the BASR is a promising wastewater treatment process with high efficiency and low operation cost.

Granular growth of sludge is an important matter in aerobic and anaerobic processes of wastewater treatment systems (482). Adequate granulation of sludge implies high settling velocities leading to good solid–liquid separation, high biomass retention, high activity, and an ability to withstand high loading rates. Beun et al. (483) demonstrated that aerobic granular sludge from both heterotrophic and nitrifying bacteria could easily be cultivated in a sequencing batch airlift reactor (SBAR), under stable operation for months. The difference in settling velocity between the granules (fast settling biomass) and the filaments and flocs (slow settling biomass) seemed to be the key factor to obtain granular sludge. The density of the granules in the SBAR was much higher than the density of comparable biofilms in a BASR. Authors attributed this difference to the different operation modes between both ALRs. Probably, selection of granules had been improved by increasing H/D ratio (column height/column diameter), taking advantage of the differences in settling velocity.

Additional advantages of SBARs have been demonstrated in similar applications. Ivanov et al. (484) observed that microbial granules with a diameter from 0.4 to 3.0 mm produced in SBAR, used for model wastewater treatment, were able not only to degrade organic matter but also to remove nano- and microparticles from wastewater due to microchannels and pores in the matrix of the granules. Granulation has also been used for many other processes: Kim and Seo (485) selectively enriched and granulated ammonia oxidizers from wastewater nitrification. Wang et al. (486) studied the effects of operation cycle time on properties of aerobic granules in SBARs using synthetic wastewater. Wang et al. (487) also demonstrated the efficacy of SBAR to treat brewery wastewater.

The composition of the microbial population may also be manipulated. Kim and Kim (488) used a continuous biofilm ALR and a SBAR for demonstrating the hypothesis that species of genus *Nitrospira* are K-strategists (it can exploit low amounts of nitrite more efficiently than *Nitrobacter*) and *Nitrobacter* species are r-strategists that can grow faster than *Nitrospira*. Genus *Nitrospira* and *Nitrobacter* species are the key nitrite-oxidizing bacteria in nitrifying wastewater treatment plants.

A different approach to the integration of nitrification–denitrification in a wastewater treatment process is the one presented by Merchuk and Shechter (489). They present an approach aiming at the upgrade of existing wastewater treatment plants rather than de novo design. The experiments presented were obtained in a 230-m^3 aeration basin that was divided into nine sections. Seven of these were converted to airlift operation, with two anaerobic sections. In this case, therefore, the system is a once-through aerobic/anoxic/aerobic/anoxic/aerobic sequence, with options of recirculation for improved denitrification. The conceptual difference between this approach and the BASE system is that the biomass is not recirculated and remains stationary in each of the nine stages, because solids circulate in each airlift stage, but only liquid passes from one stage to the other. In the BASE approach, all the biofilm-coated particles transit cyclically both aerobic and anaerobic sections.

42.8.8.3 Xenobiotics. Many organic sulfonates considered xenobiotic compounds (e.g. benzene and naphthalene sulfonates) that are used as intermediates or obtained as byproducts in the manufacture of several chemical products (e.g. dispersants, detergents, and azo-dyes) may appear in wastewater streams from these industrial processes. They are in general scarcely biodegradable (490). Their biological oxidation is carried out by slow-growing microorganisms, requiring a long retention time inside the reactor, resulting in large volumes required to complete the degradation and large areas to be occupied by the treatment device.

ALRs have provided satisfactory results (12,309). These reactors allow biomass retention at high dilution rates, thus enabling high reactor biomass concentrations to be achieved without the need of biomass separation and recirculation as in the activated sludge process. Wagner and Hempel (491) used a biofilm EL-ALR to study the biodegradation of naphthalene-2-sulfonate with *Pseudomonas* sp. Recently, Nicolella et al. (492,493) used an IL-ALR to degrade a mixture of aromatic sulfonates with biofilms generated from industrial sewage sludges. The degradation rate observed in the ALR was higher than that in the activated sludge process installed at the industrial site producing the leachate.

The biodegradation of an azo dye typical of textile, paper-making, and cosmetic industries by means of *Pseudomonas* sp. OX1 was studied by Lodato et al. (494). The culture system was a conventional internal ALR operated in batch and fed-batch modes with respect to the liquid phase, continuously with respect to the gas phase, and batchwise with respect to the biomass phase. Assadi et al. (495,496) used *A. niger* and *Phanerochaete chrysosporium* for textile wastewater treatment (biological decoloration) in an ALR.

42.8.8.4 Metal Refinery Wastewater. Metal refinery wastewater (MRWW) contains high amounts of metal-bound nitrogen species. Biological treatment methods routinely adopted for municipal wastewater nitrification/denitrification are hardly applicable to treatment of MRWWs. Metal complexes in MRWW alter or occupy the active sites of nitrification and denitrification enzymes, complicating its treatment (497). Manipura et al. (498) compared a CSTR, an DT-ALR, and a packed bed reactor (PBR) for removing ammonium from MRWW. The efficiencies were $>85\%$ in all cases.

42.8.8.5 Toilet Wastewater. As most of the ammonia or phosphorus, and a significant part of organic pollutants in domestic wastewater, come from toilet wastewater, mainly in big cities, this is becoming a problem of special interest. Fan et al. (499,500) have developed a novel full-scale MBR named airlift external circulation membrane bioreactor (AECMBR) to treat toilet wastewater for reuse. AECMBR has the advantages of the conventional cross-flow MBRs and the submerged MBRs. As there is no recycling pump in AECMBR, the energy consumption and operation cost are lower. The membrane cleaning or maintaining can be done online or only in the membrane tank without interfering with the aeration tank.

42.8.8.6 Phenol Biodegradation. Phenol and their derivatives are one of the most highly toxic water pollutants (501). Many attempts are being devoted to explore the efficiency of bioreactors in the treatment of wastewater-containing phenol. IL-ALR has been used with success. Rao et al. (502) found that the biodegradation of phenol under the application of a superimposed magnetic field was faster in airlift bioreactor than that in BC. Quan et al. (503) developed a packed DT-ALR, with honeycomb-like ceramic as the carrier to immobilize *Achromobacter* sp., for simultaneous phenol and 2,4-dichlorophenol biodegradation under fed-batch and continuous operations. Viggiani et al. (504) addressed phenol biodegradation with *Psudomonas stutzeri* OX1 by continuous operation of a bench-scale biofilm three-phase reactor operated in the IL-ALR mode.

Jia et al. (505) have recently proposed a mathematical model for simulating the dynamic behavior of batch phenol biodegradation processes in a DT-ALR using *C. tropicalis* freely suspended cells. Fluid dynamics, mass balances, and kinetics were satisfactorily coupled in the model. Loh and Liu (383) used an EIFBAB for treatment of high strength phenolic wastewater. To control the oxygen transfer, they used the increase in gas holdup that they got by closing a valve in the downcomer and restricting liquid circulation. The range of variation in their device goes in fact from holdup in an airlift with unrestricted circulation to the holdup in a BC, for similar diameters and gas superficial velocity. Obviously, the case of a completely closed valve implies that the downcomer volume will not contribute to the process. Later, Loh and Ranganath (384) integrated a fluidized bed of granular activated carbon into the EIFBAB for the enhanced cometabolic biotransformation of 4-chlorophenol (4-cp) in the presence of phenol as a growth substrate.

42.8.8.7 Wastewater from Fertilizer Production. The chemical fertilizer industry generates effluents with enormous loads of NH_4-N and COD. Its environmental impact on aquatic environments has been clearly established. Removal of NH_4-N by biological nitrification is a widely used process in wastewater treatment. Appropriate bioreaction conditions need to be handled to obtain a full conversion of NH_4-N to nitrate. Airlift bioreactors appear to meet these requirements. Wen et al. (506,507) used a 80-m^3 pilot-scale three-phase ALR consisting of several internal draught tubes and a low ratio of height-to-diameter, in which a biological membrane (bacteria attached onto the carriers) replaced the activated sludge, for nitrifying treatment of a real effluent from a fertilizer plant. The influences of the ratio of bed (settled) volume to bioreactor volume, superficial air velocity, hydraulic residence time, and pH value on ammonia nitrogen and COD reduction were analyzed. Under the optimum operating conditions, the COD and NH_4-N in the effluent were far below the primary discharge standards for the chemical fertilizer industry in the People's Republic of China. The sludge waste generated by this biotreatment system was significantly inferior to that from traditional activated sludge process. The same authors previously experimented with a laboratory-scale ALR of an only draught tube and similar results were obtained (508). Liu et al. (13) have also used satisfactorily a 170-m^3 pilot-scale three-phase ALR for aerobic biotreatment of the refinery wastewater. The bioreactor produced only one third of the sludge waste generated in the traditional activated sludge process.

42.9 SUMMARY

ALRs are suitable for the particular characteristics of biological processes where high mass transfer rate is required, but excessive power input may lead to damage of the cells due to shear effects. ALRs also have very appealing characteristics for bioprocesses for low value products in which efficiency of energy utilization is essential for design. Such is the case for ALRs for wastewater treatment. The ALR is particularly effective for solid fluidization, which is important in many biological processes in which the biocatalyst is in the form of pellets or immobilized on a solid support.

The distinctive characteristics of ALRs are conferred by the fluid dynamics of the liquid–gas or liquid–gas–solid mixtures in it. These characteristics are expressed as gas holdup, liquid velocity, and mixing in each of the zones of the ALR. It is important to recognize the differences in the fluid dynamic characteristics of these zones: the riser, the gas separator, and the downcomer. Only a correct understanding of behavior and interconnection of these regions can make possible the correct design of a new reactor or the scale-up of a laboratory device up to pilot or industrial size.

The purpose of scale-up is to conserve and repeat on a larger scale the fluid dynamics of the reactor. Therefore, one of the most important factors in the design and scale-up of reactors is the influence of the geometric characteristics of the system on the flow of the different phases present. The variables affecting the performance of the reactor are geometric design, operation variables, and fluid properties. Several correlations are available for predicting the fluid dynamic characteristics of the reactor (gas holdup, liquid velocity, and mixing time of axial dispersion coefficient) and the mass and heat transfer coefficients. Significant progress has been done in the application of computational tools to the simulation and design of ALRs. In parallel, innovative and sophisticate methods have been applied to obtain a deeper insight into the mechanisms of fluid motion and the flow patterns in the reactor. Although attempts have been made to study all the aspects described, no single research group has managed to cover all the variables over a wide range. It is therefore extremely important that the engineer confronting scale-up or de novo design of an ALR analyzes in depth the range of validity of the correlations and computation methods used for the calculations.

LIST OF ABBREVIATIONS

AECMBR	airlift external circulation membrane bioreactor
ALR	airlift reactor
ANN	artificial neural network
BASR	biofilm airlift suspension reactor
BC	bubble column
BPNN	back-propagation neural networks
CFD	computational fluid dynamics
CMC	carboxymethyl cellulose
DT	draft, draught, or concentric tube in ALR
SV	split vessel
EL	external loop
EL-IALR	external loop inverse fluidized ALR
ERT	electric resistance tomography
GLAD	gas lift advanced dissolution
ICR	internal circulation reactor
IL	internal loop
IL-IALR	internal loop inverse fluidized bed ALR
LDV	laser Doppler velocimetry
MRWW	metal refinery wastewater
PPBR	particle-based biofilm reactors
RTD	residence time distribution
RSV	rectangular split vessel
SBAR	sequencing batch ALR
STR	stirred-tank bioreactor, fermenter, or reactor
VOC	volatile organic chemical

NOMENCLATURE

a	interfacial area ($m - 1$) or constant in Equation 42.8
A	cross-sectional area ($m - 2$)
B	heat transfer area (m^2)
Bo	bond number or Bodenstein number
C	concentration (mg/L), fiction losses coefficient
Ca	capillary number
C_b	bottom clearance (m)
C_t	top clearance (m)
C_d	hydraulic resistance coefficient
C_o	distribution parameter
C_p	heat capacity of liquid (J/K/K)
C^*	equilibrium concentration (mg/L)
d	diameter (mm)
d_0	diameter of the sparger orifice (m)
d_{32}	Sauter mean diameter (m)
D_L	diffusivity (m^2/s)
D_z	axial dispersion coefficient (m^2/s)
E	energy (J)
f	friction factor
F_f	filling factor
F_r	Froude number
g	gravitational constant (m/s^2)
Ga	Galileo number
h	height (m)
h_w	overall heat transfer coefficient ($W/m^2/s/K$)
I	degree of homogeneity
J	superficial velocity, volumetric flow density (cm/s)
K_b	hydraulic coefficient bottom
k	thermal conductivity of liquid (W/K/m) (Eq. 42.49)
k_La	volumetric mass transfer coefficient ($h - 1$)
K_t	hydraulic coefficient top
L	loop length, characteristic length (m)
M	wetted surface parameter, constant in Equation 42.29
Ma	bubble coalescence parameter
Mo	Morton number
n	flow index
n_i	number of bubbles with diameter d_i
N	agitation speed ($s - 1$)
Nu	Nusselt number
N_W	power consumption function
OTR	oxygen transfer rate ($mol/m^3/s$)

P pressure (Pa), power input (W)
Pe Peclet number
Pr Prandtl number
Q volumetric flow rate (m^3/s)
Re Reynolds number
S surface area (m^2)
Sc Schmidt number
Sh Sherwood number
t time (s)
U velocity (m/s)
U_b bubble terminal rise velocity (m/s)
$U_{b\infty}$ single bubble rise velocity (m/s)
U_c cell circulation velocity
U_{GS} gas slip velocity
U_L overall liquid circulation velocity (m/s)
U_{GJ} weighted mean drift velocity (m/s)
V volume (m^3)
We Weber number
Wi Weissenberg number
W_s shaft work done by the surroundings on the system

BIOREACTORS, CONTINUOUS CULTURE OF PLANT CELLS

H.J.G. Ten Hoopen
Delft University for Technology, Delft, The Netherlands

43.1 INTRODUCTION

The first suspension culture of plant cells in a nutrient solution was reported in 1954 by Muir (1). Only two years later cultures of plant cells in bioreactors were carried out by Melchers and Engelmann (2). Bioreactors can be employed in batch, fed batch, or continuous mode. In a continuous culture, the nutrients consumed by the organisms are continuously replenished by an inflow of fresh medium. In most cases the culture volume is kept constant by an equal outflow of the cell suspension (Fig. 43.1). Stable steady states can be achieved at dilution rates (flow rate/volume) smaller than the maximum specific growth rate of the organism, as predicted by mathematical derivation. Intuitively, it is understandable that steady states occur, because the limiting nutrient concentration and the biomass growth are coupled in a stable control cycle: Increasing nutrient concentration stimulates growth resulting in increased biomass concentration, but increased biomass concentration decreases the limiting nutrient concentration. In a steady state, all concentrations (biomass, biomass composition, and nutrients) are constant. The biomass concentration in the culture is controlled by the concentration of the growth-limiting nutrient in the medium; the average specific growth rate in the culture is identical with the dilution rate. This "balanced growth" in the chemostat is a very attractive tool in physiological studies or in research on growth and production kinetics. It provides an experimental system with completely controlled conditions. In fact, it is opposite to batch culture, where all conditions are continuously changing. (In specific cases this may be advantageous; for example, nongrowing cells in the stationary stage can only be studied in a batch culture.) Furthermore, in continuous culture it is possible to study a cell culture under various limitations (carbon, nitrogen, or phosphate source). Continuous culture could be attractive for industrial fermentations too because of the relatively long run times compared to short down times in the production process. However, the number of current applications in the fermentation industry is rather small. The most common type of continuous culture, controlled by the influent flow, is more specifically called a *chemostat.*

A different approach of running a continuous culture is by monitoring the biomass concentration and controlling the influent/effluent rate by this parameter. The monitoring device used is a turbidimeter, and the system is called *turbidostat*. A disadvantage of this system is that the tubidimetric biomass determination is not very reliable, because of its sensitivity for changes in cell or aggregate size. Phototrophic biomass uses light as an energy source. Therefore, phototrophic cultures can be grown in continuous culture with light as the limiting "nutrient." The concept of this photostat has several specific features, such as the correlation between cell density and light absorbance. In a low-density culture part of the "nutrient" light is lost through the glass wall or absorbed by the wall of the vessel. This makes the theoretical and practical basis considerably different from the chemostat. Phototrophic plant cell cultures are not very common. Therefore, only the chemostat will be discussed in detail. Some publications refer

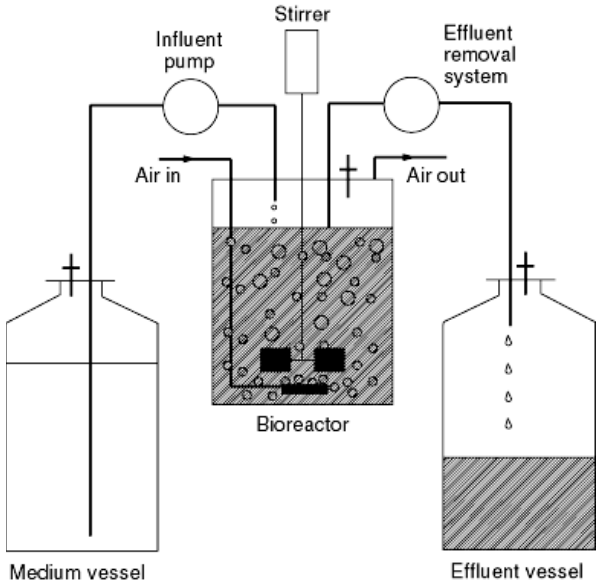

Figure 43.1. Basic setup of continuous culture.

to continuous culture systems, if the medium flow is continuous but the biomass is retained in the culture vessel (perfusion cultures, hairy root cultures, immobilized cells). These systems are not discussed here.

The number of applications of continuous culture of plant cells is small compared to continuous cultures of bacteria and yeasts. There are several reasons for this difference. Plant cells in suspension culture have some characteristics that complicate the performance of a continuous culture. The low specific growth rate of plant cells (generation times usually between 20 and 60 h) means that it takes a long time to reach a steady state; the total duration of an experiment can extend from some weeks up to more than a year. The risk of calamities (contamination, equipment failure) is then, of course, considerable. On a volume basis, plant cells are up to 200,000 times larger than bacteria and may have a relatively high specific density because of the formation of intracellular starch. Furthermore, in a plant cell culture there will be always some aggregate formation. The size of these aggregates can vary widely with the cell line and the environmental conditions, but it can be up to several millimeters in diameter. The large and "heavy" cells and aggregates tend to settle in the reactor. Another problem is the sticky character of several cell lines and the excretion of sticky and viscosity-increasing polysaccharides. This makes it difficult to maintain an ideally mixed suspension, a prerequisite for continuous culture.

In subsequent sections, practical problems and pitfalls in the setup of the continuous culture, the design of continuous culture equipment, the mathematical description of the continuous culture, and a literature survey will be discussed, all with an emphasis on plant cells in suspension culture.

TABLE 43.1. Assumptions in the Operation of Continuous Culture

Assumption	Points of concern
Continuous feed	Addition by drops
All biomass in suspension and ideally mixed	Wall growth, settling, buoyancy
Biomass in reactor and effluent equal (100% efficiency)	Effluent removal device
Biomass in steady state	Intracellular adaptation
Limiting factor defined	Defined media, validation

43.2 ASSUMPTIONS IN CONTINUOUS CULTURE THEORY AND THEIR PITFALLS

Continuous culture theory is built on a set of assumptions (Table 43.1). The inflow of fresh medium into the well-mixed culture should be continuous. All cells in the culture should face the same environmental conditions, particularly the concentration of the growth-limiting component. However, in most cases influent is added dropwise at one place in the culture, hence discontinuously in time and place. After addition to the culture, nutrients are diluted by mixing, taken up by the cells, and metabolized. The problem of the discontinuous addition can be analyzed by a comparison of the characteristic times of the involved mechanisms: addition, mixing, uptake, and metabolic conversion. When the characteristic time for uptake is short compared to the mixing time, a drop of medium serves only a part of the culture. This effect is smoothed if the mixing time is short compared to the metabolic conversion time: All cells will pass through a relatively nutrient-rich zone before starvation will occur. However, a fast uptake of the limiting nutrient and a slow metabolic conversion causes a relatively high nutrient concentration in the cell; this could trigger alternative metabolic pathways like formation of storage products or production of secondary metabolites, especially in the case of plant cells.

Another assumption in continuous culture theory is that the biomass suspension is ideally mixed. Then the biomass concentration in the vessel and in the effluent are equal. As already mentioned in the introduction, this is a critical point with plant cells. This assumption can be checked by estimating the *effluent efficiency*. This efficiency is 100% if the biomass concentration in the vessel and in the effluent are equal. Inadequate mixing in the culture vessel is caused by three phenomena: wall growth, settling, and buoyancy. The effect (decrease) on the effluent efficiency is increased by the use of an inadequate effluent removal system. It is more common than realized, not only in plant cell cultures. Noorman *et al*. (3) analyzed the kinetic consequences of nonideal mixing.

The biomass in a continuous culture is assumed to be in steady state. However, multicompartment plant cells

may require a relatively long intracellular adaptation time to reach balanced growth and steady-state biomass composition compared to bacteria. After a change in conditions it takes roughly 5 residence times [= 5/dilution rate, where dilution rate = flow (m^3/s)/volume (m^3)] to reach a steady state if hydrodynamics is the ruling mechanism. In plant cell cultures, where the intracellular adaptation might be controlling, there are examples known where as many as 12 residence times were needed to attain a constant biomass composition in a phosphate-limited continuous culture.

The growth-limiting factor in continuous culture studies is always assumed to be known, but analysis of such experiments may reveal scepticism about this. A completely defined medium is advantageous, and medium components such as coconut milk should be avoided. A distinct test of the limiting factor is to decrease the concentration of the apparent limiting component; if this results in a proportional change in the biomass concentration, the assumption is correct.

43.3 THE PRACTICAL SETUP OF A CONTINUOUS CULTURE

The concept of the continuous culture as described in the introduction can be translated into the basic design (Fig. 43.1): a culture vessel with an ideally mixed cell culture, a medium vessel for the addition of fresh medium through the influent pump, and an effluent system (a pump or an overflow device) connected to a waste vessel. The influent pump controls the dilution rate; the effluent system is designed in such a way that the volume remains constant for example through the level of the outlet tube. Many additions to and modifications of this setup are possible, dependent on the particular application. A culture of aerobic organisms needs an aeration system. Probes for online measurements of volume, temperature, pH, redox potential, and foam development can be attached. Control systems based on the sensor signals to control volume, temperature, pH, and foam level may be installed. Online analysis equipment to determine the influent and effluent gas composition and essential medium components are very useful. A sampling device for off-line analysis of the broth is in fact essential. A condenser to avoid loss of water from the culture vessel by evaporation is especially recommended for slow-growing organisms, such as plant cells. In these cultures the evaporation can be considerable in comparison with the medium flow through the system. Several modifications have been reported on the aeration and stirring systems. In the case of plant cells the objective is to achieve sufficient mixing of the culture without damaging the cells. Aeration and stirring generate hydrodynamic (shear) stress in the reactor. Therefore, the applicability of stirred tank reactors have been disputed for several years. However, Scragg *et al*. (4) and Meijer *et al*. (5,6) demonstrated that cells from various plant species are relatively shear tolerant. They concluded that large differences in shear sensitivity exist among plant cell lines, and that stirred tank reactors in most cases are the best choice for plant cell cultures. An option to reduce the negative effects of shear stress imposed by the impeller in a stirred tank can be achieved by modifying the design of the routinely used Rushton turbine impeller. Among those modified impellers are the hollow paddle (7,8), the marine (9), the cell lift (9,10), the large flat blade (11), and the helical-ribbon (12) impeller.

The effluent system needs special attention in continuous cultures of plant cells. As mentioned before, plant cells settle and stick to themselves and the culture vessel relatively easy. In combination with the low flow rates in a continuous culture of plant cells (because of the low growth rate), this makes the common effluent systems fail. These systems remove effluent from the surface of the culture, either by an overflow device, or an effluent pump through a level tube. Application of this system in a plant cell culture causes a low effluent efficiency, because the surface of the culture shows a difference in composition with the average of the culture due to settling or buoyancy. Furthermore, the cells will stick and eventually block the effluent tubing, especially because of the low flow rates in continuous culture of plant cells. Van Gulik *et al*. (13) developed an outflow device avoiding these problems (Fig. 43.2). The objective was to design a system that removes effluent from an optimally mixed section of the reactor (close to the stirrer) and at a high flow rate to avoid sticking or settling in the tubes. To achieve this the outflow device operates discontinuously. At regular time intervals a pneumatic valve system forces the effluent under air pressure into the waste vessel at a high flow rate. The timing is such that the culture volume stays within 1% of the set point. The effluent efficiency of this system was tested and approached the theoretical maximum of 100%.

The sticky and foamy character of some cell cultures makes it difficult to keep the cells inside the broth: They tend to form a layer above the suspension. Bertola and Klis (14) attacked this problem by the use of short periods of increased stirrer speed at regular intervals. Cells were taken up in the suspension again, and no cell damage was observed. Another way to avoid this problem is to leave out as much as possible objects protruding through the culture surface, such as baffles and probes. A double-wall bioreactor with sensor ports on the bottom is advantageous from this viewpoint. The wall can be cleaned either by shaking the culture vessel daily, or with a magnetically activated cleaner. Foam can be controlled by addition of antifoam substances, either at regular time intervals based on observation of the foam development, or controlled by a foam sensor. Bond *et al*. (15) published a study on the effect

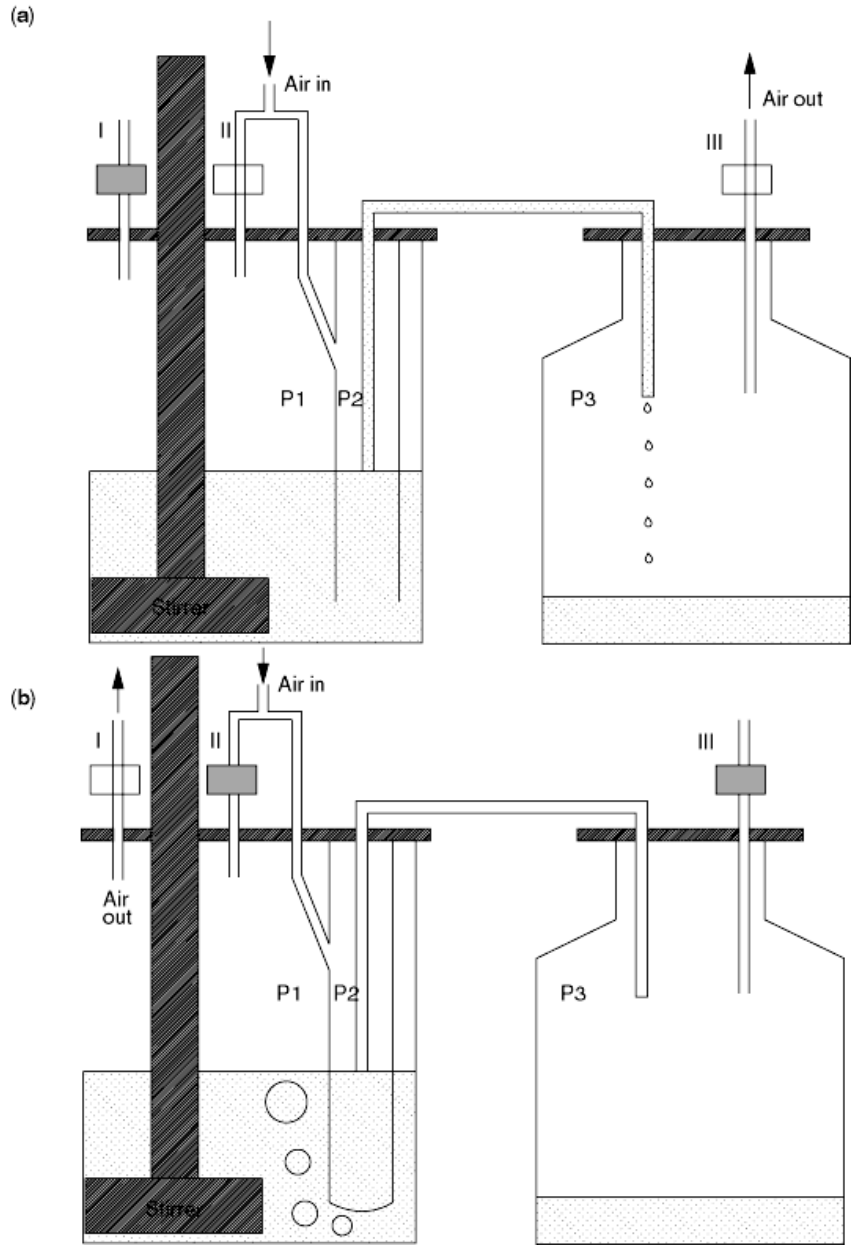

Figure 43.2. Principle of the effluent removal system. P1 = pressure inside the headspace of the reactor, P2 = pressure inside the effluent removal tube, and P3 = pressure inside the headspace of the effluent vessel. (**a**) When valve I is closed while at the same time valves II and III are opened, this will cause pressure P2 being equilibrated with pressure P1, resulting in a rise of the culture fluid in the effluent removal tube. Because of the aeration of the reactor, P1 (=P2) will exceed P3, resulting in withdrawal of all culture fluid above the inner tube. (**b**) If valve I is open and valves II and III are closed, a small stream of air keeps the effluent removal tube empty to avoid wall growth and clogging. In this case pressure P2 (=P3) exceeds P1 (13).

of antifoam on plant cells. The tested antifoam substances appeared not to harm the plant cells under normal experimental conditions. A point of general concern in continuous culture is of course the maintenance of aseptic conditions. High-quality equipment is a first prerequisite, particularly with the long run times of the continuous culture. A thorough leak test before sterilization is essential. In general, membrane filters are excellent to prevent contamination. However, it should be realized that the amount of aeration gas passing through the bioreactor during the culture period

is huge. Therefore, it is advisable to extend the contamination prevention in the air inlet with a large cottonwool depth filter. Membrane filters may be clogged by moisture. To avoid blowing up the equipment in such a case, because of the pressure of the air inlet line, it is essential to build in some safety device. An inexpensive safety measure is to provide a relatively loosely connected tube in the setup.

43.4 MATHEMATICAL DESCRIPTION OF CONTINUOUS CULTURE

The formulation of unstructured models of fermentation processes is comprehensively treated in textbooks on biotechnology (16,17). Here, only a few very general aspects are presented. The basis of these models is a set of balance equations for extensive properties. The general form of the balance equation is:

$$\begin{aligned}\text{rate of accumulation} = {} & \text{rate of inflow} - \text{rate of outflow} \\ & + \text{formation rate} \\ & - \text{consumption rate}\end{aligned}$$

The extensive properties considered to be important in the case of continuous culture of plant cells will be viable biomass X, nonviable biomass, limiting substrate S, and product. Nonviable biomass and product can be left out if the concentrations are negligible. This set of equations is completed with kinetic rate equations for biomass growth, biomass decay, substrate consumption, and product formation. As an example the general balance for biomass read (See end of chapter for nomenclature):

$$d\frac{VX}{dt} = F_i X_i - F_o X_o + V r_X - V r_d \tag{43.1}$$

In a standard chemostat the biomass concentration in the influent is zero. With the assumption that the death rate of the biomass may be neglected, and realizing that the accumulation term in a steady-state situation is zero, Eq. (43.1) becomes:

$$0 = -F_o X_o + V r_x \tag{43.2}$$

Introduction of the dilution rate D and the specific growth rate μ in Eq. (43.2):

$$D = \frac{F}{V} \tag{43.3}$$

$$\mu = \frac{r_x}{X} \tag{43.4}$$

gives the important correlation:

$$\mu = D \tag{43.5}$$

This illustrates the characteristic of the chemostat that the average specific growth rate can be controlled by setting the dilution rate.

By introduction of relations for r_X and r_s, the system is completely described. The commonly used growth expression is the Monod equation:

$$r_X = \mu X = \mu_{\max}\frac{S}{S + K_s}X \tag{43.6}$$

where $\mu_{\max}$ is the maximum specific growth rate and K_s the saturation constant. Substrate is assumed to be used for growth and for maintenance purposes of the biomass according to the expression:

$$r_s = q_s X = \left(\frac{\mu}{Y_{SX}} + m_s\right)X \tag{43.7}$$

Y_{sx} is the true yield of biomass on substrate and m_s gives the substrate consumption for maintenance processes. Worked examples of Eqs. (43.6) and (43.7) are depicted in Figure 43.3. The parameters used are typical of plant cells. On the curve of r_x it is shown that at a substrate concentration equal to the saturation constant K_s the growth rate has half the value of the maximum growth rate. The curve of r_s shows a shortcoming of the model used at substrate concentration 0; there is still substrate consumption although there is no substrate available. This situation is better described by a different concept, where the maintenance energy is provided by endogenous respiration of biomass. With the introduction of the Eqs. (43.6) and (43.7) the set of equations describing the growth of an organism

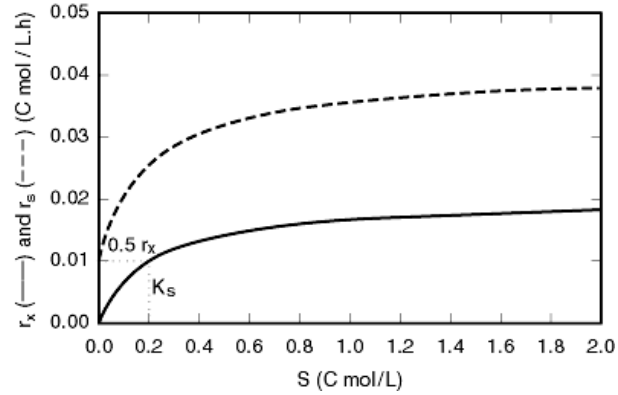

Figure 43.3. Growh rate r_x (—) and consumption rate r_s (- - -) versus limiting substrate concentration S [Eqs. (43.6) and (43.7)]. Parameters used $\mu_{\max} = 0.02\ h^{-1}$, $K_s = 0.2$ C mol/L, $Y_{sx} = 0.65$ C mol/C mol, $m_s = 0.01\ h^{-1}$, $X = 1$ C mol/L.

in continuous culture is complete. The biomass and the substrate concentration can be solved as a function of the dilution rate D, resulting in:

$$X = \frac{D(S_i - S_o)}{D/Y_{SX} + m_s} \tag{43.8}$$

$$S = \frac{k_s D}{\mu_{\max} - D} \tag{43.9}$$

These solutions still contain the organism-dependent parameters Y_{sx}, m_s, and K_s.

The yield Y_{sx} and the maintenance coefficient m_s can be determined from a series of continuous culture experiments at various dilution rates. An example of Eqs. (43.8) and (9) is plotted in Figure 43.4. At low dilution rates (= specific growth rates), the substrate consumption for maintenance is relatively important, resulting in a low apparent yield of biomass on substrate. At high dilution rates near the maximum specific growth rate, the culture starts to wash out, resulting in biomass concentration zero and maximal unconsumed substrate concentration. Van Gulik *et al*. (18,19) used this model extended with balance and rate equation for product formation and validated this model in a comprehensive continuous culture study. They could fit their experimental data roughly with this model and could estimate the organism-specific parameters. However, statistical analysis revealed that this model was certainly not a perfect description of a plant cell culture in continuous culture. Important observations were that although the carbon source was presumed to be the limiting nutrient, the phosphate concentration was always almost zero in the broth, and that the cells formed internal storage polysaccharides ("starch") in a dilution-rate-dependent quantity. On the basis of these observations van Gulik *et al*. (19) developed a structured

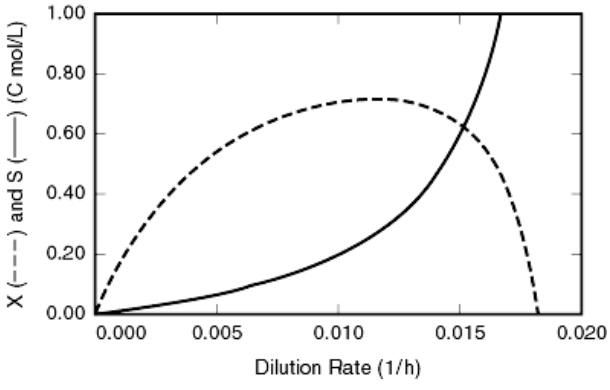

Figure 43.4. Biomass concentration X (- - -) and limiting substrate concentration S (—) versus dilution rate D in a chemostat [Eqs. (43.8) and (9)]. Parameters used S_i = 2 C mol/L; for other parameters see Figure 43.3.

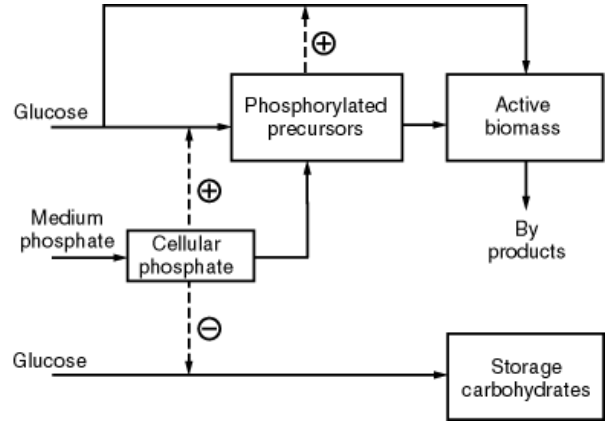

Figure 43.5. Schematic representation of the structured growth model (19).

model as depicted in Figure 43.5. The biomass was divided into two compartments: the active biomass part where all the biochemical activities take place, and the storage compartment containing the storage polysaccharides. The flow of material between medium and active biomass compartment, and between active biomass and the storage compartment, was controlled by the external carbon source and the internal phosphate concentration. This model is considerably more complex than the basic model mentioned previously. It includes 7 balance equations, 9 rate equations, and 15 unknown parameters. The number and structure of the equations is not a problem; it can be simulated by a computer. However, for a validation of the model it is necessary to have estimates of the real values of the parameters. A sensitivity analysis of the parameters revealed that only 7 of them were important. These parameters were either determined or obtained from the literature. Three parameters were optimized by fitting the experimental data with the model equations. The results of continuous culture and batch experiments were used to validate the model. It presented a satisfactory description of both type of experiments.

43.5 APPLICATIONS OF THE CONTINUOUS CULTIVATION OF PLANT CELLS

The earliest attempts to set up a continuous culture of plant cells were published by Tulecke (20) in 1966 and by Miller *et al*. (21) in 1968. These studies have only historical value, because the authors could not achieve any steady states. The systems developed by Wilson *et al*. in 1971 (22), Kurz (23), and Wilson (24) are more important, because these designs have been used in several other studies. The chemostat system of Wilson (22) consisted of a round-bottomed Pyrex flask with a volume of 4 L. The culture was aerated through a sintered glass sparger, and mixing of the

culture broth was accomplished by means of a magnetic stirrer. Effluent was withdrawn using a specially designed system consisting of a valve, controlled by an constant-level device. They achieved steady-state growth of *Acer pseudoplatanus* cells at several dilution rates. Kurz (23) designed a chemostat that was rather unique in its mixing and aeration system. A small and long cylindrical vessel is mixed and aerated by large air bubbles filling up the diameter of the tube rising at regular intervals from the bottom of the cylinder. Influent was introduced at the bottom, and effluent was removed through an overflow device at the top. A different air-mixed chemostat culture system was used by Wilson (24). This relatively simple chemostat was made of an inverted erlenmeyer flask. Mixing and oxygenation of the culture were accomplished by forced aeration. Also in this design the effluent was withdrawn by means of an overflow tube. Unfortunately, Sahai and Shuler (25) concluded in a detailed study that the outflow efficiency of these systems is below 100%. This makes the quantitative results of these investigations relatively useless. However, several studies using these setups showed at least that continuous cultures of plant cells could be carried out under carbon, nitrogen, and phosphate limitation. The work done by de Gucht and van der Plas (26) is an exception. They used the Kurz chemostat, but were aware of the problem of the outflow efficiency and took it into account in their calculations. They achieved six steady states with a culture of *Petunia hybrida* cells. From their experimental data they estimated the maintenance and true yield of biomass on glucose and ATP.

Bertola and Klis (14) reported the use of a continuous culture system that was based on a 2-L standard turbine-stirred fermenter and the outflow system designed by Wilson (22). These authors published glucose-limited chemostat cultures of *Phaseolus vulgaris* cells. They determined the outflow efficiency to be 53%. After some modifications the outflow efficiency was improved to 80% (27). Their results were corrected for the outflow efficiency of the chemostat system. Van Gulik *et al*. (18,19) used a comparable system, but with a more sophisticated outflow device and coupled gas analysis equipment. Combination with off-line analysis of the spent medium and the biomass provided the opportunity to check their experimental data with elemental balances. Results of these investigations have been mentioned.

The aim of these studies was mainly the formulation and validation of models describing growth kinetics. The application of continuous culture for production of secondary metabolites has not been investigated extensively. In most cases secondary product formation is considerably depressed under growth conditions. Sahai and Shuler (28) proposed a multistage continuous culture system with variation in growth rates to create optimal conditions for both growth of the biomass and product formation. Lima Costa (29) investigated the production of an extracellular protease by a cell culture of *Cynara cardunculus* in continuous culture. The production of this protease was growth coupled, and continuous culture appeared superior to batch culture in this particular case.

NOMENCLATURE

D	dilution rate (1/s)
F	flow (m^3/s)
S	substrate concentration (kg/m^3)
X	biomass concentration (kg/m^3)
V	volume (m^3)
K_s	saturation coefficient (kg/m^3)
Y_{sx}	true yield (−)
m_s	maintenance coefficient (1/s)
r_d	death rate (kg/m^3/s)
r_s	substrate consumption rate (kg/m^3/s)
r_x	growth rate (kg/m^3/s)
q_s	specific substrate consumption rate (1/s)
μ	specific growth rate (1/s)
μ_{max}	maximum specific growth rate (1/s)

BIOREACTORS, FLUIDIZED-BED

WINFRIED STORHAS
Department of Technical Microbiology and Biochemical Engineering, Mannheim University of Applied Sciences, Mannheim, Germany

44.1 HISTORY AND INTRODUCTION

44.1.1 Background and Development

Nearly 90 years ago, on September 28 1922, the first patent for a fluidized-bed reactor (FBR) was applied. The applier was, BASF, the Chemical Company. The purpose was for coal gasification, a long way from any biotechnological purpose (1). Nevertheless, this technology has classic applications in the modern mammalian cell biotechnology as well (2).

Solid–liquid FBRs are also very widely distributed in ion-exchange technology and drinking water preparation as well as in wastewater treatment.

Coming from the very simple concept of a fixed bed, the fluidized bed should help to eliminate all the disadvantages such as channel-forming, resulting in a nonhomogeneous bed, reduced efficiency, reduced heat transfer, a tendency to block, and reduced replacement of dead cells.

Fluidized-bed technology presents several advantages, with the only disadvantages being a larger volume and abrasion of cells from the surface of beads. In some cases, this abrasion can be an advantage when the thickness of the biofilm has to be controlled.

It has to be remembered that high-tech development and application started before biotechnology became important in modern industry. There was a time before this!

A lot of historical papers (publications) dealing with FBRs, which are still up-to-date have been cited in this chapter. Nevertheless, this traditional and well-tried technology is validated by current research and publications (papers). This chapter deals only with homogeneous particulate liquid fluidization.

44.1.2 Introduction

Biotechnological processes use any kind of enzyme available as catalysts for biotransformation. Most are available only in living, complete, and active cells, but if it is possible to isolate the only enzyme responsible, it could be a step toward becoming an economically viable process. Since enzymes are soluble in water and other solvents, they are used in homogeneous catalysis. There are different ways to fix enzymes. One uses physical and chemical properties (forces) such as physical adsorption, covalent chemical binding, cross-linking, or complete encapsulation in a gel (Fig. 44.1). A very common technique is the chemical reaction using covalent binding as shown in Fig. 44.2. Usually after an immobilization procedure, some activity gets lost but greater temperature, pH and other media concentration stability can be achieved as well longer duration. There are a lot of biotransformations of industrial importance, which use immobilized enzymes as catalysts (3).

Using immobilized enzymes in a bioreactor offers the possibility to retain the enzymes inside the reactor. Immobilized enzymes (fixed onto carriers) bring not only easier reusability (recycling) but also more stabile enzymes (Table 44.1 and Fig. 44.2) for longer process operation.

A suitable concept to handle economic carrier systems is FBR. These types involve a lot of processes which can be very advantageous regarding mass and heat transfer. The obvious advantages in such a system are:

- higher active surface of the particle,
- good conditions for heat and mass transfer,

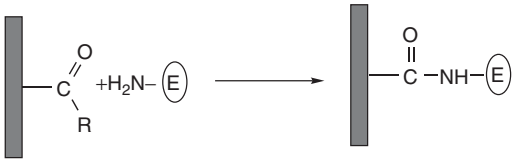

Figure 44.2. The acylic reaction as an example of a covalent binding of an enzyme (E) at a carrier.

- the pressure drop stays constant, and
- low temperature and concentration gradients.

A necessary condition for these advantages is good homogeneity. Without this, heat and mass transfer are inhibited.

Because of better mass transfer, a high cell density is possible. An increase of the catalyst concentration (cells or enzymes) brings a higher reaction rate space time yield (STY), and if there is no transfer limitation, a reduction of the reaction volume is possible (lower investment for better economy).

When using mammalian cells in biotechnological processes, most of the time, it is necessary to offer carriers on which the cells can grow because of the adherent behavior of these cells. These beads can be compact solids or porous particles. In the case of compact particles, the available surface to grow on is small compared to porous beads with their large inner surface (Fig. 44.3), and the cells are more mechanically stressed. If mass and heat transfer by diffusion inside the beads is too slow, this can cause substrate limitation and/or product and heat inhibition of cellular activity (2,5).

For bioreactions, a lot of bioreactors are available. In the case of handling carriers, bed reactors as already shown, are the best choice (2,5,6).

44.1.2.1 Using Fluidized Bed in Biotechnology. There are two ways to run an FBR, the gas–solid system (GSS) (5), and the liquid–solid system (LSS) (2). In the field of biotechnology, GSSs are used for cleaning pollution from exhaust gas streams. Here, microorganisms are immobilized on a microcarrier, and the exhaust gas stream expands (fluidized) the carrier bed in an FBR. The gas components are transported by convection and diffusion to the enzyme-loaded carrier. There follows a chain of operations: adsorption, reaction, desorption, transport back, and the metabolites are transported out of the FBR via the exhaust gas stream.

Generally, it is necessary to moisten the inlet gas to keep the water activity at a necessary level. In a GSS, bubble formation makes the system very complicated for modeling. However, in a LSS, such phenomena do not appear (1).

For biotechnological purposes, an LSS is usually chosen (2,5). This system is described below.

The fluidized bed is not only used directly as a bioreactor, but is also suitable in downstream processing. It has been shown that lactic acid can be purified directly from fermentation utilizing a fluidized-bed column refilled with a

strong anionic exchange resin. By changing the settling bed height, it is possible to obtain a 50% increase in the binding capacity (7). This technology is also known as expanded bed adsorption (EBA).

More for analytical purposes, a fluidized-bed cell culture reactor with on-line radioactivity detection was developed for the *in vitro* evaluation of radio pharmaceuticals. The technique was applied to measure the dependency of the lumped constant (LC) of FDG (2-[^{18}F]luoro-2-deoxyglucose) on the glucose concentration in the culture medium in a human glioma cell line (8).

There is a variety of applications of fluidized-bed systems, often technically or industrially useful, for instance, in producing erythropoietin (EPO) from CHO cells in a continuous FBR (9). It was possible to run this process in a 2-L scale in serum-free and protein-free medium for 48 days. The cell density increased to a maximum of 2.3×10^7 cell/mL. The product concentration (EPO) was significantly higher at least twice that in a controlled stirred-tank bioreactor, in a spinner flask or in a stationary T-flask culture.

FBR is also used for environmental purposes. A liquid–solid FBR was used to carry out sulfate reduction with a mixed culture of sulfate-reducing bacteria. The bacteria were immobilized on porous glass beads where stable fluidized-bed operation with these biofilm-coated beads was possible. The low specific gravity of the hydrated beads allowed operation at low liquid circulation rates, meaning at low superficial velocity (10). Sulfate reduction rates of up to 6.33 g of sulfate/L/day were attained in the reactor at a hydraulic retention time of 5.1 h. The efficiency of sulfate reduction increases considerably as the hydraulic retention increases until the bacteria became very strongly substrate-limited at a hydraulic retention time (HRT) of 55 h.

A model for the reactor was developed. Simulation of the continuous flow experiments indicate that the model can describe the system well, and can therefore be used in the design/scale-up of such reactors (10).

Another way to apply fluidized bed is in combination with downstream processing as an integrated purification step. As an example, a dual-particle liquid–solid circulating fluidized bed (DP-LSCFB) bioreactor was constructed and used in the investigation of the simultaneous production and extraction of lactic acid using immobilized *Lactobacillus bulgaricus* and ion-exchange resins. The studies in a lab-scale reactor system of approximately 70 L volume showed 93% lactic acid removal and 46% recovery. Such results prove the functionality of using the newly developed bioreactor design for the continuous production and recovery of products of biotechnological significance (11).

Recent investigations in production of biotechnological products prove the applicability of fluidized-bed technology (12). A continuous production of oxytetracycline in a fluidized-bed bioreactor by immobilized cells was investigated under the special effects of dilution and glucose load rates. The *Streptomyces varsoviensis* cells were immobilized on cross-linked calcium alginate beads (Fig. 44.1) and it seems to be a technology with a future.

Since one of the smaller disadvantages for an FBR is oxygen supply, anaerobic processes can be prioritized. One such application is the treatment of high strength corn steep liquor using cultivated polyvinyl alcohol (PVA) gel beads (13). The wastewater treatment process achieved a chemical oxygen demand (COD) removal efficiency in excess of 96% at an organic load rate (OLR) of 27.5 g/L/h with an HRT of only 6 h.

44.2 PLANT CONCEPTION AND OPERATION

44.2.1 Design of a Fluidized-Bed Reactor

An FBR consists of a cylindrical reaction tube frequently with a widening at the top. The widening leads to a reduction of the superficial fluid velocity of the fluid and prevents entrainment velocity of (smaller) particles (Figs 44.4 and 44.5).

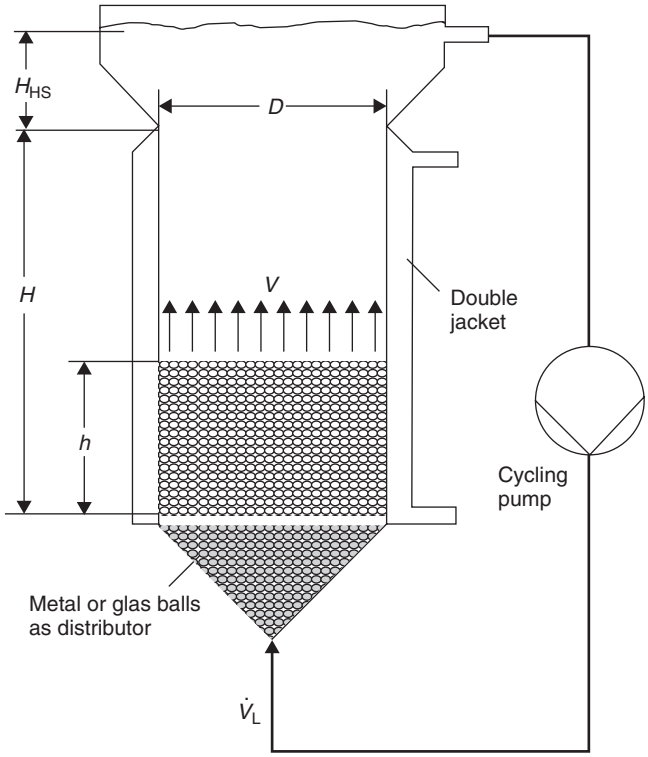

Figure 44.4. Principle sketch of a fluidized-bed reactor (FBR) with the main dimensions.

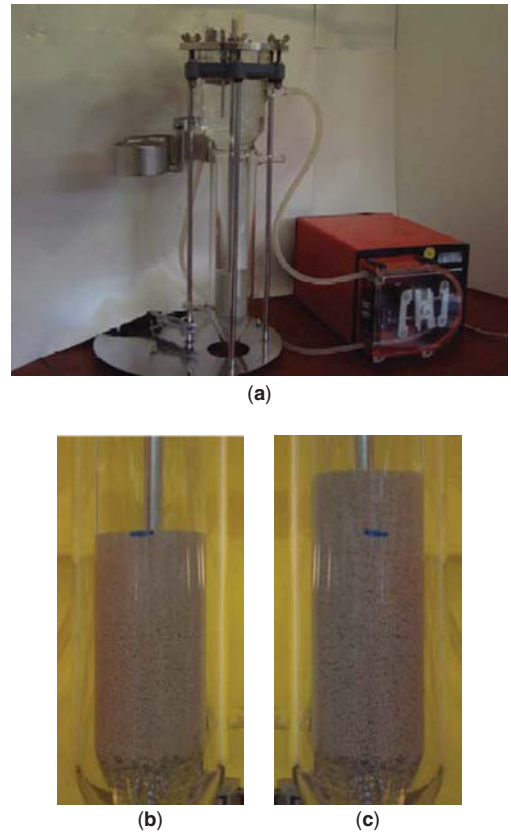

Figure 44.5. (a) Laboratory-scale FBR ($V_{B,max} = 1.0$ L): $D = 50$ mm; $H = 300$ mm; $h = 115$ mm (Fig. 44.4) [Bioengineering AG, Wald CH]; (b) before starting, fixed bed; (c) expanded bed with superficial velocity $v = 0.0089$ m/s. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Since a fluidized bed is only fed from the bottom, a distributor system should be installed in front of the bed. The role of this distributor is to provide a higher axial pressure drop compared to the radial one so that it is possible to distribute the flow evenly. For the purposes of heat transfer and temperature control, the reactor tube is coated with a jacket as a heat exchange area. The next piece of equipment is a pump to provide the flow and the necessary power input.

As the probe positioning is not so easy in an incomplete mixed reactor, it is advisable to use a control vessel where all the parameters (temperature, pH, and concentrations of components) are checked (Fig. 44.6).

44.2.2 Operation of a Fluidized-Bed Reactor

If the immobilized cells or enzymes, which are fixed on the carrier are filled into a bed reactor, then the particle will settle down to the bottom of the column and build a fixed-bed reactor as long as the density of the particles is higher than the surrounding fluid (liquid, Figs 44.7 and 44.8). Packing is achieved when the distance between the particles is fixed and stable (immobilized) (6).

In fixed-bed reactors the pressure drop can be calculated by Carman (14):

$$\Delta p = \frac{3}{4} \frac{\rho_L \times v^2 \times h}{\varphi_S \times d_{PS}} \frac{1 - \varepsilon_L}{\varepsilon_L^3} c_W \qquad (44.1)$$

A fixed-bed reactor can be driven from the bottom as well as from the top (Fig. 44.8). From the point of view of a fluidized bed, the fixed bed is only a special case when the superficial velocity is below the minimal velocity at the incipient fluidization point.

There are some advantages in the fixed bed. First, the catalysts are more densely packed and this increases the specific reaction rate and reduces abrasion.

The disadvantages are mass and heat transfer limitations, channel-forming, and problems with loose material (with bad packing) to remove or blocking.

In a fixed bed, no or negligible back mixing appears, which leads to a concentration gradient.

As an example for substrate consumption:

$$r = \frac{dc}{dt} = -k(T) \times c^n \qquad (44.2)$$

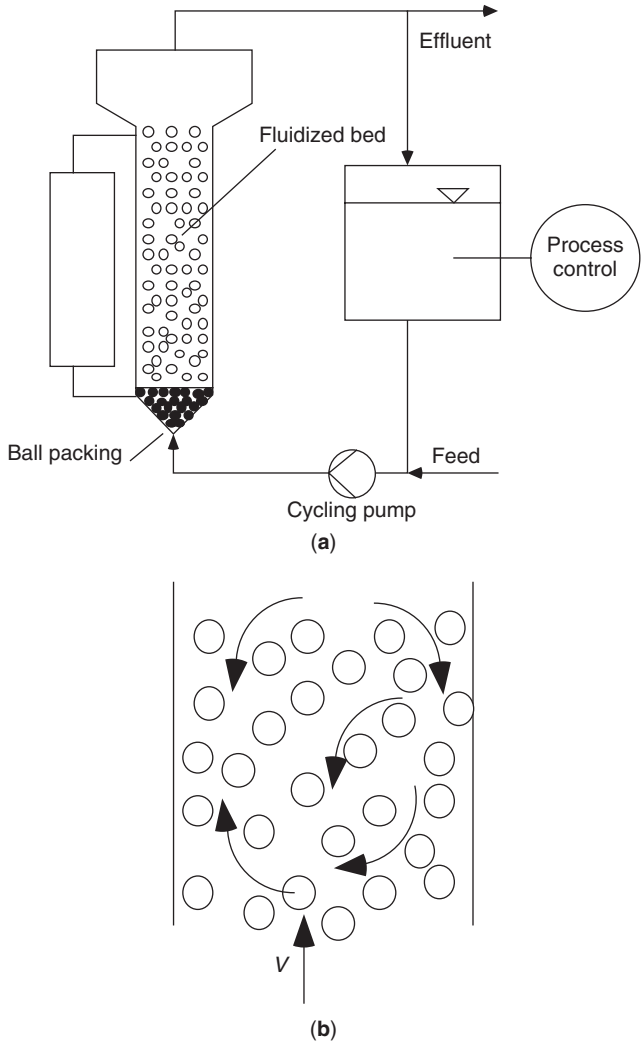

Figure 44.6. (a) Principles of a fluidized-bed reactor plant. (b) Details of a fluidized bed: the flow direction for a fluidized-bed reactor is from the bottom. A minimum fluid velocity is necessary to keep the particles in motion (movement, incipient fluidization). Compared to the empty reactor, the liquid velocity v is the superficial liquid velocity. The maximum velocity is the wash out point (entrainment velocity). Beyond this point, a single particle will sink down. Only a group of particle will rise again.

with n = reaction order (0 order, reaction rate $\neq f$(substrate concentration) (Fig 44.8).

Fluid (gas or liquid) now passes upwards through a fixed bed. On increasing the flow rate, a point is reached when the solid bed hovers. The next small step in increasing the velocity leads to fluidization of the bed. The velocity in this state is the minimal or minimum fluidizing velocity v_L (incipient fluidization) (Fig. 44.9a).

A further increase of fluid velocity brings the expansion of the bed and some channels appear (channelling and aggregative fluidization, see Fig. 44.9b). Since a collection

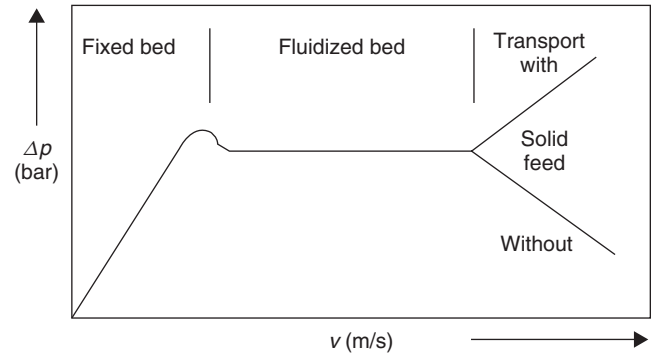

Figure 44.7. Fixed-bed reactor.

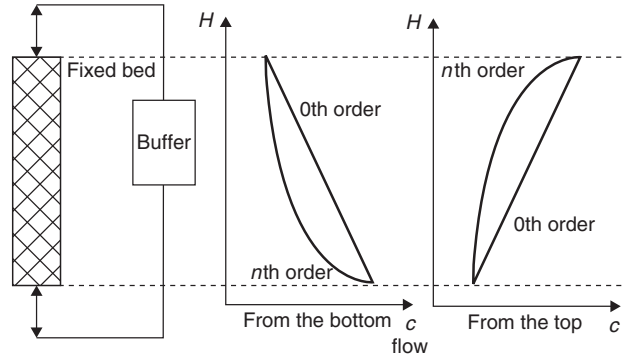

Figure 44.8. Concentration gradient in the fixed-bed reactor is given, and is a function of the reaction order because there is a minimum of back mixing.

of particles act like a larger particle for the flow, it is lifted up until the particle escapes from this compound and then sinks as a single particle, refinds neighbors, forms a new compound and rises again, and so on, a dynamic behavior in a steady state.

By increasing the velocity further, the next state in a fluidized-bed operation is a particulate fluidization. A further slight increase in velocity leads to the entrainment velocity of the particles. The velocity a little below this point is the entrainment velocity w_f (Fig. 44.9c). So, the stationary fluidized bed has a well-defined existing range (space).

In this state of the fluidized bed, the pressure drop is equal to the remaining weight gravity per cross section (gravity force −lift force) in pascal.

The pressure drop in the incipient fluidization can be calculated as:

$$\Delta p = (1 - \varepsilon_L) \times h \times \Delta\rho \times g + \rho_L \times g \times h \qquad (44.3)$$

In Equation 44.3, the first term represents the flow resistance and the second term shows the overcoming of the hydraulic pressure in the start position of the fluidized bed (packing in pending, see Figs 44.4 and 44.7).

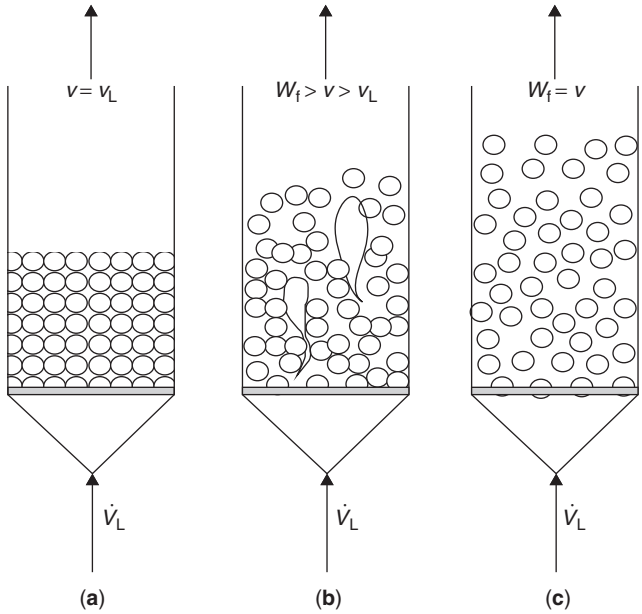

Figure 44.9. Three states of a fluidized bed. (a) The whole tower packing is in the incipient fluidization. (b) Some particles start fluidizing and leave the packing. The packing starts to fluidize. (c) Expanded fluidized bed just before the entrainment velocity (wash out).

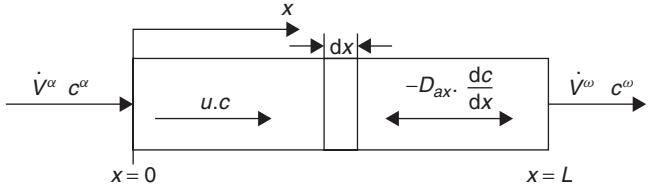

Figure 44.10. Model for describing retention time distribution in a tube reactor (15,16).

44.2.3 Design of a Fluidized-Bed Reactor

44.2.3.1 Hydrodynamic Conditions. In engineering, suitable dimensionless numbers are often used, and some important ones are used to describe a fluidized bed (Figs 44.11 and 44.12) (17).

One of them is the Archimedes number, which is defined by Equation 44.4. The Archimedes number only represents system parameters and no process parameter. Archimedes number:

$$Ar = Re^2 \times Fr^{-1} \frac{\Delta\rho}{\rho_L} = \frac{g \times d_{PS}^3}{\nu^2} \frac{\Delta\rho}{\rho_L} \tag{44.4}$$

The second number is the omega number. In this number, only the left process parameter, the superficial (relative) velocity v, is involved. In classical stationary fluidized bed, the superficial velocity is

$$v = \frac{\dot{V}_L}{A_R} \tag{44.5a}$$

Omega number:

$$\Omega = Re \times Fr \frac{\rho_L}{\Delta\rho} = \frac{v^3}{\nu \times g} \frac{\rho_L}{\Delta\rho} \tag{44.5b}$$

with

$$Fr = \frac{v^2}{g \times d_{PS}} \tag{44.6a}$$

and

$$Re = \frac{v \times d_{PS}}{\nu} \tag{44.6b}$$

$$\text{Archimedes number} = f(\text{system parameter particle, diameter}) \neq f(\text{velocity})$$

$$\Omega \text{ number} = f(\text{process parameter, superficial velocity}), \neq f(\text{particle diameter})$$

$$\text{Froude number} = \frac{\text{inertia} \times \text{force}}{\text{gravity}} \times \left(\frac{\rho_L}{\Delta\rho}\right).$$

The correction $\frac{\rho_L}{\Delta\rho}$ considers the lift force. A very important tool for working with fluidized beds is the fluidized-bed state diagram. In Figs 44.11–44.13 the working sector, the working conditions, and the drag resistance coefficient can be found (17). This is a great help.

In designing a fluidized bed, the following series of steps is helpful:

- Archimedes number via system parameters.
- For the Ω number, the superficial velocity has to be chosen (it is between v_L and w_f).
- With Ar and Ω, we can obtain the working point in the diagram (Fig. 44.11, Fig. 44.7) and this has to be in the fluidized-bed section.
- Additional boundary conditions come from heat and mass transfer, shear stress $= f$(velocity), and looking for the optimum working point.

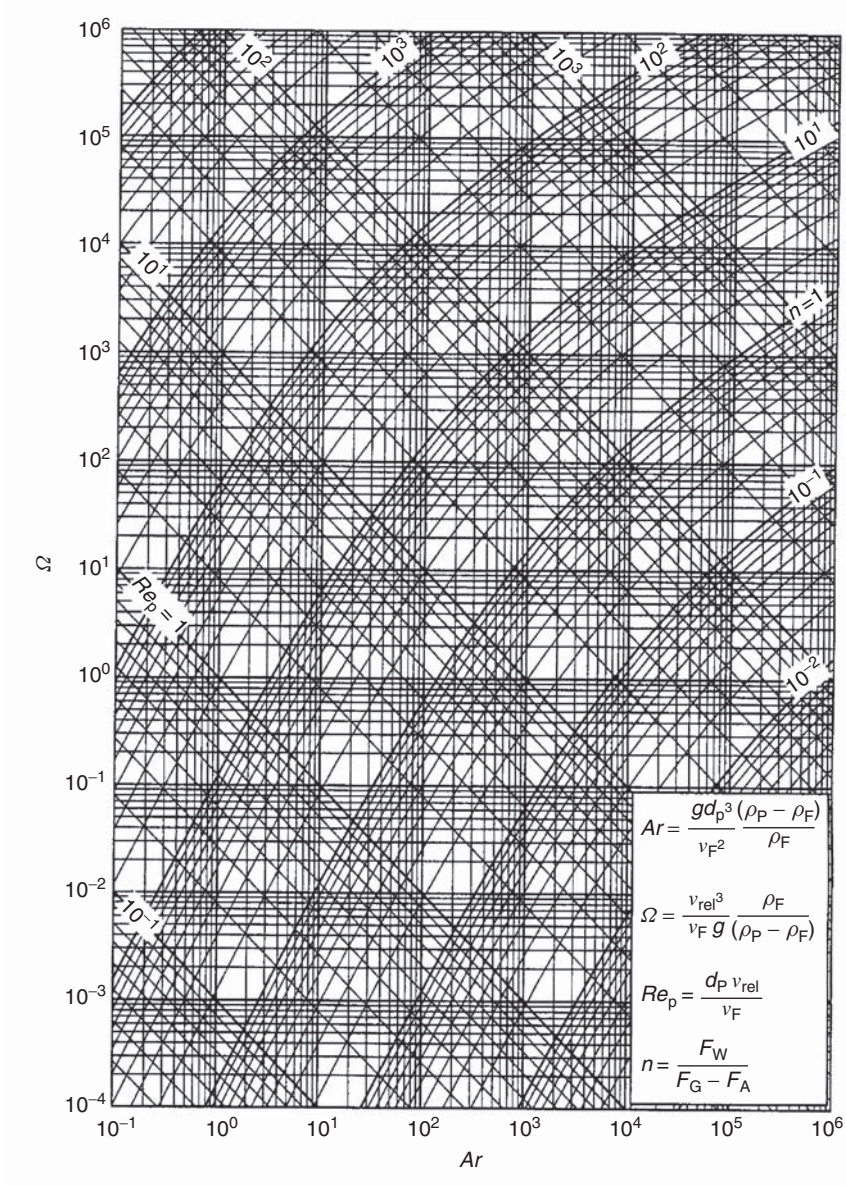

Figure 44.11. Ar-Ω diagram for a single stiff spherical particle. Principles of the fluidized-bed state diagram (17). From this diagram one can get the Ar number to find the section of fluidized bed. The Ar number can be calculated with system parameters (Eq. 44.4) and for Ω number (Eq. 5) the average superficial velocity is necessary.

- Pressure drop inside the fluidized bed is calculated by Equation 44.3. The pressure drop before, for the fixed bed, is calculated by Equation 44.1.
- The pressure drop in the fluidized bed is (nearly) constant, because the losses through resistance on the column wall is negligible.
- In practice, there is a rough value: the expansion of the bed should be of a factor of 1.3–2.5 above fixed bed (packing).

44.2.3.2 Basic Design Details

44.2.3.2.1 Range of Operation Velocities. Because of the immobilization of the cells or the enzymes on FBRs, FBRs have a high cell and enzyme concentration through the help of carriers, which the cells or the enzymes are immobilized on (Fig. 44.1).

In the FBR, the particles are fluidized by lift forces and resistance (friction) forces, which are at least equal to the gravity force.

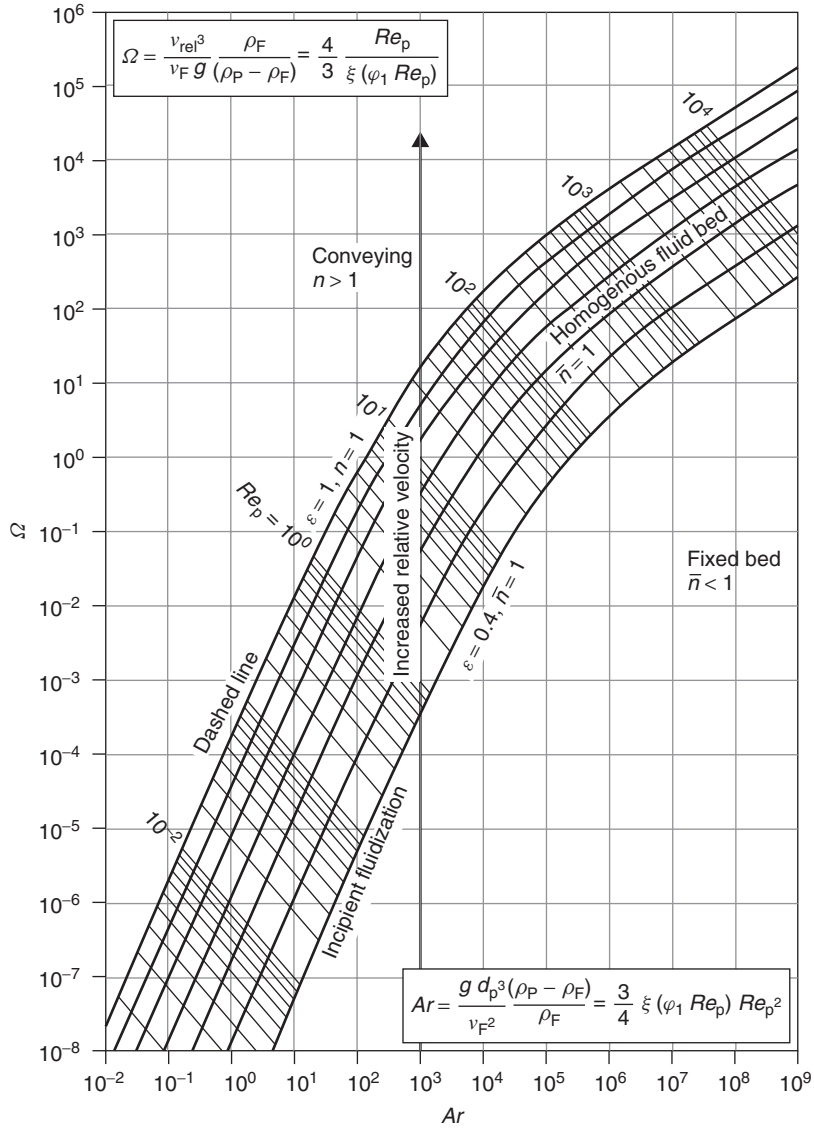

Figure 44.12. Diagram of situation for monodispersed, spherical particles at even flow input.

Flow should be evenly distributed. This is done by spherical particle packing—the axial pressure drop is much higher than the radial (Figs 44.4–44.6).

The velocity has to overcome the minimum velocity v_L = incipient fluidization. The drag force can be calculated as:

$$F_R = c_W \times \rho_L \times A_C \times \frac{v^2}{2} \tag{44.7}$$

The resistance factor c_W can be found from Fig. 44.14. The other parameters, density ρ_L, projected area of the particle, and the velocity v are system parameters.

The first thing which has to be considered when designing an FBR is the calculation of the existence range of a fluidized bed in the velocity between the minimal fluidizing velocity (incipient fluidization) v_L and the entrainment velocity w_f.

The necessary parameters are the average particle diameter, the density of both solid and liquid, and the viscosity. The velocity in the lowest working point (incipient fluidization) can be calculated as
laminar,

$$Re_L = \frac{v \times d_{PS}}{\nu} \leq 1,0: \tag{44.8}$$

$$v = v_L = \frac{1}{150} \frac{\varphi_S^2 \times \varepsilon_L^3}{1 - \varepsilon_L} \frac{g \times d_{PS}^2}{\nu} \times \left(\frac{\rho_S}{\rho_L} - 1 \right) \tag{44.9}$$

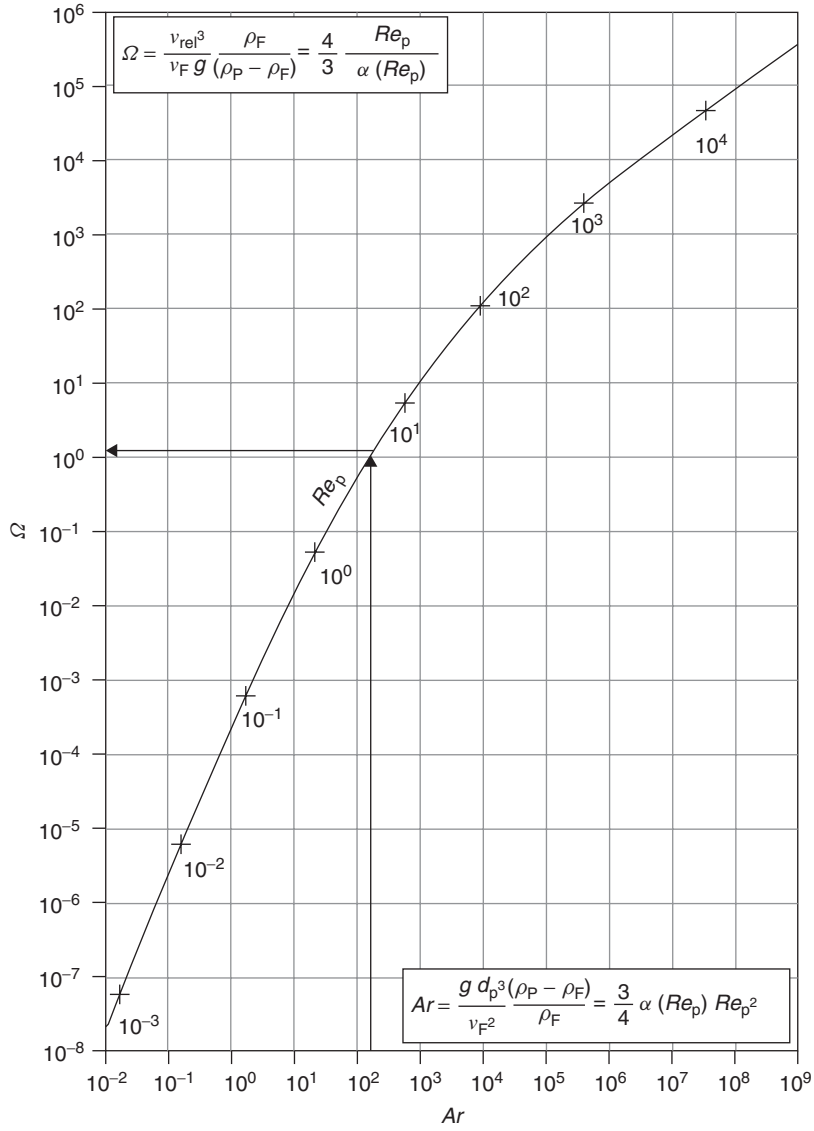

Figure 44.13. Ar-Ω diagram for a stationary, sinking, stiff spherical particle (the arrows show the way to the sink velocity).

turbulent,

$$Re_L > 500 : v = v_L = \left(\frac{1}{1.75} \times \varphi_S \times \varepsilon_L^3 \times g \times d_{PS} \times \frac{\Delta\rho}{\rho_L} \right)^{0,5} \quad (44.10)$$

First we start with either a laminar or turbulent assumption, and then follow the calculation with a control check. If the assumption is wrong, the opposite situation has to be considered.

The next step is to calculate the sink velocity, which is roughly equal to the entrainment velocity w_f. Again, it is necessary to make the assumption laminar or turbulent flow and in the case of a wrong assumption, again the opposite route has to be taken.

The equation for the velocity in the incipient fluidization is given as:
laminar, $Re \leq 1.0$ (Eq. 44.8):

$$v = w_f = \frac{1}{18} \frac{g \times \varphi_S \times d_{PS}^2}{\nu} \times \left(\frac{\rho_S}{\rho_L} - 1 \right) \quad (44.11)$$

turbulent, $Re > 500$:

$$v = w_f = \left(\frac{4}{3} \frac{g \times \varphi_S \times d_{PS}}{c_W} \frac{\Delta\rho}{\rho_L} \right)^{0,5} \quad (44.12)$$

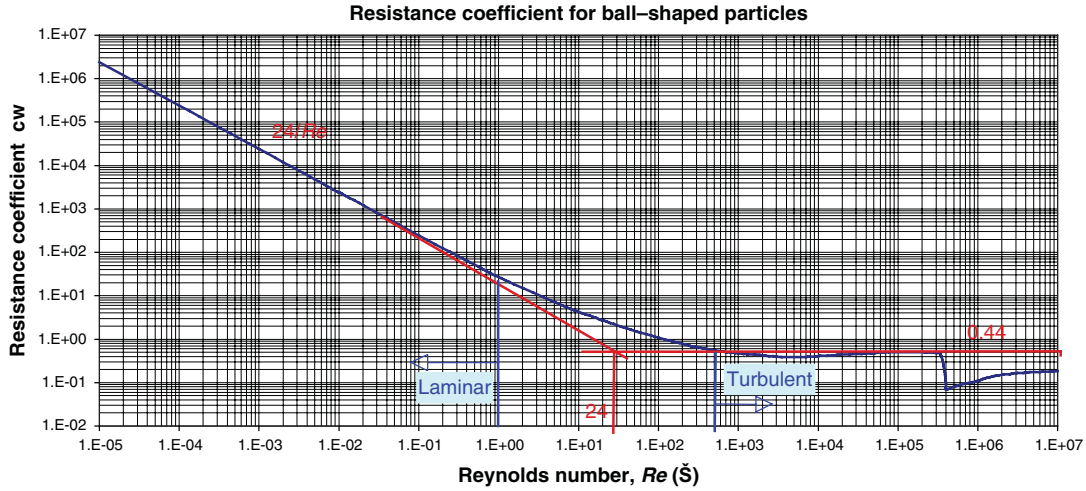

Figure 44.14. Flow resistance coefficient of a ball-shaped particle as a function of the Reynolds number. Below $Re = 1.0$ conditions are laminar conditions, and above $Re = 500$, turbulent. At $Re > 500$ the resistance coefficient is constant ($c_W = 0.44$). In the laminar section, $c_W = 24/Re$. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

For a spherical particle, Equation 6 can be easily determined using a force balance.

In this situation, a force equilibrium is given:

$$F_L + F_R = F_W \tag{44.13}$$

$$\text{lift} + \text{resistance} = \text{weight}$$

For the different forces, the following calculations are useful:

$$F_R = c_W \times \rho_L \times A_C \times \frac{w_f^2}{2} \tag{44.14}$$

$$F_L = V_P \times \rho_L \times g \tag{44.15}$$

$$F_W = V_P \times \rho_P \times g \tag{44.16}$$

In Equations (14–16) the particle volume is

$$V_P = \frac{d_{PS}^3 \times \pi}{6} \tag{44.17}$$

and the projected area is

$$A_C = \frac{d_{PS}^2 \times \pi}{4} \tag{44.18}$$

By transforming Equation 44.13 with Equations 14–16 we get:

$$w_f = \left(\frac{4}{3}\frac{g \times d_{PS}}{c_W}\frac{\Delta\rho}{\rho_L}\right)^{0,5} \tag{44.19}$$

Equation 44.19 is very similar to Equation 44.12. The only difference is the spherical factor ϕ_S (Eq. 44.24), which is a correction factor for the deviation of the particle shape from a spherical particle.

Using Stoke's law (Fig. 44.14) for the laminar regime:

$$c_W = \frac{24}{Re} \tag{44.20}$$

we get:

$$w_f = \frac{1}{18}\frac{g \times d_{PS}^2}{\nu}\frac{\Delta\rho}{\rho_L} \tag{44.21}$$

and this equation is similar to Equation 44.11, except again, for the parameter ϕS.

The expansion behavior of a fluidized bed can be calculated by Richardson and Zaki (18)

$$\varepsilon = \sqrt[n]{\frac{v}{w_f}} \tag{44.22}$$

With:

$$n = 4.65 \text{ for } Re < 0.2$$

$$n = 4.35 \times Re^{-0.03} \text{ for } 0.2 < Re < 1.0$$

$$n = 4.45 \times Re^{-0.10} \text{ for } 1.0 \leq Re < 500$$

$$n = 2.39 \text{ for } Re > 500$$

This allows us to calculate the column height:

$$H = h\frac{1 - \varepsilon_L}{1 - \varepsilon} \tag{44.23}$$

All models assume spherical particle and uniform diameters. A representative particle in the case of shape and diameter has to be found. For another shape we correct with the sphericity factor ϕ_S and the diameter with the Sauter mean diameter.

The spherical factor is defined as ratio of the surface of a spherical particle with the same volume as the original particle to the surface of the particle:

$$\phi_S = \frac{A_B(V_P)}{A_P} \tag{44.24}$$

Since the surface of a spherical particle with a given volume has the smallest available surface, the spherical factor is always lesser than 1, that is, $\phi S \leq 1.0$.

To define a mean diameter $d_{P32,}$ using the Sauter mean diameter d_{PS} is advisable. This diameter is a common measure in fluid dynamics as a way to estimate the average particle size. It is defined as the diameter of a sphere that has the same volume/surface area ratio as a particle of interest and is defined as (23,20)

$$d_{PS} = d_{P32} = 6 \times \frac{V_P}{A_P} = \frac{\sum_{i=1}^{m} n_i \times d_i^3}{\sum_{i=1}^{m} n_i \times d_i^2} \tag{44.25}$$

44.2.3.2.2 Oxygen Supply. When using living cells, adequate oxygen supply is necessary. Mammalian cells are sensitive to high levels of dissolved oxygen as well to rising bubbles because of shear stress (2). Therefore, the aim is to both avoid and provide bubble-free oxygen externally, outside the cell-containing reactor (6). An aeration vessel with different equipment is used in combination with an FBR. A bubble-free membrane aeration or submersed aeration (considering foam situation) is possible.

44.2.3.2.3 Energy Dissipation. Each event required the energy to be managed and should be conducted in a closed time frame; so, it is necessary to provide the required power. In technical operations, we use the specific power input or the mass related power density ε (watt per kilogram). This value can be calculated from the absolute power input, the system volume (reaction volume), and the system density (medium) (6)

$$\varepsilon \equiv \left(\frac{P_i}{V_R \times \rho_M} \right) \tag{44.26}$$

Generally, the volume in a reactor is the reaction medium (gas or liquid) and the density of the medium, M. For power input into a reactor, three types are available: power input by gas prepressure and expansion, by pumps and hydraulic stream, and by mechanical equipment such as agitators (stirrers).

FBRs belong to type two; they are hydraulically driven reactors. The pump causes a medium flow $\dot{V}_L$ (L–liquid) against a drag resistance, causing a pressure drop Δp. These two parameters allow us to calculate the necessary power input generated by the pump:

$$P_L = \dot{V}_L \times \Delta p \tag{44.27}$$

With the reaction liquid volume $V_{R,L}$ and the liquid density Δ_L, we get the specific power input:

$$\varepsilon_L = \frac{P_L}{V_{R,L} \times \rho_L} \tag{44.28}$$

There are several ways to get this required power input. In the volume stream, the desired capacity of production is C_P representing what has to be produced in, for example, 1 year. With the available hours per year HPA (e.g. 7000 h/a), the product concentration P (gram per liter) in the effluent of the reactor, and the overall downstream efficiency α we get:

$$\dot{V}_L = \frac{C_P}{HPA \times P \times \alpha} (m^3/h) \tag{44.29}$$

Using Equation 44.29 combined with Equation 44.1 in the case of fixed bed, and Equation 44.3 for a fluidized bed, we can calculate the power input with Equations 44.27 and 44.28.

44.2.4 Heat Exchange

In a fixed bed, the heat transfer is influenced by three factors:

- convection through fluid;
- transport from solid, conductivity in solid, transfer of heat from solid to fluid;
- conductivity through solid.

It is conceivable that a lot of transport resistance inhibits the overall transfer a great deal as the predominate part is the convective transport.

A better situation is given in the fluidized bed (Fig. 44.4). As expected, the bed to wall heat transfer coefficient increases with increased velocity.

In contrast to fixed beds, in a fluidized bed, heat transfer is caused not only by fluid but also by moving solids. The solids act as a heat transfer medium (transporter). In zones of lower temperatures, they lose heat and vice versa.

An improvement of heat transport is reached by:

- increasing the turbulent mixing movement of the fluid and
- additional nonstationary heat transfer of the solids.

The laminar border layer between reactor wall and fluidized bed, in contrast to a fixed bed, is continuously destroyed and therefore thinner.

Within equal conditions, with the same fluidization, the same density, the same particle size, and the same surface shape and configuration, the heat transfer increases by 35% or more in a fluidized bed.

With the assumption that:

- no temperature gradient in the particle;
- the heat exchange surface corresponds to the projected area of the particle on the wall

the following calculation for an individual particle results:

$$\begin{aligned} \mathrm{d}q \times \mathrm{d}t &= \frac{\lambda_\mathrm{f}}{\delta}\frac{d_\mathrm{P}^2 \times \pi}{4} \times (T_\mathrm{wall} - T_\mathrm{P}) \\ &= c_\mathrm{P} \times \gamma_\mathrm{P}\frac{d_\mathrm{P}^3 \times \pi}{6}\Delta T \end{aligned} \tag{44.30}$$

which means transported heat in a moving particle = transfer to wall = lost heat (watt second).

The more particles which arrive at the wall over time and area, the more heat can be exchanged. Heat transfer is influenced by:

- heat conductivity in the laminar boundary layer while the thickness of the laminar layer is influenced by the flow conditions and the impulse forces of the particles;
- the time of contact of the particle at the wall. The smaller the contact time, the better the heat transfer(!).

As it is seen in Fig. 44.15, the heat transfer coefficient has a maximum. For this situation, a relationship to calculate the maximal heat transfer coefficient (19) is given as:

$$\frac{Nu_\mathrm{max}}{1-\varepsilon_0} = 1.8 \times Ar^{0.18} \times \left(\frac{c_\mathrm{P}}{c_\mathrm{L}}\right)^{0.36} \tag{44.31}$$

In reality, there is an approximate range of $0.5 < Nu_\mathrm{max} < 8$. The following characteristic numbers are often very useful:

Reynolds:

$$Re \equiv \frac{v \times x}{\nu} \text{with } x = \text{characteristic length (m)} \tag{44.32}$$

Nusselt:

$$Nu \equiv \frac{k_\mathrm{q} \times x}{\lambda} = \frac{\text{heat} \times \text{transfer}}{\text{heat} \times \text{conductivity}} \tag{44.33}$$

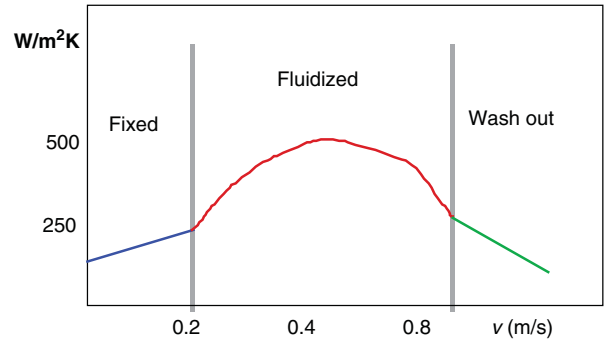

Figure 44.15. Heat transfer coefficient in a fluidized bed (qualitative manner). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Prandtl:

$$Pr \equiv \frac{\nu}{\frac{\lambda}{\rho \times c_\mathrm{p}}} = \frac{\nu}{a} = \frac{\text{impulse} \times \text{transport}}{\text{heat} \times \text{transport}} \tag{44.34}$$

For mass transfer:

Schmidt:

$$Sc \equiv \frac{\nu}{D} = \frac{\text{impulse} \times \text{transport}}{\text{mass} \times \text{diffusion}} \tag{44.35}$$

Sherwood:

$$Sh \equiv \frac{k_i \times x}{D_i} = \frac{\text{mass} \times \text{transfer}}{\text{mass} \times \text{diffusion}} \tag{44.36}$$

There are numerous relationships between several characteristic numbers in literature. For the Nusselt number we find (15)

$$Nu \equiv \frac{k_\mathrm{q} \times x}{\lambda} = 0.664 \times \sqrt{Re_x} \times \sqrt[3]{Pr} \tag{44.37}$$

The Prandtl and the Schmidt number combine mass and heat transfer:

$$Sh = Nu \times \sqrt[3]{\frac{Sc}{Pr}} \tag{44.38}$$

All these relationships are very helpful in designing an FBR.

44.3 SCALE-UP CONSIDERATIONS

44.3.1 Heat Exchange Situation

Heat transfer needs a suitable heat exchange area but heat production comes from the reaction volume. One pattern is related with a length square and the other to power to length cube. In scale-up, this involves the available heat exchange area decreasing with increased volume.

In terms of formula we get:
for input,

$$\dot{Q}_{\text{in}} = \Delta H \times STY \times V_{\text{R,L}} \propto V \propto \text{L}^3 \tag{44.39}$$

for output,

$$\dot{Q}_{\text{out}} = k \times A \times \Delta T \propto A \propto \text{L}^2 \tag{44.40}$$

So the ratio is

$$\frac{\dot{Q}_{\text{in}}}{\dot{Q}_{\text{out}}} \propto \text{L} \tag{44.41}$$

which means with rising volume, the removal of the heat becomes more and more difficult and can only be achieved with additional heat transfer area.

44.3.2 Scale-Up of Fluidized Bed

Scale-up considerations look into the results from the model scale to laboratory scale or pilot scale to production scale for the conditions for transfer. Because it is not possible to keep all parameters constant, it is very important to find the most sensitive one and test whether these are transferable. For instance, the mixing time is a parameter, which is often not possible to be transferred because of the necessary increase of the power input.

To analyze the parameter responsible for scaling up in an FBR system, it is very helpful to draw up a relevance list. The first law for scale-up is geometric similarity, which means all length ratios in each scale are equal.

It seems to be necessary to keep the local microdynamic situation constant to achieve the same conditions for the reaction rate to fulfill the desired capacity rate. Therefore, for the superficial velocity, all medium parameters (densities, diffusion coefficients, particle shape and size, and so the bed porosities in fixed as well in expanded position) and geometric factors as well as the feed concentrations should be kept constant.

The value necessary for the flow rate leads directly through the superficial velocity v to the main dimension parameters H and D. The condition for H is a very good distribution of the inlet flow at the bottom. If this is realizable, then the height has to be increased by about 10%.

There are a few parameters that will inevitably change during scale-up. Of course, for the capacity, these are the flow rate, all geometric nonspecific parameter, pressure and pressure drop, as well as temperature gradient to the heat exchange area and the heat exchange area itself.

All these considerations lead to the following relevance list:

Scale independent parameters or to be kept constant: $\{v, \epsilon, \epsilon_{\text{L}}, d_{\text{PS}}, \phi_{\text{S}}, \rho_{\text{L}}, \rho_{\text{P}}, \upsilon, D_{\text{i}}, c^{\alpha}, f_{\text{S}}, f_{\text{B}}\}$

Scale-dependent parameters to be adapted: $\dot{V}_{\text{L}}, V_{\text{R}}, H, \text{h}, \text{p}, \Delta p, A_{\text{J}}, \Delta T_{\text{wall}})$.

To successfully transfer the process from model to the production scale, a few further investigations are necessary to clear up the pressure and the temperature situation. The solubility of gases is directly connected with changing pressure and if there are still problems with the heat exchange, it is not possible to have the best conditions for the reaction.

To avoid problems with too small bed diameter D because of the wall influenced flow behavior, it may sometimes be advisable in model (laboratory) scale to use diameters above 50 mm.

44.4 MODELING AND SIMULATION

Generally, the FBR is a hydraulically driven tube-type reactor. If there is no carrier inside, the reactor is a simple tube reactor with more or less back-mixing behavior. Under the assumption of plug flow and an overlapped dispersing flow to describe the back mixing, the balance for a compound "i" with the concentration c_i in a small element $dV = A \times dx$ at the position "x" reads as follows (15,16) under steady-state conditions (Fig. 44.10):

$$\begin{aligned} \text{d}V \times \frac{\text{d}c_i}{\text{d}t} &= 0 \\ &= -\frac{\text{d}}{\text{d}x}\left(u \times c_i + D_{\text{ax}} \times \frac{\text{d}c_i}{\text{d}x}\right)\text{d}\,x \times A - \dot{n}_{\text{diff}} \end{aligned} \tag{44.42}$$

In this small element, convection ($u \times c_i$), back mixing ($D_{\text{ax}} \times dc_i/dx$), and the supply for the consumption inside the beads (n_{diff}) determine the result.

The assumed average plug flow velocity has to be corrected because of the solids present: $u = \frac{F}{A \times \varepsilon_{\text{L}}}$

With dimensionless length

$$\chi \equiv \frac{x}{\text{L}} \tag{44.43}$$

and concentration

$$C \equiv \frac{c}{c^{\alpha}}, \tag{44.44}$$

we get

$$\frac{\text{d}^2\text{C}}{\text{d}\chi^2} = -Bo \times \left(\frac{\text{dC}}{\text{d}\chi} + \dot{n}_{\text{diff}}\right) \tag{44.45}$$

The diffusion terms in Equation 44.45 look for the path along z (coordinate inside the particle from the center to

$z = r_{PS} = d_{PS}/2$) inside the porous particle. Again for steady-state conditions, we get

$$\frac{dn_i}{dt} = D_i^e \times 4 \times \pi \times (z + dz)^2 \times \frac{dc_i}{dz} - D_i^e \times 4 \times \pi \times z^2 \times \left(\frac{dc_i}{dz} - \frac{d^2 c_i}{dz^2} dz \right) - k_S \times S_V \times c_i \times \left(4 \times \pi \times z^2 \times dz\right) = 0 \quad (44.46)$$

transferred by neglecting all dz^2 terms as they can be assumed as zero, we get

$$k_S \times S_V \times c_i^n = \frac{2}{z} \times D_i^e \times \frac{dc_i}{dz} + D_i^e \times \frac{d^2 c_i}{dz^2} \quad (44.47)$$

Again with dimensionless length and concentration (Eqs 44.43 and 44.44), we get

$$r_{PS}^2 \frac{k_S \times S_V}{D_i^e} \frac{c_i}{c_{i,S}} = \frac{2}{z/r_{PS}} \frac{d\left(c_i/c_{i,S}\right)}{d\left(z/r_{PS}\right)} + \frac{d^2\left(c_i/c_{i,S}\right)}{d\left(z/r_{PS}\right)^2} \quad (44.48)$$

with the solution

$$\frac{c_i}{c_{i,S}} = \frac{\sinh\left[\Phi \frac{z}{r_{PS}}\right]}{\frac{z}{r_{PS}} \sinh \Phi} \quad (44.49)$$

Last, but not least, we get the effective reaction rate, which is equal to $\dot{n}_{diff}$:

$$r_{eff} = \frac{3}{\phi} \times k_S \times S_V \times c_{i,S} \times \left(\frac{1}{\tanh \phi} - \frac{1}{\phi} \right) \quad (44.50)$$

where $c_{i,S}$ is the concentration of the considered component in front of the particle (carrier, bead) at position x.

In the mathematical model, Equation 44.50 replaces the diffusion term in Equation 44.42.

In a solid containing tube reactor, the diffusion (dispersion) coefficient is inhibited because of the obstacles (beads, carriers, and solids) and became smaller. This change diffusion coefficient is called *effective diffusion coefficient* D^e. In practise, the effective diffusion coefficient is approximately 10% compared to the original, uninhibited coefficient.

In the Equations 44.49 and 44.50, the Thiele modulus Φ appears. This dimensionless number is defined as follows:

$$\Phi = \frac{d_{PS}}{2} \sqrt{\frac{k_S \times S_V}{D_i^e}} = \frac{r_S \text{without pore diffusion inhibition}}{\text{diffusion inside pore}} \quad (44.51)$$

All the equations discussed above are available for modeling and simulation to optimize the fluidized bed process. Further aspects for a mathematical model for use in the design and optimization of fluidized-bed reactors can be found in literature (21,22).

44.5 PRAXIS EXAMPLES

Let us calculate the situation shown in Figs 44.4 and 44.5. The laboratory plant has the following dimensions:

$H_{max} = 300$ mm; $D = 50$ mm; $h = 115$ mm; pump rate $F = 63.5$ L/h; $d_{PS} = 8 \times 10^{-4} m$; $\rho_P = 1.25$ kg/L; $\rho_L = 0.98$ kg/L; $v = 0.95 \times 10^{-6}$ m^2/s; $\phi_S = 0.95$.

First we calculate the superficial velocity v.

The cross section is:

$$A = \frac{0.05^2 \times \pi}{4} = 2 \times 10^{-3} \text{m}^2$$

$$v = \frac{1.06}{2 \times 10^{-3} \times 10^3 \times 60} = 0.0089 \text{ m/s}$$

The entrainment velocity, assuming turbulent conditions is

$$w_f = \left[\frac{4}{3} \frac{g \times 0.9 \times \left(8 \times 10^{-4}\right) \times 0.27}{0.44} \right]^{0.5} = 0.076 \text{ m/s}$$

Control is

$$Re = \frac{0.076 \times 8 \times 10^{-4}}{0.95 \times 10^{-6}} = 64 < 500 \rightarrow \text{not turbulent!}$$

Next laminar assumption is

$$w_f = \frac{1}{18} \frac{g \times 0.9^2 \times \left(8 \times 10^{-4}\right)^2}{0.95 \times 10^{-6}} \times 0.27 = 0.08 \text{ m/s}$$

New Reynolds number is

$$Re = \frac{0.08 \times 8 \times 10^{-4}}{0.95 \times 10^{-6}} = 67.4$$

This is in the same range, but still above $Re = 1.0$ but much nearer to 1.0 than to 500, and so we decide to calculate the next steps with this value.

Next, we calculate the expansion with (18) $n = 4.45 \times Re^{-0.1}$. Thus we need Re for the running conditions

$$Re = \frac{0.0089 \times 5 \times 10^{-4}}{0.95 \times 10^{-6}} = 4.7 \rightarrow n$$
$$= 4.45 \times 4.7^{-0.1} = 3.81.$$

We get for the liquid fraction in bed, Equation 44.22

$$\varepsilon = \sqrt[3.81]{\frac{0.0089}{0.08}} = 0.56$$

With this porosity, we can calculate the height of the expanded bed:

$$H = 115 \cdot \frac{1-0.4}{1-0.56} = 156.4\,\text{mm}$$

The reaction volume is now:

$$V_{R,L} = 2 \times 10^{-3} \times 0.1564 \times 10^3 = 0.31\,\text{L}$$

Power input Equations 44.1 and 44.27:

$$\Delta p = g \times 0.115 \times [(1-0.4) \times 0.27 + 0.98] \times 10^3$$
$$= 1288.35\,\text{Pa}$$

$$P_L = \frac{63.5 \times 1288.35}{3600 \times 10^3} = 0.0227\,\text{W}$$

$$\varepsilon_L = \frac{0.0227}{0.31} = 0.073\,\text{W/L}$$

Just to compare the pressure drop via the tube flow, this amounts to only 0.03%!!

This specific hydraulic power input is low for bacteria or yeast fermentation processes, but rather high for mammalian cell cultivation.

44.5.1 Using the Reh Diagram for Homogeneous Fluidization

With the system parameter, we first calculate the Archimedes number:

$$Ar = Re^2 \times Fr^{-1} \frac{\Delta\rho}{\rho_L} = \frac{g \times d_{PS}^3}{\nu^2} \frac{\Delta\rho}{\rho_L}$$
$$= 4.7^2 \times 61.9 \frac{0.27}{0.98} = 375 \qquad (44.52)$$

Then the Ω-number:

$$\Omega = Re \times Fr \frac{\rho_L}{\Delta\rho} = \frac{v^3}{g \times \nu} \frac{\rho_L}{\Delta\rho}$$
$$= \frac{(0.0089)^3}{g \times 0.95 \times 10^{-6}} \frac{0.98}{0.27} = 0.28 \qquad (44.53)$$

Now in the Reh diagrams (Figs 44.11–44.13), we find a value for the force ratio $n = 0.35$, which enables us to calculate the resistance coefficient under these conditions:

$$c_W = \frac{4}{3} \frac{n \times g \times d_{PS}}{\nu^2} \frac{\Delta\rho}{\rho_L}$$
$$= \frac{4 \times 0.33 \times g \times \left(510^{-4}\right) \times 0.27}{3 \times (0.0089)^2 \times 0.98} = 7.5 \qquad (44.54)$$

Compared with Fig. 44.14 this value fits.

NOMENCLATURE

A	heat exchange area (m^2)
A_B	surface of a spherical particle (m^2)
A_C	projected area (m^2)
A_P	surface of a particle (m^2)
A_R	cross section of the reactor (m^2)
Ar	Archimedes number (Eq. 44.4)
Bo	Bodenstein number (Eq. 44.47)
c	concentration (mol/L)
C	dimensionless concentration (Eq. 44.44)
C_P	capacity of product (kg/a)
c_P, c_L	heat capacity of particle, liquid (J/kg/K)
c_W	resistance factor
D_{ax}	dispersion coefficient, back-mixing factor (m^2/s)
D^e	effective diffusion coefficient (m^2/s)
d_{P32}	Sauter LNCS diameter (m)
d_{PS}	Sauter mean particle diameter (m) (Eq. 44.25)
F	flow rate (L/min)
f_B	bed to reactor height ratio
f_S	slenderness factor; H/D
F_L, F_R, F_W	forces for lift, resistance, weight (N)
g	gravity = 9.81 (m/s^2)
h	bed height (m)
H	height of reactor, expanded bed (m)
h	height of the bed (m)
HPA	available working hours per year (h/a)
k	heat transfer coefficient ($W/m^2/K$)
k_S	surface related reaction rate constant (m/s)
$k(T)$	reaction rate constant $\left[\frac{m^{3\cdot(n-1)}}{s\times mol^{(n-1)}}\right]$
L	characteristic length of a system (m)
n	reaction order
n	exponent in Equation 44.22
n	force ratio $= \frac{F_R}{F_W - F_L}$, Fig. 44.11
$\dot{n}_{diff}$	diffusion stream ($mol/s/m^3$)
Nu	Nusselt number (Eq. 44.33)
P	product concentration (g/L)
P_i	general power input (W)
Pr	Prandtl number (Eq. 44.34)
Q	heat flow (W)
dq	differential heat (J)
r	reaction rate (mol/s/L)
Re	Reynolds number (Eq. 44.32)
Sc	Schmidt number (Eq. 44.35)
Sh	Sherwood number (Eq. 44.36)
STY	space time yield ($kg/h/m^3$)
S_V	specific active catalyst surface (m^{-1})
t	time (s; min; h)
T	temperature (K)
ΔT	temperature difference (K)

dV	volume element (m^3)
$\dot{V}_L$	flow rate, volume stream, liquid (m^3/s)
V_P	particle volume (m^3)
$V_{R,L}$	volume (m^3)
w_f	sink velocity, to the entrainment velocity (m/s)
x	coordinate (m)
z	coordinate (m)
α	downstream efficiency
Δp	pressure drop (Pa)
ε	porosity of the expanded bed
ε	specific power, power density (W/kg)
ρ_L	bed porosity $= V_L/V_B$
F	Thiele modulus (Eq. 44.51)
v	kinematic viscosity (m^2/s)
ρ_L	density of liquid (kg/L)
ρ_L	liquid density (kg/m^3)
ρ_P	particle density (kg/m^3)
ϕ_S-	sphericity coefficient (Eq. 44.24)
X	dimensionless coordinate

BIOREACTORS, GAS-TREATMENT

Graham Andrews
MMBD Consulting, Gresham, Oregon,
William Apel
Idaho National Engineering and Environmental Laboratory, Idaho Falls, Idaho

45.1 INTRODUCTION

The most common type of bioprocess, at least in the United States, is the aerobic treatment of wastewater, in which contaminants in the aqueous phase are biodegraded with the help of oxygen transferred from the gas phase (air) to generate a metabolic product (carbon dioxide) that, being volatile, is then stripped out of the aqueous phase into the gas. The familiarity of this arrangement should not be allowed to limit our imaginations about the possibilities of bioprocessing. It is perfectly possible to construct a process in which a gas-phase contaminant (hydrogen sulfide) is biodegraded with the help of a nonvolatile oxidant (nitrate), generating a product (sulfuric acid) that remains dissolved in the aqueous phase. The bioreactor for such a process must share many of the features found in aerobic wastewater treatment, such as efficient gas–liquid contacting, cell recycling or immobilization to create a high concentration of biomass, control of temperature and pH, and addition of nutrients in order to create a comfortable environment for microbial metabolism. However, the different objective, the treatment of a gas rather than a liquid, must dictate differences in the details. This point can be illustrated by thinking of a conventional trickling filter not as a device for treating sewage, but as one for removing oxygen from the air that flows through it. It would work, but terribly inefficiently, with a fractional removal on the order of 1%.

This chapter presents a three-step study of the use of bioprocesses for the removal of undesirable components from gas streams. The existing and potential applications are described first, followed by the types of bioreactors that may be employed. A simple process analysis is then presented to illustrate how the choice and design of the bioreactor is dictated by the particular application, the type of microbial metabolism involved, the concentration and solubility of the contaminant, and so on. It should be noted that there are also a number of potential bioprocesses in which the objective is not the removal of a contaminant from a gas stream, but the bioconversion of gaseous substrates into useful products. They include the partial oxidation of methane to methanol, and the production of ethanol and acetic acid from mixtures of carbon monoxide and hydrogen. Work on these processes is not described in detail, except when doing so illustrates the common problems of bioreactors with gaseous substrates.

45.2 MICROORGANISMS AND APPLICATIONS

Due to inherent difficulties in achieving the sterile conditions necessary for prolonged maintenance of pure cultures in field-scale bioreactors, most gas treatment bioreactors contain a mixed culture or consortium of microorganisms. These consortia may be derived from a number of different inocula, from common sources such as sewage-treatment facilities, biofilms from established bioreactors used for similar applications, or soils and waters from areas contaminated with the substrate of interest. In some instances, it is possible to enrich for the desired microbial consortium directly from the bioreactor bed medium, particularly

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

when media components such as soil, compost, peat, or bark chips are used, because these materials naturally contain a mixture of microbes with wide-ranging physiological capacities. Regardless of the inoculum source, the bioreactor must be operated under conditions that select for and maintain, over the life of the bioreactor, microorganisms with the physiological capabilities necessary to catalyze the desired bioconversion. Typical selective factors include the electron donor (i.e., the metabolizable energy source), available terminal electron acceptors, supplemental nutrients, pH, Eh, and temperature.

Regardless of the selection strategy used to achieve a microbial consortium with the desired physiological properties, the use of a consortium versus the attempted use of a pure culture of microbes has a number of practical advantages. As mentioned above, it is difficult to achieve the sterility standards necessary to maintain a pure culture of microbes in a gas treatment bioreactor under field conditions. In addition, a pure culture of microbes is often metabolically incapable of fully degrading a contaminant, so hazardous intermediates may be created and build up within the bioreactor or in effluent streams from the bioreactor. Because mixed consortia inherently tend to be composed of a number of different microbial species with a gamut of physiological capabilities, undesired intermediates that may be created by pure cultures are often fully degraded by consortia. Similarly, in many applications, the concentrations and chemical compositions of gas streams to be treated may be transient. Consortia generally have a higher probability than pure cultures of adapting to this transience. The contaminant gases and vapors that can be successfully biodegraded can be classified by their role in microbial metabolism.

45.2.1 Electron Donors

Microorganisms require a constant supply of metabolic energy, which is normally derived from the oxidation of either organic or inorganic compounds, with these compounds serving as electron donors to the microorganisms. Many environmentally or industrially significant gases and vapors are metabolically oxidizable by microorganisms and can serve as electron donors. Thus, many different types of gas and vapor streams can be and have been, treated microbiologically (1). Microbially oxidizable gases and vapors that have been treated in bioreactors include hydrocarbons, ketones, ammonia, xylene, alcohol, terpene, and carbon disulfide vapors, as well as gases such as methane and hydrogen sulfide (2–10). In the case of carbon-containing substrates (hydrocarbons, carbon monoxide, etc.), the metabolism of these compounds provides heterotrophic microbes not only with an electron source, but also with a source of cellular carbon. Non-carbon-containing substrates such as ammonium, while providing a metabolic electron source, must be metabolized by autotrophic microorganisms capable of obtaining their cellular carbon via the fixation of atmospheric carbon dioxide.

45.2.2 Cometabolism

Some substrates cannot serve as sole energy sources for microorganisms, but are nevertheless potentially bioconvertable. Their biodegradation is achieved in the presence of another compound that serves as the microorganism metabolic electron donor, a process that is termed cometabolism. Trichloroethylene (TCE) provides a well-documented example of a substrate that is oxidized cometabolically by microorganisms. Typical of cometabolic TCE degraders are the methanotrophic bacteria, aerobes that oxidize methane as their sole carbon and energy source (11). This oxidation takes place in a sequential manner, with methane first being converted to methanol, which is in turn oxidized to formaldehyde, formate, and finally, carbon dioxide. Along this oxidative pathway, the methanotrophs generate cellular energy as well as fixing methane-derived carbon into additional biomass. The first step, in which methanol is formed from methane, is catalyzed by the enzyme methane monooxygenase (MMO) (12,13). Although MMO is selective for its natural substrate, it can, under certain conditions, catalyze the oxidation of a variety of other compounds (12–14), including partially chlorinated aliphatic solvents such as TCE. Two distinct forms of MMO have been identified, membrane MMO (mMMO) and soluble (sMMO) (15,16). sMMO, expressed by methanotrophs growing under copper-limited conditions, supports much higher rates of TCE oxidation than does mMMO, which is expressed under conditions of copper sufficiency (17).

Air streams contaminated with TCE and similar chlorinated solvents are generated by industrial operations and the remediation of contaminated ground and water by air stripping. They can be treated in a bioreactor that is started up with methane as the sole carbon and energy source, while supplying the necessary oxygen and supplemental nutrients under copper-limiting conditions (6). After the methanotrophic consortium is established, the methane load to the reactor can be decreased or fed on an intermittent basis concurrently with TCE vapors. The methanotrophic microbes then will be maintained by the lessened methane feed, while catalyzing the oxidation of the TCE via their sMMO. The reduced or intermittent methane feed not only reduces the amount of methane that must be supplied, but is essential in achieving optimal TCE removal rates since methane itself is an effective competitive inhibitor of TCE oxidation. An alternate, but more expensive, strategy used to avoid this type of

competitive inhibition is to supply a catabolic intermediate such as formate in order to provide energy to the methanotrophs, because formate does not compete with TCE for access to the sMMO. It should be noted that a number of other microbial oxygenases have been shown to be capable of catalyzing cometabolic TCE oxidation. These include toluene oxygenases from a number of *Pseudomonas* spp., propane monooxygenases from propanotrophs, and ammonia monooxygenase from *Nitrosomonas europea* (18–21).

45.2.3 Electron Acceptors

Most gas treatment bioreactors remove contaminants from air streams and oxidize them to innocuous end products (CO_2, Cl^-, etc.), using the oxygen in the air as the electron acceptor. However, there are also gas streams containing little or no oxygen where the objective is to remove a compound that can act as an alternative physiological terminal electron acceptor. This approach has been shown to work for compounds like sulfur oxides (SO_x) and nitrogen oxides (NO_x) (8,24,25). NO_x biofilters have been developed using a consortia of denitrifying microbes that have the physiological capacity, as a part of their normal metabolism, to use a variety of NO_x compounds as terminal electron acceptors, reducing them to innocuous nitrogen gas (N_2). This process generally requires low-oxygen conditions because denitrifiers preferentially use oxygen, if present, as their terminal electron acceptor. As a result, selective conditions for denitrifying microbes include a suitable carbon and energy source with a NO_x compound as a terminal electron acceptor, a lack of oxygen, and the presence of supplemental nutrients necessary for microbial growth. The potential application to stack gases raises the question of the maximum temperature at which the microbes will function. Research (25) has shown that naturally occurring thermophilic microbes selected for from compost are capable of reducing nitric oxide (NO) to nitrogen gas (N_2) at temperatures up to 60°C.

Other processes are far more sensitive than denitrification to trace amounts of oxygen. The sulfite-reducing bacteria responsible for the removal of SO_2 are obligate anaerobes, although they may be active in anoxic microniches, for example, deep in a biofilm. Chlorinated aliphatic solvents will also accept electrons under anaerobic conditions, a degradative mechanism that works best on the completely chlorinated compounds that are not touched by the oxidative enzymes already discussed (22,23). Carbon tetrachloride, for example, will be progressively reduced to chloroform, dichloromethane, and methyl chloride. This mechanism is often categorized as cometabolism, implying that the microbes derive no metabolic benefit from it, but this remains uncertain.

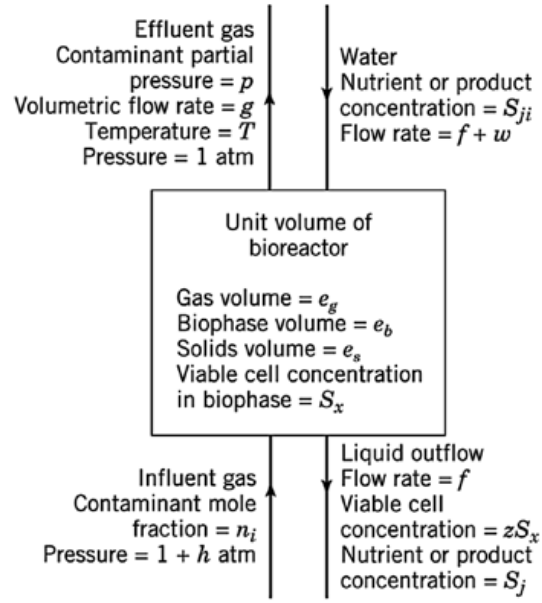

Figure 45.1. The generic gas-treatment bioreactor.

45.3 BIOREACTOR TYPES

Figure 45.1 shows a generic gas treatment bioprocess along with the nomenclature to be used in the subsequent analysis. Gas treatment bioreactors are sometimes described as *gas-phase bioreactors*, but this term is inexact in the sense that the actual reactions happen inside a microbial cell, which is necessarily an aqueous phase. Some reactions carried out in immobilized enzyme reactors do seem to involve direct interaction between the gas and the enzyme (33), although even here the humidity remains a critical variable and the enzyme may be covered with a layer of water a few molecules thick. For our purposes, the bioreactor is divided into a gas phase, a solid phase consisting of any solid packing or biofilm support particles, and a biophase, which contains the water and the microorganisms. The fraction of the bioreactor volume occupied by each phase is called its holdup, and the three values, e_g, e_s, and e_b, must add up to 1.

For convenience, we think in terms of a bioreactor of unit volume and express the gas flow rate as the volume per volume per minute (VVM) flow rate, g, at the effluent gas conditions, taken as temperature T and atmospheric pressure. Others choose to work in terms of the molar outlet gas flow rate (g/RT, where R is the gas constant) or a gas residence time, either the empty bed residence time, $1/g$, or the average time an element of gas actually spends in the reactor, e_g/g. The flow rate of the influent gas is not the same as g because its temperature may not be T, it is at a higher pressure, ($1 + h$ atmospheres, where h is

the pressure drop through the reactor), and because various components (contaminant, oxygen, metabolic products, water vapor) are added to, or removed from, the gas stream as it flows through the reactor. When these effects are significant, it is essential to specify exactly what is meant by "gas flow rate."

The objective of some processes is to remove a gaseous contaminant by converting it into a soluble, nonvolatile metabolic product. Some such products, H^+ for example, can be neutralized in the bioreactor, but others, such as the Cl^- from the degradation of chlorinated organics, must be removed in the liquid if they are not to accumulate to concentrations that inhibit the microorganisms. There may therefore be a liquid outflow, f per unit bioreactor volume, and an inflow that must be greater than f to allow for the evaporation rate, w. This outflow tends to wash microorganisms out of the bioreactor, and it is usually beneficial to retain them either by cell recycle or immobilization, making the parameter z in Figure 45.1 less than 1.

The question is what type of bioreactor should be put in the "black box" in Figure 45.1. Almost every possible configuration by which a gas can be contacted with a biofilm or a suspension of microorganisms has been employed in some application, and these can be roughly divided into four categories.

45.3.1 Biofilters

The earliest gas-treatment bioreactors were used to control odors in air coming from slaughterhouses and rendering plants and consisted of porous pipes buried in the ground, the noxious compounds being removed by a combination of adsorption and biodegradation as the air flowed up through the soil (26). Applications of the idea have since expanded to include the removal of hazardous, volatile compounds from chemical plants, paint shops, foundries, and a variety of agricultural and food-processing operations. Although often effective, the operation of these simple soil beds depends critically on the local soil and weather conditions. Unless they are covered and/or periodically sprayed with water, they may stop working, either due to becoming waterlogged or to drying out. They have largely been replaced by custom-made biofilters, which are essentially boxes made of plastic, wood, sheet metal, concrete, or even stainless steel, containing a bed of media and a gas distribution system to ensure uniform flow of the gas through the bed.

In terms of the variables defined in Figure 45.1, biofilters are the small e_b, small f, and small z approach. The biophase consists of individual microorganisms attached to the media, perhaps enough to constitute a thin biofilm. The amount of moisture in this layer is critical, and is controlled by humidification of the inlet gas and/or by spraying water directly over the bed. Little or no water drips out of the bed, making it difficult to provide soluble nutrients and pH control chemicals, or to wash out nonvolatile metabolic products. Biofilters are thus best suited to applications that generate no such products and involve no pH swings, the treatment of air streams containing low levels of volatile organics being the obvious example.

The great advantage of biofilters over the early soil beds is that they allow the choice of the nature and particle size of the bed media. This media must support a high density of attached microorganisms suited to the particular application, perhaps even providing some of the nutrients needed for their growth. The ability to adsorb the contaminant is an advantage because adsorption can provide some contaminant removal during the start-up period, before a large population of well-acclimated microorganisms has developed (sometimes called "the bed-ripening period"), and during any sudden slugs of concentrated contaminant in the influent gas. Also, although the interactions between such adsorption and biodegradation are complex and poorly understood, they are generally favorable to biofilter performance. Finally, the media must be mechanically strong and resistant to disintegration, compacting, and the resulting channeling of gas flow. Soil, compost, peat, and wood-chip mixtures are all inexpensive media that have been used successfully. Materials such as activated carbon and limestone, although more expensive, may be mixed in to provide extra adsorption and pH buffering.

The particle size of the media is critical. Small particles give a huge gas–biophase interfacial area per unit bed volume (a quantity subsequently called "a"), thus eliminating concerns about mass-transfer limitations between the two phases. But beds of small particles have a higher resistance to gas flow, are more prone to waterlogging and plugging by excess biofilm, and if too light, may get blown out of the reactor altogether. A general guideline is to choose the smallest available particles that avoid the latter problems, and then ensure that the shape of the bed is optimized to give the desired contaminant removal with a reasonable pressure drop (see "Scale-Up").

If the life of the bed is found to be finite due to compaction, loss of pH buffering capacity, accumulation of salts from the evaporation of added water and so on, one solution is to employ two beds in series. Bed 1 can provide most of the contaminant removal, while bed 2 polishes the effluent, mainly by adsorption, while developing its own population of well-acclimated microorganisms. When bed 1 is exhausted it can be replaced by bed 2, which is itself replaced by a bed of fresh media. The arrangement of the media on a series of trays in the bioreactor facilitates this mode of operation.

45.3.2 Bubble-Gasified Reactors

Conventional bubble-aerated fermenters make poor gas treatment bioreactors because they are designed for a high rate of transfer of gaseous nutrients and products (O_2 in and CO_2 out), rather than a high fractional removal of a component from the air stream. This latter objective requires taller bioreactors with longer gas residence times, but tall reactors mean higher pressure drops due to the hydrostatic head. Nevertheless, tall, mechanically agitated bioreactors with multiple impellers have been proposed for removing H_2S from industrial gas streams (29), and bubble columns with no mechanical agitation have been demonstrated for the removal of TCE from air using a toluene-oxidizing organism (30).

These bioreactors are in many ways at the opposite extreme from biofilters. The biophase occupies most of the reactor ($e_b \rightarrow 1$ in Fig. 45.1), and it is dilute and well-mixed rather than dense and immobilized. The large volume of water makes it easy to add soluble nutrients, control the pH, and remove water containing nonvolatile products. However, care must be taken to not wash out the biomass, because $z = 1$ (Fig. 45.1) unless there are extra surfaces in the bioreactor for the attachment of a biofilm, or if a cell separation and recycle loop is added. Another major difference is that the gas–biophase interfacial area, a, is not only much smaller than in a biofilter, but is not even a constant, varying with the gas flow rate. Bubble gasified bioreactors are therefore best suited to contaminants like NO_x that are very soluble in water (thus reducing concerns about the gas–liquid mass-transfer rate), whose dissolution in water cause pH swings, and whose metabolism requires large amounts of dissolved nutrients.

45.3.3 Biotrickling Filters

Trickling filters for gas treatment are similar to, but usually taller than, those in use for decades for the secondary treatment of municipal and industrial wastewaters. Like biofilters, they consist of a bed of media through which the gas flows either upward or downward, but unlike biofilters, the microbial culture is recirculated continuously over the bed from a reservoir beneath it. Stone aggregate or wood chips are the traditional media, but even seashells have been used (27). Most modern filters employ ceramic or plastic media, Pall rings, Raschig rings, and so on specifically designed to make a bed with a high surface area to maximize gas transfer, and a high porosity to minimize the pressure drop and the chance of clogging or flooding (28).

These bioreactors can be thought of as intermediate between biofilters and bubble-gasified systems and are best suited to applications between those already described. If the characteristics of the media and the microorganisms are such that most of the biomass stays attached, then a trickling filter is essentially a biofilter with a higher liquid flow and a smaller gas–biophase interfacial area, a, due to the larger media. If on the other hand, most of the biomass stays suspended and the recycle ratio (RR = flow of recycled liquid/f) is high enough to keep the biophase well mixed, then it is functionally similar to a bubble-gasified bioreactor. The main differences are that the pressure drop, h, is usually much smaller, and the interfacial area, a, is a constant that is independent of the gas flow rate.

45.3.4 Bioscrubbers

The systems just described essentially combine two functions, stripping the contaminant from the gas into the aqueous biophase and then subjecting it to biodegradation. But what if the physicochemical conditions in the biophase resulting from the stripping are not suitable for the microbial metabolism? The removal of sulfur dioxide from stack gas is a good example because stack gases contain a small percentage of oxygen that although relatively insoluble, inhibits the bacteria responsible for the reduction of the sulfite formed by the dissolution of SO_2. One solution is the bioscrubber, which consists of an aqueous stripper in which the contaminant is transferred from the gas to water, and a separate bioreactor, in which the liquid effluent from the stripper is essentially treated as wastewater. The bioreactor should be a completely mixed, immobilized-cell type so that a large population can grow up in a well-controlled environment without continuously being recirculated through the potentially toxic environment in the stripper. Several configurations are possible, the simplest being that in which the liquid reservoir at the bottom of a packed-bed stripper is used as the bioreactor. Bioscrubbers are not considered further here because building a separate bioreactor and stripper is necessarily more expensive than combining them in a single unit, and when it is necessary, the two unit operations can be designed by conventional methods.

45.4 BIOREACTOR DESIGN

A process variable is any quantity that is under the direct control of the designer or operator of the process. For gas treatment bioreactors, the variables to be fixed by the designer include the bioreactor type, shape, and size, whereas those fixed by the operator include the addition of water, nutrients, and chemicals for pH control. The objective in fixing these variables is to satisfy a set of process requirements that specify the flow rate and composition of the gas stream, the nature and concentration of the contaminant, and the fractional removal required. The difficulty is that many designs, that is, many combinations of the process variables, will meet the process requirements for a particular case. The proper

goal of engineering design is not simply to pick one of these designs at random, but to find the single design that meets the requirements at the lowest possible cost. The design of gas treatment bioreactors, like that of any other process, is an economic optimization problem, but one that is so complex that the exact solution cannot be found within the constraints of time and money normally imposed on the design process. The best solution for a particular case will certainly depend on the scale of the problem, the solubility and possible inhibitory effects of the contaminant, the type of microbial metabolism (aerobic or anaerobic, growth associated or cometabolic, etc.) needed to degrade it, and the temperature and pressure of the gas stream. Even coming close to the best solution requires a careful scale-up program in which the insights available from education and experience are used to integrate experiments at different scales with mathematical models that can extrapolate the results from one scale to the design of the equipment at the next scale. The bioreactor analysis presented in this section is intended as a guide to this program, suggesting which bioreactor types be chosen for experimental evaluation in each case, specifying the operating conditions around which the experiments should be designed, and showing how performance may be expected to vary with scale.

Because the design goals are essentially economic, the relationship of the variables shown in Figure 45.1 to the process costs must be kept in mind. The volume of the commercial-scale bioreactor equals the actual gas flow to be treated (a process requirement) divided by g; a large value for g translates directly into a smaller and, all other things being equal, cheaper bioreactor. The liquid flow, f should be kept as small as possible because providing clean water and disposing of any process wastewater both cost money, as do any nutrients and chemicals that must be added. The pressure drop, h, through the bioreactor may be significant, particularly on a large scale, and it determines the capital cost of the gas compressors and the energy costs for running them. Compressing the feed gas is not only expensive in itself, it heats the feed such that heat exchangers may be needed to cool it to the desired temperature.

45.4.1 Process Analysis

It will be assumed that the biophase is completely mixed and that the gas approximates plug flow through the bioreactor. This provides a realistic description of some bioreactors (bubble columns, some biotrickling filters), and a reasonable starting point for quantitative thinking about the others. More detailed mathematical models are available in the literature for specific types of bioreactors and metabolism (31,32). The equilibrium solubility of the contaminant in the biophase, S^*, will be described by Henry's law, $S^* = p/H$, where p=partial pressure of the contaminant in the gas and H=Henry's law constant. Although this is adequate for relatively insoluble and dilute contaminants, it is a considerable oversimplification for others. For example, the dissolution of oxides of nitrogen (NO_x: a mixture of NO and NO_2) from stack gases into water is an extremely complex process (34,35) that involves the gas-phase chemical oxidation of NO to NO_2 and a dissociation reaction that generates H^+, NO_3^-, and NO_2^- when the gas dissolves. In such cases, Henry's law can only be interpreted in the purely qualitative sense that low H means a soluble gas.

Any complete bioprocess model combines the mass conservation equations that describe the bioreactor with equations that try to approximate the complexities of microbial metabolism. Because the objective here is to compare different bioreactor configurations, it is essential to have consistent descriptions of the metabolism. In most gas treatment applications the contaminant is a major microbial nutrient, either the electron donor or the electron acceptor. Its consumption provides metabolic energy for growth and cell maintenance, so its specific consumption rate, q is given by the yield equation

$$q = \frac{\mu}{Y} + k \tag{45.1}$$

where μ is the specific growth rate of cells, Y is the cell-yield coefficient, and k is the cell-maintenance coefficient.

In a well-operated bioreactor, the pH and temperature are carefully controlled and all required nutrients are provided in adequate amounts, making the specific consumption rate a function only of the concentrations of contaminant, S, and any inhibitory product, S_m, dissolved in the biophase. The exact form of this function, written $q(S, S_m)$, will not be specified because it varies among cases, but it must describe the effects on the metabolic rate of substrate limitation, product inhibition, and possibly (when n_i/H is large) substrate inhibition. It is more common to describe the specific cell growth rate, μ, by a Monod-type function of the concentration S, but this is clearly incorrect at the low concentrations found in gas treatment bioreactors, because it predicts that growth stops and substrate uptake continues when no substrate is available ($\mu = 0$ and $q = k$ when $S = 0$). In fact, when a major nutrient is exhausted, its consumption must stop, and the microorganisms go into an endogenous state in which the viable biomass declines, a phenomenon correctly approximated by requiring that $q(S, S_m) = 0$, and thus $\mu = kY$ (equation 45.1) when $S = 0$. Cell growth now stops at a nonzero "stationary phase" concentration, S_s, corresponding to the point where substrate uptake is just sufficient to satisfy the maintenance requirement, and defined by $q(S_s, 0) = k$.

For cometabolic processes, the contaminant is neither the main electron donor nor the acceptor; two rate equations are needed, and equation 45.1 contains an extra parameter whose value may be found from knowledge of the degradative pathway. See, for example, the analysis by Andrews of chloroform degradation by methanotrophic bacteria (36). The design of cometabolic bioreactors follows many of the principles described here but is too complex and case specific to be analyzed in detail.

At steady state the conservation of mass requires that the rate of growth of microorganisms in the bioreactor, $\mu e_b S_x$, equals the rate at which they flow out, fzS_x (see Fig. 45.1 for nomenclature). The loss of microorganisms in mist suspended in the effluent gas may be significant in some bioreactors without demisting devices but is not included explicitly in the analysis. The specific growth rate, μ, a measure of the physiological state of the microorganisms, thus equals zf/e_b, the reciprocal of the mean cell-residence time (the number of cells in the bioreactor divided by the cell outflow rate), which is a quantity under our direct control. This remarkable result, although well known for chemostats, has not been fully appreciated for gas treatment. It follows from equation 45.1 that the concentrations in the biophase, S and S_m, are constrained by

$$q(S, S_m) = k(1 + D) \tag{45.2}$$

where $D = zf/Yke_b$ is the dimensionless dilution rate or reciprocal mean cell-residence time.

The steady-state conservation of mass for the contaminant requires that whatever is removed from the gas phase be transferred to the biophase, where it is either consumed by the microorganisms or flows out in the liquid. For a bioreactor, as opposed to a gas stripper, the latter term should be negligible, but the flows of dissolved nutrients and nonvolatile metabolic products must be included

$$\frac{g}{RT}(n_i - p) = \frac{k_1 a(n_i - p)}{H\ ln\dfrac{(n_i - HS)}{(p - HS)}}$$

$$= e_b q S_x = \pm\frac{(fS_j - (f + w)S_{ji})}{y_j} \tag{45.3}$$

where y_j is the amount of component j produced (+ sign) or consumed (− sign) per unit of contaminant consumed (see "Nutrient Addition and Start-Up").

The description of the driving force for mass transfer in terms of the log–mean concentration difference in the second term of this equation follows from the assumption of plug flow of the gas. The expression is not strictly correct when the pressure drop through the bioreactor is large, as in a tall bubble column, because the contaminant partial pressure in the influent is then $(1 + h)n_i$; but this complication is rarely included in practice. The essential points here are that the mass-transfer factor, k_1a, is an empirically determined parameter, that it can be based on different forms of the driving force, and that the best choice depends on the reactor type and must be clearly understood by everyone involved in a project.

Equation 45.3 can be rearranged to give the fractional removal of the contaminant from the gas, only the product (subscript m) being considered in the last term:

$$x = 1 - \frac{p}{n_i} = (1 - e^{-G})\left(1 - \frac{HS}{n_i}\right)$$

$$= \frac{S_x}{X}(1 + D) = FD\frac{S_m}{S'_m} \tag{45.4}$$

where $G = k_1 aRT/gH$ is the dimensionless mass transfer coefficient; $F = YS'_m/zXy_m$ is the dimensionless product inhibition factor; $X = gn_i/ke_bRT$ is the maximum possible viable cell concentration in the biophase; and S'_m is the product concentration that completely inhibits cell growth.

Rather than solving equations 45.2 and 45.4 exactly, which would require the form of the inherent kinetic function $q(S, S_m)$, consider some limiting cases in order of decreasing liquid outflow rate. These cases are used to summarize the bioreactor performance in Figure 45.2, a graph that can be universal, at least within the limitations of the assumptions, because the parameters describing the contaminant (H, n_i), the reactor (f, k_1a), and the metabolism (k, S'_m) in individual cases have been incorporated into the dimensionless numbers x, D, F, and G.

- *Washout*. $D > (q(n_i/H, 0)/k) - 1$: Because the dissolved concentration, S, must obviously be less than that in equilibrium with the feed gas, n_i/H, equation 45.2 now has no solution, meaning that all of the biomass is washed out of the reactor and there can be no contaminant removal.

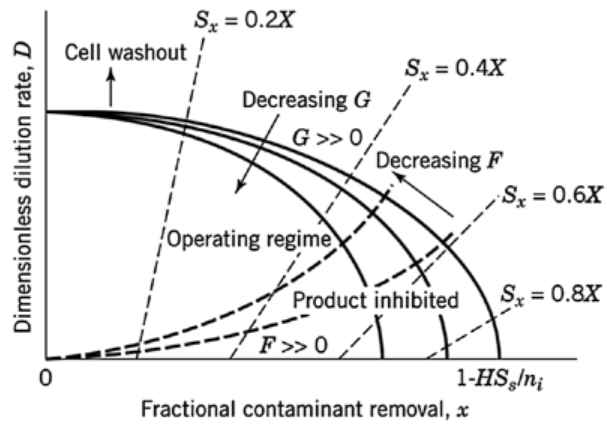

Figure 45.2. Operating regime for a completely mixed bioreactor.

- *Substrate limitation*. $D > (1 - e^{-G})/F$: Equation 45.4 shows that under this condition, $S \to 0$, while $S_m < S'_m$, meaning that microbial kinetics are limited by the availability of substrate rather than product inhibition and the exact value of the inhibition number, F, is irrelevant. If gas-biophase mass transfer is very rapid, the dissolved contaminant is in equilibrium with the outlet gas, giving the best possible bioreactor performance. The shape of this $G = \infty$ line in Figure 45.2 is simply a reflection of the relationship between $\mu(= zf/e_b)$ and $S(= p/H)$ from the inherent microbial kinetics. Mass-transfer limitation ($G < \infty$) leads to a progressive reduction in the contaminant removal, x.
- *Product inhibition*. $D < (1 - e^{-G})/F$: Now the concentration of metabolic products, S_m reaches inhibitory levels, S'_m, while dissolved contaminant is still available, meaning that metabolism is limited by product inhibition rather than substrate limitation, and the exact value of G is irrelevant. Increasingly stronger inhibition (smaller F) produces a series of curves in Figure 45.2 whose exact shape depends on the details of the inherent inhibition kinetics. All of these curves pass through the origin because, with no liquid outflow ($D = 0$), any soluble, nonvolatile metabolic products must eventually accumulate to inhibitory levels.

45.4.2 Consequences for Process Design

Any pair of values of F and G define a regime in Figure 45.2 within which the bioreactor can operate. The most important result is that for any such pair of values there exists a value of D that maximizes the contaminant removal, x. If the form of the rate equation $q(S, S_m)$ were known, the pointed maximum seen in Figure 45.2 would be replaced by a smooth curve that defined this optimum design more accurately. In the absence of such detailed modeling the optimum must be found experimentally, the analysis providing a starting point and overall guidance. Because the gas flow rate, g, appears in the denominator of both F and G, the first step is to establish the maximum g for which the desired contaminant removal, x, falls safely within the operating regime. It is clear from equation 45.4 that a high removal rate (e.g., $x = 0.95$) with reasonable values of $S(\gg Hn_i)$ and $S_m(< 0.5\ S'_m)$ requires both $G \sim 3$ and $FD \sim 2$, and such values are reasonable, if approximate, general design goals. Much larger values represent inefficient design because they imply excessive consumption of energy and water.

For processes that produce large amounts of very inhibitory, nonvolatile, soluble metabolic products, the problem is to wash the products out of the bioreactor without washing out the biomass. Mathematically, $y_m/S'_m \to \infty$, making it difficult to keep $FD > 2$ without D exceeding the washout criterion. These are the processes that require cell retention ($z \to 0$), either by cell recycle or by immobilization as a biofilm. For processes with more moderate values of y_m/S'_m, the analysis shows that there exists an optimum set of values of the process variables g, f, and z. Some processes, the aerobic mineralization of hydrocarbons for example, generate only innocuous (H_2O) or gaseous (CO_2) products, so $y_m/S'_m \to 0$, and the analysis suggests operating with no liquid outflow. This not only gives the best effluent-gas quality (Fig. 45.2 with $F = \infty$) but, because the biomass is in a maintenance condition ($\mu = 0$ when $D = 0$), it also avoids the cost of adding nutrients, such as phosphates, that are needed for microbial growth (see "Nutrient Addition and Start-Up"). In practice there are reasons to avoid this condition. Even if y_m/S'_m is too small to be observed in short-term laboratory experiments, any nonvolatile product must eventually accumulate to inhibitory levels in a continuous bioreactor with no liquid outflow. Salts in the water added to compensate for evaporation or for pH control will also accumulate in the biophase. Also, it must not be forgotten that complete mixing of the biophase is an abstraction never achieved in practice and sometimes, as in the biofilter, not even attempted. The discussion prior to equation 45.2 shows that any bioreactor with $D = 0$ must have a cell growth rate $\mu = 0$ as an average, but it will contain microniches where cells are dying because conditions are worse than average, and others where conditions are slightly better and cells are growing. Although the growing cells may assimilate some of the material released by the lysis of the dying cells, there must be some long-term accumulation of dead biomass, with consequent reduction in bioreactor performance. Keeping D on the of order of 1, a very low flow rate in most cases can wash out the dead biomass and ensure stable operation for the cost of a few growth nutrients.

The analysis assumed the usual case in which the cell concentration in the bioreactor is kept as high as possible, with sufficient amounts of other nutrients provided to ensure that the contaminant is the limiting nutrient. The quantity X, defined under equation 45.4, is then the maximum possible viable-cell concentration in the biophase, corresponding to the situation where all of the contaminant flowing into the bioreactor, gn_i/RT, is being used to satisfy the cell maintenance requirement, ke_bX. The actual concentration at any given operating condition, S_x, can be calculated from the fourth term of the equation and is shown in Figure 45.2 as a function of D and x. There is, however, no guarantee that this concentration corresponds to a dilute, easily mixed cell suspension. If the maintenance requirement, k, is small, and the contaminant loading gn_i is large, it may be a paste of cells too dense to be, for example, pumped around a biotrickling filter. Although it is possible

to reduce S_x by restricting the amounts of growth nutrients provided, such artificial reductions in the microbial "catalyst" concentration are generally poor bioprocess design. The alternative is to choose the right type of bioreactor, recognizing that, although the mass of microorganisms in the bioreactor is fixed by the process requirements and the microbial metabolism, the amount of water is a process variable that can be controlled. The concentration, X, is an order of magnitude higher in a trickle-bed type bioreactor where $e_b \approx 0.1$, than in a bubble column where $e_b \approx 1$.

45.4.3 Nutrient Addition and Start-Up

In some processes, the aerobic mineralization of organics in beds of compost for example, the air provides the electron acceptor and the media provides what little growth nutrients are needed. In other processes these substances, and sometimes the electron donor, must be provided in the liquid inflow. The amounts can be estimated from the "stoichiometry" of metabolism, a procedure best illustrated by example. Ongcharit et al. (37) have shown that hydrogen sulfide can be removed from industrial gas streams by the acidophilic, autotrophic, sulfur-oxidizing, denitrifying bacterium *Thiobacillus denitrificans*. Even such esoteric metabolism can be approximated by a pseudo-chemical reaction in which all of the main nutrients and products are written in the ionic form in which they enter or leave the reactor. After performing all of the element and charge balances the result is

$$\begin{aligned} H_2S + (1.6 - 0.2y\gamma)NO_3^- + yCO_2 + ypH_2PO_4^- \\ \rightarrow\!\!\!\!\rightarrow\ yCH_hN_nO_oS_sP_p + (0.8 - 0.1y(\gamma + 5n))N_2 \\ + (1 + ys)SO_4^{2-} + (0.4 + y(0.2\gamma - p - 2s))H^+ \\ + wH_2O \end{aligned} \tag{45.5}$$

The first term on the right-hand side represents the dry weight of the biomass produced. $\gamma = 4 + h - 2o + 6s + 5p$ is a measure of its oxidation/reduction state and is remarkably consistent between species (36) (note that the base oxidation state for nitrogen here is N_2). The actual cell yield is y, the ratio of cells produced to H_2S consumed. For a completely mixed biophase this equals μ/q or, from equations 45.1 and 45.2,

$$y = \frac{DY}{(1 + D)} \tag{45.6}$$

The "stoichiometric coefficients" on the other components in equation 45.5 then provide the y_j values needed to calculate the concentrations of nutrients and products from the last term in equation 45.3. These simple calculations can provide a surprising amount of approximate information about process design and development. A feature of the example in equation 45.5 is the large amount of acid (H^+) produced by the metabolism. Even with the high liquid flow rate allowed by cell immobilization or recycle (29,37) its neutralization requires a high pH in the liquid inflow, so the biophase must be very well mixed if metabolism is not to be inhibited by pH gradients, suggesting some type of bubble-gasified bioreactor. If all of the NO_3^- and OH^- are provided by their sodium salts, then the salinity in the biophase would be high, suggesting a need for halophilic strains of bacteria. A reasonable alternative would be to explore the use of calcium salts, which would precipitate some of the product sulfate as gypsum, reducing inhibitory effects.

Like all the previous analyses, equation 45.6 applies only to steady-state operation. Gas treatment bioreactors, like any other bioprocess, are generally started with a relatively small inoculum of acclimated microorganisms, the objective of the start-up period being to increase the population to the steady-state value, S_x. This requires additional growth nutrients, and the initial feed concentration, S_{ji}, can be calculated as above, but with setting the observed cell yield, y, equal to the growth yield coefficient, Y. These concentrations can then be decreased slowly as steady state is approached. Start-up of biofilters is sometimes called ripening of the bed, and it is not always necessary to add growth nutrients, because the microorganisms capable of growth on the contaminant may obtain nutrients from the support material (compost, soil, etc.), or may grow at the expense of cells that die and lyse under conditions in the biofilter. If these sources are not sufficient to produce the biofilm thickness needed for maximum contaminant removal, some nutrient addition after steady-state contaminant removal has been reached will further improve performance. However, excessive nutrient addition must be avoided because modeling (38) suggests that, under contaminant limited conditions, a biofilm will grow much thicker than is needed. The inlet end of the biofilter may plug with useless biofilm.

Just because a steady state exists in theory, it does not follow that it can be reached by any start-up procedure. Of particular concern are those contaminants that are so concentrated (high n_i) and soluble (low H) that they will cause substrate inhibition of the microbial metabolism if their dissolved concentration in the biophase ever reaches equilibrium with the feed (n_i/H). The steady state analyzed above still exists, but $S \ll n_i/H$ only as a consequence of the metabolism of the large numbers of microorganisms present. Starting with a small inoculum, the dissolved concentration in the biophase will be much higher, metabolism will be inhibited, and the biomass may wash out. For similar reasons, batch experiments may produce the erroneous conclusion that the gas cannot be treated biologically. A proper start-up procedure may involve dilution of the feed gas and careful control of the dilution rate and nutrient

addition, until a dense, well-acclimated microbial culture has developed.

45.4.4 Gas-Biophase Mass Transfer

Figure 45.2 shows that high levels of contaminant removal require high values of the dimensionless mass-transfer factor, G, which is actually the product of two dimensionless numbers: H/RT, an inverse measure of the contaminant solubility, and k_1a/g, a measure of the efficiency with which the gas flow generates mass transfer. This is not usually a difficulty for biofilters with their thin biophase and very large a but how can it be achieved for other bioreactor types? Measurements of gas–liquid mass transfer factors (28) are often given as correlations of the form

$$k_1a = AU_g^c \tag{45.7}$$

The superficial gas velocity U_g is related to the flow rate g by $U_g = gL$, where L is the bioreactor height. Consider first an idealized bubble column, a hypothetical device in which all the bubbles are the same size, and doubling U_g simply doubles their number. The exponent c must then be 1, making $k_1a/g = AL$, a constant dependent upon scale but independent of gas-flow rate. In real bubble columns, with their imperfect bubble dispersion, c is closer to 0.7, but this still implies that G varies only slightly with g. The copious data available for oxygen transfer from air (28) shows that, at normal gas flows (g on the order of 1 VVM), k_1a/g is on the order of 1 at the laboratory scale, rising toward 10 in commercial-scale equipment. Assuming for the purposes of illustration that k_1 for a gas is proportional to its diffusivity in water raised to the 2/3 power (strictly valid only for relatively insoluble gases, for which most of the mass-transfer resistance is on the liquid side of the gas–biophase interface), this can be used to estimate G and the maximum possible fractional removal, $1 - e^{-G}$, (equation 45.4 with $S \to 0$) for contaminant gases of low, medium, and high solubility. The results shown in Table 45.1 suggest that bubble columns would be useless for insoluble contaminants like carbon monoxide, but worth consideration for moderately soluble contaminants like hydrogen sulfide. Most hydrocarbon vapors fall into the former category, but many alcohols and chlorinated aliphatic solvents are in the latter (30). For very soluble contaminants, such as sulfur dioxide, G tends to be unnecessarily large in bubble columns, and while acceptable removal with a moderate pressure drop could be achieved in very short, wide columns, this configuration has not been explored in practice.

The addition of a mechanical agitator can increase k_1a by roughly one order of magnitude, mainly by breaking up the gas flow into many small bubbles with a large interfacial area. Equation 45.7 still applies, but the A parameter becomes a function of the mechanical power input per unit reactor volume. Unfortunately, agitation also undermines the assumption that the gas moves though the reactor in plug flow. In a mechanically agitated tank, the gas bubbles are assumed to recirculate several times so that the gas phase is completely mixed; a sample of gas containing many bubbles taken from anywhere in the tank would have the same composition as the outlet gas. The effect on the driving force for mass transfer can be seen by comparing the concentration profiles shown in Figure 45.3a and b. Mathematically, the long-mean concentration difference used in equation 45.3 must be replaced by the more familiar effluent partial pressure driving force ($p/H - S$), which makes the maximum possible removal not $(1 - e^{-G})$, but $G/(1 + G)$. These two functions are virtually identical at small G, which explains why the exact definition of the driving force is not an issue for aeration (oxygen is an insoluble gas, $H/RT = 30$ at 20°C, and its small fractional removal from the air stream in conventional fermenters is unimportant). However, a goal of 95% contaminant removal now requires not $G > 3$, but $G > 19$, which gives some idea of the lower effectiveness of a completely mixed gas phase. The numbers in Table 45.1 show that this lower effectiveness cancels out the increased k_1a leading to conclusions similar to those for bubble columns. The extra expense of mechanical agitation is rarely justified in gas treatment bioreactors, although reactors designed for a high k_1a/g with large aspect (height:diameter) ratios and multiple impellers to prevent bubble coalescence (29) have been proposed for removing hydrogen sulfide. Stirred tanks have been used successfully (39) for the microbial production of ethanol and acetic acid from carbon monoxide and hydrogen (another insoluble gas; $H/RT = 51$ at 20°C), but the objective there was high volumetric productivity, rather

TABLE 45.1. Performance of Bioreactors for which $k_1a/g = 1 - 10$ for O_2

			Maximum possible removal	
Contaminant gas	H/RT at 20°C	G	Mixed gas phase $G/(1 + G)$	Plug flow gas $1 - \exp(-G)$
CO	37	0.023–0.23	0.022–0.19	0.023–0.20
H_2S	0.41	1.8–18	0.65–0.95	0.84–1
SO_2	0.0088	88–880	0.99–0.999	1

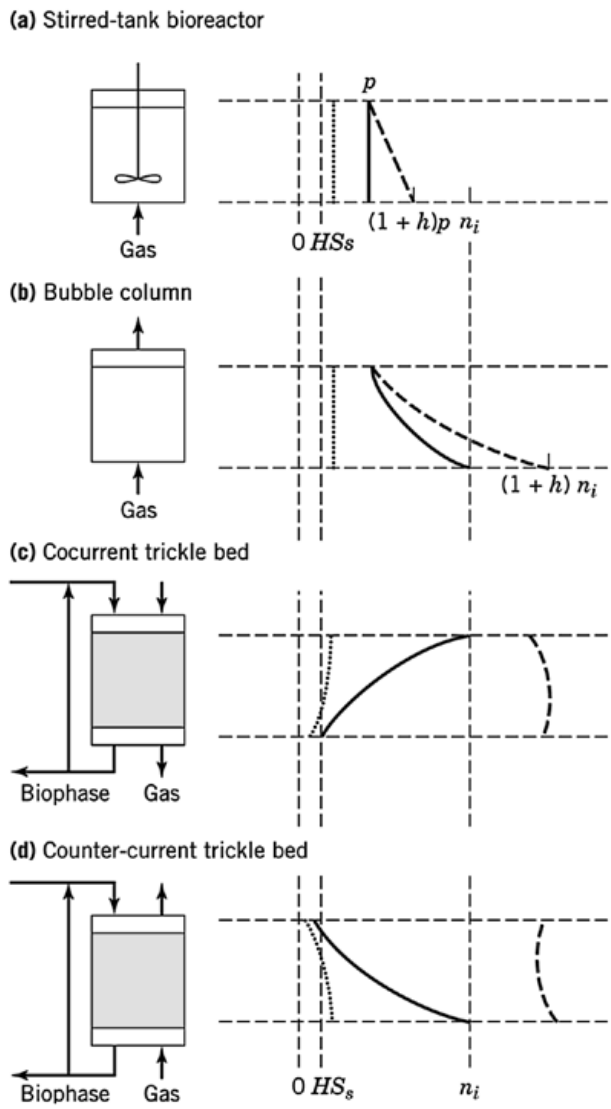

Figure 45.3. Concentration Profiles in Different Bioreactors. (**a**), (**b**) Partial pressure in gas phase, dot-dash line (**c**), (**d**) Viable biomass concentration, dot-dash line. Dotted line, partial pressure in biophase $= HS$; solid line, mole fraction in gas phase.

than complete gas consumption. Several tanks were used in series, and they were pressurized to several atmospheres to improve gas transfer.

In contrast to bubble-gasified reactors, the gas–biophase interfacial area in biotrickling filters is almost constant, fixed by the choice of packing media and only slightly influenced by U_g and the superficial velocity at which the liquid is pumped over the bed U_1. This makes it possible to achieve the necessary value of G for contaminants of almost any solubility by appropriate choice of the packing media and the gas flow per unit volume, g. Many types of packing are available and the best choice in a particular situation is a complex trade-off between the following considerations:

- Less soluble contaminants will need the large a provided by smaller media and the small g implied by the lower permeability of such media to gas flow. For these contaminants, most of the gas–biophase mass-transfer resistance is on the biophase side of the interface, so in correlations of the form of equation 45.7, $c \to 0$, but A is a fairly strong function of U_1.
- More soluble contaminants can achieve the same G with the smaller a and larger g given by larger media. In this case most of the mass-transfer resistance is on the gas side of the interface, so $c \rangle 0$ and A is less dependent on U_1.
- The conservation of mass shows that the change in concentration of a nonvolatile metabolic product in the biophase as it moves down the bed is $U_g x n_i y_m / U_1 RT$. If this number is small then the biophase approximates complete mixing. If it is large, then the concentration gradients, including that of pH, may be large enough to inhibit metabolism.
- Although a high liquid flow improves mixing and mass transfer, there is a definite upper limit of U_1 at which the bed floods. This limit is predictable (28) and is much smaller for small media.
- It is difficult to generalize about the attachment of the microorganisms to the media because this depends on both the nature of the media and the type of biomass involved. However, it is clear that a bed of small media with attached biomass may quickly become plugged if the contaminant is sufficiently concentrated and the biofilm is allowed to grow. It is reasonable to suppose that the larger the media and the higher the liquid velocity, the more cells will be suspended in the liquid rather than being attached. The z parameter in Figure 45.1 will be correspondingly larger.
- A biophase containing suspended and attached biomass may, if too thick or too dense, have its own mass-transfer resistance (38). While such resistance is usually to be avoided, it may be beneficial. For example, in trying to separate one electron acceptor, NO_x, from stack gases that contain another, O_2, which is preferred by the microorganisms, it should be possible to take advantage of the much higher solubility of the NO_x to create locally anaerobic environments in the biophase.

Somewhere among all of these considerations is a best choice of media for any situation. For dilute, less-soluble contaminants whose metabolism does not produce any nonvolatile metabolic products, the biotrickling filter will

look more like a biofilter, with small media, little liquid flow, and attached biomass. For more soluble contaminants which do generate such products, it will tend toward the other extreme of high liquid flows and a completely mixed biophase. If there seems to be no sensible solution, the answer may be to adopt a bioscrubber. Although more expensive, it greatly simplifies the design problem by separating gas–liquid mass transfer from the microbiological considerations. It is certainly preferable to think in terms of this continuum of possibilities and to choose the one best suited to a particular application, rather than considering the different types of gas treatment bioreactors as completely separate technologies, each of which can be forced to fit any job.

45.4.5 Biophase Mixing and the Minimum Effluent Concentration

The single bioreactors with a completely mixed biophase analyzed here have an obvious drawback: all of the microorganisms are exposed to the same physicochemical environment, it is the worst possible environment for metabolism, with the lowest nutrient concentrations and the highest concentrations of metabolic products. One consequence appears in Figure 45.2. Even with no mass transfer resistance ($G = \infty$), no product inhibition ($F = \infty$), and no wastage of biomass ($D = 0$), the analysis suggests that complete contaminant removal is still impossible. With no biomass outflow there is no net cell growth, and all of the contaminant is used for maintenance metabolism (equation 45.2 with $\mu = D = 0$ gives $q = k$). Under these conditions, the dissolved contaminant concentration is not zero, but the stationary phase concentration, S_s, so the partial pressure in the effluent gas cannot be less than HS_s, and the fractional removal, x, can never exceed $(1 - HS_s/n_i)$, even with perfect mass transfer (equation 45.4 with $G = \infty$). This maximum removal also exists for completely mixed biological wastewater treatment systems, but in that case it does not matter because S_s is much less than common effluent standards. It may matter for some insoluble gas-phase contaminants because the corresponding minimum-achievable partial pressure, HS_s, may be significant, even when S_s is small. Bioreactors with a completely mixed biophase are a poor choice for such contaminants.

The simplest improvement would be two bioreactors through which the gas flows in series and between which the microbial culture is continuously recirculated. Reactor 1 would have a relatively high effluent partial pressure and dissolved contaminant concentration, providing a good environment for metabolism and cell growth. If the process variables are fixed correctly (a complete analysis is beyond the scope of this chapter) reactor 2 could run with a dissolved concentration $S < S_s$. The biomass in reactor 2 would then be in an endogenous state, but this would no longer matter because fresh, viable cells would be continuously supplied from reactor 1, and the dying cells would either flow back there to recover or be lost in the liquid effluent. The liquid inflow would go to reactor 1, where the growth nutrients are needed, and where it would dilute the concentrations of any metabolic products.

The more bioreactors in series, the better the average physicochemical environment for metabolism. Columns containing many sieve trays or bubble-cap trays have long been used for gas–liquid contacting in the chemical process industry and should be considered for the biological treatment of gases in cases where the biomass grows best in suspension and the contaminant is relatively dilute, insoluble, and a poor microbial substrate (i.e., HS_s/n_i is large). These columns are inherently countercurrent contacting devices with the gas flowing upward while the microbial culture falls down from tray to tray. An individual microorganism experiences a series of environments with ever-increasing dissolved contaminant concentration, S, until it is suddenly pumped back to the top tray where conditions are endogenous ($S < S_s$), but where it can continue metabolizing contaminant and survive long enough to start through the cycle again. Nutrient addition and pH control can be done on each tray as needed, and the liquid effluent can be taken from near the top of the column where cell viability is lowest.

A similar effect, with the gas closer to the theoretical optimum of plug flow, can be achieved in an upflow biotrickling filter with a small liquid recycle ratio. The only drawbacks are that pH control and nutrient addition can now only be done at the top of the bed, and the liquid can only be removed from the bottom, which is not necessarily the best arrangement. If all the microbial cells are suspended, the concentration profiles of viable biomass and contaminant will be as shown in Figure 45.3d. In real trickle beds some of the biomass remains attached, which is a great advantage over tray columns when a nonvolatile metabolic product is generated, because it allows a large liquid outflow to remove the product without the danger of washing out the biomass. (Mathematically, D is small because z is small, even though f is large.) Biotrickling filters can also be operated in the gas-downflow, cocurrent mode, which gives concentration profiles (again assuming suspended biomass) more like those shown in Figure 45.3c. Now, the microorganisms moving down the bed experience an ever-worsening environment for metabolism, with lower S and higher product concentration S_m. They leave the bottom of the bed in an endogenous, low-viability state, which is very suitable for the liquid outflow stream, but which may cause a significant lag phase when cells are recycled to the better environment at the top of the bed. The question of whether the cocurrent mode works better can only

be answered definitively by experiments on a particular gas stream.

In biofilters the biophase is far from being completely mixed. It consists of an immobilized mass of up to xXe_b viable cells per unit bioreactor volume (less if cell growth has been limited by some nutrient other than the contaminant), and one of the goals of media selection is to provide sufficient surface area so that these cells can be distributed as a biofilm thin enough to avoid mass transfer limitation due to diffusion through the film. However, simple models (38) suggest that biofilters should share the minimum effluent partial pressure, HS_s, predicted earlier for bioreactors with a completely mixed biophase, because biofilms exposed to any lower partial pressures near the biofilter effluent would be in an endogenous state and eventually die. Experience suggests otherwise, probably because the adsorption of the contaminants on the media increases their effective concentration in the microorganisms' immediate environment. It follows that highly adsorptive support particles, such as compost or activated carbon, will work best, and that biofilters can treat very insoluble, hydrophobic contaminants if they adsorb well.

45.4.6 Scale-Up

First-stage scale-up experiments can be done in a reactor of any size that is convenient or available, as long as it is large enough so that the flows of gas and liquid are not significantly altered by entrance effects, channeling, or wall effects. Ideally, several different bioreactor types or packing materials are studied, but this is not always possible. The objective is to vary the gas flow, g, the liquid flow, f, nutrient addition, S_{ji}, and so on, to determine how the specified contaminant removal can be achieved most economically. The scale-up problem is then to extrapolate the results in order to calculate the necessary volume (volume = gas flow to be treated/g) and shape (specifically the height, L) of the commercial-scale bioreactor, which must satisfy the process requirements without further experimentation immediately after start up. The best combination of process variables found in the experiments must be close to the optimum identified by the point at the right end of the operating region in Figure 45.2. To preserve this solution at the commercial scale, the dimensionless numbers D, F, and G that define this point must be kept the same between scales. Scaling up a gas treatment bioreactor is thus an example of Reynold's similarity principle, which states that two physical situations are similar only if the all of the relevant dimensionless numbers are identical.

Consider first the case where there is no inhibitory metabolic product and the process needs little or no liquid outflow. $F(\rightarrow \infty)$ and $D(\rightarrow 0)$ both drop from the list of relevant dimensionless numbers, and the scale-up problem reduces to finding combinations of gas flow, g, and bioreactor height, L, that keep G constant between scales. Given a mass-transfer correlation of the form of equation 45.7, G can be written $ARTL^c/Hg^{(1-c)}$. The problem is illustrated graphically in Figure 45.4, where lines of constant G are drawn on a log–log plot of g versus L. If the small-scale experiments have found different combinations of g and L that produce the specified contaminant removal, x, then this data should fall on such a line, labeled *empirical* in Figure 45.4, because the theory suggests that "constant x" implies "constant G." Also shown in Figure 45.4 is an upper limit on the gas superficial velocity, $U_g = gL$, caused by physical phenomena such as slugging of bubble columns, fluidization of the media in upflow biofilters, or flooding of the impeller in stirred tanks. This limit may be slightly different at different scales. Two extreme cases of the scale-up problem can be identified.

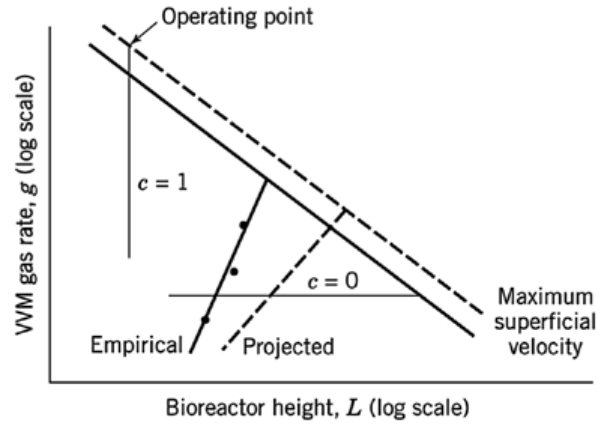

Figure 45.4. Dotted line, large scale; solid line, small scale.

For a biofilter or a biotrickling filter treating sparingly soluble contaminants, the mass-transfer factor is little affected by the gas velocity, implying that $c = 0$ and making the empirical line horizontal. Several important phenomena are lumped into the parameter A, but there is no reason to expect them to vary with scale because microorganisms cannot "know" if they are in a small or large bioreactor. Consequently, performance on the large scale is defined by the same horizontal line, meaning that scale-up is done at constant g, or equivalently at constant gas-residence time ($= 1/g$). Because $g = U_g/L$, constant g can be achieved either with a deep bed and a high gas velocity, the right end of the $c = 0$ line in Figure 45.4, or with a shallow bed and a low velocity, the left end of the line. Although the former are easier and cheaper to build, they have a much higher pressure drop though the bed, meaning higher costs for gas compression and possibly subsequent cooling to return the gas to a temperature tolerable to the microorganisms. The latter are much cheaper to operate and work well as long as the beds are deep

enough (at least several hundred times the particle size) to avoid problems of channeling and short-circuiting of the gas flow. Many biofilters consist of shallow beds of media on trays arranged in various configurations in a reactor designed to ensure an even flow of gas into the beds.

At the other extreme is the ideal bubble column described in the section "Gas Biophase Mass Transfer" for which $c = 1$. The value of G, and thus the contaminant removal, is now independent of gas flow but proportional to bioreactor height. Scale-up must therefore be done by keeping L constant but increasing the reactor width, the large-scale bioreactor operating at maximum g in order to minimize its volume (the *operating point* in Figure 45.4). Although this ideal bubble column is an abstraction, it illustrates a paradox that can arise in scaling up practical bubble columns (for which $c \cong 0.7$); if the desired removal can be achieved in a small-scale column, then a bubble column is probably not the best solution at the commercial scale. For very soluble contaminants, the L needed to obtain the desired fractional removal may be in the range of laboratory reactors, around 1 m. Scale-up would produce a very unusually shaped large-scale bioreactor, a similar height but several meters wide. There would be no point in making it any deeper, except to provide a safety factor in the design, and it could not be made any narrower and still meet the process requirements. For insoluble contaminants the necessary L may be several meters. The conclusion from laboratory experiments would then be that a bubble column is not a feasible bioreactor, even though the desired contaminant removal may be achievable (albeit with a high pressure drop) with the reactor heights used at the commercial scale.

All practical situations fall between these two extremes, so neither simple scale-up rule, constant g or constant L, is necessarily appropriate. The empirical line will have a positive slope, and a similar line for the same G at the larger scale can be projected from it if any variations of the parameters A and c with scale can be estimated from the published literature, experience, consultations with equipment manufacturers, and so on. The design of the large-scale bioreactor can be anywhere along this projected line in Figure 45.4, the exact design point again being constrained by the maximum U_g line, but essentially an economic trade-off between the large bioreactors demanded by a small g and the large pressure drops associated with a large L. The essential point is that the shape, and the size of the large-scale bioreactor are fixed by this procedure and should not be chosen based simply on guesswork or convenience.

Some bioreactor types allow design flexibility because they have variables that can be adjusted when drawing the projected line. Both A and c tend to decrease with scale in any bubble-gasified reactor due to poorer gas dispersion, but in mechanically agitated tanks, A is a function of the power input per unit volume, which can be varied to some extent. For trickle beds and biofilters, both A and the bed permeability are predictably related to packing size, allowing the packing to be chosen to give the large-scale reactor both a convenient shape and a reasonable pressure drop. Note that, whether or not such changes are made between scales, the estimates on which the projected line in Figure 45.4 is based should always be conservative in order to provide a factor of safety in the large-scale design.

When product inhibition is significant, the liquid outflow, f, becomes a critical variable, and all three dimensionless numbers D, F, and G must be kept constant if the physicochemical environment of the biomass (S, S_m) and the optimum bioreactor performance established in the small-scale experiments are to be extrapolated to the large scale. An exact solution is possible only when the retention of the biomass by cell immobilization or recycle (the z parameter) can be controlled, although when retention is almost complete ($z \to 0$) only the product DF (from which z cancels) is important, implying that the liquid flow, f, must be kept proportional to the gas flow, g. Biotrickling filters have an extra dimensionless number, the liquid recycle ratio, RR, which introduces the extra difficulty that increasing the bed height, while keeping f and RR constant increases the liquid superficial velocity [$U_l = Lf(1 + RR)$], thus changing the mass-transfer situation and possibly flooding the bed. The procedure just described will not work in these more complex situations (constant x no longer implies constant G), but the general considerations still apply, including the physical limits on the gas superficial velocity, the desirability of tall small-scale bioreactors to reduce uncertainties, the need for compromise between capital and energy costs, and the possibility of predicting a very inconvenient aspect ratio for the large-scale bioreactor. Judgment and calculation are needed in each case because the trivial solution to the scale-up problem—"build a bigger bioreactor with the same shape, f, and g as the small one"—is unlikely to be the best. Gas treatment bioreactors are one of the few devices whose performance tends to improve with scale, but taking advantage of this tendency in practice is not straightforward.

NOMENCLATURE

a	Gas–biophase interfacial area per unit bioreactor volume
A, c	Constants in mass-transfer correlation
D	$zf/e_b Yk$ = dimensionless liquid flow rate
e	Hold-up
f	Liquid outflow rate per unit bioreactor volume
F	$YS'_m/zy_m X$ = dimensionless product-inhibition number
g	Volumetric gas outflow rate per unit bioreactor volume (the VVM gas rate)

G	k_1aRT/Hg = dimensionless mass-transfer-effectiveness number
h	Gauge pressure (atm) at gas inlet
H	Henry's law constant
k	Cell maintenance coefficient
k_1	Gas-to-biophase mass-transfer coefficient
L	Bioreactor height
n_i	Mole fraction of contaminant in feed gas
p	Partial pressure (atm) of contaminant in effluent
q	Specific consumption rate of contaminant
R	Gas constant
S	Dissolved concentration in biophase
S_s	Stationary phase contaminant concentration (concentration at which $\mu = 0$)
S'_m	Product concentration that totally inhibits metabolism
T	Outlet gas temperature
U_g	Superficial gas velocity at bioreactor outlet
U_1	Superficial liquid velocity in a trickle bed
X	gn_i/ke_bRT = maximum possible cell concentration in biophase
x	$1 - p/n_i$ = fractional removal of contaminant
w	Evaporation rate per unit bioreactor volume
y	Mole of nutrient consumed or product formed per unit of contaminant metabolized
Y	Cell-yield coefficient
z	Cell concentration in liquid effluent/cell concentration in biophase
γ	Available electrons per carbon equivalent of biomass
μ	Specific growth rate of biomass

Subscripts

i	Inlet conditions
j	Any nutrient or product
m	Metabolic product
x	Biomass

BIOREACTORS, PERFUSION

Wei Wen Su
Department of Molecular Biosciences and Bioengineering, University of Hawaii, Honolulu, Hawaii

46.1 INTRODUCTION

Mass cultures of higher eukaryotic cells derived from mammalian, insect, and plant systems represent important sources of high value therapeutic products. While mammalian cell culture has progressed to a state that allows reliable process development and operation at large scales, the use of mammalian cell expression system remains very costly compared with some alternative expression systems such as insect and plant cell cultures (1). These latter systems are not as widely used in the industrial settings, but do offer certain merits and have continued to attract interest as alternatives to mammalian cell culture (1–3). Advocates for insect cell cultures point to advantages such as ease of culture, higher tolerance to osmolarity and by-product concentration, and higher expression levels when infected with a recombinant baculovirus (3). As for plant cells, they are easier and less expensive to culture compared to their mammalian counterparts, requiring only simple, chemically defined media (4). For now, mammalian cell culture remains the production system of choice in the biotechnology and pharmaceutical industries for large-scale production of complex recombinant proteins, monoclonal antibodies, recombinant viral vectors, and vaccines (1,5). This is due, in part, to the fact that mammalian cell expression systems produce proteins with *N*-glycans similar to those in human proteins (1). A survey of biological products (protein drugs, vaccines, and cells) approved by the US Food and Drug Administration (FDA) from 1996 to 2000 indicated that 21 approved therapeutic and diagnostic biological products were produced by mammalian cell cultures (5). As shown in a more recent survey, over 20 new therapeutic biological products had been approved by FDA between mid 2000 till early 2004, with over 60% being produced using mammalian cell cultures (6). This trend of mammalian cell culture dominance on producing therapeutic biological products continues as evidenced in the latest information on biological license approvals (BLAs) issued by FDA (Center for Drug Evaluation & Research; visit Drugs@FDA).

Various systems have been used to culture higher eukaryotic cells in bioreactors. These include free cell suspension, suspension of immobilized or entrapped cells, as well as immobilized cell culture in packed bed or hollow fiber reactors. Among these systems, free cell suspension culture is most amenable to large-scale operation. Suspension cultures, as opposed to immobilized cultures, provide a more homogeneous culture environment that is easier to operate, monitor, and control. Although growth of most mammalian cells requires surface attachment, for example via growth on microcarriers, hollow fibers, or beads, some can grow or be adapted to grow as suspension without surface attachment. Hydrodynamic shear problem associated with free suspension of mammalian cells can be minimized by appropriate design of agitation and aeration systems in the bioreactor, and by including protective polymeric additives such as Pluronic F68 in the media (5). Surveys of FDA BLAs indicated that the biotech industry has converged on using suspension culture of mammalian cells in large-scale stirred-tank bioreactors for producing therapeutic biological products (5,6). Currently, three suspension cell lines have been most widely used. They are suspension-adapted Chinese hamster ovary

(CHO) cells, and murine myeloma lines SP2/0 and NS0 (5).

Suspension culture can be operated in a batch, fed-batch, semi-continuous (repeated batch), continuous, or perfusion mode, or even a hybrid fed-batch/perfusion mode (7). In general, a relatively simple process with low up-front investment requirement that is readily scalable and capable of providing high and stable volumetric productivity with low nutrient input is preferred. In addition, the operating strategy is selected based on the kinetic pattern of product formation and the way the product is translocated following its synthesis (i.e. whether the product is excreted into the medium or retained in the cell). It is most common to relate the pattern of product synthesis to cell growth. That is, product synthesis is frequently characterized as growth associated or non-growth associated.

Industrial mammalian cell culture processes for production of recombinant proteins and monoclonal antibodies are currently dominated by fed-batch and perfusion processes (8,9). In fed-batch processes, concentrated nutrient solution is supplied to the culture via an appropriate, typically computer-controlled feeding strategy. Perfusion culture entails a continuous or semi-continuous flow of a nutrient solution through a cell population while the cells are retained in bioreactor (Fig. 46.1). Oftentimes, a cell bleed stream is implemented in perfusion cultures. Fed-batch processes are popular since they are relatively simple and flexible, with reduced quantities of product at risk because it is limited to a single batch if a process failure occurs, and they oftentimes yield much higher product titers than their batch-culture counterparts. On the other hand, perfusion culture offers the following advantages over batch and fed-batch cultures:

1. Longer operation with reduced plant downtime
2. Reduced unproductive growth phase as a proportion of the total process time
3. Potentially more consistent product quality as a result of constant nutrient supply and removal of toxic extracellular metabolic byproducts
4. Requiring a smaller bioreactor [and lower up-front start-up cost (10)]
5. Higher cell density and productivity
6. Reduced product residence time (via product recovery and hence reduced product degradation).

As a result of the above advantages, under optimal operating conditions, perfusion culture generally gives similar or higher productivity compared with fed-batch operations (11,12). According to Kompala and Ozturk (9), at least eight marketed pharmaceutical products have been produced using perfusion mammalian cell culture systems. A notable disadvantage of perfusion culture, however, is its added complexity from incorporating a cell-retention device. For long-term perfusion cultivation, a major concern is the steady-state instability and process variability. To this end, it is also important to determine the long-term genetic stability of the cells employed in such a process.

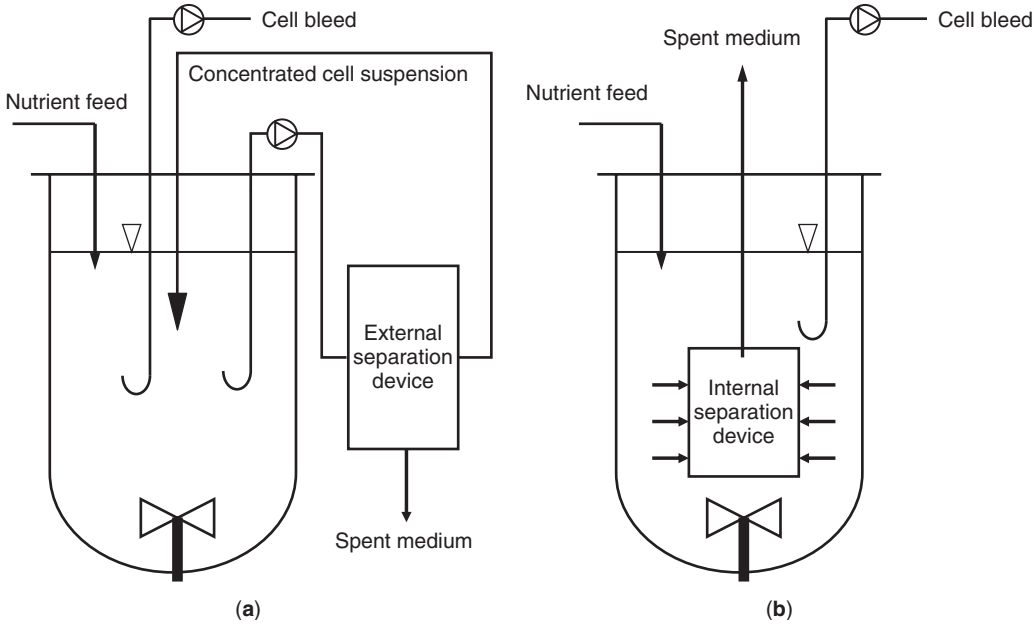

Figure 46.1. In a perfusion bioreactor a cell-retention device installed external (a) or internal (b) to the bioreactor is used to retain the cells within the bioreactor while allowing exchange of the culture medium. Sometimes, a cell bleed stream is used to stabilize the culture.

Since culture perfusion typically leads to high cell densities, oxygen transfer often becomes a limiting factor and introduces additional constraints on the process. Lim *et al*. used a computer-aided decision-support tool to compare the cost effectiveness of large-scale production of monoclonal antibodies by fed-batch and perfusion culture modes (10). In that study, Monte Carlo simulation technique was used to account for uncertainties in titer and yield, as well as the risks of contamination and malfunctioning of the perfusion device so as to imitate the randomness inherent in biopharmaceutical manufacture. The study by Lim *et al*. stressed the importance of minimizing probabilities of contamination and malfunctioning of the cell-retention device to achieve the high productivity promised by the perfusion option.

Generally, the most suitable type of products to be produced using perfusion bioreactors is the non-growth-associated, secreted products. In this case, the reactor is operated at a high cell density without rapid cell division for a long period. The product can be continuously harvested from the spent medium. For growth-associated, secreted products, a cell bleed stream may be incorporated in the perfusion operation. A high perfusion rate with the bleed stream adjusted to give a high specific cell growth rate could be used to increase the product output. For growth-associated, intracellular products, a culture strategy that gives a high biomass output rate with high product content is most desirable. Perfusion culture with a bleed stream may be considered for the production of this type of products. In this case, a much higher cell density can be obtained in perfusion cultures compared to continuous or semi-continuous cultures, because cells are retained within the reactor via a cell-retention device. By incorporating a bleed stream, the perfusion reactor can in principle be operated under a steady state at a very high cell concentration. For a culture system that follows simple Monod kinetics, the maximum biomass output rate in a perfusion reactor with a bleed stream is higher than that in a chemostat by a factor of $1/\zeta$, where ζ is the bleed ratio (the ratio between flow rates of the bleed stream and the feed stream) (13).

In this chapter, perfusion bioreactor development is reviewed, with emphasis on the design of the cell-retention system. In a perfusion culture, a means for cell–medium separation, or a cell-retention device, needs to be incorporated into the perfusion bioreactor (Fig. 46.1). Practical cell–medium separation in large-scale perfusion bioreactors is most commonly achieved on the basis of cell size or a combination of size and density differences between the cells and surrounding media, whereas other properties such as cell electrical charges, surface properties, and dielectric properties may be considered in small-scale operations (14). Thus far, two major classes of techniques have been employed to separate cells from the medium in perfusion reactors, namely, filtration and gravitational or centrifugal sedimentation. A summary of cell-retention systems used in perfusion bioreactors is summarized in Table 46.1. In this review, emphasis is placed on those systems that have been identified as capable of operating at a scale greater than 250 L per day [Table 46.1; (14)]. A more detailed discussion on other retention systems can be found in several extensive reviews published within the last decade (9,12,14–16).

46.2 CELL RETENTION BASED ON FILTRATION

Cell retention by filtration is based mainly on the size difference between the cell particles and the pore opening of the filter. It is also affected by a number of additional factors. These include cell morphology, cell concentration, viscosity of the cell suspension culture, and compositions of the spent media (e.g. presence of cell debris and bio-macromolecules such as nucleic acids, proteins, and polysaccharides that might clog the filter). As far as the filter is concerned, size of pore opening and porosity, filter/membrane material, filter geometric properties and configuration, and hydrodynamics in the filter systems are of primary importance. Since a physical barrier is used to retain the cells in the perfusion bioreactor, a major consideration in using filtration for cell retention is to minimize filter/membrane fouling. As summarized in Table 46.1, several notable culture perfusion systems are based on filtration. These include spin filters, membrane stirrers, circulating cross-flow filters with hollow fiber, plate-and-frame, or spiral-wound modules, controlled shear filtration, vortex flow filtration (VFF), and alternating tangential flow (ATF) filters. Some of these devices can be used externally or internally, and involve stationary or moving filters/membranes. It is easier to retrofit an existing reactor with an external separator than with an internal separation device. The major drawback of external separators, however, involves potential problems associated with prolonged continuous circulation of the culture suspension through an external loop that may cause shear damage or oxygen deprivation. To alleviate oxygen deprivation, the external separators are commonly operated under reduced temperature so as to slow the metabolism of the cells while outside the bioreactor. Among filtration-based perfusion systems, spin filter and the ATF systems have been considered most attractive for large-scale operations to produce perfusion rates in the range of 250–1000 L per day (14). Spin filter has been scaled up to produce a perfusion rate of 500 L per day (36); although the manufacturer of the ATF filters claims a scale-up capacity up to 1200 L per day (37), data in refereed literature to confirm this claim are not yet available. The following discussion focuses on these two systems; information for other filtration-based

cell-retention systems can be found in recent reviews on perfusion bioreactors published elsewhere (9,12,14).

Spin filter is among the first filtration devices used in perfusion culture of mammalian cells, and the one that is most widely used in industrial-scale operations. It is a rotating cylindrical filter cage housed internal or external to the bioreactor. Various spin filter designs have been reported and are depicted schematically in Fig. 46.2. Having separate motor drives for the spin filter and the bioreactor stirrer is preferred but it adds additional mechanical complexity to the bioreactor construction. Placing baffles within the spin filter has been reported to improve medium homogeneity and reduce cell accumulation within the spin filter (6). During the culture perfusion process, cell particles are subject to gravity force, axial force from bioreactor agitation, centrifugal force generated by the spin-filter rotation, radial force (drag) resulting from the perfusion flux, as well as a hydrodynamic lift force produced by the rotation of the filter cage that counteracts the drag force generated by the perfusion flux (12). The balance of these forces determines the migration of the cell particles around the spin-filter surface and hence the cell-retention efficiency. Beyond certain filter rotation speeds, centrifugal and lift forces are sufficiently high as to exceed perfusion flow and result

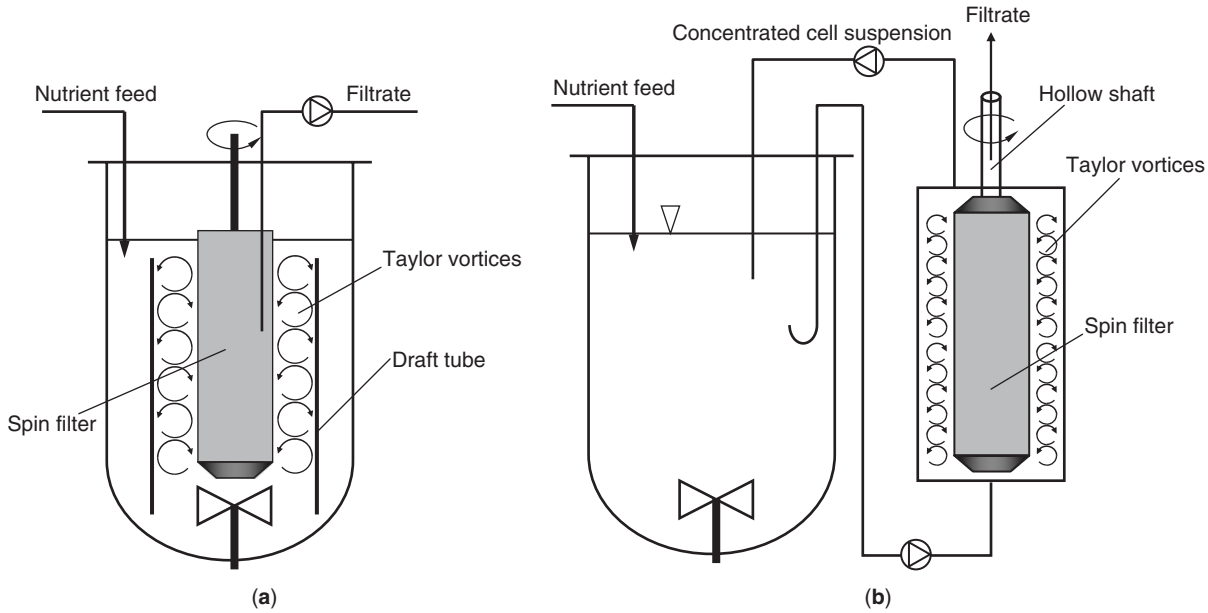

Figure 46.2. Spin-filter bioreactor: (a) internal spin filter with a draft tube; (b) external spin filter.

in the movement of cell particles away from the filter to enable effective particle retention. By considering only the lift force and the permeation drag (assuming centrifugal force is nil compared with the lift force), Yabannavar *et al*. (17,18) proposed to use the ratio of permeation drag to lift drag, φ, as the basis for designing and scaling up spin-filter systems, using the following equation:

$$\varphi \propto J_p/u_f^2 \tag{46.1}$$

where J_p is the perfusion flux and u_f is the tangential rotation velocity at the spin-filter surface. Since $J_p = D \cdot V/\varepsilon A$, where D is the specific perfusion rate (i.e. volumetric perfusion rate divided by the reactor volume), V is the reactor volume, ε is the filter porosity, and A is the filter surface area, Equation (46.1) can be rewritten as

$$\varphi \propto \frac{D \cdot V}{A \cdot u_f^2} \tag{46.2}$$

assuming constant screen porosity. By keeping φ constant at a value less than 1, Yabannavar *et al*. (18) demonstrated that efficient spin-filter operation could be scaled up without filter fouling. The same authors also showed that by keeping geometric similarity during scale-up, the filter rotation speed or angular velocity ω_f is proportional to $(V)^{-1/6}$. Furthermore, they suggested that the rotation speed of the agitator should be proportional to $V^{-2/9}$ to maintain a constant power per unit volume during scale-up. Under these conditions, fluid exchange per unit volume decreases slightly during scale up ($\propto V^{-1/18}$). According to Yabannavar *et al*. (18), increased fluid exchange may lead to more serious cell leakage through the perfusate, especially if the screen pore size is much greater than the cell size (e.g. 50 μm screen for 10–15 μm mammalian cells). A strategy similar to that of Yabannavar *et al*. (18) was adopted by Deo *et al*. (36) to scale up spin-filter perfusion cultures. Deo *et al*. (36) found that the perfusion flux at which the actual perfusion rate drops below the expected perfusion rate (indicating filter fouling) is proportional to u_f^2/X and derived the following equation for the maximum specific perfusion rate D_{max}:

$$D_{\max} \propto \frac{A \cdot u_f^2}{V \cdot X} \quad \text{and} \quad A \cdot u_f^2 \propto h_f \cdot r_f^3 \cdot \omega_f^2 \tag{46.3}$$

where X is the cell concentration, and h_f and r_f are, respectively, the height and radius of the spin filter. It should be noted that although the effect of cell concentration was included in the above equation, changes in cell morphology/aggregation and culture rheology during long-term perfusion cultivation were not considered. Therefore, if these changes are substantial in particular perfusion culture systems, the above approach should be examined further and applied with caution. Guided by Equation (46.3), Deo and coworkers (36) successfully scaled up a perfusion culture of a recombinant myeloma cell line to 500 L based on 5-L results. By keeping the same *A/V* ratio during scale up, both scale-up strategies of Yabannavar *et al*. (18) and Deo *et al*. (36) are based on maintaining a constant filter tangential velocity (i.e. perfusion capacity increases with square of the screen tangential velocity) (14). Spin-filter tangential velocities in the range of 28–60 cm/s have been reported to give satisfactory performance without serious filter fouling (14). Keeping constant *A/V* ratio during scale up implies that as the size of the bioreactor increases, the spin filter will occupy proportionally a larger volume of the reactor vessel. Also in these analyses, the centrifugal force due to spin-filter rotation was considered negligible, which might need to be evaluated more closely for a given operating condition. As an alternative to filter rotation, filter vibration using a piezo actuator installed inside a stationary filter cage has been shown recently to slightly prolong the operation of the filter (compared to the stationary filter without vibration) (38).

In some designs a draft tube is installed around the spin filter (Fig. 46.2a) or in the case of an external spin filter, the rotating filter is housed in a cylindrical vessel with a narrow annular gap (Fig. 46.2b). This is done in a way to produce axial and rotational shear and Taylor vortices in the gap between the spin filter and the draft tube (or the vessel wall in external spin filters) to clean the filter surface, thus preventing the plugging of pores of the filter medium. Taylor vortices are pairs of counter-rotating, toroidal vortices stacked in the annulus between a rotating inner cylinder and a concentric, stationary outer cylinder (Fig. 46.2). The transition from the stable circular Couette flow to Taylor vortex flow and hence generation of the Taylor vortices occurs when the Taylor number ($\mathrm{Ta} = \omega_i r_i d/\nu$, where ω_i is the angular rotation velocity of the inner cylinder, *i.e*. the spin filter, r_i the radius of the inner cylinder, d the gap between the cylinders, and the kinematic fluid viscosity) exceeds a critical value Ta_c. The value of Ta_c for a spin filter in a draft tube can be estimated based on the flow between rotating porous cylinders with radial and axial flow that has been reported by Johnson and Lueptow (39). In Fig. 46.3 (taken from Johnson and Lueptow (39)), the critical Taylor number is shown as a function of the radial Reynolds number α, at two representative axial Reynolds numbers β (0 and 10) and three radius ratios η ($= r_i/r_o$ where r_o is the radius of the outer cylinder, i.e. the draft tube). Note that $\alpha = u_i r_i/\nu$and $\beta = \overline{w}d/\nu$, where u_i is the radial velocity through the wall of the inner porous cylinder, i.e. the perfusion flux, with a positive value when outward from the axis of rotation, and $\overline{w}$ is the average axial velocity. In a spin filter system with solid draft tube, α is typically between -10 and -0.1, while β is between 1 and 50 (39). Since Ta_c is not very sensitive to axial flow, and hence to β, Fig, 46.3 could be used as a guideline to aid the design and

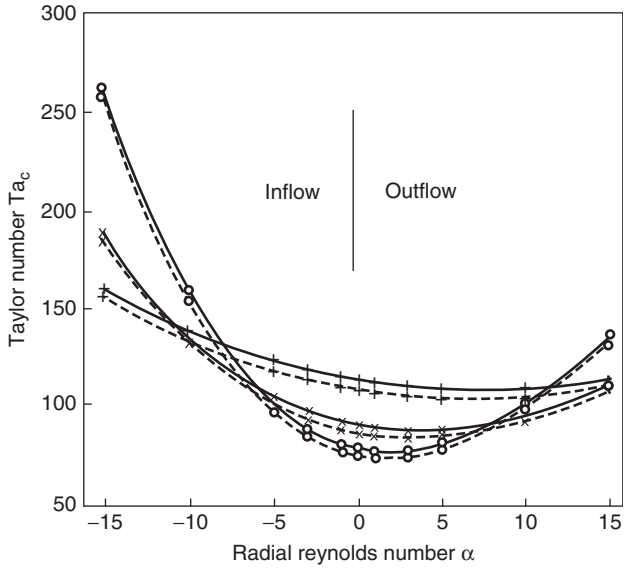

Figure 46.3. Estimation of the critical Taylor number based on the radial Reynolds number α, at two axial Reynolds numbers β (0 and 10) and three radius ratios η (see text for details; taken with permission from Johnson and Lueptow (39)).

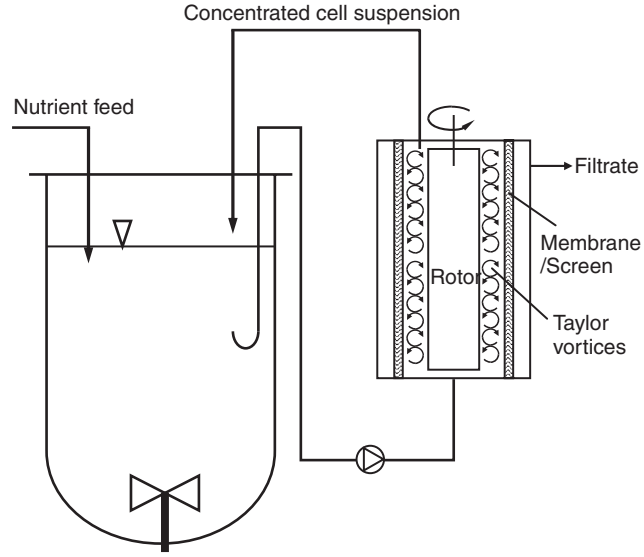

Figure 46.4. Perfusion bioreactor using an external vortex flow filtration device for cell retention.

operation of a draft-tube/spin-filter system for perfusion cultures. According to Fig. 46.3, Ta_c for systems with smaller η (i.e. bigger gap between the spin filter and the draft tube) is more sensitive to changes in the radial Reynolds number, and hence the perfusion flux. At a high perfusion flux, a higher filter rotation rate is required to achieve Taylor vortex flow (i.e. higher Ta_c) in systems having a bigger gap between the filter and draft tube (i.e. lower values of η), yet at low or zero perfusion rates, the phenomenon is reversed. According to Schwille *et al*. (40), rotational shear resulting from the circular Couette flow is as important or more so than the Taylor vortices in assuring high permeation fluxes in rotating filter systems. Since the induction of rotational shear is favored with small constant annular gaps between the rotor and the filter screen, Voisard *et al*. (14) warned that such condition might be difficult to realize at a very large scale. Another filtration system that takes advantage of the Taylor vortices to reduce filter fouling is the VFF (21–23). Hydrophilized microporous polysulfone membranes (22,23) and 10-μm stainless steel wire screens (21) have been used in VFF for perfusion culture and the latter was reported to allow operation up to 100 L/day for 30–60 days without clogging (21). Unlike spin filters, in VFF systems, the cylindrical filter membrane/screen is kept stationary whereas Taylor vortices are generated through the rotation of a concentric cylindrical rotor (Fig. 46.4). VFF is typically used as an external filtration system in perfusion culture. Again, Fig. 46.3 should provide a reasonable estimate of the Ta_c necessary to have vortical flow, except in this case the flow is outward, corresponding to the positive values of α.

In addition to the above-mentioned operating and geometric parameters, the spin filter performance is greatly affected by the properties of the filter screen (pore size, screen structure, and material). Most commonly, stainless steel mesh screens with pore sizes larger than the average cell size are used to make spin filters for mammalian cell cultures. For instance, Varecka and Scheirer (41) used wire cages with 53-μm mesh opening and cells of approximately 20 μm size, and observed no sign of fouling for more than 2 months of continuous operation. Esclade *et al*. (42) compared fouling of spin filters made out of stainless steel versus polyamide mesh (both having about 10 μm pore size). Using scanning electron microscopy, Esclade *et al*. (42) revealed that nearly all the pores in the stainless steel screen were fouled with DNA and cell debris, whereas the polyamide screen was relatively clean. To combat fouling by DNA, addition of nuclease such as deoxyribonuclease I may help, as demonstrated by Favre and Thaler (43). The difference in the extent of fouling seen with steel versus polymeric screens was believed to be owing to the different surface charge densities on the two materials. Since metal is highly positively charged, although polyamide is more neutral, more cells and cell debris (which are rather negatively charged) were attracted to the metal screen. Avgerinos *et al*. (44) carried out perfusion cultivations up to 54 days using a spin filter made out of a polymeric ethylene-tetrafluoroethylene (ETFE) screen (120 μm pore size) without filter fouling. The hydrophobic nature of the ETFE screen apparently minimized the cell attachment of cells to the screen and thus extended the life of the spin filter. In the commercial Sartorius (Goettingen, Germany) external spin filters, a multilayer stainless steel woven wire cloth with a mean pore opening up to 20 μm was used

for bioreactors up to 50 L in scale. Sartorius also offers an internal spin filter made out of precision-woven, open mesh polyethylene terephthalate polyester (PETP) fabric with pore sizes up to 40 μm.

Microporous membranes configured as hollow fibers, spiral-wound membrane cartridges, or plate-and-frame modules in tangential-flow filtration systems have been widely used in small-scale culture perfusion (14). Although hydrophilic microporous polypropylene membrane fibers can be installed inside a bioreactor as a microfilter/membrane stirrer to retain and mix animal cells (20), most membrane filtration systems have been used externally and involve continuous unidirectional recirculation of the culture suspension through the filter (Fig. 46.5a). The fluid flow in the circulating loop has to be optimized to minimize shear damage yet at the same time provide sufficient tangential flow to reduce premature membrane fouling. Oftentimes, membrane back flushing is necessary to prolong the operation, yet membrane fouling was frequently reported to be inevitable, in part, owing

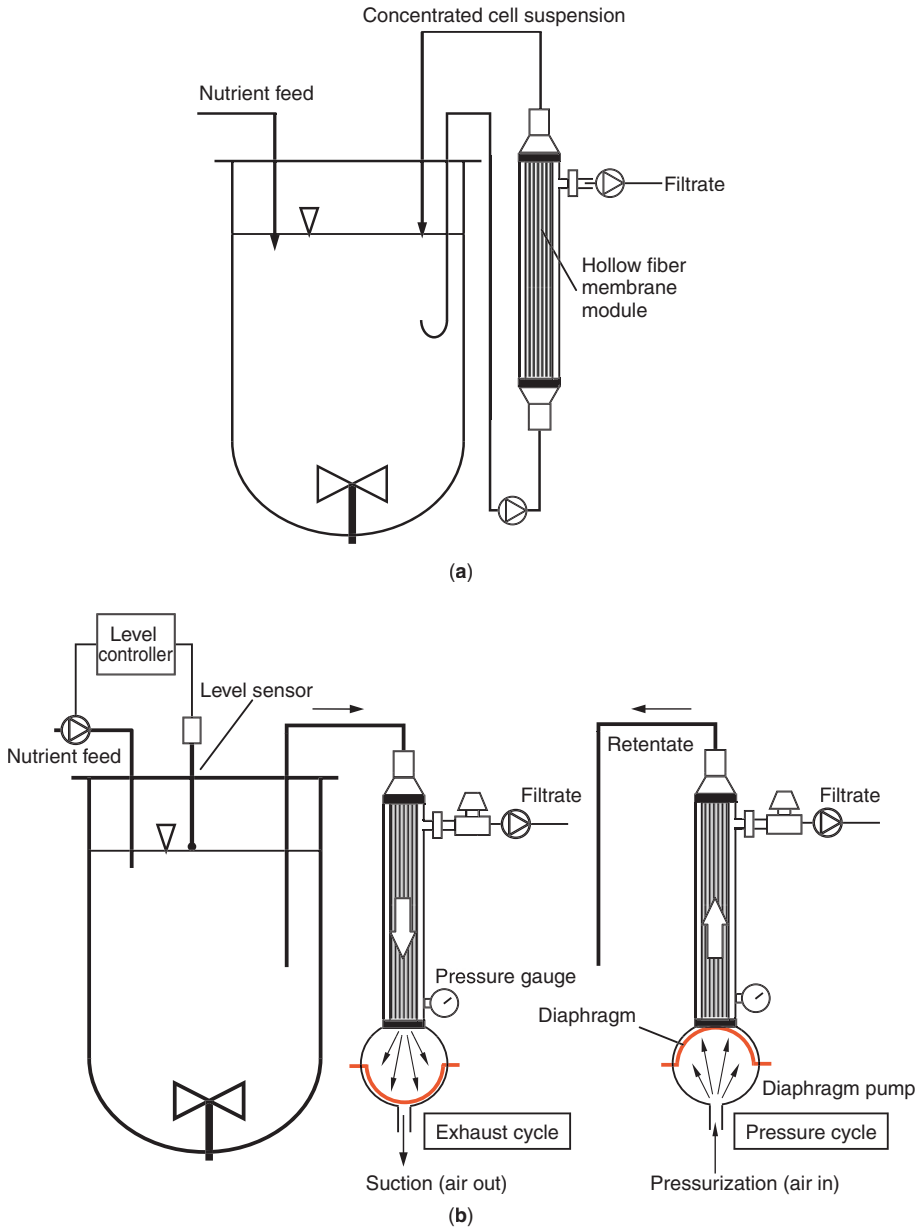

Figure 46.5. Cell retention via (a) unidirectional recirculation of culture fluid through an external cross-flow microporous membrane module; or (b) an alternating tangential flow (ATF) filtration system. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

to the small pore size used in these membrane filtration systems. In the ATF filtration system developed by Refine Technology (Edison, NJ), culture suspension is circulated back and forth between the bioreactor and an external filter via a single port. A diaphragm pump is used to draw culture suspension into a filter module and to push concentrated culture back to the perfusion bioreactor while removing filtrate in the process (37). By reversing the culture flow directions in the filter module during each pump cycle, the pressure gradient across the filter wall is reversed, resulting in a momentary back flush during each pump cycle, and thus prevent filter fouling under low shear. The ATF system uses a 0.22-μm hollow fiber module for perfusion of suspension cell culture and a mesh screen module for microcarrier cultures. Using a hollow fiber membrane module with a surface area of 16.8 m^2, the ATF in principle can operate at over 1000 L/day, and thus representing a promising system for large-scale perfusion culture. Bleckwenn *et al*. (25) applied the ATF system containing a polyester 200-mesh screen module with 75 μm pores for perfusing microcarrier culture of HeLa cells in a 1.5-L bioreactor at up to 1 reactor volume per day. The system cycled about four times per minute for a slow pull up of the culture into the mesh filter module followed by a fast push of the culture back into the reactor to clean the mesh surface and allowed sufficient mixing with the contents of the reactor (25). The ATF diaphragm pump displaced approximately 80–100 mL bioreactor culture per cycle. In another study, Yuk *et al*. (24) reported perfusion culture of the HeLaS3 human tumor cell line using ATF at the bench (15 L) and pilot (70 L) scales for propagating a recombinant oncolytic adenoviral vector. The hollow fiber module used by Yuk *et al*. (24) had a 0.46 m^2 filter area, a 1-mm lumen, and a 0.2-μm pore rating. The cell-free spent media withdrawn by a peristaltic pump on the filtrate side of the hollow fiber module was automatically replenished with fresh medium using a medium supply pump actuated via a level sensor. Volumetric perfusion rates up to 3.5 culture volumes per day were used. The average shear rate in the filter module due to culture circulation was estimated to be about 750/s which was low enough not to create shear damage to the cells (24). According to the original ATF patent (45), it is desirable to install a pressure dampener for damping the pressure in the overall system to facilitate passage of the filtrate across the membrane and to improve membrane back flushing.

46.3 CELL RETENTION BASED ON SEDIMENTATION

The simplest type of sedimentation is driven by gravitational force, while enhanced sedimentation by centrifugal force or by promoting temporary cell aggregation via acoustic standing waves has also been reported for cell retention in perfusion bioreactors. Gravitational sedimentation provides a gentle process for cell separation. It is mechanically simple, exploiting the inertial properties of the cells instead of using physical barriers as in the case of filtration, to perform the separation. Sedimentation devices, however, do have a large holdup volume with potentially suboptimal culture conditions. To begin an analysis of cell sedimentation, one may consider the simple process of a particle freely falling in a liquid. For a dilute suspension of spherical cell particles, the terminal cell settling velocity (v_{so}) in the laminar region under the influence of a gravitational or centrifugal field can be estimated using the Stokes' law:

$$v_{so} = \frac{d_p^2}{18\mu}(\rho_s - \rho)\psi \tag{46.4}$$

where d_p is the cell particle diameter, μ is the suspension viscosity, ψ is the acceleration, ρ_s and ρ are the density of the cell and media, respectively. In a gravitational field, ψ is equal to gravitational acceleration, g, while in the centrifugal field, ψ is equal to $r\omega^2$ where r is the radial distance from the center of the centrifuge to the cell particle and ω is the angular rotation velocity. In concentrated suspensions, hindered sedimentation occurs as a result of interactions between neighboring particles. The settling rate in this case is greatly affected by the solids concentration. The hindered settling during gravitational sedimentation could be accounted for in calculating the particle settling rate using, for instance, Equation (46.5):

$$v_s = v_{so} \cdot e^{-KC} \tag{46.5}$$

where K is an empirical constant related to cell suspension's surface properties, size distribution, morphology, and viscosity (46), which can be determined from batch sedimentation data. To size a conventional continuous gravitational settler, the following analysis, based on the design of settling tanks, for wastewater treatment can be employed (29). Based on batch sedimentation experiments, the ascending height of the solid–suspension liquid interface (h) is recorded over time (t), and from which Equation (46.6) can be used to estimate the particle sedimentation velocity (v_s) as a function of particle concentration (C) for a given initial solids concentration (C_o) and initial interface height (h_o) (29).

$$h = \frac{C_o h_o}{C} - v_s \cdot t \tag{46.6}$$

For a continuous settler shown schematically in Fig. 46.6, and by assuming no solids in the clarified effluent, the settler area, A_S, can be estimated as

$$A_S = \frac{Q_o C_o}{G} \tag{46.7}$$

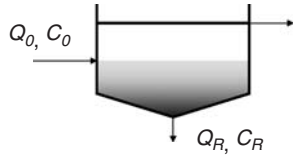

Figure 46.6. Flow diagram of a continuous vertical gravitational settler.

and

$$G = \frac{v_s}{\left(\frac{1}{C} - \frac{1}{C_R}\right)} \tag{46.8}$$

for a given volumetric feed rate to the settler (Q_o) and desired C_R value (the solids concentration in the concentrated suspension withdrawn from the bottom of the settler). Here G is known as the sedimentation capacity and A_S is typically calculated based on the minimum G value (29). Total volume of the settler is divided into two compartments: the volume occupied by the clarified liquid that contains no solids, and the volume occupied by the solids suspension. The latter (V_S) can be estimated using the following equation:

$$V_S = \frac{\tau \cdot Q_o \cdot h_\tau}{h_o} \tag{46.9}$$

where τ is the desired cell residence time in the settler and h_τ is the interface height at time τ, which is determined from the batch sedimentation tests. The desired cell residence time needs to be evaluated for each cell lines to avoid metabolic deterioration as a result of prolonged retention in the settler. The total settler volume is then estimated by adding the clarification zone volume, which has no influence on the sedimentation and hence can be freely adjusted within a large margin (29). For internal settling devices, most commonly countercurrent sedimentation occurs at the bottom entrance of the settler, the settling zone may be sized by equating the upward superficial liquid velocity and the terminal sedimentation rate of the cell particles. Here the hindered settling effect should be considered in determining the particle settling rate.

Vertical settlers were among the first tested for retaining mammalian cells in perfusion bioreactors. Conical-shaped vertical settlers, installed internal or external to the bioreactor, are commonly used. The conical designs take advantage of the reduced culture fluid superficial upward velocity in a settling zone with enlarged cross section area. Conical settlers have usually been placed external to the bioreactor as, for example, in the work of Hulscher *et al*. (Fig. 46.7a) (27). Sato *et al*. (47) described an internal conical cell separator consisting of a tapered conical sedimentation chamber affixed to the head plate of a stirred bioreactor. Spent medium was removed through the top of the cone and cells settle and slide down the steep wall of the cone to the bioreactor (Fig. 46.7b). Hamamoto (48) incorporated an annular settling zone with a stirred-tank bioreactor for continuous perfusion culture of mammalian cells. In this case, a cylindrical baffle was inserted into a stirred-tank reactor to create an annular settling zone (Fig. 46.7c). A similar design was adapted for continuous perfusion culture of plant cell suspension (49). Pressure equilibration between the settler and the reactor is crucial for the proper operation of the system. Internal settlers in the form of internal settling zones have also been incorporated into the downcomer section of an external-loop air-lift bioreactor to enable continuous culture perfusion of plant cells (50) and fungal pellets (51). The very design concept was adopted by Wen *et al*. (52) for perfusion culture of mammalian cells. In its simplest form, the internal settling zone in the external-loop air-lift perfusion bioreactor is created by inserting a baffle plate into the upper portion of the downcomer (Fig. 46.7d). Clarified spent medium containing secreted metabolic products is continuously removed via the overflow from the settling zone, while fresh medium is fed into the well-mixed riser to replenish nutrients. By incorporating the settling zone into an external-loop, instead of an internal-loop air-lift reactor, improvement on cell-retention efficiency was noted with plant cell suspension culture, which resulted from the much lower downcomer gas holdup in the external-loop air-lift reactor due to its more efficient gas disengagement at the reactor headspace (50). By taking advantage of the well-defined flow pattern in the air-lift reactor, the downward bulk liquid flow in the downcomer can guide the cell particles away from the settling region so that only few cell particles are present in the settler. However, it should be pointed out that there were noticeable eddies that provoked some degrees of mixing at the entrance of the settling region. The eddies carried some of the cells into the inlet region of the settler. These cells nonetheless were carried back to the bulk of the culture by the downward liquid flow, and hence there was a constant turnover of cells at the settler entrance. With increased gas velocity and thus faster culture circulation, mixing at the settler entrance was augmented. The effect of aeration on cell-retention efficiency, however, was minor compared with perfusion rate and cell loading (50). This was due to the fact that the settling zone for the most part was not stirred by the localized mixing at its entrance. To improve the sedimentation capacity, a conical settling zone can be incorporated into the upper portion of the downcomer (16). To enhance oxygen supply in the settler, membrane aeration tubing or surface aerator may be installed to provide bubble-free aeration without disturbing cell sedimentation (16).

Gravitational sedimentation can be enhanced in a shallow tilted settling chamber via inclined sedimentation. This

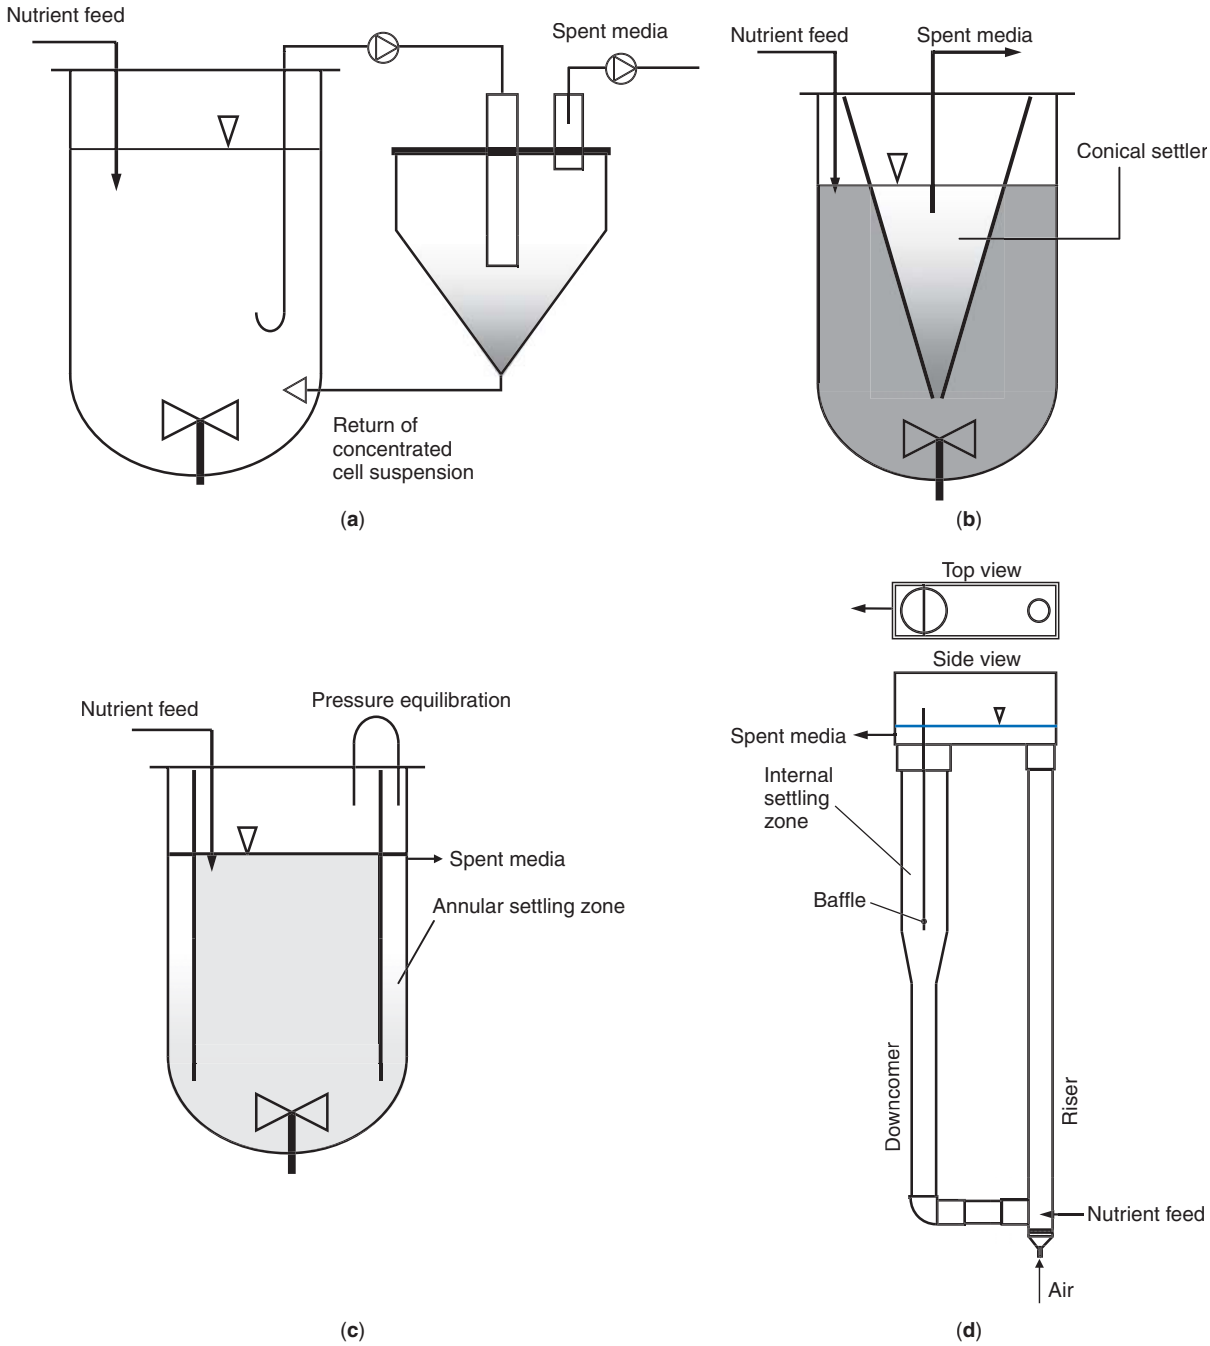

Figure 46.7. Perfusion bioreactors with vertical settlers: (a) external conical settler; (b) internal conical settler; (c) internal annular settler; (d) air-lift bioreactor with an internal settling zone. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

phenomenon was first observed by Boycott (53), and analyzed, among others, by Acrivos and Herbolzheimer (54). For a dilute, monodisperse particle suspension, the particle sedimentation rate can be expressed as

$$v_{si} = v_{sv}\left(1 + \frac{h_s}{H}\sin\theta\right) \tag{46.10}$$

where v_{si} is the settling rate in inclined sedimentation, v_{sv} is the settling rate in vertical sedimentation, h_s is the vertical height of the solid suspension, H is the plate distance of the settler, and θ is the angle of inclination from the vertical axis. Note that in order to take full advantage of inclined sedimentation, a shallow settler (small H) with a large angle of inclination should be used. The large inclination angle,

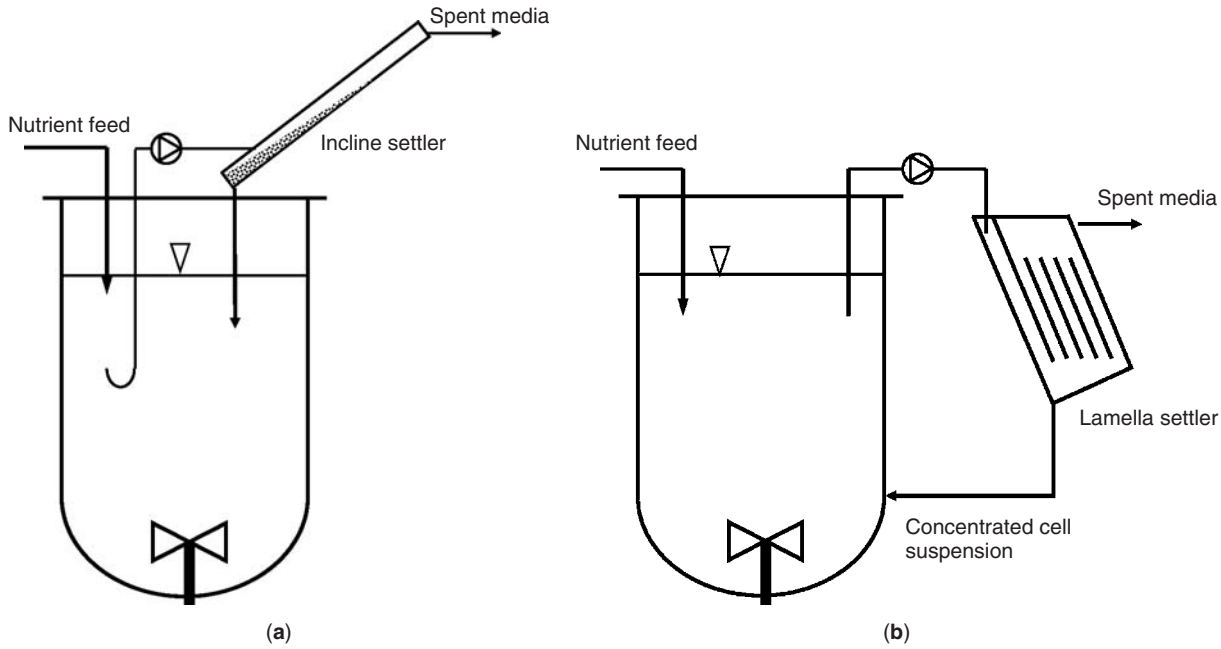

Figure 46.8. Perfusion bioreactor with (a) inclined settler; (b) lamella settler.

however, needs to be counter-balanced by the ease of cells to slide back to the bioreactor. Typically, inclination angle from 30 to 60° and plate distance from 0.5 to 2 cm is used (9). In the reactor of Davison *et al*. (55), a large inclined shallow settling chamber is integrated into a stirred fermenter as a side arm. As the culture is withdrawn through the settling chamber, cells undergo countercurrent inclined sedimentation, settle, and slide down the lower surface of the settler to the fermenter. Searls *et al*. (28) modified the inclined settler of Davison *et al*. by placing it on the top of the bioreactor and therefore allow cells to undergo cross-current sedimentation (Fig. 46.8a). To alleviate cell attachment to the settler wall, Searls *et al*. also tried bubbling and vibrating to periodically clean the settler. According to Kompala and Ozturk (9), an inclined plate settler has been scaled up to industrial operation by Biotechnology Solution (Orinda, CA). Incline sedimentation in the form of lamella settlers contain a large number of closely packed, parallel inclined plates, and hence analogous to multiple inclined plate settlers stacked together (Fig. 46.8b). This type of settler has been used by a number of researchers for perfusion culture of mammalian cells. Tyo and Thilly (56) described an interesting internal lamella settler system consisting of a series of nested truncated cones with an innermost solid cone. In this reactor, cells and medium are pumped up through the cones while cells are collected on the lower face of the cones, thereby resulting in a virtually cell-free fluid. For the same settler volume, the lamella settler offers much more sedimentation area than a conventional vertical settler. The total effective sedimentation area in a lamella settler is about half of the sum of the horizontally projected areas of all plates (12). One common problem with inclined settlers is that the cells tend to adhere to the plates and hence are not able to slide back to the bioreactor. Surface coating of the plates and vibration of the lamella pack have been suggested to alleviate this problem (12). Even though lamella settlers are more compact than conventional vertical settlers for the same sedimentation area, they are still associated with a relatively large holdup volume and long cell residence time that may be especially problematic as the settler is scaled up.

A relatively new approach to enhance cell sedimentation and thus improve cell retention involves the use of ultrasonic field forces to promote cell aggregation (Fig. 46.9a). When an ultrasonic wave is reflected in the direction opposite to the propagation of the wave, resonant standing waves are formed (Fig. 46.9b). As cells are exposed to this ultrasonic field, they are initially trapped in the pressure node planes of the standing wave, and then coalesce to form aggregates that sediment from the fluid by gravity. There are three major forces responsible for the aggregation of cells in the resonance field. They are the primary radiation force, the secondary radiation force, and the Bernoulli force. The primary radiation force drives cells toward the velocity antinodes of the resonance field, bringing the cells close together. When the cells become very close to each other, there also exists the secondary radiation force that results from the interaction between the cells. The magnitude of the primary radiation force is generally much greater than that of the secondary radiation force. The magnitudes of both primary and secondary radiation forces are proportional to the cell

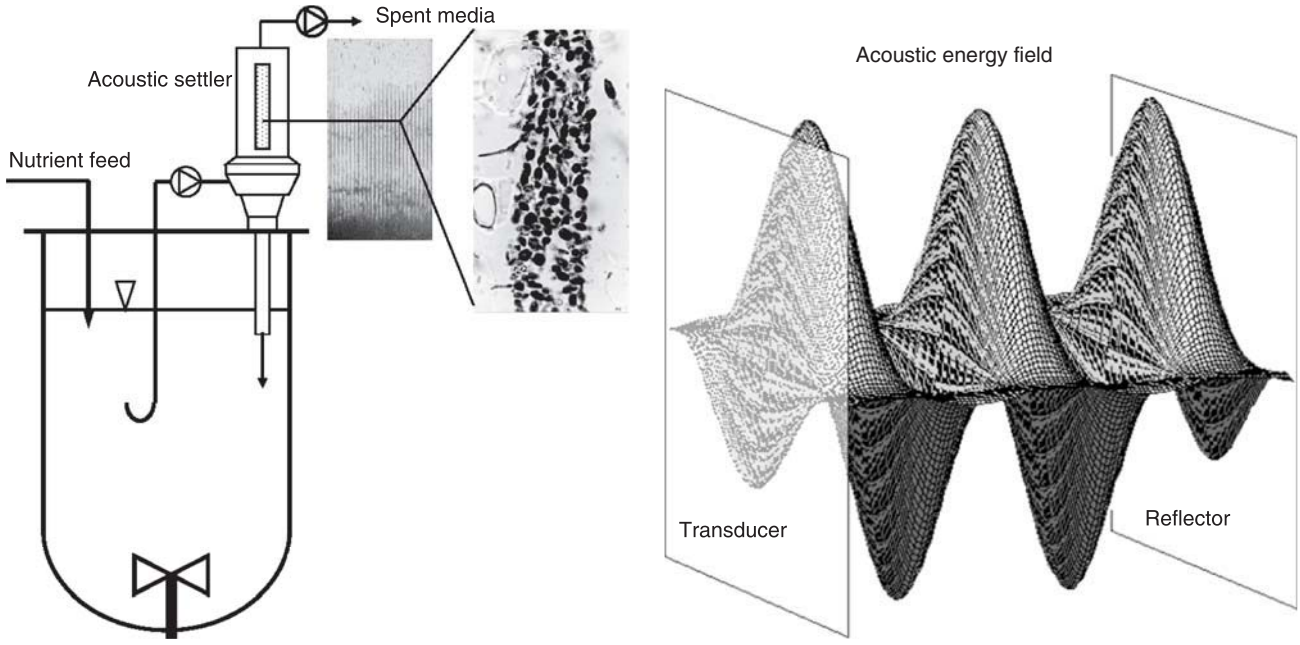

Figure 46.9. (a) Perfusion using an acoustic settler; note that cells within the velocity antinode planes are driven to form striated columns of cell aggregates oriented perpendicular to the antinode planes. (b) When an ultrasonic wave is reflected in the direction opposite to the propagation of the wave, resonant standing waves are formed.

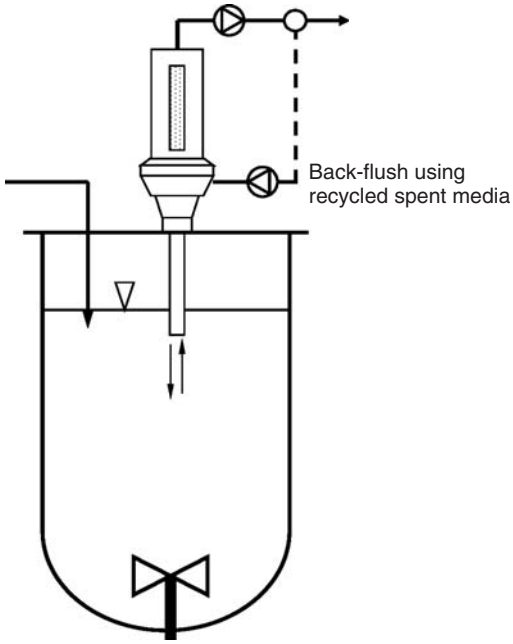
volume, and hence increase with the size of the aggregates. The Bernoulli force results from the nonuniform acoustic field that drives the cells within the velocity antinode planes to form striated columns of cell aggregates oriented perpendicular to the antinode planes (Fig. 46.9a). The performance of acoustic cell-retention devices depends on the magnitude of the acoustic forces that are a function of the acoustic energy density distribution in the liquid. This distribution is a function of the dimensions, imposed boundary conditions, and physical properties of the reflector and transducer. Factors affecting the separation efficiency of acoustic cell-retention devices include (i) acoustic frequency, (ii) power input, (iii) duty cycle, (iv) culture recirculation rate, (v) perfusion/harvest rate, and (vi) back-flush frequency. Among these factors, power input and perfusion/harvest rate are considered most important (31). Most of the acoustic cell-retention devices operate at a fixed frequency (ranges between 2 and 3 MHz) but with adjustable power input. Power input requirement increases with increasing perfusion capacity and hence scale of the acoustic retention device. For a 10-L separator, 5–7 W power input is required, whereas for a 200-L separator, it requires 60–90 W to achieve similar retention efficiency (31). Acoustic cell settler is capable of operating in the pulse mode with on/off duty cycles. Duty cycle facilitates the removal of the aggregated cells in the chamber and, hence, to minimize the residence time of the cells in the acoustic settler. However, according to Shirgaonkar *et al*. (31), duty cycle has little influence on the performance of the acoustic settler. Standard operation of the acoustic settler involves pumping the cell suspension from the reactor to the acoustic settler below the separation chamber at a recirculation rate higher than the harvest rate (Fig. 46.9a). Gorenflo *et al*. (30) suggested an optimum recirculation rate that is twice that of the perfusion rate. Shirgaonkar *et al*. (31) recommended not to increase the recirculation rate above three times the harvest rate at high cell density to avoid shear damage and excess turbulence in the bottom portion of the settler that may disturb the sedimented cells in the acoustic chamber. For shear sensitive cell lines, constant recirculating of the cell suspension using a peristaltic pump may lead to shear damage. Merten (57) therefore recommended an alternative operation strategy of the acoustic settler by eliminating the recirculating stream. To do so, the settler is basically operated under countercurrent, as opposed to crosscurrent, sedimentation. A portion of the spent medium leaving the acoustic settler can be used to periodically back flush the settler (Fig. 46.10). In this case, however, the recirculation rate and perfusion rate become a single parameter, and hence reduces the process flexibility and complicates dynamic adjustment of culture perfusion. Perfusion rate or the harvest rate of clarified spent media affects the settler performance greatly. At high perfusion



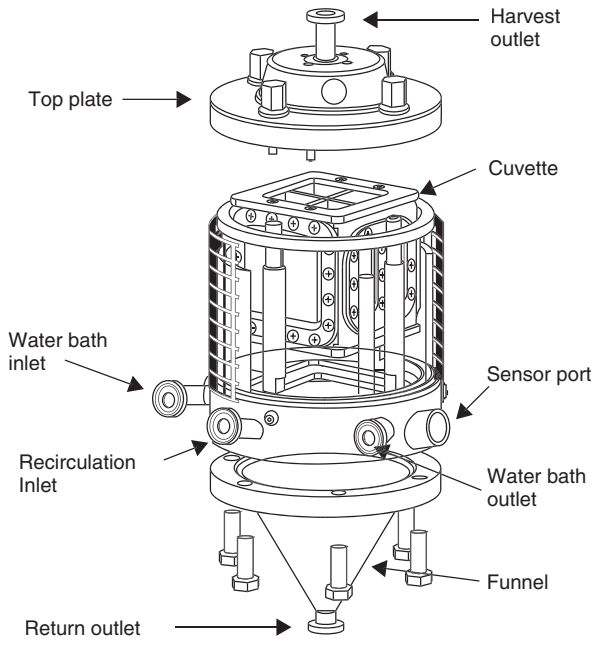


Figure 46.10. An alternative operating strategy of the acoustic settler (cf. Fig. 46.9a).

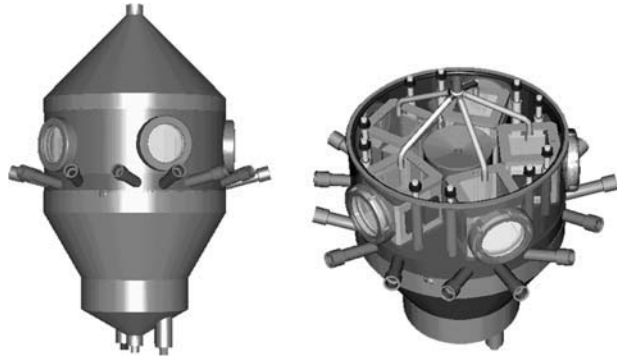
rates, cell washout may occur, which may be alleviated by increasing the acoustic power input. However, acoustic power cannot be increased indefinitely as excess power results in heating the transducer and raising medium temperature in the acoustic chamber to generate slow but free convective flow (58). Pui *et al*. (59) reported temperature increase at a rate of 1.3°C/min in a 75-mL static batch acoustic chamber operated at 0.7 L/h and 13.5 W. This temperature rise resulted from attenuation of the acoustic energy in the transducer, reflector, and cell suspension. To overcome this drawback a good cooling system is necessary to maintain the temperature of the transducer. A two-chamber acoustic device was proposed by Doblhoff-Dier *et al*. (60) to cool the transducer by passing water through one chamber while introducing cell suspension into the other, leading to substantially improved separation efficiency. In the commercial BioSep 200 L system (AppliSens), the chamber's temperature is controlled by means of a refrigerated water bath circulator (30). At high cell densities, the acoustic chamber may be filled with entrained cells, which could reduce the separation efficiency due to attenuation of the intensity of the standing waves. This also increases the residence time of the cells in the acoustic chamber. It is therefore necessary to transport the cells back to the bioreactor via back flushing. Gorenflo *et al*. (58) suggested an air back-flushing approach in which an injection of bioreactor air downstream of the separator periodically returned the trapped cell aggregates back to the reactor. During air back flushing, the acoustic power and the harvest pump are turned off while the fresh media feed pump remains on. Afterwards, the back-flush pump is reversed to refill the acoustic chamber with fresh cell suspension from the bioreactor. Gorenflo *et al*. (58) reported that the separation efficiency increased from 73% at a back-flush frequency of 6/h to a maximum of 91% at frequencies between 12 and 20/h. A further increase in back-flush frequencies requires an increase in the harvest flow rate to the point that separation efficiency starts to decrease. Acoustic cell settlers have been used quite extensively for mammalian and insect cell cultures (31) up to 200 L/d perfusion rate, using a BioSep-200 system that contains a sectioned resonator made out of four 500-mL 1.4-MHz BioSep resonator chambers (Fig. 46.11a, b). A large 1000 L/d capacity acoustic settler (BioSep 1000) has been developed by AppliSens which is believed to be the largest possible scale of this technique (14) mainly because of the technical challenge in keeping the temperature down in the acoustic chamber to prevent liquid convection that reduces the separation efficiency. In the BioSep 1000 system, five BioSep 200 resonators are bundled in a single housing (Fig. 46.11c). It is worthy of pointing out that by proper tuning of the acoustic settler, one may achieve selective retention of viable cells in the bioreactor (31), which is a major advantage of this type of separator over membrane-based systems.



Another way to enhance sedimentation is by virtue of centrifugal forces, typically via the use of external centrifuges operated under continuous or semi-continuous modes (14,15). Conventional centrifugal separators involve rotary seals and are constructed to provide a good clarification of the supernatant, but usually generate too much mechanical stress to the cells and it is difficult to operate under sterile conditions for prolonged periods. An interesting centrifuge design (Centritech centrifuge, Pneumatic Scale, Akron, OH) was used by Johnson *et al*. for hybridoma perfusion cultures (34). In this study, an average perfusion rate of 0.5 culture volume per day, with over 98% viable cell retention was reported. More recently, Cruz *et al*. used the Centritech centrifuge in perfusion culture of (BHK) cells at a volumetric perfusion rate up to two culture volumes per day (61). The centrifuge (Fig. 46.12a) utilizes an "inverted question mark" anti-twist mechanism that makes it possible to rotate one end of a flexible tube while the other is standing still, thus eliminating the need for rotating seals (Fig. 46.12b). A key to the anti-twist design is to rotate the conical rotor at a velocity equal to twice the velocity of the rotating platform (Fig. 46.12a, b). This mechanism was first disclosed in a patent by Adams (62) and later modified in a number of other patents, among others, US patent 4778444 of Westberg and Ehnstrom (63). In the Centritech system, separation takes place in a disposable insert (Fig. 46.12c), where the suspension enters at an

inner radius through a tube at one end of the rotor, flows around the circumference, and exits through the tube at the other end. Since cells are slightly heavier than the liquid, they move outward and are discharged using a pneumatic system through a tube connected to the separation chamber at its outer radius. As the suspension flows around the rotor's circumference, it is subject to low centrifugal forces for enough time for separation to occur. Utilization of the centrifuge in an intermittent fashion decreased the daily cell residence time outside the bioreactor, the

(**c**)

Figure 46.12. (Continued)

daily pelleted-cell residence time in the centrifuge, and the frequency of cell passage to the centrifuge (34). It was suggested by Johnson *et al*. (34) that having cells periodically packed at the bottom of the centrifuge insert is deleterious to the culture by exposing the pelleted cells to prolonged nutrient limitations. In general, centrifugal separators, although more suitable for large-scale perfusion operations, are complex and more prone to mechanical failure than simple gravitational sedimentation devices. These devices are also associated with the drawbacks inherent to external separators. For continuous centrifugal separators, the Sigma factor concept ($\Sigma = Q'/v_{so}$, where Q' is the volumetric throughput of the centrifuge) (13) may be applied to determine the size of the centrifuge. The Sigma factor for certain newer centrifuge types, such as the Centritech centrifuge, has yet to be derived. The residence time in the centrifuge, frequency of cell passage to the centrifuge (during intermittent operations), the magnitude of centrifugal force applied, and the rate of external culture circulation (which may lead to shear and anoxic stresses), will need to be optimized.

46.4 CONCLUSION

Culture perfusion is a proven approach to achieving high productivity in mammalian cell cultures. As reviewed in this chapter, although several cell-retention systems have been demonstrated to enable culture perfusion at a capacity over 200 L/day, a key technical challenge to continuing success and more widespread usage of culture perfusion in industrial-scale operations remains on developing systems that can handle even higher perfusion rates (over 1000 L/day) with improved robustness but

without compromising their mechanical simplicity, to allow stable long-term operations with minimum operator attendance.

BIOREACTORS: ROTATING BIOLOGICAL CONTACTORS

Susana Cortez, Pilar Teixeira, Rosário Oliveira, and Manuel Mota
Institute for Biotechnology and Bioengineering, Centre of Biological Engineering, University of Minho, Braga, Portugal

47.1 INTRODUCTION

At present, there are a wide variety of bioreactors in wastewater treatment, which may be broadly categorized as suspended or attached growth processes. During the 1970s and 1980s, due to its advantages, the rotating biological contactor (RBC), an efficient attached biofilm system, became very popular and thousands of RBC units were installed all around the world. Many of these facilities did not perform as predicted and experienced mechanical failures well before their expected lifetime. As a consequence, the process has fallen into disfavor with many consulting engineers. However, experience with existing installations, over the past 40 years, has established the appropriate range of applications for the RBC process, as well as the range of operating conditions resulting in acceptable performance. Furthermore, RBC manufacturers have reexamined the basic process to identify shortcomings and deficiencies and while many design parameters have remained unaltered, significant changes have been made in other areas to produce a low cost, robust process where unnecessary costs are eliminated. For these reasons, we believe that the RBC system should deserve greater consideration than what is currently paid during process selection.

Existing RBC facilities can now be reliably upgraded and expanded. Plant owners and operators can also properly evaluate RBCs as an alternative for new applications. This has resulted in an increase in interest from both academic and industrial sources. Indeed, there are recent publications detailing the development of RBC technology to accomplish higher levels of treatment and documenting its appropriate range (1–5).

This chapter provides an overview of RBCs, focusing on their main characteristics, advantages and drawbacks, hydrodynamics, factors affecting performance, biofilm characteristics, and some aspects about design and scale-up. The main operational problems and their resolution as well as the general application areas of this reactor are also presented.

47.2 BACKGROUND

47.2.1 Description of the RBC

Different terms are used in the literature to describe the RBC, namely, rotating biological disks, biodisks, rotating disk bioreactor, rotating biological surfaces, and rotating biological filters.

An RBC unit typically consists of a set of closely spaced large flat or corrugated disks that are mounted on a common horizontal shaft and are partially or completely submerged in the effluent to be treated (Fig. 47.1).

A drum filled with packed supports can also be used instead of conventional disks. The shaft continually rotates by a mechanical motor or a compressed air drive and a biofilm is built-up onto the entire surface area of the supporting media, metabolizing the organic materials contained in the wastewater. In aerobic processes, rotation of the media promotes oxygen transfer and maintains the biomass in aerobic conditions. Rotation also provides turbulence in the mixed liquor surface and originates shearing forces,

enabling the removal of the surplus microorganisms from the media (6,7). This excess of biomass is carried out along with the flow of effluent to a clarifier where it is separated from the treated effluent. The reactor may comprise a single compartment (one stage) or several compartments, with a group of disks or a random packed medium in each stage. Stages are accomplished by using baffles fixed to the tank or using a series of tanks.

The main equipment items of RBCs include a basin, baffles, shafts, supporting media, drive systems, and a cover. It must be noted that the designation for individual equipment components may differ slightly, depending on the manufacturer. The reactor basin is the physical tank that holds the media, shaft, and drive assembly through which the wastewater flows. Internal baffling or weir structures separate the stages of the RBC reactors, preventing short-circuiting of wastewater. Removable baffles are often used to allow process changes after the facility is constructed. The shaft is the central structure of an RBC unit. RBC shafts are used to support and rotate the media (disks or filled drums) and expose the media to alternate cycles of wastewater and air. The shafts are usually fabricated from steel and are covered with a heavy protective coating suitable for water and high humidity. RBC drive shafts are mounted perpendicular or parallel to the direction of flow. The media provide the support for organisms to attach and to develop a biofilm. Various media configurations with different thickness, shape, or corrugation patterns have been available from manufacturers, each with its own claimed advantages. The drive assembly rotates the media. There are two types of drive assemblies: mechanical drives and air drives. A mechanical drive is attached directly to the shaft providing constant speed capability only. This type of

(a)

(b)

Figure 47.2. Examples of commercial-scale rotating biological contactors. (a) Detail of a rotating biological contactor with biofilm in the support media. (b) Rotating biological contactors covered. Photographs courtesy: Seprotech Systems Inc.

drive is used most often. An air drive consists of deep plastic cups attached to the perimeter of the media, an air header located beneath the media, and an air compressor. The release of air into the cups tends to aid in shearing excess biomass from the media, thereby reducing film thickness and corresponding loads on the shafts. Both types of drives have bearings to support the RBC shafts. Covers or enclosures are often made of fiberglass or other reinforced resin plastics. Another approach involves housing a number of shafts in a building. In either case, the RBC enclosure must have ventilation, humidity and condensation control, and heat loss provisions. RBCs are covered to protect the media from UV radiation, which can weaken them, to protect biological slimes from freezing, to prevent intensive rain from washing off biofilm growth, and to control media exposure to sunlight, which results in algae growth. Examples of commercial RBC units are presented in Fig. 47.2.

47.2.2 Advantages and Disadvantages

Due to their advantages, RBCs are widely used for secondary and/or advanced treatment in municipal and industrial wastewater applications. In fact, these reactors have more advantages than disadvantages (Table 47.1).

47.2.3 Typical Applications

RBCs have been successfully used to provide secondary treatment (the removal of organic carbon) of municipal wastewater in small to medium size wastewater treatment plants. They have also been applied to the oxidation of ammonium (NH_4^+) to nitrate (NO_3^-), either in combined carbon oxidation and nitrification applications or in separate stage nitrification applications, denitrification (reduction of NO_3^- to N_2), and phosphorus removal (9–11). In addition, they have also been used in bioremediation of landfill leachate (12–14), refinery and petrochemical effluents (1,15), pulp and paper mills effluents (16,17), leather tanneries effluents (18), mining, nuclear and electronics industries effluents (19,20), effluents from food and beverage industries, including wineries (22,21), bakeries (23), or food processors (24,25), as well as for decolorization of wastewaters such as textile dyes (26,27), colored sugar refinery (28), or paper mill effluents (29).

TABLE 47.1. Advantages and Disadvantages of Rotating Biological Contactors

Advantages	Disadvantages
Mechanically simple	Performance susceptible to wastewater characteristics
Simple process control and monitoring	Limited process flexibility
Easy to operate	Limited ability to scale-up
Low energy requirements	Adequate primary treatment and secondary clarifier required
Modular configuration allows easy construction and expansion	Slow process start-up
Low land requirement	Sensitivity to industrial wastes
Compact design with separate compartments	Must be protected against sunlight, rain and snow
Low operating and maintenance cost	Requires permanent skilled technical labor for operation and maintenance (but less than the required by a conventional activated sludge plant)
Short hydraulic retention times	Mechanical failures
High oxygen transfer efficiency	
High biomass concentration per volume reactor	
Low solids generation	
No requirement of sludge recirculation	
High process stability	
Process relatively silent

47.2.4 Hydrodynamics

The efficiency of wastewater treatment in an RBC depends on the active biofilm developed on disk surface and at the contact area between the biofilm and the effluent to be treated. Therefore, an efficient mixing regime in the reactor is needed. In this type of reactor, the mixture depends on the media rotational speed, the degree of media submergence, the hydraulic retention time (HRT), and the biomass present. The existence of corners in the reactor, for example, may give rise to stagnant areas, which disturb mixing conditions and must be avoided. Regarding the mixing conditions within the RBCs, no common agreement exists on whether RBC behaves like a plug-flow or a completely mixed reactor. Experimental results of Banerjee (30) justify the use of staging in an RBC reactor, because mixing decreases gradually along the reactor, approximating the system to a plug-flow regime. Patwardhan (6) reported that as a first approximation, one could assume that each unit of an overall RBC system behaves as a continuous stirred-tank reactor (CSTR). It must be noted that most studies have been performed without biomass in the reactor, which does not reflect a real situation and may lead to erroneous results on the hydraulics of the reactor. Teixeira *et al.* (31) studied the effect of biofilm in the nonideal behavior of a laboratory anoxic RBC through the determination of residence time distribution using the stimulus–response technique. These authors observed that when the disks were covered by biofilm and with biogas production, the existence of hydraulic dead volumes decreased significantly. In practice, the hydrodynamic behavior of any biofilm reactor lies somewhere between these two ideal flow patterns and is always affected by the existence of bypass, short-circuiting, recycling, and dead zones. Another point to be considered is that most RBC hydrodynamic studies were performed in RBC systems with plain disks. Detailed experimental investigations with other media need to be carried out to assess the axial mixing.

47.2.5 Factors Affecting Performance

Although the parameters that determine the efficiency of the reactor will depend on the wastewater to be treated, there are always factors that are common to all processes and that affect the performance of the RBCs. Particularly significant are rotational speed, organic and hydraulic loading rates (HLRs), HRT, RBC media, staging, temperature, dissolved oxygen (DO) levels, effluent and solids recirculation, step-feeding, and medium submergence. There is no consensus on which parameter is more important.

47.2.5.1 Rotational Speed. The rotational speed of the RBC media is crucial for the RBC efficiency because it affects the mixing regime in the reactor, biofilm thickness, and nutrient and oxygen mass transfer inside the biofilm and consequently substrate removal. Many authors have investigated the effect of rotational speed in the performance of RBC systems (1,3,9,32,33). Usually, an increase in the rotational speed increases the DO concentration available to the microorganisms and as a result they are able to degrade the substrate at a higher rate (1). For instance, Najafpour *et al.* (32) observed that the soluble chemical oxygen demand (SCOD) increased from 62.7% to 93.7% relative to a disk rotational speed increase from 3 to 11 rpm. However, the removal efficiency of any substrate increases with the medium speed of rotation

up to a limit. High rotational speed leads to high shear stress, causing the detachment of biomass, deteriorating the effluent quality and reducing the biodegradation rate in the reactor. Besides, an increase in the rotational speed leads to higher power consumption, which may not be economical for wastewater treatment applications (29). Packed supports will provide considerably more oxygenation than disk RBCs at the same rotational speed, but they will require greater power consumption (34). Thus, the guiding principle is to adopt the minimum speed commensurate with acceptable treatment. According to Mathure and Patwardhan (35), typically, rotational speeds are 1–10 rpm for RBC media in disk form with disks of 1- to 4-m diameter mounted on shafts around 5- to 10-m long.

The use of variable rotational rates or the ability to reverse shaft rotation have been suggested to enhance the sloughing of biofilm, in RBC units (36).

47.2.5.2 Organic Loading. The organic loading of an RBC reactor must be accurately defined during planning and designing, but is often overlooked. This parameter allows direct comparison of the RBC system performance when operated under various circumstances and with different kinds of wastewater. The variation of the organic loading rate (OLR) is generally accomplished by changing the inlet flow rate or the HRT, which also results in a change in the hydraulic loading (32). Table 47.2 summarizes the experimental details and performance results of different studies on the effect of organic load on the performance of some RBC systems.

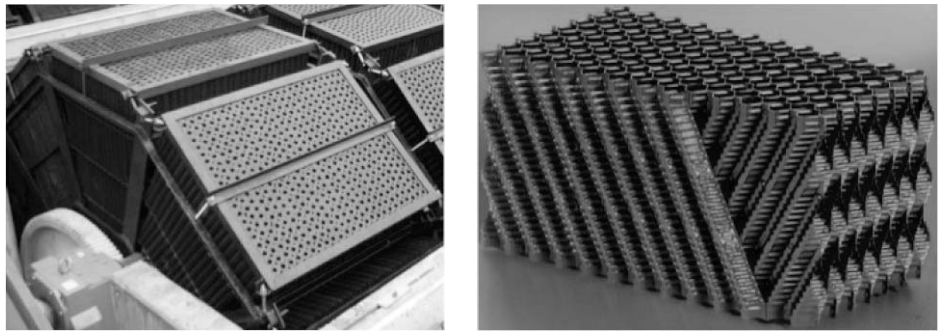
Available data show that, for a given system, as the applied OLR increases, removal efficiency decreases and the substrate removal rate increases. This substrate removal rate rises up to a limit, after which the loading rate has no or limited impact on the removal rate (33,41).

Under normal operating conditions and for low organic loadings, the carbonaceous substrate is mainly removed in the first stage of the RBC. To avoid oxygen transfer limitations, the first-stage design load must be limited to a 5-day biochemical oxygen demand (BOD_5) load 30 g BOD_5/m^2 day or to a soluble BOD_5 load of 12–20 g BOD_5/m^2 day according to Water Environment Federation (WEF) and American Society of Civil Engineers (ASCE) (42). The use of higher first-stage organic loadings will increase the probability of developing problems such as excessive biofilm thickness, depletion of DO, deterioration of process performance, appearance of H_2S odors, and excessive growth of nuisance organisms such as *Beggiatoa* (8,36). Overloading problems can be overcome by removing baffles between the first and second stages to reduce surface loading and increase oxygen transfer. Other approaches include supplemental air systems, step-feed, or recycle from the last stage (40).

The organic loading strongly affects nitrification in an RBC unit. In the initial stages, where the organic load is high, heterotrophic bacteria offer strong competition to nitrifiers displacing them within the bioreactor (43). Therefore, the maximum nitrification rate occurs when the soluble BOD load reduces sufficiently, which always takes place in the latter stages of the RBC. In the case of full-scale RBCs for nitrification of municipal wastewater, Griffin and Findlay (44) found that the OLR imposed to the RBC system should not exceed 4 or 2.5 g BOD_5/m^2 day to achieve an effluent quality of 15 or 10 mg $N–NH_4^+/L$. Nowak (45) proposed that an OLR of 2.5 g BOD_5/m^2 day is desirable to keep the effluent ammonium concentration below 5 mg $N–NH_4^+/L$, at temperatures above 12°C.

47.2.5.3 Hydraulic Loading. As in any other reactor, the performance of RBC units is highly correlated with hydraulic loading, defined as the flow of wastewater introduced into an RBC per surface area unit. In general, increasing the flow rate through the bioreactor reduces the liquid retention time in the system and results in a reduction in removal efficiency (Table 47.2). In defined conditions, increasing HLR also leads to an increase in the attached biomass on RBC media surface (46).

HLR values vary widely depending on the design, the substrate being removed, and the effluent concentration desired (34). Some RBC manufacturers developed design relationships for municipal wastewater in which effluent quality is plotted as a function of hydraulic loading, at a specified temperature. These relationships are very useful to predict the unit performance, although they do not take into account the intrinsic biodegradation constants and hydrodynamics of the system. Moreover, equipment manufacturers often provide optimistic estimates, thus attention should be paid to the selection and application of such empirical relationships (8). Typical HLR range recommended by RBC manufacturers is 1.292–6.833 $dm^3/m^2/h$ (36).



Due to the large amount of biological mass present (low operating feed/microorganisms), RBCs offer good stability under high or toxic hydraulic and organic loadings (38).

47.2.5.4 Hydraulic Retention Time. The HRT depends directly on the volume of liquid in the tank, and the effluent flow studies with RBC systems have shown that longer contact times improve the diffusion of the substrate into the biofilm and its consequent removal from the influent (9,32). This trend is also verified with toxic and heavy metal substrates (17,47,48).

A too short HRT will result in low removal rates, whereas a too long HRT will not be economically feasible. For a biological system to compete successfully with conventional physicochemical methods of treatment, the shortest possible HRT associated with the most efficient

removal rates is required (47). A significant advantage offered by full-scale RBCs is to require short hydraulic retention periods (generally <1 h) (49).

47.2.5.5 Media. The main functions of the RBC media are to provide surface area for biological growth, to promote the contact between the wastewater and the microorganisms, and to achieve oxygen transfer from air into the film of wastewater and biofilm. Over the years, RBC systems have evolved considerably from the original design of rotating disks made from wood. With the introduction of plastic (polyvinyl chloride, polymethylmethacrylate, polycarbonate, polystyrene, polyethylene, etc.), the media fabrication costs reduced and many variations now exist, ranging from simple flat disks through corrugations to cellular meshes.

It has been shown that the adhesion of bacteria to scratched or corrugated media is stronger than adhesion to flat surfaces (3). Furthermore, biofilm build-up is slower on flat surfaces. Rough surfaces ensure zones of low shear stress where attached bacteria are protected from the forces that could remove them. Corrugations enhance structural stability, improve mass transfer, and increase the available surface area (8). High density polyethylene (HDPE) is the material most used in RBC media and is commercialized in different configurations or corrugation patterns commonly termed *low (or standard) density, medium density*, and *high density* according to the basis of surface area provided (7). Standard-density media are defined as having $115\,m^2m^3$ of reactor, with larger spaces between media layers, and are normally used in the former stages of an RBC process train. Medium and high density media have $135-200\,m^2m^3$ of reactor and are used typically in the middle and final stages of an RBC system where thinner biological growth occurs (36).

Some modifications of conventional RBC media have been explored at laboratory-scale with positive results concerning substrate removal. To increase the area and volume for filamentous organisms, one has to solve the problem of slow start-up, improve turbulence near the bulk liquid interface, facilitate efficient mass transfer, and enhance the capacity of handling high OLR; Guimar aes *et al.* (28) attached a layer of polyurethane foam on plastic disks. More recently, Tawfik and Klapwijk (50) compared the efficiency between polyurethane foam and polystyrene rotating disk units, at the same operational conditions, and even though both reactors achieved almost the same chemical oxygen demand (COD) removal, the unit with polyurethane disks performed significantly better for ammonium and *Escherichia coli* removal. These authors concluded that channels and pores of the polyurethane material make substrate transfer efficient, which increased the performance of the simultaneous nitrification and denitrification (SND) processes. Chen *et al.* (51) modified the RBC disks covering them with a net-like structural rubber material with 97% porosity and also verified the occurrence of SND.

During the past two decades, random packed media were successfully used as substitutes for disks at the laboratory and pilot-scale. Such media provide more area for attachment of the biofilm within the same reactor size, contributing to higher mass transfer efficiency due to increased turbulence. In addition, the fabrication cost is nearly one third of that of disks (35). Different types of packing such as Pall rings, saddles, and cylindrical plastic elements with distinctive sizes have been applied in random packed RBC systems presenting attractive results (23,35,38) (Fig. 47.3).

While the use of random packed media is not new, few manufacturers are commercially exploiting it. At large-scale, such as with conventional disks, some

operational problems can occur, leading to a lot or variable biofilm growth. With careful design and further research, it may be possible to develop packing media with the appropriate orientation and movement, allowing the development of a suitable biofilm in a full-scale packed cage.

As recommendation, at the design stage of a particular RBC system, it is necessary to evaluate the characteristics of the wastewater to be treated and the treatment objectives and to compare the various types of biofilm-supporting media reported in the literature in terms of costs, the interfacial area offered, mass transfer coefficients, and power consumption. This will enable the consulting engineer to choose the most appropriate type of medium (6). However, it must be noted that as the supporting medium gets more complex, its cost increases accordingly.

47.2.5.6 Staging. Radwan and Ramanujam (52) referred that staging in the design of RBC systems is especially important at higher organic loadings and also if high effluent treatment quality is required. According to Tawfik *et al.* (53), staging of RBC decreases the detrimental effect of shock load on the performance of the system.

As the wastewater flows through an RBC system, each subsequent stage receives an influent with an organic concentration lower than the previous stage. Because heterotrophic bacteria usually grow faster than nitrifiers, the first stage of an RBC tends to be primarily a BOD or COD removal device, unless the wastewater organic content is very low. As the wastewater moves to the second and subsequent stages, the RBC tends to first remove ammonium and then nitrite with the final product being nitrate, assuming the RBC is sized and operated correctly (34). These facts are corroborated, for instance, by Tawfik *et al.* (53), who studied two RBC units connected in series and observed that the two-stage RBC system provide a better effluent quality over a single-stage RBC. Most of the COD reduction was observed in the first stage, while in second-stage nitrification was performed efficiently. Therefore, staging promotes a variety of conditions where different kinds of microorganisms can flourish.

In secondary treatment applications, RBCs shall be designed and operated in a series of three stages per flow. For combined BOD_5 and $N–NH_4^+$ removal, a minimum of four stages is recommended per effluent flow. When there is recycling of wastewater from the last stage to the first one, denitrification may be achieved in the first stage, where there is high organic loading and low DO content.

For small plants, multiple stages are acceptable on a single shaft oriented in parallel to the direction of flow. In larger installations, shafts are mounted perpendicular to the flow with several stages in series (36). Typical RBC staging arrangements are illustrated in Fig. 47.4.

Different numbers of stages have been used in several applications (Table 47.2). Staging calculations, based on COD and $N–NH_4^+$ effluent concentrations, can be assessed using literature tables, with the appropriate adaptations.

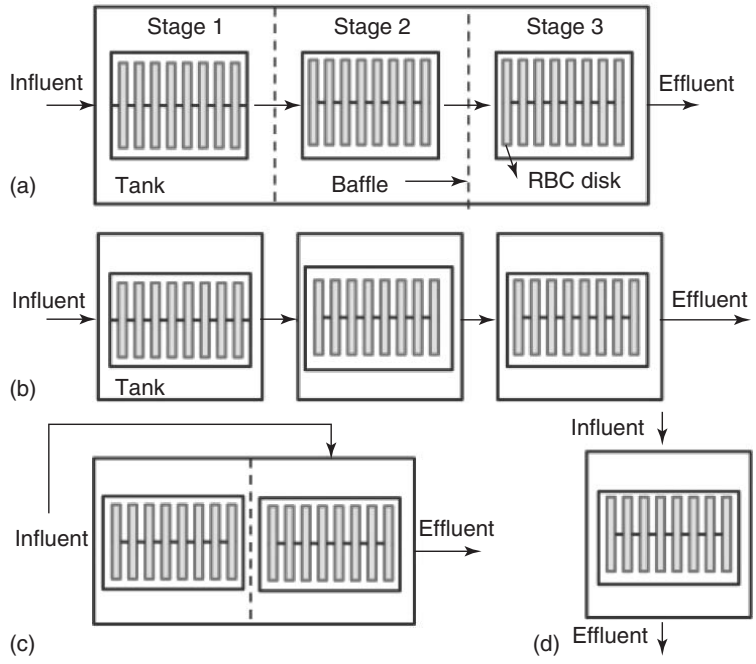

Figure 47.4. (a) One flow parallel to shaft, one RBC unit, three stages; (b) one flow parallel to shaft, three RBC units; (c) step-feed flow, one RBC unit, two stages; (d) one flow perpendicular to shaft, one RBC unit.

47.2.5.7 Temperature. The performance of the RBC system is temperature dependent because temperature is one of the most important parameters that affect the rate of biological processes. At limited conditions, an increase in the influent temperature leads to an increase in the microbial activity and a higher substrate removal can be observed in all RBC stages (1,30). Low influent temperatures can adversely affect biofilm establishment and consequently the reactor performance, particularly in its early stages (47). However, water will hold more DO at colder temperatures as compared with warmer temperatures. Water in the winter can hold almost twice as much DO as in the summer.

Temperature correction factors need to be taken into account in design criteria and can be obtained from the equipment manufacturers or from pilot studies. Generally, when the temperature drops from 13 to 5°C, nearly 2.5 times more media surface area is required for achieving the same performance (7). In biofilms, the nitrification process is less temperature dependent than in activated sludge (AS). The nitrification rate increases by about 4.5%/°C (45). Year-round operation requires that rotating contactors be covered to protect the biological growth from freezing temperatures or excessive heat gain, which accelerates media deterioration. The highest removal efficiencies occur in warmer weather.

47.2.5.8 Dissolved Oxygen Levels. The importance of DO in aerobic wastewater treatment is well known. An inadequate DO concentration may be a major cause of process failure. In an aerobic RBC system, the biofilm gradually forms on the disk surface. The constant rotation of the disk causes mixing of the liquid. Also, the rotating disk surface alternately comes into contact between air and wastewater and thus acts as an aeration device for wastewater treatment. Oxygen transfers from the air to the RBC unit in three ways: by oxygen absorption at the liquid film over the biofilm surface when the biofilm is in the air, by direct oxygen transfer at the air–water interface, and by direct oxygen absorption by the microorganisms during the air exposures (54).

Occasionally, as a consequence of an active respiration in the initial stages, the oxygen concentration reaches minimal levels, increasing along the reactor where substrate concentration is low. In these conditions, in the former compartments, denitrification might take place.

An increase in the speed of rotation, at a given level of submergence, leads to an increase in the oxygen transfer capacity of an RBC, in terms of the overall oxygen transfer coefficient, $K_L a$ (7). At a particular rotational speed, as submergence increases, the $K_L a$ decreases (35). Some researchers (33,55) have improved empirical/mathematical models for the estimation of $K_L a$ in RBC reactors (Table 47.3).

It is very difficult to model the oxygen transfer because these systems are very complex and include biofilm growth and detachment, the participation of suspended biomass,

TABLE 47.3. Proposed $K_L a$ Models for RBC Reactors

model	RBC Media	Predicted $K_L a$ Model	Nomenclature	Reference
Kim and Molof	Disks	$K_L a = 0.011\left(\frac{w^{1.5}D^{0.5}}{d}\right)^{0.732}$	ω - rotational speed [T]$^{-1}$ D - disk diameter [L] d - distance between the discs [T]	(56)
Kubsad et al.	Disks	$K_L a = 0.01315\left(\frac{1.697Anw^{1.5}D^{0.5}}{V}\right)^{0.73778}$	A - exposed surface area to air of one disc [L]2 n - number of discs ω - rotational speed [T]$^{-1}$ D - disc diameter [L] V - working volume of the reactor [L]3	(57)
Chavan and Mukherji	Disks	$K_L a = \left(\frac{D}{A_d^{0.5}}\right)^{\psi}\left(\frac{\rho A_d \omega}{\mu}\right)^{\varepsilon}\left(\frac{A_d}{A_t}\right)^{\theta}\left(\frac{\delta}{V^{1/3}}\right)^{\lambda}\left(\frac{\mu}{\rho A_d}\right)$	D - disc diameter [L] A_d - disc area [L]2 ρ - liquid density [M] [L]$^{-3}$ ω - rotational speed [T]$^{-1}$ μ - liquid viscosity [M] [L]$^{-1}$ [T]$^{-1}$ A_t - cross-sectional tank area [L]2 δ - liquid film thickness [L] V - working volume of the reactor [L]3 $\psi\varepsilon\theta\lambda$ - fitting parameter	(55)
Palma and Verdone	Disks	$K_L a = 134.07\omega^{1.5}C^{0.5}\left(\frac{2.15}{\omega} + 0.006\right)$	ω - rotational speed [T]$^{-1}$ C - carbon removal rate reduction in oxygen limiting conditions (%)	(33)

and so on. However, the proposed empirical models will facilitate the scale-up of RBC units.

During operation oxygen levels must be properly controlled and to prevent oxygen concentration from becoming a limiting factor, initial stages should have at least 2 mg DO/L (45). If the rotating motion does not supply sufficient oxygen, a supplemental aeration system should be installed (7,40). Usually this promotes a remarkable performance of the RBC, with an established thinner and active aerobic biomass, allowing considerable cost savings in design and construction of RBC units.

47.2.5.9 Effluent and Solids Recirculation. Recirculation of the RBC-treated effluent (either before or after the secondary clarifier) does not significantly improve the treatment efficiency (5). Nevertheless, under certain conditions (e.g. during the start-up or in the treatment of high strength effluents), recirculation may avoid overloading and thus lead to more reliable RBC performance. Therefore, in spite of being optional, recirculation should be considered in the RBC design for adverse conditions. The rate of recirculation recommended is approximately 25% of the average design flow (58).

Improved ammonium removal efficiencies have been occasionally reported when recirculation is applied, increasing with recirculation ratios (59,60). Improved nitrification with recirculation is attributed to the dilution of influent biodegradable organic carbon.

47.2.5.10 Step-Feeding. To reduce or prevent overloads and increase the process capacity, a step-feeding of the RBC stage(s) should be provided. Lv *et al.* (61) and Saikaly and Ayoub (62) indicated that working in a step-feed mode improved the removal rates of both total nitrogen (TN) and $N–NH_4^+$. The latter authors also found higher DO values in RBCs with step-feeding. The combined effect of step-feed and effluent recirculation in increasing RBC activity was reported by Ayoub and Saikaly (63), but for a simple soluble substrate.

47.2.5.11 RBC Medium Submergence. Typically, in aerobic processes of municipal wastewater treatment, the RBC media submergence is about 40%, although in nutrients removal it can attain 60%. Considering industrial effluents, due to their diversity, there is no standard value for media submergence. Submergence to 70–90% might be an alternative option, providing the advantages of less loading on the shafts and bearings, larger media volume available, and fewer RBC units required (64). However, if the deeper submerged RBC is used to treat wastewater aerobically, DO in the liquid will be lower and as a consequence, additional air drive units must be used to provide oxygen and rotation (7). The increased submergence combined with the air drive rotation of the deeper submerged RBC has dramatic economic and operating benefits (64).

The deeper submerged RBC units can also be applied as anaerobic RBCs (65,66) or used for denitrification (9,14,67,68). In these applications, the reactors are completely closed to avoid air entrance.

According to Laquidara *et al.* (69), anaerobic RBC systems combine advantages of the aerobic RBC reactor with the anaerobic process (no oxygen transfer limitations, low quantities of waste biological solids, and recovery of the usable energy in the form of methane). Due to these advantages, the anaerobic RBC process appears to be well suited for treating both medium and high strength organic wastewater (66). Lu *et al.* (66) studied the effect of increasing disk submergence (40%, 70%, and 100%) in an anaerobic RBC and verified that the degree of mixing increased with the decrease in disk submergence. On the contrary, COD removal efficiency increased with the increase in submergence. There is a great scope of application for anaerobic RBCs in industrial wastewater treatment, which are at present considered suitable for treatment by other anaerobic processes. It is in anaerobic degradation that RBCs could prove to be even more successful than they have been in aerobic treatment (70).

Teixeira and Oliveira (67) investigated the effect of disk submergence on the performance of lab-scale RBCs, in terms of the denitrification process. For an influent $N–NO_3^-$ concentration of 50 mg/dm^3, the removal efficiencies obtained were 37 and 17 g $N–NO_3^-$/m^3·m^2 for, respectively, 100% and 64.5% disk submergence. Using a pilot-scale RBC with a completely submerged plastic tubular medium, Mohseni-Bandpi and Elliot (68) achieved a maximum nitrate removal rate of 168 mg $N–NO_3^-$/m^{2}h for an influent of 130 mg $N–NO_3^-$/dm^3.

Cortez *et al.* (14) observed that the completely immersed disks of the anoxic RBC achieved $N–NO_3^-$ removal efficiencies above 95% for concentrations up to 100 mg $N–NO_3^-$/dm^3. The highest observed denitrification rate was 55 mg $N–NO_3^-$/dm^3/h (15 g $N–NO_3^-$/m^2 day) at a nitrate concentration of 560 mg $N–NO_3^-$/dm^3.

Recently, a three-stage, fully submerged anaerobic/anoxic/aerobic RBC hybridized with a suspended sludge system was found to be an efficient and controllable process for carbon, nitrogen, and phosphorus removal (71).

47.2.5.12 Biofilm Characteristics. A layer of biological growth, also known as a *biofilm*, develops on the surface of the RBC media. This layer constitutes a biocatalyst and the degradation of the substrate depends on the rate of metabolism of the microorganisms present. The microorganisms grow by degrading the substrate and, in turn, promote biofilm growth. A biofilm consists of a complex structured community of bacterial cells enclosed

in a self-produced polymeric matrix and adherent to an inert or living surface (72).

Observations of full-scale RBC biofilms treating municipal wastewater report that a biofilm from the initial stages has a gelatinous aspect, being usually grayish and may present some white zones probably due to filamentous bacteria-like *Beggiatoa*. In addition, in this part of the reactor, biofilm is almost entirely constituted by species of ciliates. Biofilm of the last stages is always thinner than in the first stages, has a brown-like color or sometimes reddish, and shows more diversified communities, not only in species of ciliates but also in flagellates, amoebae, and metazoa (rotifers, nematodes, and annelids). The main limiting factor of microfauna growth is the degree of pollution in the influent expressed in terms of COD or BOD_5. As long as this parameter decreases along the RBC, its effect as a limiting factor decreases too, resulting in an increase in the majority of existing species (73).

The outer biofilm layer of a full-scale RBC disk is very heterogeneous and complex, while the inner layer is more uniform and compact with a reduced microbial density and a larger percentage of nonviable bacteria (7). According to Okabe *et al.* (74), the active metabolic cell fraction decreases from $35 \pm 13\%$ in the outermost to $15 \pm 4\%$ in the innermost biofilm.

When the depth of the biofilm is large and the concentration of DO in air is low, the outer layer acts aerobically and the inner side acts anoxic or anaerobically (23). For example, Chen *et al.* (51) verified SND in a net-like RBC. Biofilm DO gradients adequately supplied growth conditions for nitrifying bacteria in the surface layers and for denitrifying bacteria in the deeper layers.

Biofilms ranging from 0.5 to 4.5 mm in thickness have been found in full-scale disk RBCs treating municipal wastewater. Biofilm thickness control is very important to avoid clogging or material fatigue stresses (44) and it is achieved through the hydrodynamic shear experienced by the biofilm.

The development of *Beggiatoa* is always taken as a warning for the performance of RBC units because its blooming prevents the sloughing of thick biofilm from the disks, which can lead to overload on the media supports (7).

The characterization of a biofilm in terms of thickness, density, total dry weight, humidity, chemical and biological composition, and activity is very useful when analyzing the performance of an RBC.

47.2.6 Process Design Aspects and RBC Scale-Up

To achieve the optimal degree of treatment, the RBC process design must consider the type and dimensions of the medium, the degree of submergence, the rotational speed, as well as the number of stages, among other parameters. The physical facilities, including the motor, gear system, and so on, have to be designed accordingly. Moreover, the selected RBC configuration must be such that the overall operation becomes economically viable and competitive (6).

During the 1970s and 1980s, the design of RBC units for the treatment of domestic and common industrial effluents relied on empirical design relationships. RBC manufacturers have developed their own empirical design curves, equations, and guidelines based on treatment data collected using their equipment. However, empirical models cannot be relied on to predict the concentration profile of a substrate through an RBC for conditions other than those studied experimentally. In addition, available RBC design curves and equations are not useful for the treatment of distinctive effluents that differ in composition from the well-characterized municipal or industrial effluents for which they were developed. Thus, the relatively slow acceptance and use of RBCs has been attributed, in part, to the lack of standardized design procedures (75).

For the rational design of an RBC system, it is important to consider the underlying hydrodynamics, biodegradation kinetics, oxygen transfer, development, and detachment of the biological film. Thus, the first step in the overall design process should be to carry out laboratory or pilot-scale experiments over a wide range of operating conditions with the particular wastewater. A step-wise process design algorithm is presented in Fig. 47.5.

From the data collected at laboratory or pilot-scale, it will be possible to scale-up the RBC system with confidence. Some RBC design recommendations, such as not to use high density media in the first stage or to prevent the biofilm from cold weather with an enclosure, along with many others, were referred along this chapter and should be respected. The performance of a RBC will be favored if it is designed to withstand both normal and unusual operation conditions. The possibility of applying supplemental aeration, step-feed, recirculation, or removable baffles (between stages) significantly improve operational flexibility of RBCs.

47.2.7 Operation and Maintenance

As any treatment process, the RBC system demands routine supervision provided by professional operators to avoid operating problems. This supervision will be different among plants but typical routine maintenance should include the inspection and maintenance of chain drives, belts, sprockets, rotating shafts, replacement of broken air cups, or media that might otherwise jam or interfere with shaft rotation and inspection of other moving parts according to the manufacturers' instructions or with guidance from the design engineer. Lubrication of all these moving parts and cleaning the attached growth media by

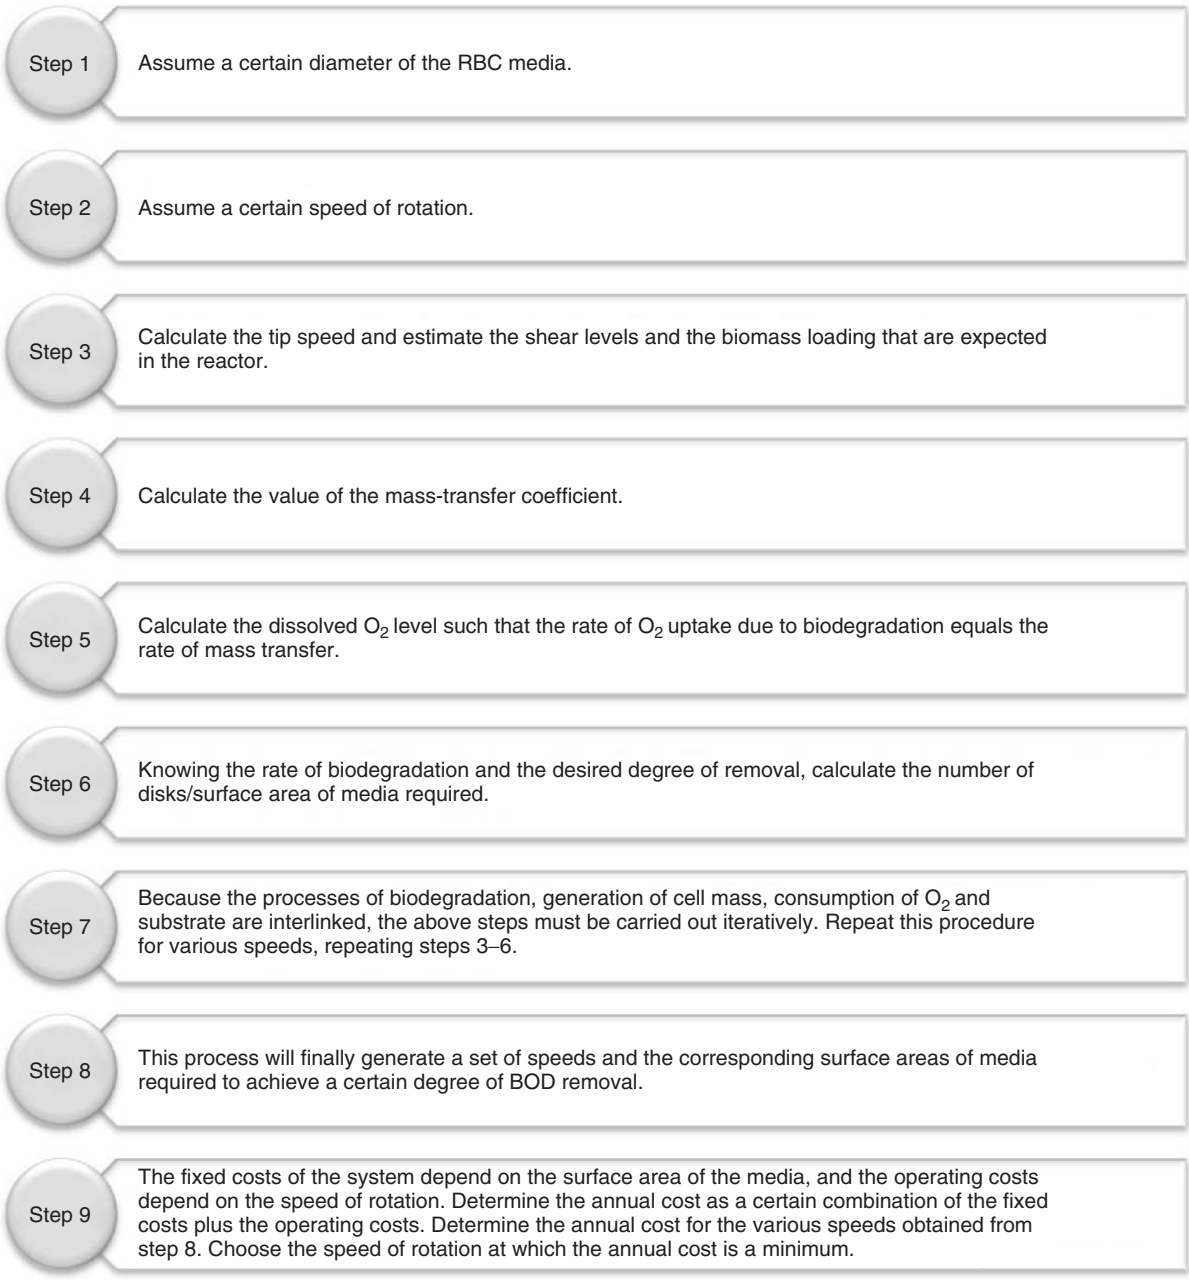

Figure 47.5. Scheme of a step-wise RBC process design algorithm (adapted from Ref. 6).

spray-washing of disks and purging of settled sludge are needed. Other metal parts should be periodically painted for protection.

In spite of all the mentioned advantages, RBC systems have some operating problems. Table 47.4 presents a troubleshooting guide for some problems associated with the design, operation, and maintenance of these reactors.

Considering mechanical failures, the most common are shaft breakage, stub shaft damage bearing failure, and media support structure fracture and degradation. These may arise due to overloading conditions, excess of biofilm growth, microbiologically influenced corrosion, low frequency corrosion fatigue, improper greasing and inadequate locking of nuts and bolts, or poor engineering design (77). Any one, or combinations, of these faults will require prompt replacement of the failed component. The most severe form of mechanical breakdown due to total replacement costs is the shaft fracture that results in complete collapse of the unit.

TABLE 47.4. Problems and Solutions for RBC Operation

Observation	Probable Cause	Monitor	Solution
Decreased treatment efficiency	Low wastewater temperature	Influent temperature	Cover RBC unit
	Organic overload	Influent BOD, TSS, pH, temperature, DO	Install equalization tanks before RBC to dilute high strength load and provide preaeration; add extra treatment units, if available; install supplemental aeration equipment to handle higher DO demands; recirculate secondary clarifier effluent to dilute influent flow
	Hydraulic overload	Influent flow	Flow equalization; eliminate source of excessive flow; balance flow between reactors
	Toxic influent	Influent COD, pH, temperature, DO	Sample the collection system to identify the source of toxicity; implement sewer ordinances to establish prohibitions and limitations of substance discharge and criminal fines if discharges occur; install equalization tanks before RBC to dilute high strength load and provide preaeration; install supplemental aeration equipment to handle higher DO demands; recirculate secondary clarifier effluent to dilute influent flow
	Short-circuiting	Check basin surface for visibly stagnant sections or dead zones	Install manifolds or diffusers on inlets and outlets; provide multiple inlets and outlets for more equal hydraulic distribution; change location of inlets and outlets; keep inlets and outlets as far apart as possible; eliminate dead zones
	pH too high or too low	Influent pH. Desired range is 6.5–8.5 for secondary treatment; 8–8.5 for nitrification	Eliminate source of undesirable pH or add an acid or base to adjust pH; when nitrifying, maintain alkalinity at seven times the influent ammonia concentrations
Excessive sloughing of biomass from disks	Toxic influent	Determine material and its source	Eliminate toxicmaterial if possible; use flow equalization tanks to reduce variations in concentration so biomass can acclimate
	Excessive pH variations	Influent pH	Eliminate source of pH variations or maintain control of influent pH
Development of white biofilm	High H_2S concentration	Influent odor	Preaerate wastewater or add $NaNO_3$, H_2O_2, or $FeSO_4$; apply supplemental aeration in the first stages
	First stage is overloaded	Organic load on first stage	Adjust baffles between first and second stages to increase fraction of total surface area in first stage
Solids accumulation	Inadequate pretreatment	Determine if solids are grit or organic	Remove solids from reactors and provide better grit removal or primary settling
Shaft bearings or motors running hot	Inadequate maintenance	Maintenance schedules, oil level, alignment	Lubricate per manufacturer's instructions

Source: Adapted from Ref. 81.

With a thorough understanding of the mechanisms involved in mechanical failure and with the development of improved RBC biofilm supports and bearings and stronger shafts, among others, a new approach to RBC design has resulted in reliable units with an expected operational life of 20 years. Furthermore, the improved design could revolutionize applicability of RBCs to high flow/highly populated regions (43,77).

47.2.8 RBC Versus Other Wastewater Treatment Systems

Although it is not possible to find easily comparable values in the literature between RBCs and other biological processes, Table 47.5 presents the characteristics and performance of several RBCs and other aerobic biofilm and AS processes.

TABLE 47.5. Performance of Different Aerobic Wastewater Treatment Systems

Type of Reactor	Type of Material and Media	Type of Wastewater	pH	HRT (h)	Hydraulic Loading/ Influent Flow Rate	Inlet Organic Loading/ Substrate Concentration	Other Related Data	Performance	Reference
Lab-scale									
Attached growth reactors									
Rotating biological contactor									
	PVC disks	Food industry wastewater	5.2	—	0.03 kg COD/m^3/d		Four-stage RBC	95%, 94%, 78%, 94%, and 87% for COD, BOD_5, TON, TSS, and oil and grease removal, respectively	(24)
	Polypropylene square-packed rings	Synthetic food industrial wastewater	6.8	12	—	2.72 g BOD_5/m^2d	One-stage RBC	89.4%, 92.0%, and 45.2% for COD, BOD_5, and TKN removal, respectively	(38)
Packed-bed reactor									
	Plastic corrugated cylindrical tubes with 2-cm length and 1.5-cm diameter	Food industry wastewater	4.6–5.0	—	0.31 m^3/m^2d 0.45 kg BOD/m^3/d 0.03 kg N/m^3/d			87%, 93%, 65%, 78%, and 73% for COD, BOD_5, TKN, TSS and oil and grease removal, respectively	(78)
Moving-bed biofilm reactor									
	Kaldnes carrier elements with 7-mm length and 10-mm diameter	Thermomechanic pulping whitewater	7.0	17.9	2.7 kg SCOD/m^3/d		Reactor temperature: 55°C	44% and 64% for COD and BOD_7 removal, respectively	(79)
Suspended growth reactors									
Activated sludge									
		Chemical industry wastewater	7.2	24			3 g MLSS/dm^3	93%, 95%, 92%, 98%, and 89% for COD, BOD_5, TON, TSS, and oil and grease removal, respectively	(80)
		Food industry wastewater	5.2	3 (SRT)			3 g MLSS/dm^3	96%, 98%, 41%, 94%, and 74% for COD, BOD_5, TON, TSS, and oil and grease removal, respectively	(24)

Large-scale									
Attached growth reactors									
Rotating biological contactor									
Pilot-scale	Polystyrene foam disks	Municipal wastewater	6.7–7.1	5	—	22 g COD/m^2d	Two-stage RBC	77%, 20%, and 31% for COD, $N–NH_4^+$, and TKN removal, respectively	(81)
Full-scale	Disks	Leather wastewater	9.0	—	—	15–20 g BOD/m^2d 50–65 g COD/m^2d	Four-stage RBCs	52.69% and 76.36% for COD and BOD_5 removal, respectively	(18)
Full-scale	Plastic packed rings	Food industry wastewater	5.2	—	0.02 m^3/m^2d		Four-stage RBC	86%, 88%, 71%, 73%, and 77% for COD, BOD_5, TON, TSS, and oil and grease removal, respectively	(24)
Moving-bed biofilm reactor									
Pilot-scale	Polypropylene corrugated cylinders with 20- to 30-mm length and 15- to 20-mm diameter	Municipal wastewater	—	—	0.61 kg COD/m^3/d	5.5 g COD/m^2d	Filling ratio: 70% Two reactors in series	76% and 92% for COD and $N–NH_4^+$ removal, respectively	(82)
Full-scale (upgrade)	Polypropylene corrugated cylinders with 20- to 30-mm length and 15- to 20-mm diameter	Municipal wastewater	—			7.9 g COD/m^2d	Filling ratio: 53%	73%, 83%, and 72% for COD, BOD_5, and $N–NH_4^+$ removal, respectively	(83)
Suspended growth reactors									
Activated sludge									
Pilot-scale		Municipal wastewater	—	—	0.61 kg COD/m^3/d	5.5 g COD/m^2d	Sludge recirculation	84% and 98% for COD and $N–NH_4^+$ removal, respectively	(82)

The efficiency of an RBC with a high rate packed-bed reactor for the treatment of an upflow anaerobic sludge blanket (UASB) reactor effluent was compared by van Buuren (84). At an HRT of 3.3 h, the packed-bed reactor removed 50% of COD, while the RBC removed 70%, indicating a better performance of the RBC. Moreover, at a much shorter HRT of 0.24 h, the RBC still achieved 40–80% COD removal.

Specifically, comparing the most common suspended growth process, the AS process, with the RBC shows that both the processes can produce high levels of treatment. However, the RBC process is easier to operate, occupies slightly less area, requires less than half of the energy, and reduces the cost of other plant processes by the nature of the excess biosolids that are generated when compared with those created in the AS process. Nasr *et al.* (80) compared, at laboratory-scale, these two biological processes for the treatment of chemical industrial wastewater (5239 mg COD/L and 2615 mg BOD_5/L). As both proved to be effective, producing effluents within the permissible limits, the engineering design of each treatment system (full-scale) was developed and the cost estimate indicated that the construction cost was similar for both the systems, while the running cost of AS was almost twice as that of the RBC. Thus, the use of the RBC system was recommended.

47.2.9 Costs Considerations

RBC units are variable with climate and location. Generally, these reactors involve high capital costs as not all materials may be locally available and motor and special material for rotation is required. Another cost factor may be the implementation, which requires skilled experts. According to a published article in 2009 (85), for the studied process, the construction cost of an RBC is US$624/inhab., while for a packed-bed filter is US$882/inhab. and for a wetland system is US$311/inhab. However, usually, maintenance and operating costs are lower for RBC units. In another research, cost estimate for the AS indicated that the construction system is US$54,912/year, while the running cost is US$19,912/year. The construction cost of the RBC is US$54,035/year, while the running cost is US$10,614/year. Therefore, an RBC system is recommended because of the management and operation of the system that will be easier and technically feasible by low skilled personnel (80).

47.3 CONCLUSIONS AND PROSPECTS

RBCs have been widely used as an efficient method of treating wastewater due to its simple process control and monitoring, ease of operation, low energy and land requirements, ability to withstand shocks or toxic loads, freedom from odors, and good sludge settling properties. These reactors offer an alternative treatment technology to the conventional AS process.

RBC units have been mainly used in aerobic processes because they provide high oxygen transfer efficiency. In this field, RBC media evolved considerably from the original design of several rotating disks into a unit filled with packed supports. There are not many studies on the influence of physical characteristics in these reactors' performance. Furthermore, studies on power consumption, hydrodynamics, mass transfer, and biofilm properties also need to be investigated for each type of packing material. Such studies should have an important bearing on scale-up and are encouraged.

Deeper submerged and covered RBCs are being used successfully at full-scale in denitrification and for the treatment of high strength industrial wastewater, constituting a promising technology. Thus, it is expected that the application of anoxic, anaerobic, or anammox RBC systems, at full-scale, with conventional or packing media, will increase. More studies with modified and improved RBC media, through utilization of new porous materials and/or application of biocoatings (86), and hybridized RBC units are likely to appear in the coming years.

Few mathematical models and with many limitations have been proposed to describe the performance of RBC reactors. For the appropriate design of an RBC system and to achieve the highest degree of treatment in an economical and suitable way, with low power input, it is important to consider the underlying hydrodynamics, biodegradation kinetics, oxygen transfer, and development and detachment of the biological film. Thus, further studies on this subject should continue to be carried out, together with laboratory or pilot-scale experiments.

To conclude, application of RBCs in new fields, such as the production of metabolites (e.g. antibiotics and vitamins) or the treatment of contaminants in different physical phases (e.g. pollutant gases), taking advantage from intense mass transfer at low power input, presents a great potential.

LIST OF ABBREVIATIONS

AS	Activated sludge
BOD	Biochemical oxygen demand
BOD_5	5-day biochemical oxygen demand
BOD_7	7-day biochemical oxygen demand

COD	Chemical oxygen demand
CSTR	Continuous stirred-tank reactor
DO	Dissolved oxygen
HDPE	High density polyethylene
HLR	Hydraulic loading rate
HRT	Hydraulic retention time
$N–NH_4^+$	Nitrogen-ammonium
$N–NO_2^-$	Nitrogen-nitrite
$N–NO_3^-$	Nitrogen-nitrate
OLR	Organic loading rate
RBC	Rotating biological contactor
$SBOD_5$	Soluble 5-day biochemical oxygen demand
SCOD	Soluble chemical oxygen demand
SND	Simultaneous nitrification and denitrification
TKN	Total Kjeldahl nitrogen
TN	Total nitrogen
TOC	Total organic carbon
TON	Total organic nitrogen
TSS	Total suspended solids
UASB	Upflow anaerobic sludge blanket

BIOREACTORS, STIRRED TANK FOR CULTURE OF PLANT CELLS

PAULINE M. DORAN

School of Biological Sciences, Department of Chemical Engineering, Monash University, Victoria, Australia

48.1 PRODUCTS FROM SUSPENDED PLANT CELL CULTURES

Plants produce a diverse range of natural products used as active ingredients in pharmaceuticals, fragrances, flavors, dyes, and insecticides. Most of these chemicals are small but complex molecules that are difficult to synthesize chemically using economically viable methods. Most valuable phytochemicals are produced by plants as secondary metabolites by means of highly branched and regulated pathways that cannot be genetically engineered readily into microorganisms.

Plant tissue culture is an alternative to whole plants for production of plant compounds, offering important advantages such as better control over product quality and quantity. Of the many different forms of plant tissue culture available, such as callus, cell suspensions, immobilized cells, embryos, roots, and shoots, suspended plant cells have been most frequently applied for bioreactor-scale production of plant compounds. Table 48.1 illustrates the wide range of natural phytochemicals synthesized using plant suspensions.

As well as natural products, plant cells are also applied for production of heterologous proteins. The advantages of using recombinant plant systems for foreign protein production include the ability to correctly assemble and fold multimeric proteins and carry out posttranslational modifications, and the low risk of contamination by animal-borne pathogens. In principle, any protein can now be expressed in plant cells. Examples of foreign proteins that have been produced using plant cell suspensions are listed in Table 48.1.

48.2 PROPERTIES OF SUSPENDED PLANT CELL CULTURES: IMPLICATIONS FOR BIOREACTOR ENGINEERING

For commercial production of natural or foreign compounds using plant cells, scale-up of the cultures into bioreactors is essential. Various conventional and novel bioreactors, including stirred tanks, bubble columns, airlift vessels, fluidized beds, bubble-free systems, spin filter devices, and cell-lift configurations, have been applied for suspended plant cell cultures. In many cases, the performance of cultures measured in terms of cell growth and/or product accumulation declines with scale-up. This reflects the difficulty of optimizing all the conditions necessary for culture activity within the bioreactor environment.

The principal functions of a bioreactor used for aerobic cell culture are to provide adequate mixing, oxygen transfer, and heat transfer without the deleterious effects of excessive hydrodynamic shear. The properties of the biomass and culture fluid can impose significant technical constraints on the design and operation of appropriate bioreactors, and this is particularly true for suspended plant cells. Unfortunately, it is difficult to generalize about several of the important engineering characteristics of plant suspensions. For example, some cultures produce viscous non-Newtonian broths (1–5), while others exhibit essentially Newtonian behavior (6) and only moderate viscosities (7,8). The tendency of plant cells to clump together as aggregates varies considerably depending on the species and culture conditions (3,5,9–14), and there are differing reports about the extent to which plant

TABLE 48.1. Examples of Natural Products and Foreign Proteins Produced Using Plant Cell Suspensions

Natural phytochemicals	Ajmalicine, anthocyanins, anthraquinones, artemisinin, azadirachtin, berberine, betalains, codeine, digoxin, ginsenoside saponins, hyoscyamine, morphine, paclitaxel, podophyllotoxin, polysaccharides, rosmarinic acid, scopolamine, serpentine, shikonin, steroidal alkaloids, thiophenes
Foreign proteins	Albumin, antibodies (IgA, IgG1, IgG2b/κ), antibody fragments (scFv, IgG heavy chain), α_1-antitrypsin, bryodin 1, erythropoietin, β-glucuronidase, granulocyte-macrophage colony-stimulating factor, hepatitis B surface antigen, interleukins (2 and 4), invertase, lysozyme, ricin

TABLE 48.2. Properties of Suspended Plant Cell Cultures and Implications for Bioreactor Engineering

Property	Engineering implication
Slow growth	Cultures prone to contamination; batch cultures prolonged and therefore expensive
Shear sensitivity	Input of mechanical forces restricted, resulting in poor mixing and solids suspension and inadequate oxygen transfer
Sensitivity to gas-phase components such as CO_2 and ethylene	Gas throughputs restricted to avoid stripping of gaseous components; greater reliance on mechanical stirring for mixing and oxygen transfer
Non-Newtonian rheology	Poor mixing and solids suspension; inadequate oxygen transfer
Tendency to clump	Complex broth rheology; wall growth; conditions experienced by cells in clumps and wall growth are difficult to control
Tendency to foam	Reduced bioreactor working volumes, resulting in low volumetric productivity; conditions experienced by cells in foams and meringues are difficult to control; use of chemical antifoams reduces oxygen transfer
Low product yield	High biomass densities needed for economic feasibility, exacerbating problems with mixing and oxygen transfer

cells are shear sensitive (4,14–18). Another property affecting many suspended plant cell cultures is low product yield. This applies to natural phytochemicals, as low yields of secondary metabolites are often associated with dedifferentiated plant cells, but also to foreign proteins, as protein yields are affected by low levels of heterologous expression as well as subsequent protein degradation (19). As a consequence, high biomass densities are required for economic feasibility for many plant cell culture systems.

Whereas the properties of suspended plant cells, such as morphology, aggregate size, and rheology, affect the performance of bioreactors and have important engineering implications, they are not always independent of the bioreactor. As an added complexity, the properties of plant cell cultures can change depending on bioreactor operating conditions. For example, cell aggregates may be smaller (5,20) and individual cells either larger (21) or smaller (22) in stirred bioreactors compared with shake flasks. The rheology of the plant cell broth may also change as a result of protein and polysaccharide secretion into the medium in response to hydrodynamic shear levels in stirred vessels (4).

Typically, plant cell cultures offer a highly challenging combination of features that distinguishes them from microbial and animal cell systems. These properties and their implications for bioreactor engineering are summarized in Table 48.2. When complex broth rheology and cell shear sensitivity are coupled together, providing adequate mixing, solids suspension, and oxygen transfer can be difficult. Although plant cultures also possess some ameliorating characteristics such as relatively low oxygen demand and, consequently, low cooling requirements, mixing and oxygen transfer are still of major concern, particularly in the presence of high biomass densities. Developing technology to meet these challenges is critical for the success of plant cell culture applications.

48.3 SUITABILITY OF STIRRED BIOREACTORS FOR SUSPENDED PLANT CELL CULTURE

Stirred tank bioreactors offer several advantages for culturing suspended plant cells. Although stirred, airlift, and bubble-column reactors achieve similarly adequate rates of mixing and mass transfer in low-viscosity fluids, air-driven reactors do not perform well with high-density cultures of viscosity greater than about 100 mPa s (23). Stirred vessels are more suitable for viscous broths because greater power can be input by mechanical agitation. Experimental (7,24,25) and theoretical (26) studies have demonstrated that mixing becomes limiting in airlift reactors when plant cell densities reach 20–30 kg/m^3

dry weight. At these concentrations, airlift performance deteriorates markedly due to poor gas disengagement, impeded liquid circulation, development of unmixed zones, and gravity settling of the cells. Increasing the aeration rate is the only operating response available to improve the hydrodynamic functioning of air-driven reactors; however, overventilation of plant cell cultures has been shown to reduce growth and product formation because carbon dioxide and other necessary volatile components such as ethylene are stripped from the broth at high gas throughputs (20,27,28). The tendency of plant cell cultures to develop dense foam layers and cell flotation is more pronounced at high aeration rates (29). Foaming should be avoided because its treatment ultimately requires the addition of chemical antifoam agents to the culture; these agents are known to significantly reduce $k_L a$ values for oxygen transfer (29,30). Mechanical agitation and the ability to increase the power input independent of gas flow rate helps ameliorate these problems in stirred tank reactors.

The engineering advantages of stirred bioreactors relative to airlift vessels for plant cell culture can be demonstrated using theoretical regime analysis (26). In regime analysis, characteristic times for different bioreactor functions such as mixing and mass transfer are used to assess the rates of these processes relative to the demand of the cells for a critical metabolic component such as oxygen (23,31). The characteristic time or time constant is defined as the ratio of capacity to flow: a small time constant represents a fast process and vice versa. Ideally, the characteristic times for mixing and mass transfer should be smaller than that for biological uptake of oxygen to ensure that cell metabolism is not limited by bioreactor function.

Characteristic times for mixing and mass transfer in airlift and stirred vessels can be estimated from equations, available in the literature, as a function of bioreactor operating conditions and the properties of the culture broth (26). The results shown in Fig. 48.1 were calculated for an external-loop airlift vessel and a baffled stirred tank, both of working volume 10 m^3. Characteristic times in the stirred tank were calculated for a single Rushton turbine and aeration at a constant superficial velocity of 0.05 m/s. The culture broth contained a moderate-to-high plant cell density of 30 kg/m^3 dry weight, yielding a non-Newtonian pseudoplastic culture fluid with flow behavior index $n = 0.71$ and consistency index $K = 0.99$ Pa s^n. The specific rate of oxygen consumption by the cells was taken to be 10^{-6} kg/(kg dry weight)/s. As indicated in Fig. 48.1a, the airlift reactor performs poorly at this biomass density: the characteristic time for mixing is greater than the characteristic time for oxygen consumption even at very high gas flow rates. Mixing is therefore likely to be inadequate, resulting in dead zones within the vessel. This prediction is consistent with laboratory findings of cell settling and poor mixing in airlift reactors containing moderate-to-high plant cell densities (7,24,25). Figure 48.1a shows that the rate of oxygen transfer in the model airlift reactor becomes adequate when the superficial gas velocity in the riser increases above a certain value (around 0.1 m/s); at this aeration rate, the characteristic time for mass transfer becomes less than that for oxygen consumption. Results for the stirred tank reactor (Fig. 48.1b) show much better mixing performance than for the airlift: the mixing time is significantly lower than the characteristic time for oxygen consumption. The characteristic time for oxygen transfer becomes smaller than that for oxygen consumption above a certain stirrer speed (shown as about 5 s^{-1}). From this theoretical analysis, stirred vessels can be considered to have greater potential for accommodating the requirements of dense suspended plant cell cultures than airlift devices.

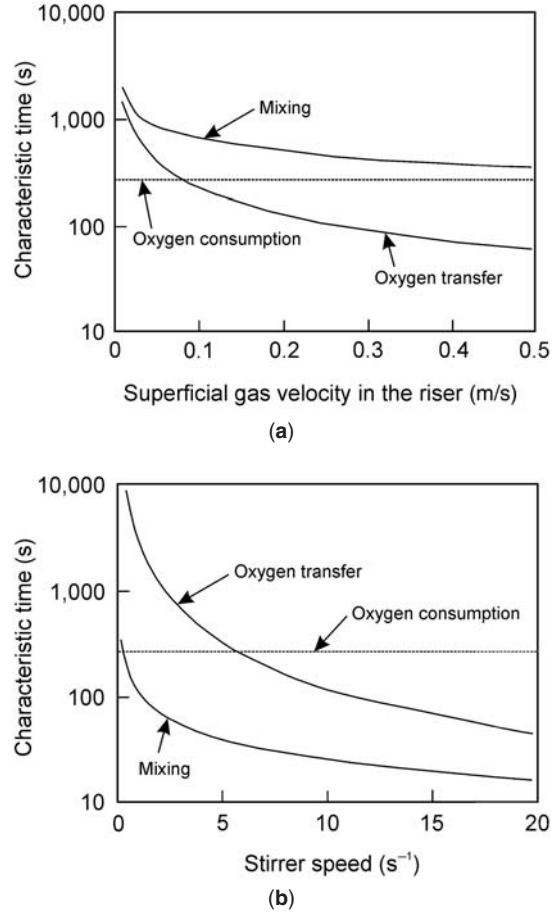

Figure 48.1. Results from theoretical analysis of characteristic times for mixing, oxygen transfer, and oxygen consumption for a suspended plant cell culture with cell concentration 30 kg/m^3 dry weight: (a) 10-m^3 external-loop airlift reactor, and (b) 10-m^3 baffled stirred tank reactor with single Rushton turbine. (Data from Ref. 26.)

A critical question in the application of stirred bioreactors for plant cell culture is whether the stirrer can be operated at the speeds required for adequate oxygen transfer without causing shear damage to the cells. Although application of stirred reactors is standard fermentation technology, conventional high shear agitation is inappropriate for plant cell culture. Modification of equipment and/or operating practice is usually required to avoid mechanical damage of the cells or other detrimental metabolic effects associated with high levels of hydrodynamic shear. The main parameters that affect shear levels in stirred vessels are the impeller geometry and stirrer speed; however, although many different styles of impeller have been tested experimentally, there are few general guidelines for optimizing this aspect of stirred reactor design for suspended plant cell culture (32). Because the generation of shear forces is intimately related to the effectiveness of mixing and mass transfer in bioreactors, development of systems for low-shear agitation that still provide adequate circulation and gas dispersion remains a key challenge. The trade-off between shear damage effects and the requirements for adequate mixing, mass transfer, and gas–liquid–solid hydrodynamics in stirred bioreactors is discussed in more detail below in the section titled "Plant Cell Culture in Stirred Bioreactors: Theoretical Analysis."

As well as providing important technical benefits for high-density plant cell culture, stirred bioreactors have a proven record of performance and reliability in the fermentation industry and have been well studied and characterized in large-scale operations. These features account for stirred tanks being the bioreactor configuration of choice for commercial scale-up of suspended plant cell processes, as indicated in Table 48.3.

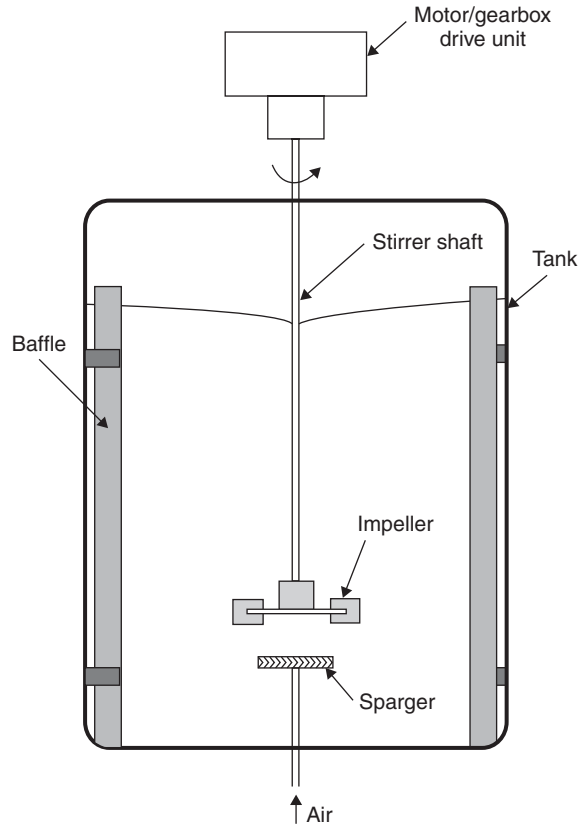

Figure 48.2. Typical equipment configuration for a stirred tank bioreactor with single impeller used for aerobic cell culture.

48.4 STIRRED TANK EQUIPMENT AND OPERATING CHARACTERISTICS

The functions of stirring in a bioreactor used for aerobic cell culture are: (i) to eliminate concentration and temperature gradients by homogenizing the vessel contents, (ii) to disperse gas in the broth to aerate the culture, (iii) to promote heat transfer between the broth and heat exchange surfaces, and (iv) to suspend the cells. The equipment chosen for stirring has a significant influence on how well these functions can be performed. The principal mechanical features and operating details of a range of mixing hardware are outlined briefly in the following paragraphs. This description provides a background for the more detailed discussion of plant cell applications in subsequent sections.

48.4.1 Stirred Vessels

Figure 48.2 shows a typical arrangement of equipment in a stirred tank (43). Not shown is the equipment for heat transfer: in large vessels this may be a helical cooling coil immersed in the broth; for small bioreactors an external water jacket is often sufficient. Standard stirred tank reactors are cylindrical in cross-section. The base profile of the tank may vary as illustrated in Fig. 48.3; rounded rather than angled corners discourage the formation of stagnant pockets into which fluid currents cannot penetrate. The energy dissipation rate required to suspend solids in stirred tanks is very sensitive to the shape of the vessel base: the modified geometries shown in Fig. 48.3b–e can all significantly enhance the suspension of particles compared with flat-bottom tanks (44,45). Because the solubility of oxygen in aqueous liquids is limited to only about 8 ppm under typical cell culture conditions, the oxygen content of the culture broth must be continuously replenished as oxygen is consumed by the cells. In stirred vessels, this is most commonly achieved using a sparger that releases air bubbles into the culture below the impeller (Fig. 48.2). When headplate access is at a premium or when mechanical stresses on the stirrer can be alleviated by using a shorter shaft, for example, in viscous fluids, the stirrer shaft may enter through the base of the vessel rather than the top, as shown in Fig. 48.4. For either top-entering or bottom-entering stirrers, the point at which the stirrer shaft enters the tank is

a potential contamination site, and several types of stirrer seal have been developed to combat this problem. Large fermenters are usually equipped with mechanical seals; for smaller vessels, magnetically coupled drives may be used so that the stirrer shaft does not actually pass through the fermenter body. In this case, a magnet attached to the end of the shaft inside the fermenter is driven by a rotating magnet in a housing outside. Use of magnetic coupling is limited to relatively small fermenters ($\leq \sim$800 L) and low-viscosity broths. In vessels with a single impeller of diameter 1/4–1/2 the tank diameter, the depth of liquid is usually limited to 1.0–1.25 times the tank diameter to facilitate good mixing. In tall fermenters with large aspect ratios, multiple impellers mounted on the stirrer shaft are commonly used to improve oxygen transfer conditions; an example is shown in Fig. 48.5. In multiple impeller systems, the distance between the agitators is an important consideration. If the impellers are too far apart, unagitated zones develop between them; conversely, impellers located too close together produce flow streams that interfere with each other and disrupt circulation to the far reaches of the vessel.

48.4.2 Baffles

Baffles are vertical strips of metal mounted against the walls of stirred vessels (Fig. 48.2) to prevent gross vortexing of

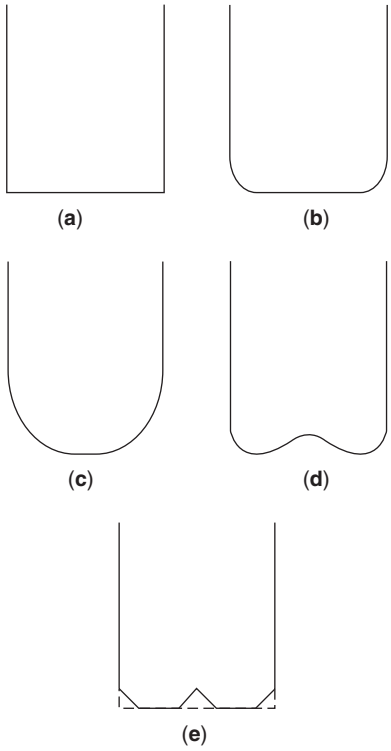

Figure 48.3. Bottom variations in stirred tank bioreactors: (a) flat, (b) dished, (c) round, (d) contoured, and (e) cone-and-fillet.

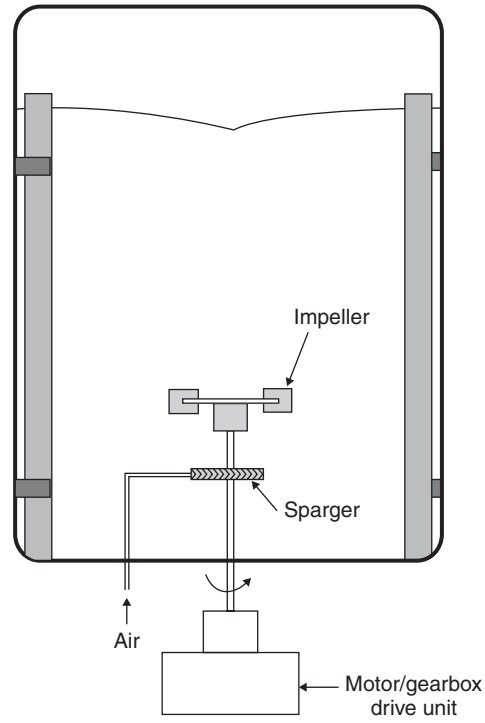

Figure 48.4. Stirred tank bioreactor with bottom-entry stirrer.

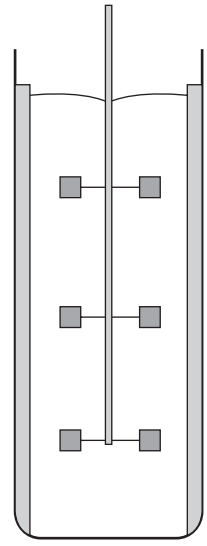

Figure 48.5. Stirred tank bioreactor with multiple impellers.

the liquid. Typically, four baffles of width 1/10–1/12 the tank diameter are installed with equal spacing around the tank circumference. Baffles may be attached to the vessel wall (Fig. 48.5), or mounted slightly away from the wall (Fig. 48.2) to prevent sedimentation of solids or development of stagnant zones at the inner edge. Baffles generate turbulence in the fluid by breaking up the circular flow produced by rotation of the stirrer. Circular flow is relatively ineffective for mixing, which is better facilitated by axial and radial currents. Circular flow can also lead to vortex development down the stirrer shaft and gas entrainment. If allowed to reach down to the impeller, deep vortices impose extraordinarily high mechanical stresses on the stirrer shaft, bearings, and seals, which must be avoided to prevent equipment damage.

48.4.3 Impellers

Impellers can be classified broadly depending on whether they generate high local shear rates or have strong pumping capacity for development of large-scale flow currents. Both functions are required for good mixing, but they do not usually work together. The relative prominence of shear- and flow-generating functions for a wide range of impellers is shown in Fig. 48.6.

Propellers, paddles, and turbines are remote-clearance impellers with typical diameters of 1/4–2/3 the tank diameter. These devices are operated at high speeds to generate tip velocities of the order of 3 m/s^{-1}. When remote-clearance agitators are used in low-viscosity fluids, a turbulent region of high shear is generated near the impeller where the essential mixing processes occur as material is exchanged between different liquid streams. High shear levels close

to the impeller are also responsible for bubble breakup in sparged systems. Because good mixing should involve fluid from all parts of the vessel, as well as turbulence, the impeller must be able to generate circulatory currents with sufficient velocity to carry material from the furthermost reaches of the tank to the impeller. In viscous fluids, it is often not possible for mechanical and economic reasons to rotate the impeller fast enough to generate turbulence; therefore, impellers used for viscous mixing are usually designed instead to provide maximum bulk movement of material. Anchor and helical impellers are large agitators that are installed with small wall clearances and operated at low speeds to generate bulk fluid currents. For viscous fluids or when high shear rates must be avoided, slow-speed, low turbulence, high-flow impellers are preferred to high-speed, high-turbulence, low-flow impellers.

There is a wide range of impellers available commercially, some of which have been applied to plant cell culture. The general characteristics of agitators used in suspended plant cell reactors are described in the following sections.

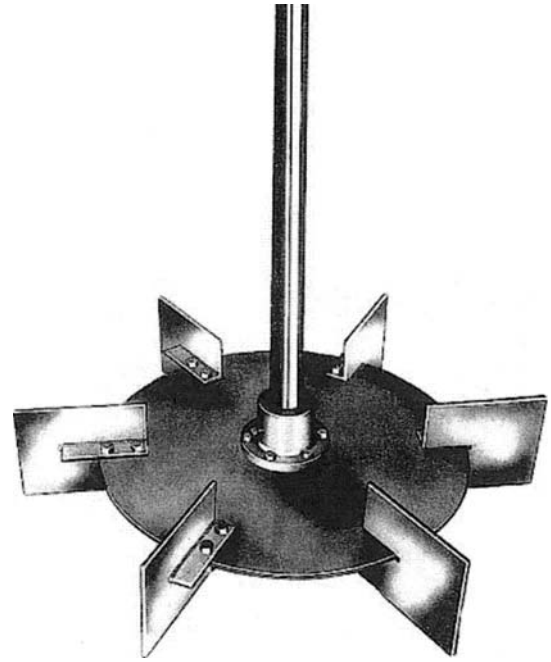

Figure 48.7. Rushton turbine.

48.4.3.1 Rushton Turbine. As shown in Fig. 48.7, the Rushton turbine is a disk turbine with six flat blades. This impeller has been the agitator of choice in the fermentation industry since the 1950s, largely because it has been well studied and characterized. Rushton impellers generate predominantly radial or horizontal flow, but have relatively low pumping efficiency resulting in low circulatory flows per unit power consumed (46,47). Rushton turbines are often chosen for their gas-handling capacity and perform well for gas dispersion. Bubble breakup is very effective near the impeller blades as air is forced into these high shear regions by the turbine disk. Changes in gas dispersion conditions with increasing stirrer speed or gas flow rate are illustrated in Fig. 48.8 (48). At high gassing rates or low stirrer speeds (Fig. 48.8a), the gas-handling capacity of the impeller is exceeded, the impeller ceases to pump the two-phase fluid, and the flow pattern is dominated by buoyant gas–liquid flow upwards the middle of the vessel as in a bubble column. This condition corresponds to impeller flooding. As the stirrer speed is increased or the gas flow rate reduced, the impeller starts to disperse the gas toward the walls of the tank (Fig. 48.8b). Complete gas dispersion below as well as above the impeller (Fig. 48.8c) is achieved at even higher stirrer speeds or lower gas flow rates; this is the desirable operating condition because it results in homogeneous dispersion of gas to all parts of the vessel. The ability to handle high gas velocities without flooding is an advantage for improving oxygen transfer conditions in the reactor. The gas-handling capacity of Rushton turbines can be improved by increasing the impeller-to-tank diameter ratio (49).

Pairs of low-pressure, high-speed trailing vortices are generated behind the flat blades of Rushton turbines (50,51). This hydrodynamic feature is responsible for the relatively high level of power drawn by Rushton turbines under nonaerated conditions. With sparging, gas readily accumulates in these low pressure regions, producing ventilated cavities behind the blades and causing a significant drop in power. The extent of this power reduction is a complex

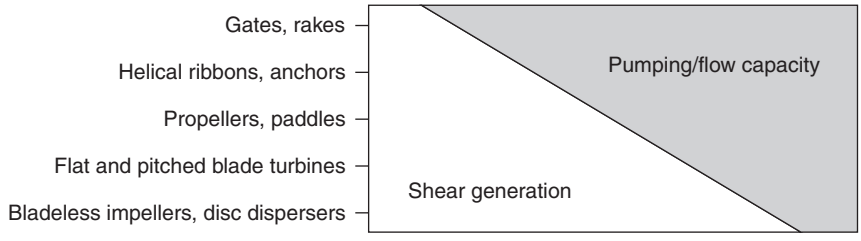

Figure 48.6. Characteristics of different impellers in terms of the ratio of shear generation to flow capacity.

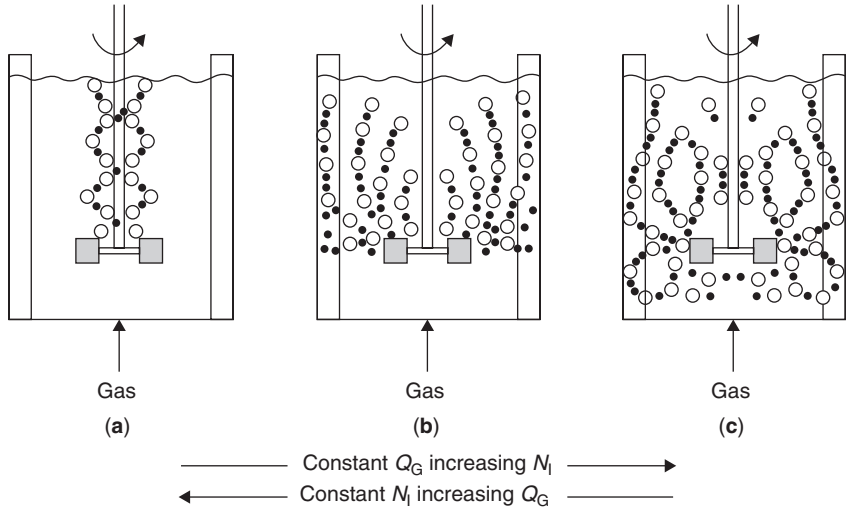

Figure 48.8. Flow patterns developed by a Rushton turbine under gassed conditions as a function of stirrer speed N_i and gas flow rate Q_G: (a) impeller flooding; (b) impeller loading, where the gas is dispersed by the impeller but poorly distributed throughout the vessel; (c) complete gas dispersion below as well as above the impeller. (Adapted from Ref. 48.)

function of the stirrer speed, air flow rate, vessel size, and fluid properties and cannot yet be accurately predicted (52). The rheological properties of the fluid exert considerable influence: practical operating conditions usually give a 40–50% loss of power with sparging in low-viscosity fluids (53), but this can increase to 80% or more in viscous or non-Newtonian fluids (49).

Rushton turbines are effective for solids suspension in three-phase systems. Suspension is generally improved by reducing the clearance between the impeller and the floor of the tank, but this can cause flow instabilities in aerated systems (54). An impeller off-bottom clearance of 1/4 the tank diameter is recommended because this allows gas dispersion under the impeller as well as adequate agitation in the upper parts of the vessel (44,55).

Single and multiple Rushton turbines have been applied for suspended plant cell culture in many experimental investigations, as indicated in Table 48.4. The suitability of Rushton turbines of different size for large-scale plant cell culture has also been analyzed in a theoretical engineering study based on a reactor size of 10 m^3 (32).

48.4.3.2 Other Disk Turbines. Disk turbines may have more or fewer blades than the Rushton turbine's standard six. Increasing the number of blades up to 18 reduces the rate at which the power drops with increasing gas flow and significantly improves the gas-handling capacity of the impeller (112). The unaerated power number also increases with the number of blades at constant impeller diameter (113). Even so, a 12-blade disk turbine has been shown to disperse about three times more gas than a larger Rushton impeller with six blades operating with the same power consumption and stirrer speed (112). Although turbine impellers with more than six blades have not been tested for plant cell culture, single and dual agitators with four flat blades have been used in several studies (Table 48.4). As an extrapolation of the above findings, decreasing the number of blades from six to four can be expected to reduce the gas-handling capacity of the impeller as well as the unaerated power number.

The blades on disk turbines may be pitched or angled rather than orthogonal to the disk. This reduces the unaerated power number by about 50% and generates impeller discharge currents with a more pronounced axial velocity component than the radial flows emanating from a Rushton turbine (54). At a given gas flow rate, lower stirrer speeds can be used without flooding compared with Rushton turbines of similar geometry; this has been attributed to the greater projected area of the pitched blades (47). The impeller discharge efficiency and gas holdup produced using pitched blade disk turbines are also improved relative to Rushton impellers (47). Disk turbines with angled blades have been applied for plant cell culture (Table 48.4).

48.4.3.3 Propellers. Propellers are usually of the three-blade marine type shown in Fig. 48.9. They generate a flow pattern with mainly axial velocity components. Propellers can be operated in either downward or upward pumping modes, downward being more common. They are generally installed with diameters of around 1/3 the tank diameter.

The unaerated power number for marine propellers is about 1/10 that for Rushton turbines, depending on the blade pitch and other geometric parameters (113).

[a]Symbols are defined in the section titled "Nomenclature".

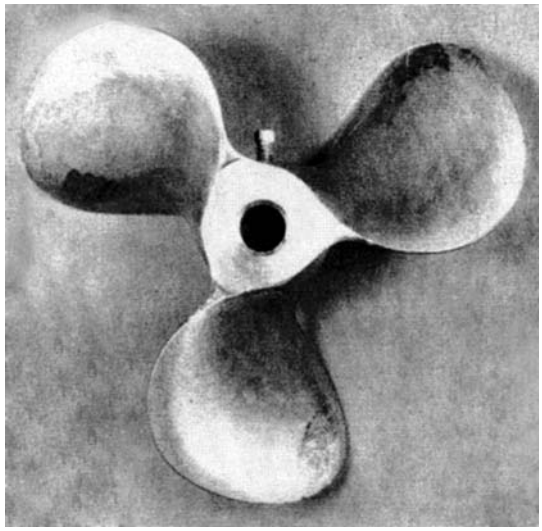

Figure 48.9. Marine propeller.

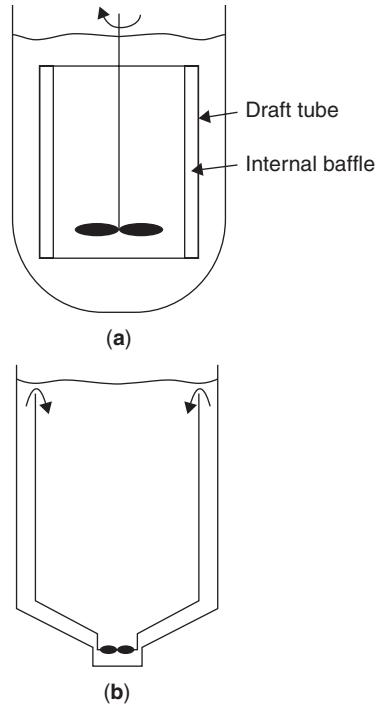
Significant power losses occur with gassing; aerated downward pumping propellers may also exhibit flow and power draw instabilities (54). Propellers are very effective for solids suspension with low power consumption and outperform disk turbines and paddles in this respect (114). Several investigators have used marine propellers for suspended plant cell culture (Table 48.4).

48.4.3.4 Axial Flow Impellers with Draft Tube. The use of a draft tube with an axial flow impeller such as a marine propeller can significantly improve particle suspension in systems containing solids (114,115). Two configurations for this type of stirring system are shown in Fig. 48.10. The position and size of the draft tube have a strong influence on the hydrodynamic conditions generated. For example, if the bottom of the tube restricts the impeller outflow, the loss of local pressure causes a marked increase in the energy dissipation rate required for solids suspension (114). The power saved by installing draft tubes to assist particle suspension is reported to be greatest at low solids concentrations (115). An axial-flow Kaplan turbine in a 75-L vessel with a draft tube performed satisfactorily for plant cell culture (Table 48.4) and compared well with other impeller configurations (14).

48.4.3.5 Perforated Disks. Rotating perforated disks are most commonly employed in two-phase liquid extraction systems, including aqueous extraction of biological molecules such as proteins (116,117). This type of contactor is very effective for high-shear liquid droplet dispersion and is associated with high mass transfer rates and separation efficiencies. Application of perforated disks for stirring in bioreactors is not well characterized in the literature; however, a perforated disk impeller operated at



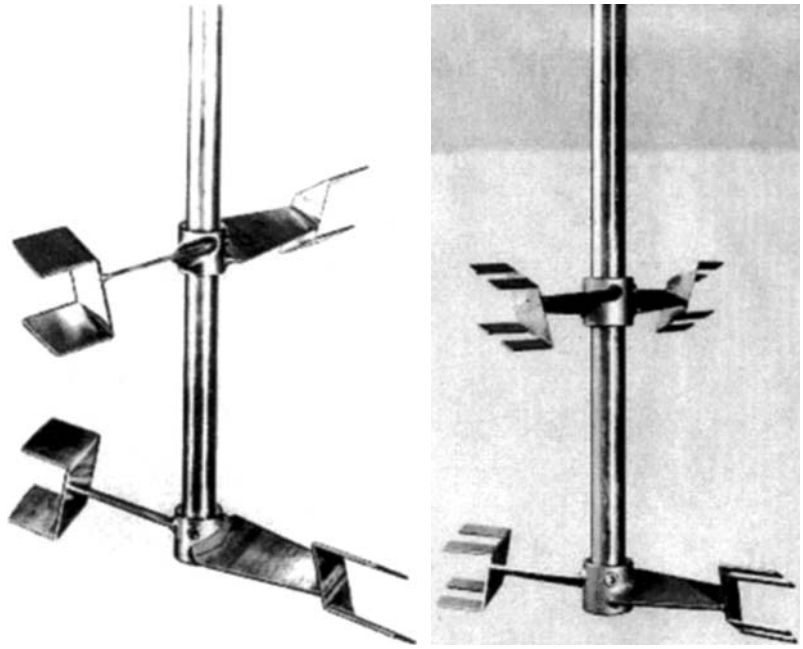


Figure 48.10. Axial flow impellers with draft tube. (a) Vessel with draft tube and internal baffles. The internal baffles prevent vortexing and liquid draw-down into the draft tube. a speed of 100 rpm was tested by Wagner and Vogelmann (14) for culturing *Morinda citrifolia* plant cells in a 10-L vessel. Its performance in terms of biomass and secondary metabolite production was similar to that of dual flat-blade turbines and a Kaplan turbine with draft tube.

48.4.3.6 Intermig Impellers. The Intermig is an impeller design of Ekato GmbH, Germany. As shown in Fig. 48.11, Intermig impellers are used in dual configuration, orthogonal to each other and positioned on the stirrer shaft about one impeller diameter apart. Each impeller has two large blades connected at the hub; each large blade supports smaller blades at its ends. The smaller blades may be either unslotted (Fig. 48.11a) or slotted to form four wing tips (Fig. 48.11b). The large and small blades pump in opposite directions; the recommended arrangement is for the small outer blades to pump downwards while the central blades pump upwards. Because the unaerated power number for each impeller is very low (about 0.35; Ref. 118), at least two Intermigs with diameter 0.6–0.7 times the tank diameter would be used instead of a single Rushton turbine.

The flow produced by ungassed Intermig impellers is very chaotic (119), and energy dissipation rates are reported to be more uniformly distributed throughout the vessel than with Rushton turbines (120). With aeration,

(a) (b)

Figure 48.11. Dual Intermig agitators with (a) unslotted wing tips and (b) slotted wing tips. (Photographs provided courtesy of Ekato Rühr- und Mischtechnik GmbH, Germany.)

the flow becomes radial due to the development of large ventilated cavities at the tips of each blade. These cavities extend back into the liquid, increase in size with increasing gas flow rate, and reduce the power draw by up to about 50% (49,52). Mixing of non-Newtonian fluids has been found to be equally satisfactory with Intermig and Rushton impellers under a range of operating conditions, with the presence or absence of slots on the blades having little effect (121). The energy dissipation rates required for particle suspension by dual Intermigs are higher than for Rushton turbines and significantly greater than for downward pumping axial flow impellers (45).

Unslotted Intermig impellers have been tested for pilot- and large-scale suspended plant cell culture (P. Forschner, Ekato GmbH, personal communication; Ref. 33). Advantages of low shearing force, good mixing, good gas dispersion, and low energy consumption have been cited (33), but more detailed quantitative information was not provided.

48.4.3.7 Paddles. Flat-blade paddles are simple in design and construction and commonly have two or four blades (Fig. 48.12a). Paddles generate radial flow patterns similar to those produced by Rushton turbines (122,123), and are intermediate between circulation- and dispersive-type impellers in their function and operating characteristics. They are often applied as large-blade-area, low-speed agitators that push or carry liquid around the vessel. Under these conditions, no high speed liquid streams are generated, and little top-to-bottom mixing takes place (124). Flat-blade paddles perform poorly compared with other impellers in terms of gas distribution, gas holdup, power consumption, and discharge efficiency, and have been reported to be unsuitable for use in gas–liquid systems (47). Their small projected blade area means that they flood relatively easily. Particle suspension efficiency in large-scale tanks is also lower with two-flat-blade paddles than with Rushton turbines (123).

A large variety of modified paddle geometries is used in industry for mixing applications; some examples are illustrated in Fig. 48.12b–d. The Maxblend impeller (Fig. 48.12d) by SHI Mechanical & Equipment Inc., Japan, is a wide impeller combining a lower paddle with a grid (125). The impellers shown in Fig. 48.12b–d are usually employed at low speeds for mixing viscous liquids. Several semiconventional paddle configurations, such as modified gate and hollow stirring wing paddles and the Maxblend impeller, have been investigated for use in plant cell reactors (Table 48.4). In most of these studies, the stirring speeds were higher (up to 630 rpm; Ref. 24) than those commonly used in viscous fluids, and cell densities of up to 75 g/L dry weight were supported without sedimentation (92). Because raising the gas flow rate reduced biomass levels, oxygen transfer rates with a wing-type paddle were increased by enriching the air supply with oxygen (92).

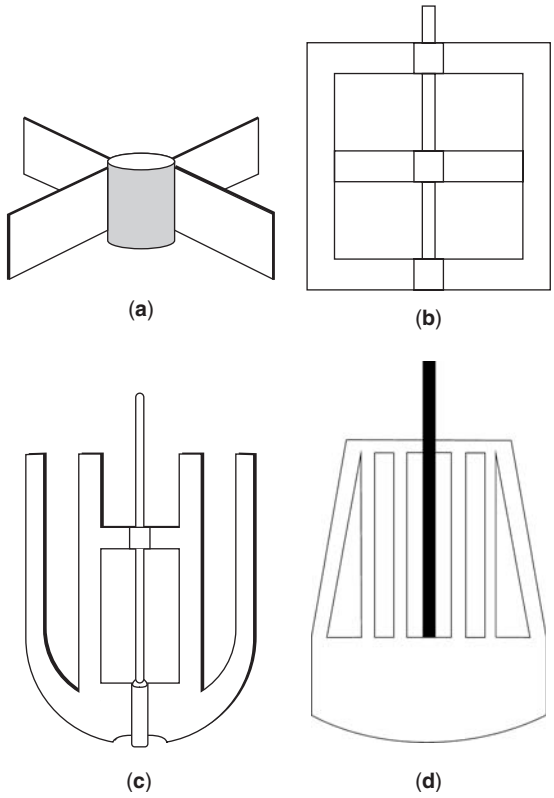

Figure 48.12. Flat-blade paddle and examples of modified paddle geometries: (a) four-flat-blade paddle, (b) frame- or wing-type paddle, (c) gate- or grid-type paddle, (d) Maxblend impeller.

48.4.3.8 Anchors. Anchor impellers such as that shown in Fig. 48.13 are applied when circulatory rather than dispersive mixing is required. Often used with high viscosity fluids for laminar blending and heat transfer applications, anchors are typically large-diameter agitators operated with small wall clearance (around 1–5% of the tank diameter) and low-speed (5–20 rpm). While producing highest shear levels near the wall, anchors generate a relatively uniform distribution of energy dissipation rates compared with small-diameter impellers (122). However, by creating primarily tangential flows, anchor impellers do not provide strong top-to-bottom mixing, although secondary axial flows may also develop at higher rotational speeds (126). Fluid near the stirrer shaft is relatively stagnant during anchor operation because there is little mixing from near the wall to the center of the vessel (127). Therefore, anchor impellers are not recommended if completely uniform mixing is required (128); breakup of bubbles sparged into the vessel is also not very effective. Wall clearance exerts a strong influence on the power requirements for mixing with anchors (129).

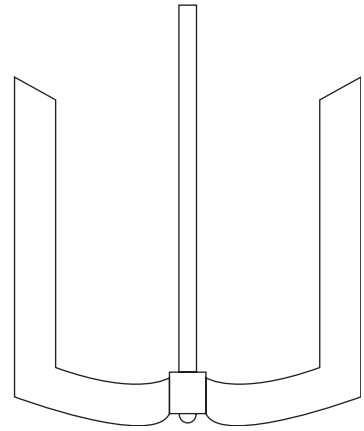

Figure 48.13. Anchor impeller.

Anchors with relatively small impeller-to-tank diameter ratios of 0.50–0.74 have been tested for plant cell culture at speeds of up to 100 rpm (Table 48.4), but have not performed as well as other agitators for secondary metabolite production (62,94).

48.4.3.9 Helical Ribbon Impellers. Helical ribbon impellers are large-diameter agitators with spiral-like motion operated at small clearance from the vessel wall to promote fluid mixing and minimize the formation of stagnant zones. Depending on the direction of rotation, upward or downward pumping can be achieved. As shown in Fig. 48.14, helical impellers may be constructed with either single or double helices. Like anchor impellers, helical ribbons are usually operated at low speeds and shear rates and have lower capacity for gas dispersion than turbines and other high-speed agitators. In non-Newtonian fluids, oxygen transfer depends more strongly on gas flow rate than power input or stirrer speed, reflecting the limited ability of helical impellers to disperse air bubbles (130). Aeration may be facilitated, however, by installing surface baffles (131), such as those illustrated in Fig. 48.14b. Circumferential flows are dominant in stirred tanks fitted with helical agitators; however, upward flows are also generated by the outer helix and downward flows are prominent along the stirrer shaft (132). Changes in impeller geometry can have a significant effect on mixing (133); for example, the mixing time may be doubled by increasing the blade width at constant impeller diameter (134). Overall, helical impellers give a positive top-to-bottom turnover without unmixed regions, thus representing a significant advantage over anchor agitators. Power requirements are similar to those for anchor impellers (135).

Helical impellers have been used for plant cell culture in several studies (Table 48.4). Biomass concentrations of

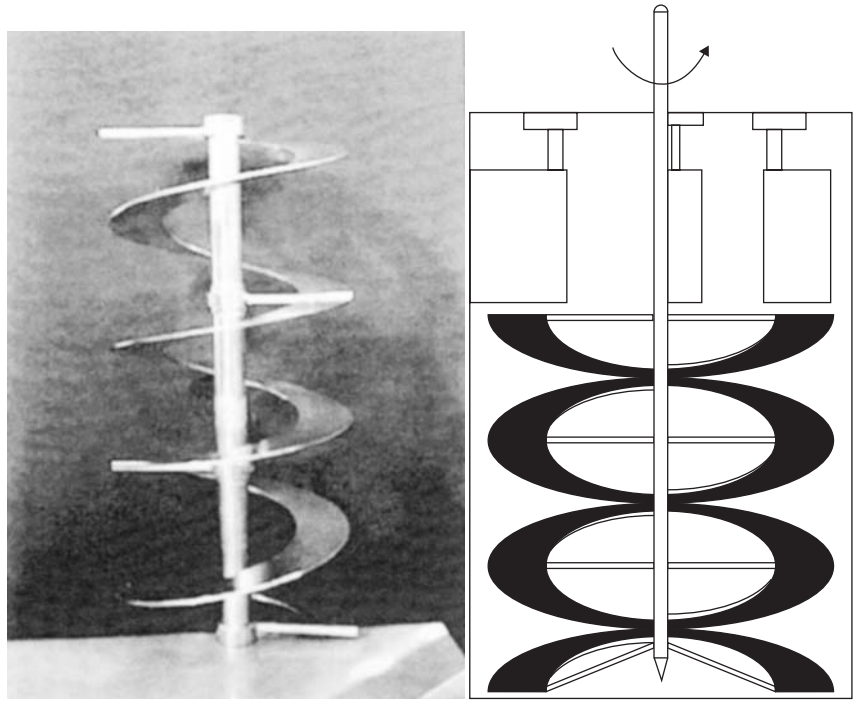

Figure 48.14. (a) Helical ribbon impeller. (Photograph provided courtesy of B. Braun Biotech International, Germany.) (b) Bioreactor with double helical ribbon impeller and three surface baffles. (Adapted from Ref. 2.)

27–28 g/L dry weight were supported using either air sparging below the impeller (98) or surface aeration only with oxygen-enriched air and surface baffles (2). For large-scale applications, oxygen transfer may present some difficulties. The success of helical impellers for plant cell culture has been attributed to their high pumping capacity and low mechanical shear forces; however, the investment costs associated with this type of stirrer are greater than for conventional equipment (2). The advantages associated with using impellers designed for mixing high viscosity fluids may be most apparent toward the end of batch plant cell cultures, when the cell density and suspension viscosity are highest.

48.4.3.10 Spin Stirrers. As illustrated in Fig. 48.15, spin stirrers consist of vertical stirrer blades that rotate independently on a stirring assembly. The length of the blades ensures that as much fluid as possible is kept in motion by the action of the stirrer. There is little general information in the literature about the performance characteristics of spin stirrers; however, they have been used for suspended plant cell culture (Table 48.4) at biomass concentrations up to 27 g/L dry weight (98). When applied for culture of *Berberis wilsoniae* cells, production of protoberberine alkaloids was lower than that achieved with a bladed turbine (97).

48.4.3.11 Cell-Lift Impellers. These novel impellers comprise a draft tube topped with radial or tangential exit ports, as shown in Fig. 48.16. With rotation, reduced

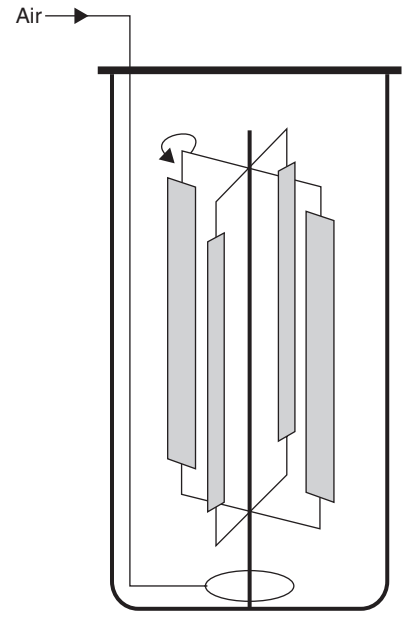

Figure 48.15. Bioreactor with spin stirrer, each blade capable of individual rotation. (Adapted from Ref. 98.)

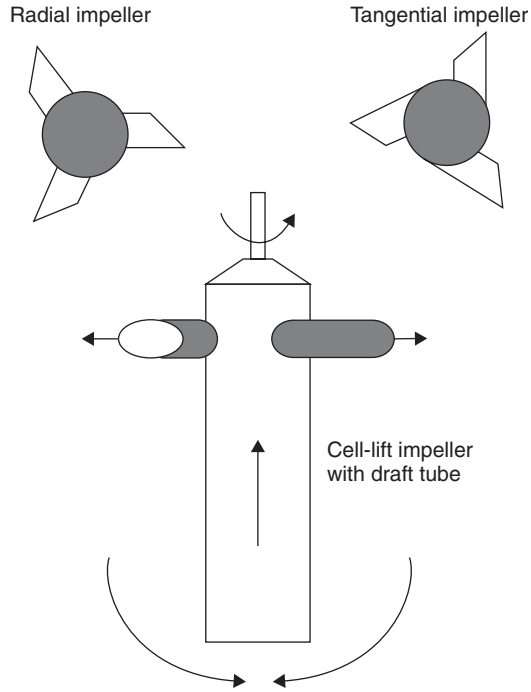

Figure 48.16. Cell-lift impeller, showing radial and tangential exit port configurations. (Adapted from Ref. 99.)

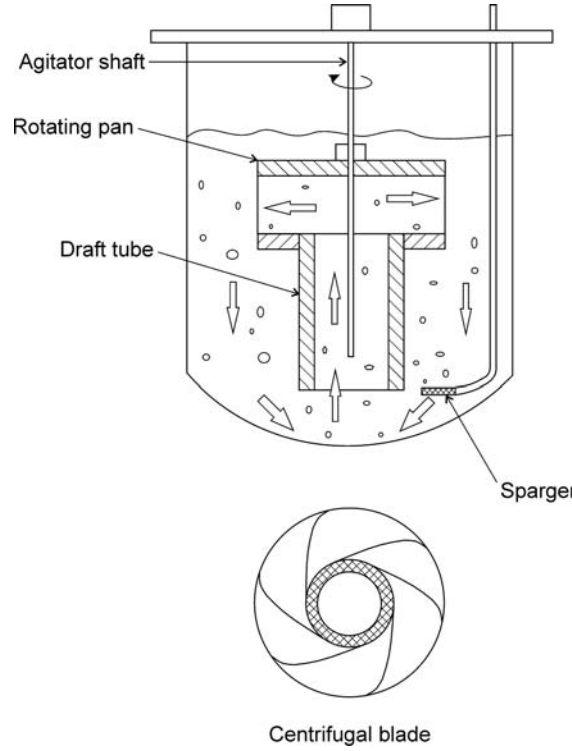

Figure 48.17. Centrifugal impeller in a sparged bioreactor. The rotating impeller consists of a draft tube topped with a centrifugal blade. (Adapted from Ref. 136.)

pressure is created at the tips of the exit ports, drawing liquid from the bottom of the reactor up the draft tube and out to the sides of the vessel for low-shear mixing. Mixing may be enhanced by installing a sparger at the base of the draft tube to generate additional airlift-type circulation (100). Cell-lift impellers have been tested for plant cell culture (Table 48.4). It was found in these studies that the tangential port configuration provided better lift than the radial design (99).

48.4.3.12 Centrifugal Impeller. As a variation on the cell-lift impeller, the centrifugal impeller (Fig. 48.17) consists of a draft tube topped with a bladed device that, when rotated with the draft tube, creates a pumping action similar to a submersible centrifugal pump (136). The centrifugal impeller was developed with the aim of reducing shear stress generation and surface liquid turbulence while maintaining liquid lift capacity. Liquid is drawn up the draft tube from the bottom of the reactor and is discharged through the bladed section of the impeller. Air is provided by sparging outside of the draft tube; this minimizes entrainment of bubbles inside the impeller, which could lead to cavitation effects at high impeller speeds. When the centrifugal impeller was applied for culture of suspended *Taxus chinensis* cells (Table 48.4), the reactor mixing time, which was dependent on both the impeller speed and suspended cell density, was identified as a critical parameter affecting taxoid production and cell aggregate size (101).

48.4.3.13 Membrane Stirrers. Membrane stirrers are used for bubble-free aeration when the effects of gas sparging, such as cell shear damage or foaming, must be avoided. To date, the major application of membrane stirrers has been in animal cell culture. Aeration is achieved by gas exchange through silicone or microporous polypropylene tubing immersed in the culture broth. For bubble-free aeration, the gas pressure inside the tubing must not exceed the bubble point, at which bubbles appear on the outside of the tube walls. Several different membrane stirrer devices have been developed (137,138). To prevent the cells from settling and to promote mixing, the tubing may be kept in motion as an effective stirrer; this also enhances mass transfer of oxygen from the air or oxygen-enriched air in the tubing to the culture fluid, and facilitates penetration of liquid into the inner sections of the tubing coil. Reactors with membrane stirrers have been used to culture plant cells to high-density (50 g/L dry weight) with little foaming and no cell flotation (Table 48.4).

An alternative reactor configuration using gas-permeable membranes and based on the Taylor–Couette flow principle has also been designed for suspended plant cell culture

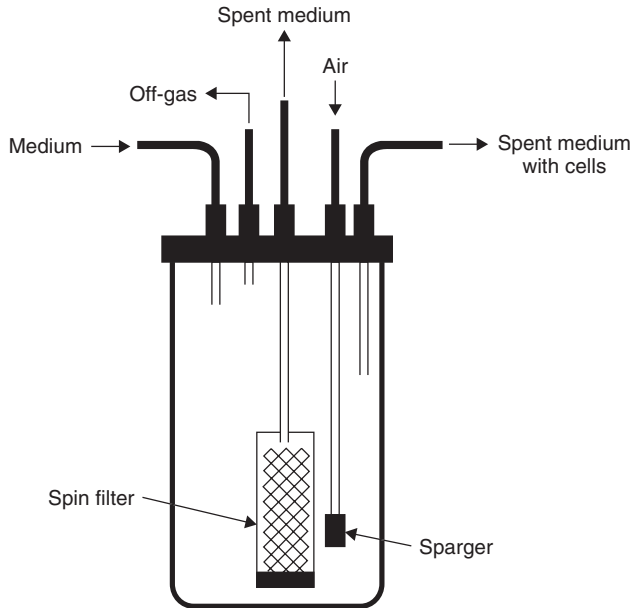

Figure 48.18. Bioreactor with spin filter unit for removal of medium in perfusion culture. The reactor also has provision for continuous whole broth removal. (Adapted with permission from Ref. 105.)

(Table 48.4). In this reactor, a perforated cylindrical glass tube covered with silicone membrane sheeting was rotated as a primitive type of stirrer generating vortex flow in the annulus between the tube and the walls of the bioreactor. The inside of the glass tube was maintained at high pressure relative to the annulus by using an air pump, so that bubble-free aeration of the culture was achieved. Some sedimentation of plant cells occurred in this reactor, prompting the investigators to suggest that the vessel could be operated with its axis horizontal (104).

48.4.3.14 Spin Filters. Spin filters are used in bioreactors for continuous perfusion culture at high cell densities. They have been applied mainly for intensive culture of animal cells. A simple spin filter system is shown in Fig. 48.18. Culture fluid is removed from inside the spin filter with minimal cell loss in the spent medium, while fouling is reduced by rotating the filter unit. Because spin filters are not designed to perform the normal mixing and gas dispersion functions of an impeller, problems with oxygen transfer may occur unless other devices, such as turbine agitators or membrane tubing aeration, are used to enhance mass transfer rates (139). As indicated in Table 48.4, spin filters have been used for culture of plant cells (105).

48.4.3.15 Magnetic Stirrers. Many of the first attempts to cultivate suspended plant cells in bioreactors involved the use of Teflon-coated magnetic stirrer bars driven by external drives at the base of the culture vessel (Table 48.4). However, because only limited power can be input by magnetic stirrers and the liquid currents generated are relatively weak, mixing was most likely inadequate in these reactors except at low cell densities. Magnetic stirrer bars are usually placed at the bottom of the vessel and rotate in contact with the reactor floor, so that the risk of plant cell damage by abrasion in this region is also high. This problem was avoided in one study by suspending the stirrer bar 1 cm from the bottom of the vessel using a flexible Teflon stalk (108). The usual position of magnetic stirrers also means that gas must be sparged into the liquid from above the stirrer. Because contact between the bubbles and agitator is minimized by this arrangement, gas dispersion and therefore oxygen transfer may be severely restricted. This is reflected in the relatively low biomass densities supported by plant cell reactors with magnetic stirrer bars, as indicated in Table 48.4.

48.4.4 Spargers

Several types of sparger are in common use. Porous spargers of sintered metal, glass, or ceramic are applied mainly in small-scale applications; gas throughput is limited because the sparger poses a high resistance to flow. Cells growing through the fine holes and blocking the sparger can also be a problem. Orifice spargers, also known as perforated pipes, are constructed by making small holes in piping, which is then fashioned into a ring or cross and placed at the base of the reactor. The individual holes on orifice spargers should be large enough to minimize blockages. Point or nozzle spargers are used in many agitated fermenters from laboratory to production scale. These spargers consist of a single open or partially closed pipe providing a point-source stream of air bubbles. Advantages compared with other sparger designs include low resistance to gas flow and small risk of blockage.

The design and location of the sparger have an important influence on gas–liquid hydrodynamics and power consumption in stirred vessels. With Rushton turbines, the fall in power with aeration can be reduced by installing a large sparger, for example, a ring sparger with diameter 1.2 times that of the impeller, rather than a small sparger (140). Use of a large ring sparger affects the formation of ventilated cavities behind the agitator blades, thus allowing a 50% increase in the aeration rate that could be used without flooding compared with a point or small ring sparger. The effect of sparger geometry is even more pronounced with downward pumping axial flow impellers: the use of point spargers increases the likelihood and severity of torque and power instabilities that can occur with these impellers in gassed systems (49). The gas-handling ability of downward pumping agitators can be improved and the stirrer speed required for complete solids suspension reduced by replacing point spargers with ring spargers of diameter about 0.8

times the impeller diameter, and increasing the separation between the sparger and impeller from 0.1 to up to 0.2 times the tank diameter (49,141).

48.5 PLANT CELL CULTURE IN STIRRED BIOREACTORS: EXPERIMENTAL FINDINGS

Studies of suspended plant cell culture in stirred vessels have been carried out for at least 40 years. A wide variety of reactor, impeller, and sparger geometries has been tested in batch, fed-batch, perfusion, draw-fill, chemostat, and turbidostat operations. A summary of the equipment and operating conditions used and the maximum cell densities achieved is shown in Table 48.4. The list includes results from vessels with working volumes of 0.5–20,000 L equipped with single or multiple impellers.

Stirrer systems for plant cell culture have often been evaluated in terms of biological rather than physical parameters: that is, cell growth and alkaloid levels are usually measured in preference to more direct indicators of stirrer performance, such as mixing time, power consumption, or gas holdup. Many papers that describe reactor culture of plant cells do not provide complete details of the vessel internals; for example, the number and width of the baffles, the diameter and position of the impeller, the type and position of the sparger, the vessel diameter, and the liquid height are often not specified. Yet, all of these geometric variables influence the effectiveness of fluid circulation and bubble dispersion in aerobic bioreactors. Despite the large number of experimental studies carried out, few general-purpose guidelines have emerged for designing and operating stirrers for plant cell culture. The lack of widely accepted design principles reflects in part the inherent complexity of stirring hydrodynamics, especially for three-phase systems such as aerobic cell suspensions, as well as the variation in critical properties, for example, rheology, cell shear sensitivity, and level of aggregation, among different plant cell suspensions.

48.5.1 Comparative Studies of Reactor Hardware: Impellers, Baffles, and Spargers

Several comparative studies have been carried out using the same cell line and vessel configuration to determine which impeller design produces the best outcome in terms of plant cell growth and/or production of valuable metabolites. These investigations are summarized in Table 48.5. The results highlight the difficulty associated with drawing general conclusions about impeller performance in plant cell systems: the relative outcomes obtained using the same or similar impellers may vary considerably between different studies. Because replicate bioreactor experiments are often not carried out, the statistical significance of any differences observed as a result of modifying the stirring equipment is also sometimes questionable.

Baffles in stirred tanks can be expected to increase levels of hydrodynamic shear as well as reduce vortexing and improve mixing. Experiments have been carried out to examine the effect of baffles on plant cell growth and product formation. Total protoberberine levels (gram per liter) produced by *Berberis wilsoniae* cells in a reactor stirred with a flat-blade turbine were about 35% greater with baffles than without (97). In other work with a cell-lift impeller, plant cells tended to accumulate in the space between the baffles and vessel wall, resulting in poor local mixing on both sides of the baffles. Removal of the baffles alleviated these fouling problems but did not significantly affect growth; only slight differences in biomass were observed for reactors with and without baffles (99). For *Catharanthus roseus* cultured in a 12-L reactor with dual 8.5-cm flat-blade turbines, the presence or absence of baffles did not have a significant effect on cell growth at most stirrer speeds. Alkaloid levels measured as milligrams per gram dry weight were similar in baffled and unbaffled vessels at 100 rpm; however at 700 rpm, specific alkaloid levels were 3.0–3.5 times higher in the baffled tank (60).

The effect of different sparger designs on *C. roseus* cultures was investigated using a 12.5-L bioreactor with dual Rushton turbines (10). When operated with the same aeration rate and stirrer speed, a sintered glass disk sparger of diameter 8 cm gave higher k_La values than a glass cross-shaped sparger with two rows of 2-mm holes. These spargers were employed at various air flow rates to produce initial k_La values ranging from 2.5 to 20 h^{-1} at a constant stirrer speed of 100 rpm. The highest biomass level was achieved with the sintered sparger at an intermediate initial k_La of 12.5 h^{-1}; k_La values above 12.5 h^{-1} obtained using the same sparger depressed growth. In a cell-lift reactor, replacing a single orifice sparger with a porous ceramic air stone resulted in the generation of smaller bubbles and an increase in k_La; changing the sparger position to slightly off-center also improved mixing in the vessel (99). A new type of spiral sparger with fine holes was used to produce small bubbles in a 2-L fermenter equipped with a two-blade grid paddle (8). High k_La values of 20 h^{-1} were obtained at a stirrer speed of 50 rpm, whereas 235 rpm was required to achieve the same k_La using a dual flat-blade turbine system and conventional ring sparger.

48.5.2 Mechanical Shear

Stirred tank reactors have been used in several studies to assess the sensitivity of plant cells to mechanical forces, and to determine the restrictions this property imposes on reactor operating conditions (17,18,58,60,67,90). Plant cell responses to short- (2–24 h) and long-term shear forces have been examined, and various criteria used to evaluate

TABLE 48.5. Results from Comparative Studies of Different Impellers Applied for Suspended Plant Cell Culture

Impeller and Operating Conditions	Performance Indicators	Bioreactor Specifications	Bioreactor Operation	Plant Species	Reference
Disk turbine (100 rpm, 0.25 vvm)	14.4 g/L dry weight cells and 50.1 mg/L saponins produced	$V_L = 25$ L	Fed-batch, 28 days	*Panax ginseng*	62
Anchor turbine (100 rpm, 0.25 vvm)	15.3 g/L dry weight cells and 43.5 mg/L saponins produced				
Angled disk turbine (100 rpm, 0.25 vvm)	17.0 g/L dry weight cells and 30.1 mg/L saponins produced				
Six-flat-blade turbine ($D_i = 6.4$ cm, $W_B = 1.4$ cm, 225 rpm, 1.0 vvm)	$k_La = 42$ h^{-1} at a cell concentration of 11 g/L dry weight Mixing and gas dispersion poor at cell densities above 20 g/L dry weight	$V_L = 1$ L $D_T = 11.3$ cm $H_L = 10$ cm Ring sparger, eight holes	—	*Cudrania tricuspidata*	24
Modified (gate-type) paddle ($D_i = 7.0$ cm, $H_i = 5.0$ cm, 400 rpm, 1.0 vvm)	$k_La \approx 52$ h^{-1} at a cell concentration of 11 g/L dry weight Mixing and gas dispersion satisfactory at cell densities above 20 g/L dry weight				
Rushton turbine ($D_i = 7.5$ cm, 1,000 rpm)	Biomass doubling time = 7.6 days Maximum cell concentration = 6.4 g/L dry weight Maximum alkaloid concentration = 10.4 mg/L	$V_L = 2$ L $D_T = 15$ cm Concave sides, flat bottom No baffles	Batch, up to 14 days	*Catharanthus roseus*	56
Vaned six-blade disk turbine, blades inclined 30° from the vertical ($D_i = 7.5$ cm, 1,000 rpm)	Biomass doubling time = 6.1 days Maximum cell concentration = 6.8 g/L dry weight Maximum alkaloid concentration = 5.5 mg/L				
Vaned six-blade disk turbine, blades inclined 60° from the vertical ($D_i = 7.5$ cm, 1,000 rpm)	Biomass doubling time = 4.5 days Maximum cell concentration = 7.7 g/L dry weight Maximum alkaloid concentration = 24.2 mg/L				
Flat-blade turbine (with baffles)	Concentration of protoberberine alkaloids produced = 3.0 g/L	Volume = 30 L	Batch	*Berberis wilsoniae*	97
Flat-blade turbine (without baffles)	Concentration of protoberberine alkaloids produced = 2.2 g/L				
Helical stirrer (upward pumping)	Concentration of protoberberine alkaloids produced = 2.3 g/L				
Spin stirrer	Lower maximum protoberberine alkaloid concentration than with the flat-blade turbine and baffles				

Six-flat-blade disk turbine (D_i = 7 cm, L_B = 1.3 cm, W_B = 1.3 cm, 200–300 rpm)	Maximum cell concentration = 18 g/L dry weight at 200 rpm Maximum L-DOPA content = 6.4% of dry weight at 200 rpm Higher levels of shear force intensity than with the six-flat-blade turbine	V_L = 5 L D_T = 21 cm No baffles	Batch	*Stizolobium hassjoo*	58
Six-flat-blade turbine (D_i = 6 cm, W_B = 0.8 cm, 100–500 rpm)	Maximum cell concentration = 21.5 g/L dry weight at 300 rpm Maximum L-DOPA content = 11.5% of dry weight at 400 rpm Lower levels of shear force intensity than with the six-flat-blade disk turbine				
Six-flat-blade turbine (D_i = 6 cm, W_B = 0.8 cm, 300 rpm, 0.06 vvm)	Maximum cell concentration = 21.3 g/L dry weight after 10 days Maximum L-DOPA content = 4% of dry weight after 11 days	V_L = 5 L D_T = 21 cm No baffles	Batch	*Stizolobium hassjoo*	65
Maxblend impeller (D_i = 10 cm, H_i = 12 cm, 100 rpm, 0.08 vvm)	Maximum cell concentration = 19 g/L dry weight after 15 days Maximum L-DOPA content = 2.3% of dry weight after 11 days				
Dual impellers; six-flat-blade turbine lower, three-pitched-blade turbine upper (D_{i1} = 6 cm, W_{B1} = 0.8 cm, D_{i2} = 7 cm, pitched blade angle = 30°, 300 rpm, 0.06 vvm)	Maximum cell concentration = 21 g/L dry weight after 13 days Maximum L-DOPA content = 2.0% of dry weight after 10 days				
Four-flat-blade impeller (D_i = 5.6 cm, W_B = 1.5 cm, 100–200 rpm, 0.2 vvm)	No growth at 200 rpm due to shear damage Poor mixing at 100 rpm Maximum cell concentration = 520 g/L fresh weight after 12 days at 150 rpm	V_L = 3 L D_T = 14 cm	Batch	*Nicotiana tabacum*	15
Large four-flat-blade impellers (D_i = 7.6 cm, W_B = 5.1–14 cm, 50–200 rpm, 0.2 vvm)	Growth rate increased with increasing blade width Maximum cell concentration = 580 g/L fresh weight after 7–8 days at 150 rpm with W_B = 14 cm Some cell damage				
Sail impeller (D_i = 7.6 cm, W_B = 14 cm, nylon cloth blades, 150 rpm, 0.2 vvm)	Longer lag phase Maximum cell concentration = 590 g/L fresh weight after 9 days at 150 rpm No cell damage Higher power requirements than for the large flat-blade impellers				

(*continued*)

TABLE 48.5. (*Continued*)

Impeller and Operating Conditions	Performance Indicators	Bioreactor Specifications	Bioreactor Operation	Plant Species	Reference
Dual Rushton turbines (60 rpm)	Maximum cell concentration = 75 g/L fresh weight after 15 days	V_L = 2.0–2.5 L	Batch	*Glycine max*	99
Dual marine impellers (60 rpm)	Maximum cell concentration = 15 g/L fresh weight after 11 days				
Cell-lift impeller (60 rpm)	Maximum cell concentration = 82 g/L fresh weight after 13 days Reduction in average biomass aggregate size				
Dual turbines (100 rpm, 0.5 vvm)	Lower biomass yield and productivity but higher anthraquinone yield than with perforated disk	Volume = 10 L	Batch	*Morinda citrifolia*	14
Perforated disk (100 rpm, 0.5 vvm)	Lower anthraquinone yield but higher biomass yield and productivity than with dual turbines				
Dual flat-blade turbines: six blades lower, four blades upper (D_i = 6.5 cm, W_B = 1.4 cm, 235 rpm, ring sparger, 0.3 vvm)	Maximum cell concentration = 9.5 g/L dry weight after 29 days Biomass yield from sugar = 0.29 g g^{-1} Cell damage observed	V_L = 2 L D_T = 13 cm H_L = 16 cm Four baffles	Batch, 29 days	*Catharanthus roseus*	8
Two-blade grid paddle (D_i = 6.9 cm, H_i = 14.8 cm, 50 rpm, spiral sparger, 0.3 vvm)	Maximum cell concentration = 19 g/L dry weight after 25 days Biomass yield from sugar = 0.43 g g^{-1} No cell damage observed				
Internal turbine (400 rpm, 1.0 vvm)	14.5 g dry weight cells and 65.7 mg total ginsenoside produced	V_L = 2 L	Batch, 42 days	*Panax ginseng* (embryogenic)	91
Paddle (50 rpm, 1.0 vvm)	23.2 g dry weight cells and 77.7 mg total ginsenoside produced				
Dual vaned six-flat-blade disk turbines (D_i = 12 cm, W_B = 1.8 cm, vane width = 0.3 cm, 100 rpm)	Biomass doubling time = 2.8 days Maximum cell concentration = 11.1 g/L dry weight Maximum alkaloid concentration = 21.8 mg/L	V_L = 7.5 L D_T = 23 cm H_L = 18.5 cm Concave sides, flat bottom No baffles C_{i1} = 7.5 cm C_{i2} = 18.5 cm	Batch	*Catharanthus roseus*	56
Dual vaned six-blade disk turbines, blades inclined 60° from the vertical (D_i = 8.5 cm, 100 rpm)	Biomass doubling time = 1.8 days Maximum cell concentration = 11.9 g/L dry weight Maximum alkaloid concentration = 25.8 mg/L				

Centrifugal impeller (six blades, $D_i = 8.5$ cm, blade angle = 60°, various stirrer speeds, 0.2–0.8 vvm)	Maximum cell concentration = 26.0 g/L dry weight Maximum saponin concentration = 0.80 g/L Lower stirrer speeds required to maintain higher dissolved oxygen tensions than with the turbine	$V_L = 2.5$ L $D_T = 12.5$ cm	Batch	*Panax notoginseng*	22
Turbine ($D_D = 6$ cm, various stirrer speeds, 0.2–0.8 vvm)	Maximum cell concentration = 22.7 g/L dry weight Maximum saponin concentration = 0.49 g/L Higher stirrer speeds required to maintain the dissolved oxygen tension above 15% air saturation than with the centrifugal impeller				
Anchor ($D_i = 19$ cm, 40 rpm, 0.6 vvm)	Maximum rosmarinic acid concentration = 2.1 g/L	$V_L = 32$ L $D_T = 25.9$ cm $H_L \approx 78$ cm	Batch	*Coleus blumei*	94
Helical agitator ($D_i = 23$ cm, 50 rpm, 0.6 vvm)	Maximum rosmarinic acid concentration = 3.3 g/L				
Spin stirrer (100 rpm, 0.15–0.55 vvm)	After 20 days, 25 g/L dry weight cells and 776 mg/L β-methyldigoxin produced	$V_L = 27$ L	Batch	*Digitalis lanata*	98
Helical stirrer (100 rpm, 0.15–0.74 vvm)	After 20 days, 23 g/L dry weight cells and 720 mg/L β-methyldigoxin produced				

[a]Symbols are defined in the section titled "Nomenclature".

shear effects. In some studies, the problem was viewed in terms of threshold values of shear rate (17,18,142) or shear stress (142,143), above which the growth rate, cell viability, product yield, or some other critical culture parameter was significantly altered. For this approach to be useful, the shear conditions present during cell culture must be quantified. Several methods have been applied to estimate shear levels in stirred bioreactors used for plant cell culture. Profiles of velocity and shear rate in an 11-L reactor stirred with dual Rushton turbines were determined using flow simulation methods; at a stirring rate of 100 rpm, shear rates varied from a maximum of 470 s^{-1} near the impeller to less than 5 s^{-1} in the bulk of the liquid (59). In other work, average and/or maximum shear rates were evaluated as a function of stirrer speed, impeller diameter, tank diameter, and blade width using correlations from the literature (56,60,144). The performance of different turbine impellers for suspended plant cell culture has also been correlated with several indirect indicators of shear force intensity, including the power input per unit mass and the Kolmogorov eddy scale, with reduced performance being associated with higher shear levels (58).

Because the hydrodynamic conditions in stirred reactors are ill-defined and spatially variable, it is difficult to predict the actual levels of shear experienced by suspended cells. Another limitation associated with the concept of threshold shear rate or shear stress for cell damage is that different threshold values may apply depending on the period of exposure of cells to the shear. If the response of plant cells to shear depends on the duration as well as the intensity of the shear forces, a parameter that takes the time of exposure into account would provide a better basis for predicting shear damage. The cumulative energy dissipated on the cells has been used as a correlating factor for shear effects in stirred plant cell reactors (32,57,64). This parameter can be calculated as the integral of the average power dissipated on the cells with respect to time. Under turbulent conditions, growth of *Atropa belladonna* suspensions in a baffled bioreactor stirred with a six-flat-blade turbine was observed to decline rapidly at energy dissipation values of about 10^8 J/m^3 (64). Sublytic effects such as changes in aggregate size, protein release, and mitochondrial activity may occur at lower cumulative dissipation energies (64,145).

Varying degrees of shear damage are known to be inflicted on plant cells by different types of impeller (8,15). If cumulative energy dissipation, as outlined above, is a satisfactory correlating parameter for shear damage irrespective of impeller design, it can be expected that of the remote-clearance impellers, low-power-number agitators such as pitched blade turbines, propellers, and hydrofoil impellers would be less damaging at the same stirrer speed and impeller diameter than high-power-number devices such as Rushton turbines. However, investigations with microbial cultures and a range of different impellers have indicated that the hydrodynamic forces generated in bioreactors and their shear effects on cells do not depend solely on overall energy dissipation levels. Additional factors, such as the distribution of energy dissipation rates within the vessel, the sweep volume of the impeller, and the trailing vortex structure behind the impeller blades, are responsible for generating local shear conditions close to the impeller where most cell damage takes place. In addition, impellers that generate strong circulation currents transport cells to the impeller region more frequently than agitators that do not promote rapid bulk liquid turnover, thus increasing the risk of shear effects. A correlating procedure for shear damage that takes all of these factors into account has been developed by Jüsten et al. (146,147) for mycelial cultures and applied to plant cell systems in a theoretical study (32). The utility of this approach for plant cultures remains to be tested experimentally.

The cell aggregate size distribution in plant cell cultures can vary significantly with stirring conditions and has been used as an indicator of shear effects in stirred reactors (5,8,17,56,64,67). Changes in aggregate size due to action of the impeller can influence cell growth and productivity in the culture. Not only is mass transfer of oxygen and nutrients affected (148,149), but a range of plant cell functions and properties including secondary metabolite synthesis, phenolic acid accumulation, enzyme activity, and levels of RNA, DNA, and protein has been found to depend on aggregate size (101,149–151). Forced breakup of aggregates, whether by shattering or attrition, may also affect viability if the plasmodesmata or cell walls are damaged. Although mechanisms of aggregate disruption have been investigated and predictive models developed for mycelial cultures in stirred reactors (152–154), similar analyses have not been carried out for plant cell systems. The factors affecting plant aggregate size appear to be complex; for example, aggregates may be larger in the presence of high shear levels (10), and complex cycles of aggregate growth, plasmolysis, and necrosis have been described in *Nicotiana tabacum* cell cultures under different agitation and aeration conditions (36). Lack of understanding in this area means that it is difficult to control cell aggregation in agitated reactors. Some models of cell damage predict that the effects of hydrodynamic shear are reduced with increasing scale (146). Consequently, it may not be possible to reproduce aggregate sizes at different equipment scales, thus affecting the success of plant reactor scale-up.

Contrary to most observations showing the deleterious effects of hydrodynamic shear on plant cell cultures, there is some evidence that increasing the average shear rate generated by turbine impellers in stirred reactors can improve secondary metabolite formation in plant cell suspensions. Increasing hydrodynamic stress was correlated with oxidative burst and transient synthesis of high levels of hydrogen peroxide in *Uncaria tomentosa* cells which, in turn, led

to a transient increase in monoterpenoid oxindole alkaloid production (144).

48.5.3 Mixing

Mixing is necessary in reactors to avoid concentration gradients and zones of oxygen and nutrient depletion. In vessels used for cell culture, the biomass represents a sink for substrates, and the sparger and medium inlet ports are oxygen and nutrient sources. Unless the cells are brought into regular and frequent contact with nutrients through good mixing, they experience deleterious physiological effects that cause a decline in overall culture performance. In the worst case, if bulk liquid velocities are very low, the cells settle out of suspension. This creates a region of high nutrient demand, rapid depletion of substrates, and high local concentration gradients at the bottom of the reactor. Because of the larger size of plant cells compared with microorganisms and their tendency to form macroscopic aggregates, cell settling is of greater concern in plant cell cultures than in most other fermentation processes.

Problems with incomplete mixing in stirred plant cell reactors have been reported in several studies (14,15,24,99). For continuous reactor operation, especially when culture overflow is used to maintain a constant liquid volume, unless special attention is given to the effluent removal, the cell concentration in the exit stream may be significantly different from that inside the vessel due to gradients of cell density developing in the broth (71,155–157). In most investigations of plant cell reactors, the adequacy of mixing has been judged qualitatively rather than measured, using visual observation of the absence of gross biomass settling or bulking. Although reported for plant cells in airlift contactors (158), spatial biomass distributions generally are not monitored in stirred reactors. However, even in plant cell broths that appear homogeneous, rates of mixing may not be adequate relative to the rates of other processes in the reactor, such as oxygen uptake and oxygen transfer. Because oxygen transfer takes place mainly in the impeller region in large stirred vessels, the time taken by cells to travel in bulk flow currents from the impeller through the remainder of the tank and back to the oxygen supply is an important consideration in assessing mixing performance.

The rate of mixing is generally quantified experimentally using tracer injection techniques (23,43), whereby the response of the system to a chemical or physical stimulus is recorded. The mixing time is the time required to achieve a given degree of homogeneity after the stimulus is imposed; the greater the mixing time, the slower is bulk mixing in the vessel and the greater is the likelihood that zones of nutrient depletion will develop. Mixing times for stirred plant cell reactors have been measured in a limited number of experimental investigations. Using a pulse of hot water as a tracer, Leckie et al. (60) estimated the mixing time in an unbaffled stirred tank of working volume 8.5 L used to culture *C. roseus* cells. With dual flat-blade turbines operated at 100 rpm, the mixing time determined from the measured temperature fluctuations was 3.6 s. In other work with an upward pumping double helical ribbon impeller, the mixing time was determined using an iodine decolorization method (2). In a flat-bottom vessel with a working volume of 11 L without baffles, mixing times of 18–25 s were measured as the stirrer speed was decreased from 150 to 120 rpm. Contouring the vessel base and installing surface baffles significantly reduced these mixing times to 4–9 s. Mixing time measured using decolorization techniques was also used to evaluate the performance of a centrifugal impeller bioreactor for *Taxus chinensis* culture (101). An increase in taxuyunnanine accumulation was correlated with a reduction in mixing time from 5 to 10 s in a 2-L stirred bioreactor. When mixing times were measured at the top and bottom of a 5-L stirred vessel containing plant pseudocells (granulated agar suspensions), the effectiveness of mixing was found to be location-dependent (65). The shortest mixing times (7–13 s) and most homogeneous mixing were found using a large Maxblend impeller; in contrast, mixing times observed using a more conventional flat- and pitched blade dual-impeller system at similar power inputs were 13–17 s.

The value of the mixing time can be used to determine whether mixing in a reactor is adequate relative to the rate of oxygen transfer or the cellular oxygen demand. Regime analysis or comparison of characteristic times (23,31) has been used for this purpose for other types of cell culture using experimental data (159), but its use with plant cell suspensions has been limited to theoretical analyses based on empirical correlations for mixing time (26,32).

48.5.4 Gas–Liquid Oxygen Transfer

An important function of reactors used for aerobic cell culture is providing adequate oxygen. Stirred plant cell reactors are most commonly aerated by bubbling air from spargers; however, surface aeration only (2) or bubble-free aeration using membrane tubing (86,104) may also be used (Table 48.4). The effectiveness of gas–liquid oxygen transfer is represented by the volumetric oxygen transfer coefficient $k_L a$; this parameter allows comparison of the oxygen transfer capacities of different reactors irrespective of their size and shape or the magnitude of the concentration difference driving force. When oxygen limits growth in cell cultures, the value of $k_L a$ determines the maximum biomass density that can be supported (43), so that increasing $k_L a$ is a common objective in reactor design and operation. Reports of higher final biomass concentrations with increasing initial $k_L a$ in batch cultures of tobacco cells (78) demonstrate this relationship. Oxygen transfer coefficients are measured experimentally using a variety of techniques (43); however, a common problem with all

k_La measurements is that it is necessary to assume that the reactor contents are perfectly mixed. If the dissolved oxygen concentration is not uniform in the vessel, measured k_La results are essentially meaningless. Because complete gas dispersion below as well as above the impeller requires relatively high power inputs for most agitators, gas-phase uniformity is often compromised in plant cell reactors to avoid the effects of shear damage (32). This means that dissolved oxygen levels, and therefore experimental k_La values, will vary depending on where in the reactor the dissolved oxygen level is measured. Practical estimation of k_La is also subject to several other common errors that affect the accuracy and value of the final results (160).

The power input, gas flow rate, and liquid properties are the principal determinants for k_La in stirred vessels. Dimensional correlations that are independent of agitator type have been developed in the following form (52,160):

$$k_La = A\left(\frac{P_T}{V_L}\right)^{\alpha} u_G^{\beta} \tag{48.1}$$

where k_La has units of s^{-1}, P_T has units of watts, V_L has units of cubic meters, and u_G has units of meters per second. The total power dissipation P_T is usually taken to be the sum of the aerated shaft power and the power provided by isothermal expansion of the gas (159,161). The values of α and β are largely insensitive to the properties of the culture broth (162) and usually fall in the range of 0.2–1.0. In contrast, liquid properties strongly influence the value of A, which includes a dependence on viscosity raised to a negative power of roughly 0.5–1 (12,161,163,164). The effects of other broth properties on k_La are complex and impossible to predict, with cell concentration and morphology, surface active agents, and coalescence-inhibiting substances such as salts, having a major influence on bubble size and gas–liquid interfacial conditions. Because changes in medium composition can alter k_La values by orders of magnitude, measurements using water or fluids other than the actual cell broth do not indicate the oxygen transfer rates achievable during reactor culture. Oxygen mass transfer coefficients have been measured in many studies of stirred plant cell reactors; examples of the results are summarized in Table 6. Because plant cells have lower specific oxygen requirements than most microbial cells, k_La values of 5–100 h^{-1} are sufficient for plant cell cultures, including those grown to high cell density (78,92,165). This range can be compared with 60–1000 h^{-1} for microbial cells and 0.1–25 h^{-1} for animal cells (166). At suboptimal k_La values, plant cell cultures may exhibit linear rather than exponential growth kinetics (78,167). The minimum k_La necessary to achieve exponential growth can be calculated using stoichiometric analysis (168).

Although the effect of suspended particles such as cells on k_La is highly variable (48), it is often found that suspended solids promote bubble coalescence, lower the gas holdup, dampen turbulence, and interfere with gas–liquid contact, thereby reducing k_La. In some cases, however, these effects are negligible below threshold particle concentrations (55,169). The data available for plant suspensions indicate that increasing the cell concentration to values as high as 20–60 g/L dry weight may have only a limited effect on k_La in stirred reactors (24,92). The influence of biomass concentration on the oxygen transfer coefficient can be expressed alternatively in terms of the relationship between k_La and the apparent viscosity of the broth (12). In other work, k_La at constant cell concentration was found to be sensitive to changes in osmotic pressure, apparent viscosity, and the biomass fresh weight to dry weight ratio. At a fixed cell density of 10.2 g/L dry weight, k_La increased from 4.8 to 5.7 h^{-1} as the fresh weight to dry weight ratio was reduced from 19.6 to 11.0 (170).

The efficiency of gas–liquid mass transfer in bioreactors depends to a large extent on the characteristics of the bubbles in the culture broth, in particular, their size. In stirred reactors with highly developed turbulent flow, the size of the bubbles produced by the sparger bears little relationship to those present in the vessel as bubble breakup and coalescence due to action of the impeller are the main influences on bubble size (171). However, because shear damage is a major concern in plant cell culture, stirred reactors will in most cases be restricted to operation at slow stirrer speeds, with the bubbles rising freely through the liquid after minimal interaction with the impeller. The same is true for large-diameter agitators such as anchors and helical impellers, which either cannot be operated at high speed because of the excessive power required or do not generate the high velocity turbulent flows needed for bubble disruption and dispersion. Because these conditions produce low gas holdups and k_La values, alternative low-shear strategies for improving the mass transfer coefficient are required. Particular attention may be given to design of the sparger because the delivery of small bubbles is advantageous for mass transfer when the impeller does not impart sufficient energy for continual bubble breakup. Improvements in k_La were achieved in plant cell reactors stirred with dual Rushton (10) or grid paddle (8) impellers using spargers that produce a greater number of smaller bubbles at the same gas flow rate. There may be practical limitations associated with this approach, however, because plant cells have a high tendency for wall growth and will invade and block porous or small-orifice spargers. Small bubbles also tend to coalesce rapidly in high-density cell suspensions. In large bioreactors affected by inadequate mixing due to stirrer speed restrictions, reducing the size of the bubbles cannot remedy the problem of poor gas distribution or the development of oxygen gradients in the vessel (32).

As indicated in Equation 48.1, the value of k_La in stirred reactors can be improved by increasing the gas flow rate at constant stirrer speed. Numerous studies have shown,

TABLE 48.6. Values of the Oxygen Transfer Coefficient (k_La) Measured in Stirred Plant Cell Bioreactors

Impeller	Stirrer Speed (rpm)	Aeration Rate (vvm)	Bioreactor Working Volume (L)	Liquid	Cell Concentration (g/L dry weight)	Plant Species	k_La (h^{-1})	Reference
Six-flat-blade turbine	225	1.0	1	Culture broth	0 and 11	*Cudrania tricuspidata*	43 and 42	24
Dual six-blade turbines	250	0.33	1.8	Sterilized culture broth with antifoam agent	—	*Catharanthus roseus*	40 ± 2	69
Marine impeller	100–325	0.43	2	Culture broth	2.5–12	*Nicotiana tabacum*	4.5–22	85
Modified paddle (hollow stirring wing)	—	0.2–1.0	2.5	Culture broth treated with formaldehyde	20–80	*Coptis japonica*	30–95	92
Modified (gate-type) paddle	400	1.0	1	Culture broth	0 and 21.6	*Cudrania tricuspidata*	55 and 48	24
—	200	—	—	Culture broth	—	*Nicotiana tabacum*	20–85	36
—	80	0.054–0.35	3.5	Medium, nonbiological	—	—	$k_La = 31.07\ (\text{vvm})^{0.792}$	167,168

however, that there are limits to which this strategy can be pursued, because reduced growth and metabolite production occur at high gas throughputs (20,27,65). This phenomenon has been attributed to stripping of carbon dioxide and other volatile components such as ethylene from the culture broth (28). The importance of gaseous metabolites in plant cell cultures was highlighted by Schlatmann et al. (69), who demonstrated that recirculating the reactor off-gas can be used to achieve a three- to fourfold increase in alkaloid concentrations in a stirred bioreactor, to reach product levels similar to those found in shake flasks. Because the mass transfer coefficient for stripping volatile compounds increases with any increase in the k_La for oxygen transfer, losses of these compounds are greater when the oxygen transfer capacity of the reactor is improved, for example, by increasing the gas flow rate or stirrer speed. Plant cell properties and metabolism may also be affected in other ways as a function of k_La. In a stirred bioreactor used for culturing *C. roseus* cells, ajmalicine was not produced at initial k_La values above 10 h^{-1}, whereas the rate of serpentine synthesis was enhanced with increasing k_La (10). The maximum specific oxygen uptake rate by cells grown at an initial k_La of 20 h^{-1} was higher than for cells grown at $k_La = 2.5$ h^{-1}. Dissolved oxygen concentrations in these reactors were not reported, although altered dissolved oxygen tension is the direct result of changes in k_La. The relationship between plant cell metabolism and oxygen concentration may be complex, with growth, secondary metabolite synthesis, and differentiation processes such as embryogenesis affected in different ways (74,75,95,172,173). The various influences of k_La on the performance of plant cell cultures reflect this complexity.

48.5.5 Gas–Liquid Hydrodynamics

For stirred bioreactors to perform their mixing and mass transfer functions satisfactorily, appropriate gas–liquid hydrodynamic conditions must be generated by the impeller. Neither bulk blending nor gas dispersion is effective when the impeller is flooded (Fig. 48.8a), and implicit in the application of k_La correlations such as Equation 48.1 is that the reactor is thoroughly mixed and of uniform composition. Impellers should be operated to achieve complete dispersion of gas bubbles above and below the impeller (Fig. 48.8c). For a given tank and agitator, the stirrer speed necessary to achieve this condition depends on the gas flow rate. The higher the gassing rate, the greater the stirring speed required.

Despite the importance of these hydrodynamic considerations, there are few reports in the literature that mention impeller flooding or are concerned with gas dispersion conditions in plant cell reactors (32). At the restricted stirrer speeds employed in many applications, adequate bubble dispersion must often be compromised to minimize shear damage. Using visual observations and computer simulation of bubble trajectories, Boysan et al. (59) demonstrated that an 11-L plant cell reactor stirred with dual Rushton turbines operated under flooded conditions at air flow rates as low as 0.009–0.2 vvm. Flooding was also reported using pitched blade and Maxblend impellers in a 5-L stirred vessel used for plant cell culture; in contrast, gas dispersion was satisfactory using a six-flat-blade turbine (65). Because the volumetric power input required to prevent flooding increases with reactor scale (49), many of the larger stirred reactors listed in Table 48.4 and operated at slow stirrer speeds are likely not to have achieved effective dispersion of the gas phase. This situation would be considered unacceptable and impractical in most applications of aerated stirred tanks.

48.5.6 Foaming

Foaming is particularly pronounced in plant cell suspensions, and its effects are exacerbated in reactor cultures by entrained cells attaching to the walls of the vessel and forming a thick meringue or crust in the reactor headspace. Plant cell meringues usually extend across the entire diameter of the vessel and prevent adequate circulation of medium, resulting in severe loss of culture performance. Foam development in plant suspensions is due mainly to the properties of the cell-free broth; the presence or absence of cells has a relatively minor influence (29). The volume of foam produced depends on the gas flow rate in the reactor; however, foam formation and stability at any given time during the culture are also strongly affected by broth properties such as pH (29). There are many reports of the use of chemical antifoam agents in stirred plant cell reactors (29,73,96,174), but a major disadvantage of antifoams is that they reduce the value of k_La and, consequently, the ability of the reactor to sustain high cell densities (29). Mechanical foam destruction is preferable if it can be made sufficiently effective, and various approaches to mechanical foam control have been reported for stirred plant cell reactors. Leckie et al. (56,60) installed a flat-blade turbine impeller at the liquid surface of a 12-L stirred bioreactor to act as a foam breaker; alternatively, periodic increases in stirring speed have been applied to clean off layers of plant cells attached to the reactor walls (57,155). For example, 2 s of high speed agitation every hour was effective in controlling meringue formation in a 2-L fermenter used for continuous culture of *Phaseolus vulgaris* cells. In other plant cell systems, foaming and wall growth were avoided by limiting the stirrer speed and air flow rate to relatively low levels (78).

48.6 PLANT CELL CULTURE IN STIRRED BIOREACTORS: THEORETICAL ANALYSIS

Although many bioreactor studies using conventional and novel impellers have been carried out to assess the effect

of impeller configuration on suspended plant cell culture, no definitive guidelines for impeller choice have emerged from this experimental work. Impeller selection affects a wide range of bioreactor functions including mixing, oxygen transfer, gas dispersion, solids suspension, and the generation of hydrodynamic shear forces.

An attempt to account for all these effects using a theoretical analysis of impeller function has been reported, based on equations and correlations from the literature (32). In this study, the performance of three different impeller designs or operating modes was compared. The impellers tested were a Rushton turbine, a downward pumping pitched blade turbine, and an upward pumping pitched blade turbine. Each impeller was fitted with six blades of width $^1/_5$ the impeller diameter; for the downward and upward pumping axial turbines, the blade angle was 45°. A model 10-m^3 bioreactor designed for mixing using a single impeller was used in the analysis; the geometric properties of the bioreactor system are listed in Table 7. The bioreactor was operated as a chemostat with a dilution rate of 0.2 day^{-1}, giving an average reactor residence time of 5 days. The plant cell broth in the reactor was assumed to contain 30 kg/m^3 dry weight of cells; other properties representative of plant cell cultures were assumed, as listed in Table 8.

Results from the theoretical analysis of impellers of diameter 1/2 that of the tank diameter are shown in Fig. 48.19 as regime maps for bioreactor operation (32). The maps indicate the performance features of the bioreactor system as a function of stirrer speed and sparging gas flow rate as operating variables. The maximum stirrer speeds allowed before shear damage affects the suspended plant cells were calculated using a typical threshold cumulative energy dissipation of 10^7 J/m^3 based on reported literature values; the effect of impeller geometry on shear damage was accounted for using the method of Jüsten et al. (146,147). As shown in Fig. 48.19, this approach allowed the maximum stirrer speeds to be estimated for each impeller type under unaerated conditions to avoid shear damage of the cells. The vertical shaded zones in Fig. 48.19a–c indicate the extent of uncertainty about the power drawn by the impellers when aerated. In general terms, to avoid cell shear damage in the model plant cell bioreactor, stirrer speeds are restricted to those in the "No damage" region to the left of the shaded zones.

The minimum gas flow rate required for adequate oxygen transfer in the bioreactors was calculated using analysis of characteristic times for oxygen uptake, mixing, and oxygen mass transfer. The results are shown as the horizontal lines across each of the regime maps in Fig. 48.19. For sufficient oxygen transfer, the bioreactor must be operated at gas flow rates above this value. Under these conditions, mixing in the bioreactor was adequate with each of the three impellers tested. The flooding/loading transition for the impellers and the conditions required for complete gas dispersion and solids suspension are also shown in the maps in Fig. 48.19. In each case, for optimum hydrodynamic performance, the impeller should be operated at stirrer speeds above those indicated by the curves representing these functions.

The results for the Rushton turbine are shown in Fig. 48.19a. At the maximum allowable stirrer speed of 0.41–0.51 s^{-1} and the minimum air flow rate of 0.13 vvm, the impeller is loaded and the cells completely suspended, but the gas bubbles are not completely dispersed. These operating conditions for the Rushton turbine are reasonably satisfactory but not ideal. The situation for the downward pumping pitched blade turbine is shown in Fig. 48.19b. Higher maximum stirrer speeds may be used with this impeller compared with the Rushton turbine while still avoiding cell damage, consistent with the lower power number for pitched blade turbines. However, the thickness of the shaded zone in Fig. 48.19b reflects the large uncertainty associated with estimating the power drawn by downward pumping turbines under aerated conditions. Because downward pumping impellers are subject to significant power and torque instabilities that can lead to mechanical damage at stirrer speeds just below those required for complete

TABLE 48.7. Properties of the Bioreactor System Used for Theoretical Analysis of Impeller Performance

Parameter	Specification
Reactor working volume	10 m^3
Tank diameter	2.3 m
Liquid height	2.3 m
Impeller type	Varies
Impeller diameter	1.15 m
Impeller clearance above the vessel floor	0.58 m
Sparger type	Ring
Sparger diameter	0.92 m
Clearance between the sparger and impeller	0.39 m
Number of baffles	4
Baffle width	0.23 m
Submerged baffle height	2.3 m

TABLE 48.8. Properties of the Plant Cell Culture Used for Theoretical Analysis of Impeller Performance

Parameter	Specification
Cell concentration	30 kg/m^3 dry weight
Cell fresh weight:dry weight ratio	15:1
Broth viscosity	30 mPa s
Suspending liquid viscosity	1 mPa s
Liquid density	1000 kg/m^3
Cell particle density	1030 kg/m^3
Cell particle diameter	500 μm

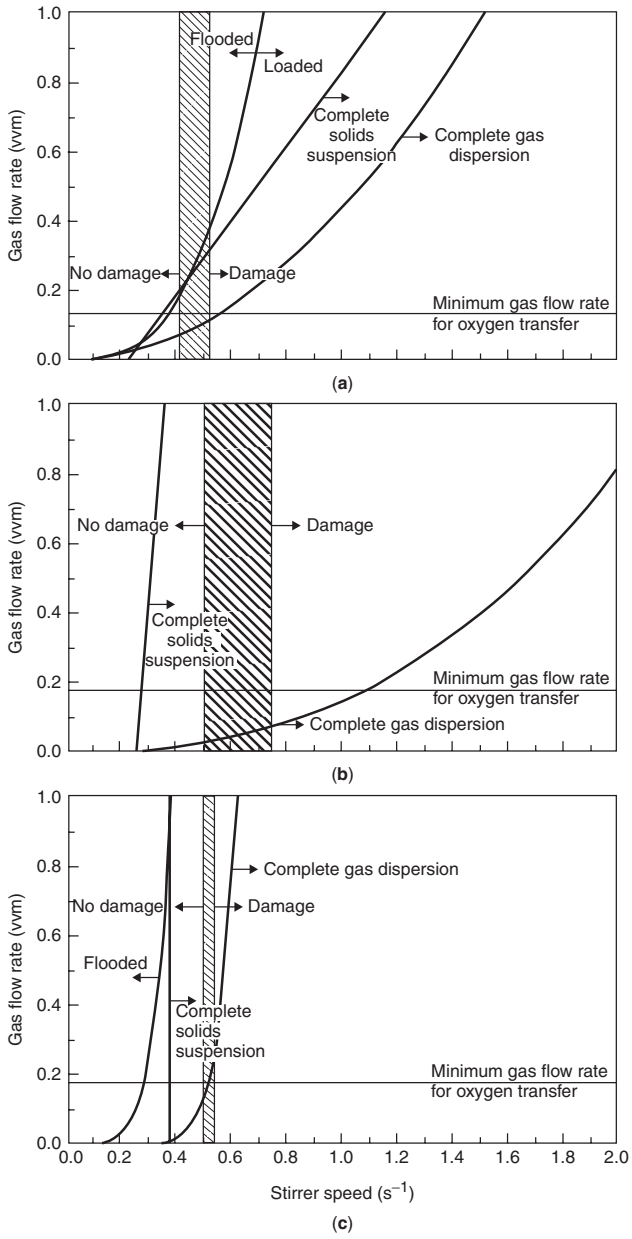

Figure 48.19. Bioreactor operating regime maps derived using theoretical analysis of the performance of different impellers for suspended plant cell culture: (a) Rushton turbine, (b) downward pumping pitched blade turbine, (c) upward pumping pitched blade turbine. The impellers were each of diameter 1/2 the tank diameter and were used to stir plant cell broth in a cylindrical vessel of working volume 10 m^3. (Data from Ref. 32.)

gas dispersion (54,163), ensuring that the gas bubbles are completely dispersed is of more practical importance than the flooding/loading transition. Accordingly, the curve for complete gas dispersion is shown in Fig. 48.19b but the flooding/loading transition is not. The results for the downward pumping pitched blade turbine show that this impeller is largely unsatisfactory for suspended plant cell culture. Although extremely effective for solids suspension, the impeller operates with far from complete gas dispersion at the minimum gas flow rate and maximum stirrer speed allowed. When the direction of rotation of the downward pumping pitched blade turbine is reversed, gas–liquid hydrodynamics in the vessel are substantially improved as shown in Fig. 48.19c for the upward pumping pitched blade impeller. Complete gas dispersion and solids suspension are achieved at relatively low stirrer speeds; at the maximum allowable stirrer speed and minimum air flow rate, all of the reactor functions are performed adequately or close to it by the upward pumping impeller. Another benefit with upward pumping impellers is that the power loss with gassing is much smaller than with Rushton or downward pumping impellers, so that the shaded region of uncertainty for the maximum allowable stirrer speed to avoid cell shear damage is reduced. An additional advantage compared with their downward pumping counterparts is that upward pumping turbines are not prone to power or torque fluctuations.

The overall conclusion from this theoretical analysis is that upward pumping axial flow impellers may offer substantial benefits for high-density plant cell culture in stirred bioreactors. The stirring speeds required to achieve complete gas dispersion and solids suspension are almost independent of aeration rate for this type of impeller. As indicated by the regime maps, this provides greater scope for effective, stable operation compared with Rushton and downward pumping impellers. Upward pumping impellers have not yet been used in any of the reported experimental studies of plant cell culture; yet the results of this analysis suggest that they deserve further investigation.

48.7 CONCLUSIONS

The ability to provide adequate mixing and oxygen transfer is the most important benefit of using stirred reactors for suspended plant cell culture. However, whether these conditions can be achieved depends on the extent to which cell shear sensitivity limits the stirrer speeds that can be employed. Other factors that play a major role in determining levels of plant cell growth and metabolite synthesis, such as aggregate formation and disruption, foam development, and stripping of volatile broth components, are also controlled by the operating conditions employed in stirred tank reactors. To date, few science-based, general-purpose rules have been developed to assist in the design of stirred vessels for plant cell culture. This reflects in large part the wide range of performance outcomes so far observed using different bioreactor hardware, operating regimes, and plant cell systems.

NOMENCLATURE

A	Dimensional constant in Equation 48.1
C_i	Impeller clearance above the vessel floor (m)
C_S	Clearance between the sparger and impeller (m)
D_D	Impeller disk diameter (m)
D_i	Impeller diameter (m)
D_S	Sparger diameter (ring-type sparger) (m)
D_T	Tank diameter (m)
H_{BF}	Baffle height (m)
H_i	Impeller height (m)
H_L	Height of liquid in reactor (m)
K	Consistency index (Pa s^n)
k_La	Oxygen mass transfer coefficient (s^{-1})
L_B	Impeller blade length (m)
L_R	Ribbon length (m)
N_i	Stirrer speed (s^{-1})
n	Flow behavior index
P_T	Total power input by agitation and gassing (W)
Q_G	Volumetric gas flow rate (m^3/s)
u_G	Superficial gas velocity (m/s)
V_L	Liquid volume in reactor (m^3)
W_B	Impeller blade width (m)
W_{BF}	Baffle width (m)
W_R	Ribbon width (m)
α, β	Exponents in Equation 48.1

Subscripts

1	Lower impeller in dual agitator system
2	Upper impeller in dual agitator system

CELL IMMOBILIZATION, ENGINEERING ASPECTS

RONNIE WILLAERT

Department of Ultrastructure, Flanders Interuniversity Institute for Biotechnology, Vrije Universiteit Brussel, Brussels, Belgium

49.1 INTRODUCTION

The immobilization of cells can be defined as "the physical confinement or localization of cells to a certain defined region of space with preservation of some desired activity" (1). The region in which the cells are localized is called the *immobilized cell system* or *immobilized cells aggregate*, which can be divided into three components: the cells, the support (or carrier or matrix) material, and the solution that fills the remainder of the space (interstitial solution). The immediate vicinity of the immobilized cells is also called the *microenvironment*. When cells are encapsulated in an immobilized cells system, the term *bioencapsulation* is usually used. Microencapsulation is used when the cells are immobilized in microcapsules, that is, micrometer-sized systems surrounded by a barrier membrane. In recent developments, active biologicals (i.e. proteins, DNA, etc.) are packed in nanoparticles of submicron or nanometer size range and is called *nanoencapsulation*.

Studies on immobilized biocatalysts were initiated by immobilizing single enzymes for simple reactions such as hydrolysis and isomerization. Subsequently, multienzyme systems, isolated cellular organelles, and treated (permeabilized) microbial cells have been used as biocatalysts for more complicated and conjugated reactions. Moreover, many applications have been developed utilizing living or growing microbial cells and cells of multicellular organisms (higher plants and animals) as well as genetically improved microbial cells. Table 48.1 lists the added beneficial characteristics cell systems obtain upon immobilization as well as the introduced drawbacks (1–11).

The successful application of immobilized cell systems relies on the proper choice of the cell system. This choice will be directed by the type of application and characteristics of the immobilization support. Accordingly, requirements will be different for each particular case. Common desirable requirements are high cell mass-loading capacity; easy access to nutrient media; simple "nontoxic" immobilization procedure; high surface area-to-volume ratio; optimum mass transfer distance from flowing media to center of support; mechanical (compression, abrasion) and chemical stability; sterilizable, reusable, or one-time use for very cheap carrier materials; low shear experienced by cells; easy separation of cells and carrier from media; suitable for conventional reactor systems; suitable for suspension as well as anchorage-dependent cells; biocompatibility with animal cells, immunoprotection barrier, and economic interesting (11,12).

49.2 INTERNAL MASS TRANSPORT

The analysis of the influence of mass transfer on the reactor performance in immobilized cell reactors is an important topic since the performance of these reactors may often be reduced by the rate of transport of reactants to and products from the immobilized cell system (external mass transfer limitation), and by the rate of transport inside the immobilized cell system (internal mass transfer limitation). External mass transfer limitations can usually be reduced or eliminated by a proper design/selection of the reactor and immobilized cell system. Several phenomena are involved

TABLE 49.1. Beneficial Characteristics and Drawbacks Created upon Immobilization of Cells (modified after (11))

Advantages
The density of immobilized cells is locally higher than that of freely suspended cells after cell growth and, consequently, results in higher productivities.
Immobilized growing cells are easily separated from the reaction system. Additionally, repeated or continuous use of immobilized growing cells is possible in various types of reactors.
Tailoring to the most efficient bioreactor is possible. Allows batch fermentors to be operated on a drain-and-fill basis.
The wash-out of cells during continuous fermentations can be avoided at high dilution rates.
Immobilized cells appear to be less susceptible to microbial contamination.
Immobilization can give rise to higher retention of plasmid-bearing cells and thus delay overgrowth by the corresponding plasmid-free cells.
Improved downstream processing: products can be recovered more easily as they are not or less contaminated by biomass.
Provides possibilities for the spatial location within reactors of different microbial populations.
Immobilizing cells can be better protected from their surroundings and thereby decrease problems to shear forces. This is especially important for shear-sensitive cells such as mammalian cells.
Immobilization can provide conditions conductive to cell differentiation and cell-to-cell communication, thereby encouraging production of high yields of secondary metabolites.
Mammalian cell immobilization behind a barrier membrane for transplantation therapy provides an effective immunoprotection. The controlled and continuous delivery of therapeutic products to the host is a potentially cost-effective method to treat a wide range of diseases.
The *in vivo* situation can be mimicked by immobilization, e.g. chondrocyte growth in Ca-alginate gel mimics the situation in the cartilage matrix.
Immobilization can have substantial effects on the physiology, resulting in higher productivities compared to free cells, e.g. production of secondary metabolites by gel immobilized plant cells, improved enzyme production by immobilized bacterial and fungal cells.
Properties of cell immobilization materials can be engineered for biocompatibility, selective permeability, mechanical and chemical stability, and other requirements as specified by the application including uniform cell distribution and a given membrane thickness or mechanical strength.
Cell immobilization can create a protective environment for the cells.
Disadvantages
Mass transfer limitations can reduce the efficiency of the reaction. The whole catalytic activity is not utilized due to restricted supply of substrate(s). Reduction of the efficiency can cause problems when high-density systems are scaled-up. Usually, this is because of oxygen transfer limitations and accumulation of toxic waste products.
The mechanical stability of some support materials limits its use.
Products are liable to be contaminated by cells leaking from the carriers. This problem can sometimes be solved by selection of a suitable carrier with a high cell-holding capacity and by limitation of excess cell proliferation.
Some immobilization techniques and materials can have an important negative impact on the economics of the bioprocess.
Biocompatibility of some immobilization matrices is not sufficient for transplantation therapy and results in fibrosis, which introduces supplementary diffusion limitation.

such as axial dispersion, convective flow, and macro- and micromixing. Internal mass transfer limitations are often more difficult to eliminate and their knowledge is a prerequisite to analyze and optimize the performance of the immobilized cell system.

Two physical phenomena are involved in the transport of molecules, that is diffusion and convection. Diffusion is the random motion of molecules that arise from thermal energy transferred by molecular collisions. Convection is a mechanism of transport resulting from the bulk motion of fluids.

49.2.1 Definition of Diffusion Coefficients

The relation between the diffusion flux and the concentration gradient was first quantified in 1855 by the German physiologist Adolf Fick (13). This relationship is known as *Fick's first law*, which states that the rate of transfer of the diffusing substance through a unit area is proportional to the concentration gradient measured normal to the section,

$$J = -D\frac{\partial C}{\partial x} \tag{49.1}$$

where J is the mass transfer rate per unit area of a section (diffusion flux), C the concentration of diffusing substance (amount per total volume of the system), x the space coordinate, and D is called the *diffusion coefficient*. D is sometimes expressed as the binary diffusion coefficient (or mass diffusivity) D_{AB}, where the subscript A refers to the solute A and B to the solvent B. In three dimensions, the flux $\mathbf{J}$ is a vector and flows can have components in all directions:

$$\mathbf{J} = -D\nabla C \tag{49.2}$$

In the biochemical engineering literature, it is general practice to use an effective diffusion coefficient (D_e), which can, for example, be readily used in the expression for the Thiele modulus and for the determination of the efficiency factor of a porous biocatalyst. When D is replaced by D_e in Equation 49.1, the corresponding concentration (C_L) is expressed as the amount of solute per unit volume of the liquid void phase. Concentration C may be correlated with C_L by using the void fraction (ε), which is the accessible fraction of a porous particle to the diffusion solute as $C = \varepsilon C_L$. Hence, the relationship between the effective diffusion coefficient and the diffusion coefficient is

$$D_e = \varepsilon D \tag{49.3}$$

Intraparticle forced convection can have a significant influence on the mass transport in a porous particle. The intraparticle convection depends on the external flow conditions and the degree of porosity, and can also be characterized by Fick's first law, where the "apparent" diffusion coefficient, which accounts for the convective mass transport, is used (14,15).

49.2.2 Internal Diffusion in Immobilized Cells Systems

The effective diffusion coefficient through a porous support material (matrix) is lower than the corresponding diffusion coefficient in the aqueous phase (D_a) due to the exclusion and obstruction effect. By the presence of the support, a fraction of the total volume ($1-\varepsilon$) is excluded for the diffusing solute. The impermeable support material obstructs the movement of the solute and results in a longer diffusional path length, which can be represented by a tortuosity factor (τ); τ equals the square of the tortuosity (16). The influence of both effects on the effective diffusion coefficient can be represented as

$$D_e = \frac{\varepsilon}{\tau} D_a \tag{49.4}$$

This equation holds as long as there is no specific interaction of the diffusion species with the porous carrier.

In the case of gel matrices, predictions using the polymer volume fractions are recommended, since, neither ε nor τ can be measured for a gel in a simple way (17–19):

$$D = \frac{(1-\phi_p)^2}{(1+\phi_p)^2} D_a \tag{49.5}$$

where ϕ_p is the polymer volume fraction. For low molecular weight (MW) solutes in cell-free gels, an approximate measure of ε can be given as

$$\varepsilon = 1 - \phi_p \tag{49.6}$$

D_e can also be expressed as a function ϕ_p by combining Eqs 49.2,49.4, and 49.5 (20–23) as

$$D_e = \frac{(1-\phi_p)^3}{(1+\phi_p)^2} D_a \tag{49.7}$$

Other physical models that have been proposed are the Phillies model, Equation 49.8 (24), and the Petit model (25), Equation 49.9:

$$D_e = e^{\left(-n_1 C_{gel}^{n_2}\right)} D_a \tag{49.8}$$

$$D_e = \left(1 + n_3 C_{gel}^{2n_4}\right) D_a \tag{49.9}$$

where C_{gel} is the gel concentration, n_1 and n_2 are parameters of the Phillies model, and n_3 and n_4 parameters of the Petit model. For example, the effect of the polyvinyl alcohol (PVA) concentration on the effective diffusion coefficient of an azo dye (Remazol Black B) could be described by the Phillies model (26).

49.2.3 Measurement Methods of Diffusion Coefficients

Both steady state and transient methods are used for measurements of diffusion coefficients; sometimes in combination as in the lag time method. A few researchers have used indirect methods, such as the use of a reaction–diffusion model, to determine the diffusion coefficient of gel immobilized cells (27–29) or biofilms (30–35). Westrin and coworkers (36) have reviewed in depth the methods for measuring diffusion coefficients. They compared different methods [including holographic laser interferometry and nuclear magnetic resonance (NMR)] with regard to accuracy, reproducibility, time, cost, and limitations.

The equation, which describes the transient diffusion, can be readily derived by writing the mass balance over the system:

$$\varepsilon \frac{\partial C_L}{\partial t} = x^{-n} \frac{\partial}{\partial x}\left(x^n D_e \frac{\partial C_L}{\partial x}\right) \tag{49.10}$$

where n is a shape factor which is 1 for planar, 2 for cylindrical or 3 for spherical geometry. In Table 48.2, the most popular methods to determine diffusion coefficients (in gels and dense cell masses) are listed. Recently, noninvasive microscopic and spectroscopic techniques have been developed. For example, Frazier *et al*. (37) used near-infrared spectroscopy to measure nutrients within a specially designed diffusion chamber that permits the noninvasive measurement of effective diffusivities in gels containing immobilized cells (e.g. D_e of glutamine in agarose gel).

TABLE 49.2. Experimental Methods to Determine Diffusion Coefficients

Method	Reference Examples
Concentration gradient methods: steady state	
True steady state diaphragm cell	38–46
Pseudo (quasi)-steady state diaphragm cell	20,45–51
Concentration gradient methods: transient	
Time-lag diaphragm cell	42,52–56
Uptake/release from particles dispersed in a stirred solution	26,57–90
Concentration profile in a material/cell mass	
Autoradiography	91
Electrode or mass spectrometric probe covering	92–95
Fixed ultrasonic probes	96

NMR: pulsed gradient spin-echo (PGSE); radio-frequency field gradient	23,137–146
Holographic relaxation spectroscopy	147,148

Experimentally, a concentration disturbance is applied over the system and the change of the concentration as a function of time is followed until the steady state is reached. Diffusion coefficients are determined by fitting the theoretical curve to the experimental one, which is obtained after solving Equation 49.9 using the appropriate initial and boundary conditions. Analytical solutions for simple cases are described by Crank (149). Crank also gives the solution in terms of M_t, the amount of solute in the matrix at time t, as a fraction of M_∞, the equilibrium amount, which is practically more accessible.

Steady state measurements can be performed by using a "diaphragm-diffusion cell" (Table 48.2). Two liquid-filled well-stirred compartments are separated by a membrane under investigation, through which a steady state diffusional flux is set up (42–44,48,49,53,54). While in the steady state method, a constant upstream and different downstream solute concentration is employed, in the pseudo-steady state method, a change in solute concentration in the compartments is allowed.

If the diffusion coefficient is measured by the steady state method, the value of the equilibrium partition coefficient (K) should be known. Another approach is to determine directly the product of K and D, which equals the effective diffusion coefficient (150). Sun and coworkers (42) used a non-steady state method to immediately determine the product of K and D_e for oxygen in cell-free and cell-containing Ca-alginate and polyvinyl alcohol stilbazolium (PVA-SbQ) gels. The partition coefficient is defined as

$$K = \frac{C_m}{C_L} \tag{49.11}$$

where C_m is the solute concentration in the matrix (amount per volume matrix) and C_L the solute concentration in the liquid phase. In the absence of specific adsorption phenomena, the partition coefficient for cell-containing matrices can be predicted by the following equation (20,49,150) :

$$K = 1 - (\alpha\phi_c + \phi_p) \tag{49.12}$$

where α represents the volume fraction of the individual cell that is not accessible to the solute and ϕ_c is the volume fraction of the cells. If the outer cell membrane totally excludes the solute, the value of α will be unity. Axelsson and Persson (49) found a value of 1 for glucose, lactose, galactose, and ethanol for alginate gels containing yeast cells deactivated by iodoacetic acid. Chresand and coworkers (52) measured the partition coefficient of labeled sodium acetate between 1% (w/w) agar gel containing mammalian cells and the surrounding solution, and found a value that was unity. This result corresponds with a value of zero for α. It can also be assumed that the solute is excluded from a certain volume fraction of the individual cell: $0 < \alpha < 1$. This volume fraction may, for example, be approximately equal to the dry weight fraction of the cells, which can be assumed to be equal to 0.25 (20). If there are no immobilized cells present, Equation 49.11 is reduced to $1-\phi_p$ which equals ε (Eq. 49.7).

Values of experimentally determined partition coefficients for cell-free gels are in a lot of systems close to unity; for example, between 0.97 and 1.02 for glucose in 2% Ca-alginate (62); 0.98 for lactose in 2.75%/0.25% (w/w) κ-carrageenan/locust bean gum (69); 1.2 for lactose, 1.3 for glucose, 1.1 for galactose, and 1.32 for ethanol in

2.4–2.8% (w/w) alginate, the higher value for ethanol was explained as adsorption of ethanol on the alginate gel; and 1.14 for catechol, 0.99 for 3,4-dihydroxy-L-phenylalanine (L-DOPA), and 2.03 for dopamine in cross-linked gelatin (10% w/v) beads at pH 7.1 and 35°C (70). For solute molecules with a large MW, a low value for K was determined: 0.57 for ovalbumin (43.5 kDa), 0.37 for bovine serum albumin (BSA) (67 kDa), and 0.18 for IgG (155 kDa) in 3% Ca-alginate; 0.48 for ovalbumin, 0.23 for BSA, and 0.17 for immunoglobulin G (IgG) in 4% agarose (81). Owing to the obstruction effect of cells immobilized in κ-carrageenan/locust bean gum, partition coefficients decreased from 0.89 to 0.79 and from 0.98 to 0.87 for lactose and lactic acid, respectively (71); Øyaas *et al*. (79) found that K was constant for both lactose and lactic acid (1.00 and 1.16, respectively) with increasing cell concentration.

The partition coefficients of Remazol Black B (azo dye) in PVA decreased from 4.1 to 1.3 with an increase in ϕ_p values ranging from 0.0521 to 0.0954 m^3 PVA/m^3 gel (26). The gel pore size was greater than the size of the Remazol Black B molecules and a strong affinity existed between PVA and the azo dye molecules. The lipoglycopeptide antibiotic, A40926, and its deacetylated derivative showed markedly different partition (and diffusion) characteristics (87). When soybean meal and/or *Actinoplanes teichomyceticus* mycelium was present in Ca-alginate or κ-carrageenan gel beads, A40926 strongly partitions to the solid phase ($K > 10$).

In biofilms, the partition coefficient between the biomass and water is determined through isotherm experiments. For biofilms composed of *Xanthobacter autotrophicus* and *Pseudomonas* sp., a value of 1 was found for 1,1,2-trichloroethane (95). The partitioning coefficient of a model hydrophobic compound (α-pinene) was approximately 100 times smaller for the air/biofilm system (in a biofilter) compared to the air/water system, indicating that α-pinene has a higher degree of partitioning into the biofilm than into water due to the presence of solids (51).

49.2.4 Diffusion in Cell-Containing Matrices

The presence of immobilized cells in the immobilization matrix can have a substantial effect on the effective diffusion coefficient, especially at high biomass concentrations. Also, the effective diffusion coefficient decreases as a function of time in growing immobilized systems because the cell volume fraction increases. Diffusion in gels containing immobilized cells has been reviewed by Westrin and Axelsson (20). The influence of the cells on the effective diffusion coefficient can be described as

$$D_e = f(\phi_c, D_c) D_{e0} \tag{49.13}$$

where D_c is the effective diffusion coefficient within the cells and D_{e0} the effective diffusion coefficient in a cell-free matrix. Two theoretical approaches have been developed: (i) the cells are impermeable to the diffusing solute or (ii) the solute diffuses in the cells with a very low D_e. Suitable expressions have been derived for $f(\phi_c, D_c)$, which were based on heterogeneous media (151,152). Expressions could be classified into five model types: (i) the exclusion model, (ii) model of suspended impermeable spheres, (iii) model of suspended permeable spheres, (iv) capillary models, and (v) empirical models.

49.2.4.1 Exclusion Model. This model assumes that D_c is zero. The presence of the impermeable cells reduces the volume available for diffusion. Equation 49.12 can now be written as

$$D_e = (1 - \phi_c) D_{e0} \tag{49.14}$$

Using this equation, effective diffusion coefficients have been determined for substrate diffusion in Ca-alginate gel with entrapped deactivated yeast cells (49,72).

49.2.4.2 Model of Suspended Impermeable Spheres. This model regards the cells as impermeable spheres (D_c equals zero), which are suspended in a continuum. The expression for this model has been adapted from the expression derived by Maxwell (154) for effective conductivity in a composite medium of periodically spaced spheres:

$$D_e = \frac{1 - \phi_c}{1 + (\phi_c/2)} D_{e0} \tag{49.15}$$

This equation has been used to correlate experimental diffusion coefficients with immobilized mammalian cells in agar gel (52), coimmobilized *Aspergillus niger* and *Zymomonas mobilis* in Ca-alginate beads (83), *Saccharomyces cerevisiae* entrapped in Ca-alginate (155) and in artificial biofilms (agar containing inert polystyrene particles of the same size as bacteria) (21,22). Owing to limitations of Maxwell's model in other immobilized cell systems, a correlation was developed by using a scaling relationship (156):

$$D^*(\phi_c) = \frac{1 - D_e/D_{e0}}{1 - D_c/D_{e0}} \tag{49.16}$$

and a polynomial approximation to D^*:

$$D^*(\phi_c) = 1.7271\phi_c - 0.8177\phi_c^2 + 0.09075\phi_c^3 \tag{49.17}$$

Diffusivity values used for constructing the correlation were generated from Monte Carlo computer simulations.

49.2.4.3 Model of Suspended Permeable Spheres. This model assumes only permeable cells ($D_c > 0$). In this case, a more complex expression (adapted from (157)) has been derived:

$$D_e = \frac{2/D_c + 1/D_{e0} - 2\phi_c(1/D_c - 1/D_{e0})}{2/D_c + 1/D_{e0} + \phi_c(1/D_c - 1/D_{e0})} D_{e0} \quad (49.18)$$

Values for D_c/D_{e0} have been determined to be 0.31, 0.30, and 0.20 for fermentation media of *S. cerevisiae*, *Escherichia coli*, and *Penicillium chrysogenum*, respectively (158). Equation 49.17 has been used to correlate experimental diffusion coefficients in cell-containing gels (52) and dense cell suspensions (158,159).

49.2.4.4 Capillary Models. Capillary models have been developed to quantify the influence of the tortuosity on the effective diffusion coefficient, that is, the model of Kozeny (160) and the improved random pore model (161). This model has been adapted to immobilized cell systems where cells are considered as impermeable (i.e. $D_c = 0$):

$$D_e = (1 - \phi_c)^2 D_{e0} \quad (49.19)$$

Several investigators have used this equation to correlate the effective diffusion coefficient with the immobilized cell concentration (26,42,57,78,85,162–167). This random pore approach has been adapted to obtain an improved general diffusion model, which accurately includes systems containing impermeable or permeable cells (168):

$$\frac{D_e}{D_{e0}} = (1 - \phi_c)^2 + \phi_c^2 \frac{KD_c}{D_{e0}} + 4\phi_c (1 - \phi_c) \frac{KD_c}{D_{e0}} \left(1 + \frac{KD_c}{D_{e0}}\right)^{-1} \quad (49.20)$$

By introducing a complex tortuosity value, $\tau_c(\varepsilon_c) = 1/\varepsilon^\beta$ and $\tau_g(\varepsilon_c) = 1/\varepsilon^\gamma$ (where τ_c is the tortuosity created by the immobilized cells, τ_g the tortuosity of the gel matrix, and β and γ are order values ($\beta < 1$, $\gamma > 1$), Mota *et al*. (169) developed the following model:

$$\frac{D_e}{D_{e0}} = \frac{D_{eg}}{D_{e0}} (1 - \phi_c)^\alpha \quad (49.21)$$

with $\alpha = 1 + \beta + \gamma$ and where D_{eg} the effective diffusion coefficient in pure gel is. This model assumes a homogeneous cell distribution in the gel. For a nonhomogeneous cell distribution, composed of two layers (where the first layer contains all the immobilized cells and the second layer is free of cells), this model was rearranged to (170):

$$\frac{D_e}{D_{e0}} = \frac{(1 - \phi_{c1})^\alpha}{\delta + (1 - \phi_{c1})^\alpha (1 - \delta)} \quad (49.22)$$

where ϕ_{c1} is the cell volume fraction in the first layer and δ is the dimensionless thickness (= thickness of layer 1 divided by the total thickness).

49.2.4.5 Empirical Models. Prediction equations have been obtained by fitting some arbitrary function to experimental data (171). Empirical models are only valid for the studied gel material and immobilized cell type, and can only be used to predict D_e between the investigated boundaries. Ogston *et al*. (172) and Cukier (173) developed an empirical equation to describe the restricted diffusion of proteins in polymer gels:

$$\frac{D_e}{D_{e0}} = \exp\left(-Br_0 C_f^{1/2}\right) \quad (49.23)$$

where r_0 is the interaction radius between the protein and the polymer fibers, B a proportionality constant, and C_f the polymer (fiber) concentration in particles. This correlation allowed the estimation of several protein diffusivities in an agarose matrix based on the MW of the protein and the polymer concentration (125). Scott *et al*. (174) used the following correlation:

$$\frac{D_e}{D_{e0}} = 1 - 0.9\phi_c + 0.27\phi_c^2 \quad (49.24)$$

Korgel and coworkers (164) also developed the following empirical correlation:

$$\frac{D_e}{D_{e0}} = 1 - 2.23\phi_c + 1.40\phi_c^2 \quad (49.25)$$

49.2.4.6 Experimental Considerations. Some researchers have reported that the diffusivity was not influenced by the presence of cells. Kurosawa and coworkers (29) found that the oxygen diffusivity in Ca- and Ba-alginate was not influenced by the presence of immobilized yeast cells up to a cell density of 30 g DW/L. Estapé *et al*. (73) studied the influence of counterdiffusion of ethanol and glucose on the diffusion coefficients of glucose and ethanol respectively: there was no significant decrease of the diffusion coefficients in the presence of yeast cells when counterdiffusion was involved; without counterdiffusion the presence of cells resulted in a significant decrease of the diffusion coefficient for ethanol, but in contrast an increase was observed for the glucose diffusion coefficient.

In the determination of the effective diffusion coefficient in cell-containing matrices by methods based solely on diffusion, the solute may not react, or erroneous results would be obtained. In the literature, different methods have been described to deactivate living cells. Cells have been deactivated using ultraviolet radiation (30); heat (26,39,42,175–177); organic solvents like ethanol (53,72),

chloroform (178), and glutaraldehyde (52,179); (organic) acids like iodoacetic acid (49,155), ethyl acetate (180), and hydrochloric acid (78); toxins or inhibitors like mercuric chloride (21,22,30,181,182), dimethyl sulfoxide (58), and sodium azide (69,71); detergents, for example, Triton X-100 (159). Some researchers have investigated the effect of the deactivating agents on the effective diffusion coefficient. Matson (183) found that the deactivation process by mercuric chloride or heat had no effect on the diffusion process. The results of Dibdin (175) and McNee and coworkers (179) suggest that neither heat treatment nor glutaraldehyde fixation have a significant effect on the rate of diffusion through dental plaque. In contrast, Tatevossian (176,177) found a significant effect by using heat deactivation. Libicki and coworkers (159) found that the mass transport of nitrous oxide in aggregates of *E. coli* prepared from cells treated with detergents or disrupted by dehydration and grinding differed only slightly from the values obtained for aggregates formed from treated cells. Pu and Yang (58) observed that the permeabilization of apple cells with dimethyl sulfoxide led to an increase in effective diffusivity. Beuling *et al*. ((21,22) showed that glucose was excluded by deactivated (with mercuric chloride) *Micrococcus luteus* cells entrapped in agar, while the cells were somewhat permeable for oxygen.

Another strategy is to select a solute that will not be consumed by the microorganism, for example, nitrous oxide (159,185), inert gases (H_2, He, CH_4, C_2H_2, N_2O, $CHClF_2$, SF_6) (28), yohimbine, which is a secondary metabolite of plant cells (58); potassium chloride (44), galactose, which is not metabolized by *Z. mobilis* (162).

Itamunoala (116) compared three methods of determining D_e based on the shape of the matrix—designated (i) thin disc, (ii) cylinder, and (iii) beads types—and showed that, by using a sensitivity and error analysis, the thin disc and cylindrical techniques gave more accurate results than the bead method. Westrin and Zacchi (186) studied theoretically, the method of calculating diffusion coefficients in gel beads based on transient experiments of solute uptake from a finite volume. Monte Carlo simulations were used to investigate the effect of random errors on concentration measurements. The influence of sampling frequency and diffusion direction was investigated. Systematic errors derived from an assumption of constant diffusion coefficient and of monodisperse beads were also investigated.

49.2.5 Diffusion in Gels

A lot of research has been performed on the diffusion in polymeric gels with and without encapsulated cells. Various values of measurements of diffusion coefficients in cell-free and cell-containing gels are presented in Refs 20 and 159; Willaert and Baron (187–189,168).

Size exclusion chromatography (SEC) has been used to study the porosity of alginate gels (190–192). Smidsrød (190) studied the porosity of alginate gels using scanning electron microscopy and found that there was a very broad distribution in pore diameter, ranging from 5 to 200 nm. Globular proteins with radii of gyration of approximately 3 nm and with net negative charges should therefore not be trapped in the alginate network, but be able to diffuse at a rate dependent upon their sizes (76). In contrast, Klein *et al*. (191) showed, using SEC and dextrans of known size, that the pore diameters in Ca-alginate gels were fairly uniform. The exclusion volumes for standard macromolecules were recorded and values of 6.8, 14.1, and 16.6 nm were estimated for three different alginates. SEC with 2% Ca-alginate beads using proteins of known Stokes radii indicated a pore diameter of 8–10 nm when eluents of 30 and 150 m*M* $CaCl_2$ were used at pH 6.2 (192). The whey proteins, α-lactoalbumine and β-lactoglobulin, easily penetrated the alginate pores and no proteins had complete access to the total internal volume of the matrix. Polakovic (193) used SEC to evaluate the pore size distribution of 5% Ca-pectate gel and predicted—using a cylindrical and slit-pore model—pore diameters of 50 and 35 nm respectively.

From pore size distribution studies using electron microscopy (194), it was suggested that there is a more constricted network on the bead surface than in the gel core. Skjåk-Bræk and coworkers (195) found that the alginate structure is governed not only by the concentration and chemical structure of the gel material, but also by the kinetics of gel formation. They showed that gels with varying degrees of anisotropy (heterogeneity) can be prepared by controlling the kinetics of the process. Therefore, it is difficult to compare the different diffusion coefficients reported by different workers because of the considerable variations in the experimental conditions of preparing alginate gels. When gels were formed in the presence of antigelling cations, such as Na^+ or Mg^{2+}, isogeneous Ca-alginate gels were obtained (196). Such beads were mechanically stronger and had a higher porosity than those formed in the absence of antigelling ions. Klein and coworkers (191) have reported that glucoamylase is retained for many days in ferric-alginate gel, although it is lost from Ca-alginate or Al-alginate beads. Gray and Dowsett (197) showed that insulin may be entrapped in zinc alginate and Zn–Ca alginate gels.

The average pore diameters of alginate and agarose gels have been estimated from the following semiempirical expression, often used to describe the diffusion of solutes in porous materials and originally derived by Renkin (198) to characterize the diffusion of protein molecules through

cellulose membranes (81):

$$\frac{D_{gel}}{D_a} = \left(1 - \frac{d}{\delta_p}\right)^2 \left\{1 - 2.104\left(\frac{d}{\delta_p}\right) + 2.09\left(\frac{d}{\delta_p}\right)^3 - 0.95\left(\frac{d}{\delta_p}\right)^5\right\} \qquad (49.26)$$

where δ_p is the average pore diameter of the gel and d is the hydrodynamic diameter of the solute. This equation accounts for steric and frictional hindrance to diffusion under Stokes flow conditions, but neglects charge related interactions between solute and matrix. The effect of varying crosslinking condition, polymer concentration, and direction of diffusion on transport for alginate and agarose gels have been investigated (81). In general, 2–4% agarose gels offered little transport resistances for solutes up to 150 kDa, while 1.5–3% alginate gels offered significant transport resistances for solutes in MW range 44–155 kDa—lowering their diffusion rates from 10- to 100-fold as compared with their diffusion in water. Doubling the alginate concentration had a more significant effect on hindering diffusion of larger MW species than did doubling the agarose concentration. Average pore diameters of approximately 170 and 147 Å for 1.5% and 3% agarose gels, respectively, and 480 and 360 Å for 2% and 4% agarose gels, respectively, were estimated using Equation 49.25.

For the case where multiple cellular inclusions (e.g. bacterial or fungal microcolonies or mammalian spheroids) are distributed in a continuous phase (i.e. hydrogel), molecules diffuse more slowly in the cell phase than in the continuous phase. Numerical (finite difference) techniques have been developed to calculate the effective diffusivities (199).

49.2.5.1 Influence of Gel Type and Concentration. Studies on the diffusion of nicotinamide adenine dinucleotide (NAD) and hemoglobin in Ca and Ba-alginate gels showed that NAD diffusion characteristics are unaffected by alginate (from 2.5% to 4% w/v) and calcium chloride (from 0.125 to 0.5 M) concentrations. However, hemoglobin diffusion was affected by the alginate concentration (200). Hannoun and Stephanopoulos (53) demonstrated that D_e for ethanol and glucose decreased when the alginate concentration was increased from 1% to 4% (w/v). Itamunoala (115) showed that by increasing the concentration of either the calcium chloride (1–4% w/v) or Na-alginate (2–8% w/v) component used in Ca-alginate formation substantially decreased D_e, but the effect of the alginate was the greater of the two. A slight reduction of the product of K and D_e for oxygen was found when the alginate concentration was increased from 2% to 4% (w/v) by Sun and coworkers (42). In contrast, Tanaka *et al*. (60) demonstrated that the diffusion of solutes with a MW less than 2×10^4 (glucose, L-tryptophan, and α-lactoalbumin) was not disturbed by increasing the alginate concentration (2–4% w/v) and $CaCl_2$ concentration used in the gel preparation; and diffusion coefficients comparable with those in water were found. For larger molecules such as albumin, γ-globulins, and fibrinogen, the diffusion in the gel was retarded to an extent that depended upon the concentration of alginate and $CaCl_2$ concentration. Moreover, these proteins could diffuse out of, but not into the beads. Therefore, it was suggested that the structure of Ca-alginate gel formed in the presence of large protein molecules was different from that of the gels formed in their absence. Axelsson and Persson (49) also found that the dependence of D_e on the alginate concentration (in the range 1.4–3.8% w/w) for glucose, lactose, galactose, and ethanol was negligible. Hulst and coworkers (67) examined the influence of the concentration of Ca-alginate, gellan gum, κ-carrageenan, agarose, and agar on D_e for oxygen. For agarose and agar, D_e decreased when the gel concentration was increased from 2% to 8% (w/v). Gellan gum and alginate showed a remarkable maximum value for the diffusion coefficient with respect to the gel concentration: at 1% and 2% (w/v) respectively. κ-Carrageenan had a maximum at 5% (w/v) in the concentration range of 1–5% (w/v). The effective diffusion coefficient determined in pure 2% alginate beads was 10–25% lower than the diffusivity in water for various solutes, and a 4% alginate concentration decreased D_e, corresponding well with increased inclusion effect due to the increase in polymer concentration (79). Chen *et al*. (201) used a linear absorption model (LAM) and a shrinking core model (SCM) to interpret the diffusion data of Cu^{2+} in Ca-alginate over a biopolymer range from 2% to 5%. The diffusion coefficient of Cu^{2+} calculated from the LAM was independent of the biopolymer concentration. The LAM had theoretical advantages over the SCM; the latter calculated an unreasonable exponential increase in the diffusion coefficient as the density of the alginate concentration increased. The diffusivity of Cu^{2+} in Ca-alginate increased by a factor of 2 when the gel concentration was increased from 2% to 5% (w/v) (202,203). The decrease of D_e for Remazol Black B (azo dye) in PVA could be described by the Phillies model up to a ϕ_p value of 0.08 m^3 PVA/m^3 gel (26).

The diffusion of solutes in alginate gel is also affected by the chemical composition of the alginate. Martinsen and coworkers (76) showed that the diffusion coefficient of albumin in 4% *Laminaria digitata*, *Macrocyctis pyrifera*, and *L. hyperborea* Ca-alginate gels decreased with decreasing content of guluronic acid (GG) and with any decrease in the average length of the GG blocks. Itamunoala (115) found a glucose diffusion coefficient which was slightly higher for Manutex RS gel compared with Manutex RH gel.

The effective diffusivity of sucrose in agar (0.5%, 1.0%, and 1.5% w/v) was similar to that in water (50). Dextran fractions (MW range from 10.5 to 1950 kDa) displayed restricted diffusion in the agar membranes. Their D_e values were a decreasing function of the agar content of the gel membrane. The diffusivity in a given membrane decreased as the MW of the diffusing molecule increased. The diffusion data did not agree with the Renkin model for a hard sphere diffusing through a cylindrical pore. Beuling *et al*. (23) studied the influence of agar concentration on the diffusion coefficient of glucose by using pulsed field gradient-nuclear magnetic resonance (PFG-NMR). The obtained values corresponded with the ones predicted by the model of Mackie and Meares.

The diffusivity of glucose in κ-carrageenan was affected by the presence of other solutes in the glucose solution (61): electrolytes such as ammonium sulfate, potassium chloride, and calcium chloride were observed to enhance the diffusion coefficient. Estapé *et al*. (73) demonstrated that the effective diffusion coefficients of glucose and ethanol were significantly reduced in the presence of counterdiffusion of ethanol and glucose, respectively.

It was found that lactic acid modified the structure of κ-carrageenan (2.75% w/w)/locust bean gum (0.25% w/w) gel (71), since lactose diffusion characteristics (D_e and K) differed significantly from other studies. Øyaas *et al*. (79) found that D_e for lactose and lactic acid in Ca-alginate were constant between pH 5.5 and 6.5, but significantly reduced at pH 4.5.

Renneberg and coworkers (93) investigated the influence of different variables on the oxygen diffusivity in gels derived from prepolymers. A series of ENT-type (prepared from hydroxyethylacrylate) hydrophilic polymers showed a steady increase in water content and diffusivity with increasing chain length of the prepolymers from 10 to 60 nm. The slightly higher diffusivity of the anionic ENT-type polymer compared with the cationic type seemed to be due to the lower water content rather than to electronic charges. The PVA-SbQ gels have a higher water content and also a higher diffusivity than the polymers of ENT-type. The polymers with 22-nm distance between the photofunctional groups showed a higher O_2 diffusion than the polymers with 6.6 and 6.5-nm distance. The PVA-SbQ 1800-100 with the highest polymerization degree (1800) and the highest saponification (100%) had the highest water content (94.2%) and the highest O_2 diffusivity.

The diffusion of negatively charged nitrate, positively charged ammonium, and a noncharged heavier molecule (glycerol) through Ca-alginate beads at pH 7.5 have been studied (88). When the residence time of gel beads in $CaCl_2$ solution was increased from 10 to 30 min, 30% more nitrate diffused in the gel, and when the alginate concentration was increased from 3% to 6%, 25% less nitrate diffused out of the beads. The diffusion of glycerol was faster than for nitrate. On the contrary, significantly less diffusion through the gel was measured for the ammonium ion. These results suggest that electrostatic interactions affect the diffusion process through Ca-alginate.

49.2.5.2 Influence of the Temperature. The influence of the temperature on the glucose diffusion in 3% (w/v) κ-carrageenan has been investigated in a temperature interval between 10 and 33°C (61). The diffusivity remained unchanged in the interval from 10 to 25°C; from 25 to 32°C, the diffusivity increased linearly from 3.73×10^{-10} to 6.10×10^{-10} m^2/s. This behavior was explained by the fact that the diffusion in the gel system is governed by the bead pore size as well as by the viscosity of the gel. The κ-carrageenan gel viscosity remains unchanged at temperatures below 20°C, and the viscosity decreases when the temperature increases above 2°C. The D_e values of glucose and galactose in κ-carrageenan (2.5% w/v) increased when the temperature was increased from 10 to 25°C and 32°C (55). The diffusion coefficient of glucose, lactate, hydroquinone, and urea in 2% collagen and 1% agar increased when the temperature was raised from 25 to 37°C (52). The temperature dependence of glucose in 3% (w/v) Ca-alginate followed the Arrhenius relation with an activation energy of 4350 J/mol (204). D_e of glucose increased from 6.1×10^{-6} to $7.8 \times 10 - 6$ m^2/s and the value for ethanol from $1.0 \times 10 - 6$ to 1.2×10^{-6} m^2/s in 2% Ca-alginate, when the temperature was increased from 22 to 30°C (54). Martinsen *et al*. (76) calculated the activation energy as 23.5 kJ/mol for the Arrhenius temperature dependence of the diffusion of albumin in 4% (w/v) Ca-alginate. The temperature dependency of the diffusion coefficients for lactose and lactic acid in Ca-alginate were found to be well described by an Arrhenius-type equation (49.70). The activation energy was constant in the temperature range tested (10–55°C), and was found to be 20.0 kJ/mol for lactose and 19.1 kJ/mol for lactic acid.

49.2.5.3 Influence of the pH. Because the alginate gel matrix is negatively charged, the pH influences the diffusion of charged substrates and products. Most proteins are negatively charged at pH 7 and will not easily diffuse into the gel matrix. However, when immobilized in the gel, they tend to leak out more rapidly than would be expected from their free molecular diffusion. The rate of diffusion of BSA out of alginate beads increased with increasing pH, due to the increased negative charge of the protein (76).

49.2.5.4 Influence of the Concentration of the Diffusing Compound. Teo *et al*. (204) found that the effective diffusion coefficient of glucose in 3% (w/v) Ca-alginate is independent of the glucose concentration over the range from 10 to 150 g/L. Concentrations of glucose

in the range 2–100 g/L and ethanol in the range of 10–80 g/L did not affect their diffusion coefficients in Ca-alginate (53). In contrast, Itamunoala (115) showed that only at low glucose concentrations was the glucose diffusivity in Ca-alginate higher. The diffusion of glucose in κ-carrageenan decreased when the glucose concentration was increased from 6.5 to 65 g/L (61). There was a minimal change in the measured values of the diffusion coefficients of Remazol Black B (azo dye) in PVA gel beads in a concentration range of 50–1000 mg/L (26).

Most of the reported effects can be explained on the basis of: a change in tortuosity τ or porosity ε change in partition coefficient, interaction of large molecules with the polymer network of the matrix, interaction between different diffusing solutes, and effect of the temperature.

49.2.6 Diffusion in Dense Cell Masses

49.2.6.1 Diffusion in Biofilms. Table 48.3 gives values of relative effective diffusive permeabilities and Table 48.4 values for effective diffusion coefficients for biofilms. The relative effective permeability (D_e/D_a) is defined as the ratio of the effective diffusive coefficient D_e (is also called *effective diffusive permeability*) of the biofilm to the diffusion coefficient D_a in water (159). The relative effective diffusion coefficient ($\mathcal{D}_e/D_a$) is the ratio of the effective diffusion coefficient to the diffusion coefficient in water, where $\mathcal{D}_e$ is defined as

$$J = -\mathcal{D}_e \nabla C_L \tag{49.27}$$

Effective diffusion coefficients and effective diffusive permeabilities have different applications (241). For analysis of phenomena involving reaction–diffusion interactions, the effective diffusive permeability (coefficient) D_e is the correct parameter. The effective diffusion coefficient D_e is appropriate for the analysis of unsteady behavior of a nonreactive solute.

Experimental measurements of relative effective diffusive permeabilities in biofilms range widely, but most of the variation can be attributed to differences in solute physical chemistry and in biofilm density (cell and extracellular polymeric substances) (241). Three categories of solute physical chemistry were distinguished: ionic solutions (inorganic anions or cations), small solutes (nonpolar solutes with MWs of 44 or less), and large solutes (organic solutes of MW greater than 44). It was proposed that large solutes are effectively excluded from microbial cells, that small solutes partition into and diffuse within cells, and that ionic solutes are excluded from cells but exhibit increased diffusive permeability (but decreased effective diffusion coefficients) due to sorption to the biofilm biomass.

Diffusion coefficients were found to be dependent on the biomass concentration, C/N ratio in the growth medium, temperature (40), and sludge age (30). Diffusion studies of lactose in acidogenic biofilms revealed that the active biofilms had about 66% void volume made up of channels through which the lactose molecules were transported into the bacterial aggregate (35). The decrease in lactose diffusivity was mainly caused by the biofilm's solid biomass fraction rather than by the tortuosity of the channels. The influence of the diffusion potential and the Donnan potential in grown biofilms have been evaluated by comparing the diffusion coefficients of positively and negatively charged ions, and a neutral molecule in experiments with different background electrolyte concentrations (238). Mass transfer effects by electrostatic forces are negligible at the ionic strength of wastewater and tap water. Holden and coworkers (228) determined the diffusion coefficient of toluene as a function of the water potential through unsaturated *Pseudomonas putida* biofilms. The effective diffusion coefficient for toluene was approximately 2 orders of magnitude lower than the diffusivity in water and did not vary markedly with the water potential.

Diffusion coefficients have been evaluated using only particulate biomass filtered onto a membrane (30,222,242). Another technique is to use an inactivated biofilm. The diffusion coefficient of a model hydrophobic compound (α-pinene) through irradiated leachate from biofilters has been determined using a diffusion cell (51).

The biofilm has been assumed to be a homogeneous phase in which mass transport is described by Fickian diffusion. More recently, insight into biofilm structures have led to the recognition that the biofilm is heterogeneous, and mass transfer also occurs by eddy diffusion and convection in the voids or channels and diffusion through the bacterial cells (95,103,105,238–240,243–249).

A 2-D and 3-D model have been developed to evaluate the effect of convective and diffusive substrate transport on biofilm heterogeneity (250). It was found that in the absence of detachment, biofilm heterogeneity is mainly determined by internal mass transfer rate and by initial percentage of carrier-surface colonization. Model predictions showed that biofilm structures with highly irregular surface develop in the mass transfer-limited regime. As the nutrient availability increases, there is a gradual shift toward compact and smooth biofilms. A smaller fraction of colonized carrier-surface leads to a patchy biofilm. Biofilm surface irregularity and deep vertical channels are caused by the inability of the colonies to spread over the whole substratum surface. The maximum substrate flux to the biofilm was greatly influenced by both internal and external mass transfer rates, but not affected by the inoculation density.

A technique, which is based on microinjection of fluorescent dyes and analysis of the subsequent plume formation using confocal laser microscopy, has been used to study the liquid flow in aerobic biofilms (251), and to determine

the local diffusion coefficients in biofilms (119). The diffusion coefficients of fluorescein (MW 332), tetramethyl rhodamine iso-thiocyanate (TRITC)-IgG (MW 150,000), and phycomerythrin (MW 240,000) were measured in the cell clusters and interstitial voids of a heterogeneous biofilm.

Zhang and coworkers (95) used a single tube extractive membrane bioreactor (STEMB) for the determination of the effective diffusion coefficient for a nonreactive tracer (1,1,2-trichloroethane). A video imaging technique was used for the *in situ* measurement of biofilm thickness and continuous monitoring and recording of biofilm growth during experiments.

Bryers and Drummond (132) refined an alternative analytical technique to determine the local diffusion coefficients on a microscale to avoid the errors created by the biofilm architectural irregularities. This technique is based upon fluorescence return after photobleaching (FRAP), which allows image analysis observation of the transport of fluorescently labeled macromolecules as they migrate into a microscale photobleaching zone. The technique allows mapping of the local diffusion coefficients of various solute molecules at different horizontal planes and depths in a biofilm. These mappings also directly indicate the distribution of water channels in

the biofilm. FRAP results indicate a significant reduction in the solute transport coefficients in biofilm polymer gel versus the same value in water, with the reduction being dependent on solute molecule size and shape.

Beuling *et al*. (23) used PFG-NMR to measure the water mobility inside complex heterogeneous systems like natural and active biofilms. Diffusion coefficients measured in both well-defined biofilms and spontaneously grown aggregates corresponded well to glucose diffusion coefficients determined in the same matrices. Diffusion coefficients of the natural biofilms could be related to their physical characteristics. The monitored PFG-NMR signal contained supplementary information on cell fraction or spatial organization, but quantitative analysis was not yet possible.

Wood and coworkers (252) developed a scheme for numerically calculating the effective diffusivity of cellular systems such as biofilms and tissues. A finite difference model was used to predict the effective diffusivity of a cellular system on the basis of subcellular scale geometry and transport parameters. These predictions were compared with predictions from simple analytical solutions (253,254) and experimental data. Their results indicate that under many practical experimental circumstances, the simple analytical solution can be used to provide reasonable estimates of the effective diffusivity.

49.2.6.2 Diffusion in Bioflocs. Microbial flocs have been reviewed by Atkinson and Daoud (255), and Kosaric and Blaszczyk (256). Yeast flocculation has been reviewed by Speers *et al*. (257), Stratford (258), Straver *et al*. (259), Teunissen and Steensma (260), and Dengis and Rouxhet (261). The growth and modeling of the growth of fungal pellets have been reviewed by Whitaker and Long (262), Metz and Kossen (263), Nielsen (264), Nielsen and Carlsen (265), and Nielsen *et al*. (266). Examples of diffusion data for bioflocs are shown in Table 48.5.

Smith and Coackley (182) used surface area determinations to calculate the mean pore radius of activated sludge flocs. This value was found to be between 108 and 130 Å. The tortuosity of the pores in activated sludge (3–9% solids) was also calculated and found to have an average value of 2.73. Libicki and coworkers (159) determined the effective diffusive permeability in aggregates of *E. coli* confined in hollow fiber reactors. It was found that the effective diffusive permeability decreased with increasing cell volume fraction to a value, for aggregates comprising 95% cells, of approximately 30%, than that obtained for cell-free buffer solution. The dependence on the cell volume fraction was described adequately by the Hashin–Shtrikman bounds for a two-phase medium (273):

$$K_2D_2 + \frac{f_1}{\dfrac{f_2}{3K_2D_2} + \dfrac{1}{K_1D_1 - K_2D_2}} \le D_e \le K_1D_1 + \frac{f_2}{\dfrac{f_1}{3K_1D_1} + \dfrac{1}{K_2D_2 - K_1D_1}} \tag{49.28}$$

where f_1 and f_2 are the volume fractions; K_1 and K_2 are the partition coefficients; and D_1 and D_2 are the solute diffusion coefficients for the two components (cells and interstitial fluid), with the indices chosen such that $K_2D_2 \le K_1D_1$.

Mass transfer limitations into fungal pellets is usually due to intraparticle diffusion (266). External mass transport resistance should be taken into account only when intraparticle mass transfer is severe. The average pellet density is found to increase with decreasing pellet radius, and the porosity is related to the pellet density (274):

$$\varepsilon = 1 - \frac{\rho_{\text{pellet}}}{\rho_{\text{hyph}}\,(1-\omega)} \tag{49.29}$$

where ρ_{pellet} is the average pellet density, ρ_{hyph} the hyphal density, and ω is the thickness of the active biomass layer

in a pellet. Metz (274) found that for *P. chrysogenum*, the average density of the pellet varies between 15 and 100 kg/m^3, and the porosity is in the range of 0.70–0.95. Similar values for the density of *P. chrysogenum* (275–277) and *A. niger* (267) pellets have been reported. The critical pellet radius for various concentrations of these substrates in the medium have been calculated using the appropriate reaction–diffusion model (265). It was observed that except for low glucose concentrations, it is most often oxygen that becomes the limiting substrate in the pellet. For pellets with a radius larger than the critical radius, there is an active growth layer. The active layer thickness depends on the pellet size. Wittler *et al*. (110) recorded the oxygen concentration profile in *P. chrysogenum* pellets using a microelectrode and found that the critical radius was in the range of 100–400 μm depending on the pellet structure and operation conditions. It was found that—as a result of zero oxygen concentration in the center of the pellet—cell lysis occurred, which led to the appearance of hollow pellets. Microelectrode studies by Cronenberg *et al*. (112) also showed that internal mass transport properties of *P. chrysogenum* pellets were highly affected by their morphological structure. Relatively younger pellets possessed a homogeneous and dense structure. These pellets were partly penetrated by oxygen at air-saturated bulk conditions. Older pellets were stratified and fluffy. They were completely penetrated by oxygen due to a decreased activity and a higher diffusivity. Investigations with glucose microelectrodes revealed that glucose consumption inside pellets of all lifetimes exclusively occurred in the periphery, indicating that growth was restricted to these regions only.

Usually, it is assumed that intraparticle molecular diffusion is the only mass transfer mechanism (for earlier work, see e.g. Refs 109,267,268,279,280). However, despite the low density difference between pellets and the bulk medium, some convective flow into the pellets can occur (110,281).

49.2.6.3 Diffusion in Mammalian Cell Aggregates. The Krogh's diffusion constant and the diffusion coefficient of various inert gases have been determined in rat skeletal muscle (38) (Table 48.6). Graham's law (inverse proportionality between the diffusion coefficient and the square root of the molecular mass) was found to represent a useful approximation for these gases. However, a better correlation between the diffusion coefficient and the molecular diameter was found.

The diffusion of ^{3}H-inulin (which does not penetrate the intact cell membrane of mammalian cells) in two types of multicell tumor spheroids have been studied (59). It was found that the value of the diffusion coefficient in spheroids with a smaller extracellular space was significantly larger than in spheroids with a higher extracellular space. It was suggested that the way the cells attach to each other and the extracellular matrix is responsible for this difference.

The diffusion of fluorescein isothiocyanate conjugated BSA, a graded series of FITC-dextrans and sodium fluorescein in both normal tissue and tumors grown in a rabbit ear chamber have been determined (282). Apparent interstitial diffusion coefficients showed a relationship with molecular size, which progressively deviated from that of free diffusion in a single solute, single phase system with values of albumin being significantly reduced from that for a dextran of equivalent hydrodynamic radius. Macromolecular transport in tumor tissue was hindered to a lesser extent than in normal tissue, which was consistent with reports of reduced glycosaminoglycan (GAG) content of tumors.

49.2.7 Diffusion in Microcapsules

The permeable membrane of a microcapsule introduces a supplementary mass transfer barrier compared to gel beads. The core of the microcapsule can be composed of cells in a liquid solution, cells in gel phase, or a combination of both. In the latter case, three mass transfer layers are present. A model for the transient diffusion of proteins from a bulk solution into microcapsules has been developed (284,285). It was used to describe the experimental concentration profiles and to determine the membrane diffusion coefficient of alginate-poly-L-lysine-alginate capsules. By introducing an effective volume fraction as parameter in the model, microcapsules with different sizes of impermeable gel cores could be studied. It was found that the ability of proteins to diffuse into the capsule was not only controlled by the membrane diffusivity, but also by the amount of Ca-alginate core remaining in the microcapsule. Diffusion of glucose, lactose, tyrosine, glutamic acid, and phenylalanine into intrahollow Ca-alginate microcapsules has been studied (89). The combined (microcapsule membrane and core solution) diffusion coefficients were 2–12% smaller than the diffusion coefficients in pure water.

The permeability of the capsule membrane is often characterized by the MW cut-off. Encapsulated cells for tissue engineering applications are better protected from the host's immune system (286,287,409). The application of microcapsules for immunoisolation required a membrane with a MW cut-off of around 50,000 to prevent the permeability of cytotoxic antibodies (288). The permeability of a membrane for a certain compound is not only dependent on the pore size and structure but also on other physical characteristics such as the hydrophobicity/hydrophilicity and charge, and the nature of the solute molecule (e.g. electrostatic interactions between proteins and synthetic polymers).

Measurement of the rate of glucose diffusion from EUDRAGIT RL and hydroxyethyl methacrylate-methyl methacrylate (HEMA-MMA) microcapsules with a Thiele modulus/Biot number analysis of the glucose utilization

rate suggested that pancreatic islets and CHO cells (at moderate to high cell densities) were not adversely affected by the diffusion restrictions associated with these capsule membranes (289). Oxygen transfer through a cellulose sulfate capsule membrane could be measured using a microcoaxial needle electrode (108). Additionally, it was measured that in the case of entrapped yeast cells in the liquid core of the microcapsule, the oxygen supply to the cells was (in the investigated case) not critically influenced by the thin polymeric wall of the capsule.

The evaluation of the mass transfer coefficient (k_s) value was proposed as a supplementary method for the characterization of microcapsules (and gel beads) with semipermeable membranes (290). Owing to a good linear correlation between k_s and the capsule diameter, each investigated capsule type could be characterized by a unique k_s/diameter value.

By manipulating the parameters involved in membrane manufacturing such as the MW and concentration of the membrane forming molecules, the reaction time, polymerization conditions (temperature, pH, ionic strength, ...), addition of (an) additional layer(s) at the outside of the capsule (usually to improve the biocompatibility). Permeation can also be influenced by changing size, swelling, and shape of the capsules (291).

A heterogeneous mixture of dextrans of different MWs (MW 10,000–500,000) has been used as a test solute to study the membrane permeability of alginate polylysine microcapsules (292). The diffusion experiment revealed that the permeability of alginate polylysine (APL) microcapsules decreased with dextrans with MW larger than 80,000. At equilibrium, dextrans of MW 104,000–112,000 represented only approximately 50% of dextrans of equivalent MW outside of microcapsules. The microcapsule membrane does not show a distinct MW cut-off to dextran, but spans a very wide range of at least 80,000–110,000. It is suggested that this can be due to differences in permeability between microcapsules within a batch or to a nonuniform membrane.

Awrey *et al*. (293) have constructed a series of genetically modified cell lines secreting recombinant gene products (human growth hormone, rat serum albumin, human arylsulfatase A, human immunoglobulin, mouse β-hexosaminidase, mouse β-glucuronidase) of different MWs ranging from 21 through 150–300 kDa. They investigated the delivery of these products by alginate-PLL-alginate microcapsules enclosing these

producer cell lines. It was found that the secretion rates of the gene product were similar between nonencapsulated and encapsulated cells with the exception of the largest molecule (the 300-kDa β-glucuronidase), which showed an eightfold reduced secretion. Increasing the thickness of the PLL-membrane did not provide a lower MW cut-off; and an additional coating with alginate reduced the leakage of the larger molecular species but the effect was short lived. Hence, they concluded that immunoisolation of encapsulated cells with alginate-PLL-alginate microcapsules cannot provide a MW cut-off below 300 kDa.

Bacterial cellulose membranes can be used for cell encapsulation since they possess excellent mechanical strength, are biocompatible and simple to produce. Diffusion coefficients of various dextrans (MW 44–260 kDa) in bacterial cellulose have been determined (294). Also the permeation and diffusion coefficients of three marker molecules (Vitamin B_{12}, lysozyme, and BSA) were measured. Using microaxial needle electrodes, oxygen kinetics in different penetration depths within cellulose sulfate hollow spheres loaded with and without yeast cells could be measured (108). On the basis of reaction kinetics, the diffusion coefficient for oxygen and the oxygen uptake rate were calculated.

49.2.8 Internal Mass Transfer by Convection

Most cell aggregates have a dense structure with either a microporous matrix material between the immobilized cells or with closely packed cells. No significant transport by convection through this type of aggregate can occur. There are two exceptions: membrane immobilization and preformed large pore carriers (295).

Membrane immobilized cells can easily be subjected to convective flow or perfusion by applying a pressure difference across the layer. When porous particles are exposed to a pressure gradient (e.g. packed bed), a flow through such particles can occur. Considering the strong diffusion limitations occurring even with very thin immobilized cell layers, convective transport can easily remove this limitation, even at low pressure drops. The flow velocity (v) through a layer of thickness L with a pressure drop (Δp) is given by Darcy's equation:

$$v = \frac{k}{\mu}\frac{\Delta p}{L} \tag{49.30}$$

where μ is the fluid dynamic viscosity and k the hydraulic permeability of the material. With a solute concentration of C_i, the convective flux (J_{conv}) is then given by

$$J_{\text{conv}} = v\, C_i \tag{49.31}$$

This flux should be compared with the diffusional flux, which is of the order:

$$J_{\text{diff}} = D_{\text{e}}\frac{C_i}{L} \tag{49.32}$$

Rewriting the convection equation (Eq. 49.29) in terms of diffusion, gives

$$J_{\text{conv}} = D_{\text{conv}}\frac{C_i}{L} \tag{49.33}$$

with

$$D_{\text{conv}} = \frac{k\,\Delta p}{\mu} \tag{49.34}$$

which should be compared to the effective diffusion coefficient (D_{e}) to determine which of them—the highest—dominates the transport. In the case of a layer with Δp across it, the estimation is simple. Measuring the flow through a slab for a known pressure difference allows for experimental determination of k with Equation 49.29. If we approximate the porous layer by a dense aggregate of spherical particles with diameter d_{p}, the permeability can be estimated from the Kozeny equation (160):

$$k = \frac{d_{\text{p}}^2\varepsilon^3}{180(1-\varepsilon)^2} \tag{49.35}$$

where ε is the porosity. Particle or pore size distribution and shape have a strong influence and d_{p} should be considered as an effective pore size parameter. To estimate the convective flux in a porous particle, say in a packed bed reactor, a similar equation can be used but a geometric correction factor has to be included. The flow will be larger in the outer layer of this particle and only a fraction of the flow will penetrate the central region. Although not exact, Equation 49.33 can be compared to D_{e} to verify if convection plays a role or not in the internal transport. A major difficulty is the estimation of k (or ε or d_{p}) when cells start to fill the pores.

It has been recognized that intraparticle convection can be significant for large pore (bio)catalysts, especially in the case of liquid phase reactions when intraparticle diffusion is too slow to provide full utilization of the internal catalytic capacity (281,296–298). The quantification of the intraparticle fluid velocities is not a straightforward matter. Only for some special cases, like creeping flow of Newtonian fluids relative to permeable spheres, the equations of motion and continuity can be solved analytically. The magnitude of the intraparticle fluid velocity will determine the relative importance of intraparticle convection in the

mass transfer process. Usually an intraparticle Peclet number is defined, which is the ratio between the convective and diffusive flows:

$$Pe = \frac{L v_{\text{int}}}{D_{\text{e}}} \tag{49.36}$$

where v_{int} is the intraparticle convection velocity, and L is the characteristic dimension of the biocatalyst. To explain the dependency of measured effective diffusion coefficients on the flow rate in packed beds of porous particles, an apparent effective diffusion coefficient ($D_{\text{e,app}}$) has been defined (297). $D_{\text{e,app}}$ lumps intraparticle convection and intraparticle diffusion. By comparing the results in packed beds of porous particles, the following simple relationship has been derived:

$$D_{\text{e,app}} = \frac{D_{\text{e}}}{f(Pe)} \tag{49.37}$$

with

$$f(Pe) = \frac{3}{Pe}\left(\frac{1}{\tanh(Pe)} - \frac{1}{Pe}\right) \tag{49.38}$$

or $f(Pe)$ can be any suitable function. Intraparticle convection in immobilized porous cell systems can be accounted for in a very simple manner by using an apparent effective diffusion coefficient instead of the real effective diffusivity in the mass balance equations (14,15,299).

Fluid flow and mass transfer phenomena in porous particles can be obtained from residence time distribution (RTD) experiments where a pulse or step in tracer concentration is applied at the inlet of a packed bed of porous particles and the tracer concentration is measured as a function of time in at least one location of the reactor (usually at the outlet of the reactor). The flow pattern in the interstitial spaces can be represented as axially dispersed plug flow (300). As the fluid velocities inside the porous particles are small compared to the interstitial fluid velocities, the fluid phase inside the porous particles can be considered as a stagnant volume. The solute (tracer or substrate) is exchanged between the extraparticle fluid phase and the stagnant volume by diffusion, convection, or a combination of both. However, the mass transfer process is described by a diffusion equation, which is characterized by the apparent effective diffusivity. RTD experiments have been performed to characterize mass transport in porous glass beads. The value of the apparent effective diffusivity for porous glass beads was obtained by fitting experimental data to model predictions (301). The RTD profiles obtained from experiments performed in the presence of immobilized *S. cerevisiae* cells were hardly influenced by the presence of these cells (302). Only for a high biomass loading at high liquid flow rates, was a noticeable change in RTD profiles observed. Computer simulations revealed that due to the presence of immobilized cells, the reduction in mass transfer rate between extraparticle and intraparticle fluid phase is compensated partially by a decrease in intraparticle porosity.

The effect of intraparticle convection on nutrient transport in porous biological pellets has been studied (281). It was shown that the intrapellet (Pe_{in}) and extrapellet Peclet numbers (Pe_{out}) are generally related by a linear scaling relationship—$Pe_{\text{in}} \sim \xi\, Pe_{\text{out}}$—where ξ is a small number proportional to the hydraulic permeability of the particle and inversely proportional to the square of the characteristic length. External transport was further studied and found to be unaffected by intraparticle flow.

Although internal convection in particles or perfusion in membrane systems is an excellent means to reduce or eliminate mass transfer limitations, it should be clear that this will occur only with exceptionally large pores or pressure drops, respectively.

49.3 EXTERNAL MASS TRANSPORT

Mass transport for solutes to the immobilized cells and the removal of products from the aggregate is usually by convection. In some special situations, like, for example, aggregates not in a mixed part of a bioreactor or encapsulated cells in human tissue, mass transport is only by diffusion. We will discuss the convective external mass transport in more detail.

External mass transfer is described in terms of a liquid phase mass transfer coefficient k_{s}, lumping convective, and diffusive mass transport in the boundary layer around a cell aggregate (295). The mass flux of compound i toward the surface is described by

$$J_i = k_{\text{s}}\,(C_{i\infty} - C_{is}) \tag{49.39}$$

where $C_{i\infty}$ is the bulk liquid concentration, and C_{is} is the concentration at the solid interface.

Several theoretical models describing mass transfer within the external liquid film at the liquid–solid interface have been described (303). The film theory is the simplest and most elementary theory, which assumes the presence of a fictitious laminar film next to the solid boundary. For a fluid flowing past a solid, the whole resistance to mass transfer is in the stagnant liquid film. The actual mass transfer coefficient k_{s} is related to the liquid film thickness δ as

$$k_s = \frac{D_{\text{L}}}{\delta} \tag{49.40}$$

where D_L is the molecular diffusivity of the compound in the liquid. The film theory is not correct since it has been shown through the Chilton–Colburn analogy that k_s is proportional to $D_L^{2/3}$ and not to D_L (304). In 1935, Higbie derived the penetration theory for diffusion into a laminar falling liquid film for short contact times. This theory assumes that the liquid surface is comprised of small fluid elements which contact the second phase for an average time, after which they penetrate into the bulk liquid. Each element is then replaced by another element from the bulk liquid phase. The penetration theory gives the following relation between k_s and D_L:

$$k_s = \sqrt{\frac{4D_L}{\pi t_L}} \tag{49.41}$$

where t_L is the time of penetration of the solute (in seconds). The penetration model was later improved by Danckwerts (305) by replacing the constant exposure time with an average exposure time calculated from an assumed time distribution (304):

$$k_s = \sqrt{D_L s} \tag{49.42}$$

where s is the mean surface renewal factor (in s^{-1}). It was assumed that the chance of an element being replaced on the surface was independent of the time during which it had been exposed. The boundary layer theory describes the formation of a hydrodynamic and concentration boundary layer around objects (303). In this case, the mass transfer coefficient k_s is usually correlated with the external flow velocity and the fluid properties by equations of the form (for particles)

$$Sh = \frac{k_s d_p}{D_L} = a + bRe^n Sc^m \tag{49.43}$$

where d_p is the particle diameter; a, b, n, and m are constants; Sh is the Sherwood number, Re is the Reynolds number, and Sc the Schmidt number which are defined as

$$Re = \frac{u_r d_p}{\nu} \tag{49.44}$$

$$Sc = \frac{\nu}{D_L} \tag{49.45}$$

where u_r is the relative velocity between the fluid and the aggregate and ν the kinematic viscosity.

In the case of permeable spheres, the effect of the external mass transfer resistance on the overall uptake and/or release rate by the beads may be quantitatively evaluated by calculating the time constant for the external film (τ_e), and to compare it to the time constant for diffusion in the sphere (τ_i) (306). The internal time constant can be calculated as (307)

$$\tau_i = \frac{R^2}{15D_e} \tag{49.46}$$

where R is the radius of the bead. Alternatively, the film thickness can be estimated according to the film theory (61). The external mass transfer resistance can also be neglected if the Biot number (Bi) is much larger than one (26,69,167,308). Bi for beads is defined as the ratio of the characteristic film transport rate to the characteristic intraparticle diffusion rate:

$$Bi = \frac{k_s R}{D_e} \tag{49.47}$$

An estimation of the external mass transfer coefficient (k_s) is required to calculate τ_e, Bi, or the film thickness. The value of k_s can be calculated by a procedure described by Harriot (309). Merchant and coworkers (62) determined Bi for a rotating sphere. Using the empirical correlation of Noordsij and Rotte (310), k_s was estimated using the following equation:

$$Sh = 10 + 0.43Re_r^{1/2}Sc^{1/3} \tag{49.48}$$

where Re_r the rotational Reynolds number. In the case of diffusion through a membrane or thin disc, Bi can also be calculated. For free-moving particles, k_s can be determined using the following correlations (83,309,311–314):

$$Sh = \sqrt{4 + 1.21\left(Re_p Sc\right)^{0.67}} \quad \text{for } Re_p Sc > 10^4 \tag{49.49}$$

$$Sh = 2 + 0.6Re_p^{0.5}Sc^{0.33} \quad \text{for } Re_p < 10^3 \tag{49.50}$$

where Re_p is the (particle) Reynolds number which can be estimated using the following correlations:

$$Re_p = \frac{Gr}{18} \quad \text{for} Gr < 36 \tag{49.51}$$

$$Re_p = 0.153Gr^{0.71} \quad \text{for } 36 < Gr < 810^4 \tag{49.52}$$

$$Re_p = 1.74Gr^{0.5} \quad \text{for } 810^4 < Gr < 310^9 \tag{49.53}$$

where Gr is the Grashof number. Another correlation which has been used to estimate k_s for gel beads in agitated reactors (80), is (315):

$$Sh = 2 + 0.52\left(\frac{e_s^{1/3}d_p^{4/3}}{\nu}\right)^{0.59} Sc^{1/3} \tag{49.54}$$

where d_p is the average diameter of the particle, ν is the kinematic viscosity, e_s is the energy dissipation given as $N_p n_i{}^3 D_i{}^5/V$ for a stirred tank (where N_p is the power

number, n_i the impeller speed, D_i the impeller diameter and V the volume of the reactor) . The ranges of validity for this correlation are:

$$10 < \left(\frac{e_s^{1/3} d_p^{4/3}}{\nu} \right) < 1500 \quad \text{and} \quad 120 < Sc < 1450 \tag{49.55}$$

A correlation, which was originally developed for fluidized particles (316), has also been recommended for agitated dispersions of small, low density solids (80,167,317,318):

$$k_s = \frac{2D_{e0}}{d_p} + 0.31\,(Sc)^{-2/3} \left(\frac{\Delta\rho v g}{\rho_l} \right)^{1/3} \tag{49.56}$$

where $\Delta\rho$ is the particle/liquid density difference and ρ_l the density of the bulk liquid.

For particles suspended in aerated reactors, Sh has been expressed as (319):

$$Sh = 2 + 0.545 \sqrt[3]{Sc} \left(\frac{\varepsilon_s d_p^4}{\nu} \right)^{0.264} \tag{49.57}$$

For spherical particles in a packed bed, k_s depends on the liquid velocity around the particles. For the range $10 < Re_p < 10^4$, the Sherwood number has been correlated by the following equation (320):

$$Sh = 0.95 Re_p^{0.5} Sc^{0.33} \tag{49.58}$$

Gutenwik *et al*. (155) used the following Sh-correlation (321):

$$Sh = 2 + 1.45 \mathrm{Re}^{1/2} Sc^{1/3} \tag{49.59}$$

An estimation of k_s can be calculated if the stirred chambers have the shape of flat cylinders (72) using the following correlation (309):

$$k_s = 0.62 D_a^{2/3} \nu^{-1/6} \omega^{1/2} \tag{49.60}$$

where ν is the kinematic viscosity and ω the rotational speed of the stirrer (in rad/s). Other correlations can be adapted from heat transfer correlations (48).

The external mass transfer limitation can be experimentally investigated by observing the concentration-time profile at different mixing regimes in the bioreactor (e.g. rotation speeds of the stirrer) (42).

49.4 REACTION AND DIFFUSION

In immobilized cell systems, cellular reactions can take place in the presence of significant concentration gradients. These reactions are also called *heterogeneous reactions*. Reactions can only take place when the substrate molecules are transported to the reaction place, that is, mass transport phenomena can have a profound effect on the overall conversion rate. The concentration in each internal position has to be known to determine the local rates. In most cases, these internal concentrations cannot be measured but can be estimated using reaction–diffusion model.

49.4.1 Intrinsic Kinetics

Intrinsic kinetics describes the growth and product formation rates of cells in the immobilized (or free) state as a function of the local concentrations. A typically simple unstructured ("black box") model of microbial kinetics for growth on a single substrate can be described by the following three equations:

$$\text{Biomass growth:} \quad \mu = f(C_S) \tag{49.61}$$

$$\text{Substrate consumption:} \quad q_s = \frac{1}{Y_{X/S}} \mu + m_s \tag{49.62}$$

$$\text{Product formation:} \quad q_p = \frac{1}{Y_{X/P}} \mu + m_p \tag{49.63}$$

where μ is the specific growth rate of the cells (g DW/g DW/h); C_S is the substrate concentration; q_s is the specific substrate utilization rate (g substrate used/g DW/h); q_p is the specific product formation rate (g product formed/g DW/h); $Y_{X/S}$ (g DW/g substrate) and $Y_{X/P}$ (g DW/g product) are the yield coefficients; m_s (g substrate/g DW/h) and m_p (g product/g DW/h) are the specific maintenance rates for substrate and product, respectively. In some cases, these maintenance coefficients may be omitted or combined with a "cell death coefficient". The specific growth rate is a function of the substrate concentration and is usually of the Monod kinetics form. The model can also be extended to include growth inhibition by the product (and biomass), and $f(C_S)$ becomes some function of substrate and product (and biomass). The Monod equation is bound by zero-order (at high substrate concentrations relative to the Monod constant K_S) and first-order (at vanishingly small substrate concentrations) kinetics. The solutions of reaction–diffusion problems with these two simple rate equations are valuable in that they can be applied as lower or upper bounds to the general problem without requiring detailed knowledge of the rate expressions and thus considerably facilitating the calculations.

In the interpretation of kinetic data for immobilized cells, it is important to assess the significance of mass transfer

limitations. If negligible mass transfer limitation is present, the externally observed kinetics are the intrinsic cell kinetics. Any external or internal mass transfer limitation will lead to externally observed lower conversion rates. Mass transfer limitations may appear either in the external film around the support matrix or within the gel matrix, or in both.

It has been reported that the physiology, as well as the observed growth rate of cells upon immobilization is changed compared to the one of free cells (11,322). For gel immobilized cell systems, it has been observed that the metabolic rates of gel immobilized cells depend usually only on the local solution concentrations, and are in this case identical to those for free cells if diffusional limitations are absent (322). Some researchers found no significant difference between the maximum specific growth rates for immobilized yeast and bacteria, and those for free cells. On the contrary, a significant decrease has been noted by other researchers for the same microorganisms. It has also been observed that for some cases the growth rate is much higher than that for free-living cells (323,324).

49.4.2 Mathematical Modeling

The major issues involved in modeling immobilized cell reactors are very similar to those in heterogeneous chemical reactors. This analogy has encouraged a rapid development in the model building for immobilized cell systems, even if the level of understanding of biocatalysts is lower than for chemical catalysis. The ability to predict the behavior of immobilized cell systems is required for the understanding, the design, and the optimization of an appropriate bioreactor. It is necessary to consider both the bioreactor performance and the microbial kinetics (266). Description of the bioreactor performance involves modeling of mass transfer effects and the flow pattern in both gas and liquid phases while microbial kinetics deals with the kinetics both on the individual cell level and on the level on the whole cell population. Single cell kinetics can be described either with an unstructured model (no intracellular components considered) or with a structured model (intracellular components considered). The population model may be either unstructured (all cells in the whole population assumed to be identical, that is only one morphological form), or morphologically structured (with an infinite number of morphological forms, the term *segregated population model* is often used (325)). The models describing immobilized cell behavior are usually of the unstructured type.

Models for diffusion and reaction in biofilms are reviewed by for example, Wanner and Reichert (249), Wood and Whitaker (326,327), and Martins Dos Santos *et al*. (328). Recently, a spatially multidimensional (2- and 3-D) particle–based approach has been described to model the dynamics of multispecies biofilms growing on multiple substrates (329–332). The model is based on diffusion–reaction mass balances for chemical species coupled with microbial growth and spreading of biomass represented by hard sphere particles.

49.4.2.1 Gel Entrapment. Initially, models, which described immobilized cell kinetics, were based on steady state models for immobilized enzymes. Steady state models can give valuable information for design purposes, but fail to describe transient phenomena (like the start-up dynamics and response to changing conditions) encountered in growing immobilized cell systems. Therefore, dynamic models have been developed to simulate the transient behavior of growing immobilized cells.

In general, gel immobilized cell systems are considered as effective continua. However, it has been observed that when gel beads are inoculated with a low cell concentration, each growing cell will be the origin of a microcolony and growth results in the formation of expanding microcolonies (e.g. (199,333–341). A rigorous modeling approach to this microcolonies system requires consideration of the microstructure of the immobilized cell system: diffusion in the gel phase, and reaction and diffusion in the microcolony ("two-phase" system).

By the entrapment of cells in gel matrices, an additional barrier to mass transfer relative to free cells is introduced. This tends to lower the overall reaction rate, as well as create a specific microenvironment around the cells. Immobilized cells can grow in the gel matrix and the mass transfer limitations on substrate delivery and product removal lead to time-dependent spatial variations in growth rates and biomass densities, which may be accompanied by alterations in cellular physiology and biocatalytic activity. Since the local effective diffusion coefficient depends on the local biomass density, this nonhomogeneous growth will influence the local diffusive rates. The existence of chemical environmental gradients in immobilized cell systems has been verified experimentally with various microprobe techniques.

49.4.2.1.1 Steady State Modeling. If the cell mass does not vary rapidly, or is fairly uniform, the concentration profiles in a gel matrix with entrapped cells can be simulated using a steady state model at any point in time. These models can give valuable information for design purposes or can be combined with experimental *in situ* measurements (e.g. microelectrodes). In this case, mathematical calculations can be very simple and straightforward analytical solutions can be obtained for simple reaction kinetics (e.g. zero- or first-order kinetics). Examples of these models for cell entrapment are presented in Table 48.7.

49.4.2.1.2 Pseudo-Steady State Modeling. Under certain conditions, the full dynamic modeling to describe transient

behavior can be simplified to "pseudo (or quasi)-steady state" modeling. Therefore, the biomass growth and the substrate consumption rate and/or product formation rate are treated separately. This approach is valid as long as the time scale for growth is much larger than the time scale for consumption and product formation. Hence, a pseudo-steady state substrate/product distribution is assumed at each instant. As a result, the system of partial differential equations is reduced to a system of ordinary differential equations, which facilitates the numerical solution. Table 48.8 gives some examples for cells which are entrapped in hydrogels.

49.4.2.1.3 Dynamic Modeling. A general dynamic model, which describes the growth of the immobilized cells and the resulting time-dependent spatial variation of substrate and product in the system, can be constructed by writing the mass balances over the immobilization matrix (it is usually assumed that diffusion in the system is governed by Fick's law; the cells are initially distributed homogeneously over the carrier and there is no deformation of the matrix due to cell growth or gas production):

$$\frac{\partial}{\partial t}(\varepsilon\beta C_i) = z^{-n}\frac{\partial}{\partial z}\left(z^n\, D_{e,i}\frac{\partial C_i}{\partial z}\right) \pm \varepsilon\beta r_i \qquad (49.64)$$

where ε is the ratio of the volume of the pores of the matrix to the total volume; β is the ratio of the volume of the pores minus the volume of the cells to the volume of the pores in the matrix; C_i is the substrate ($i = S$) or product ($i = P$) concentration (expressed per volume available for substrate; n is a shape factor of value 0 for planar, 1 for cylindrical or 2 for spherical geometry; and $D_{e,i}$ is the effective diffusion coefficient for species i. The substrate consumption rate ($r_i = r_s$) and the product formation rate ($r_i = r_p$) are linked to the growth rate (r_x) by the following equations:

$$\frac{\partial}{\partial t}(\varepsilon C_X) = \varepsilon\, r_x = \varepsilon\,\mu\, C_X \qquad (49.65)$$

$$r_s = \frac{1}{Y_{X/S}}\, r_x \text{ and } r_p = \frac{1}{Y_{X/P}}\, r_x \qquad (49.66)$$

where C_X is the biomass concentration expressed per volume available for the cells. Since ε is constant with time, the left hand side of Equation 49.64 can be written as

$$\frac{\partial}{\partial t}(\varepsilon\beta C_i) = \varepsilon\beta\frac{\partial C_i}{\partial t} + \varepsilon C_i\frac{\partial \beta}{\partial t} \qquad (49.67)$$

If a dry weight cell density ρ_c is defined as the ratio of the cell dry mass per cell volume, β can be expressed as function of C_X:

$$\beta = 1 - \frac{C_X}{\rho_c} \qquad (49.68)$$

Using the relationship $Y_{X/S} = dC_X/dC_S$, the second term on the right side of Equation 49.59 is negligible when C_S is much smaller than $\beta\rho_c\, Y_{X/S}$, and under those conditions substitution into Equation 49.64 gives

$$\varepsilon\beta\frac{\partial C_i}{\partial t} = z^{-n}\frac{\partial}{\partial z}\left(z^n D_{e,i}\frac{\partial C_i}{\partial z}\right) \pm \varepsilon\beta r_i \qquad (49.69)$$

These equations can be integrated to yield the substrate and biomass profiles as a function of time (usually together with the reactor model) using the correct initial and boundary conditions. These equations are valid for a wide range of immobilized cell systems. Table 48.9 shows some examples for cells entrapped in hydrogel systems.

49.4.2.2 Microcapsules. Mathematical models have been developed to simulate the membrane formation of microcapsules. A pseudo-stationary state approximation has been used to simulate the membrane thickness as a function of the reaction time (393). The electrostatic droplet formation during microcapsule production was modeled and a reasonably good agreement was obtained between calculated and

experimental values of microbead diameter (394,395). Only a few models including mass transfer and reaction kinetics, have been developed. Steady state as well as transient models, with or without cell growth within the capsules, have been constructed.

49.4.2.2.1 Models without Cell Growth

49.4.2.2.1.1 Steady State Modeling. Heath and Belfort (396) constructed a steady state model to simulate glucose and oxygen concentration profiles in microcapsules. Assumptions included homogeneous cell suspension, Fickian diffusion, and kinetics described by the zero and first-order limits of the Monod equation. Furthermore, it was assumed that the capsule membrane provides negligible resistance to diffusion compared to the resistance of mass transfer in the cell suspension; there is no convective fluid motion inside the particles (the validity of this assumption depends on the rate of stirring of the solution and the permeability and flexibility of the capsules); diffusion within the spheres is a geometrical function of radius only; and the bulk solution is well mixed (no external mass transfer limitation) and is maintained at a constant substrate concentration. The simulated concentration profiles indicated the possibility of a necrotic core due to insufficient substrate in those cases where diffusion is low and/or uptake is high. The model equations provided a means of estimating the maximum capsule radius, which would allow adequate diffusion of nutrients to all contained cells.

Willaert and Baron (188) constructed a model, which describes the oxygen diffusion and consumption by microencapsulated islets of Langerhans. The model deals with the situation where the islets of Langerhans in the microcapsule core are embedded in a gel. The influence of the oxygen mass transfer on the oxygen consumption is evaluated by calculating concentration profiles and Thiele modulus versus effectiveness factor plots. The oxygen transfer process for microcapsules containing animal cells has been modeled and investigated in an air-lift bioreactor (395,397).

49.4.2.2.1.2 Dynamic Modeling. Morvan and Jaffrin (398) have constructed a bioartificial pancreas model, constituted by a microencapsulated islet of Langerhans implanted in the peritoneal cavity, to study the effect of

different physical parameters upon the glucose and insulin kinetics during their transfer between an implanted islet and an arteriole. For each solute (glucose and insulin), the mass conservation equations inside and outside the microcapsule were reduced to a set of coupled integral equations, which were solved numerically (boundary element method associated with subregions formulation). The insulin release localized on the islet of Langerhans was controlled by the local value of glycemia. The analysis was made for a two-dimensional geometry. The numerical experiments demonstrated that the insulin quantity diffusing through the arteriole wall depends on the resistance to diffusion of the medium located between the islet and arteriole wall. While the kinetics of glucose did not seem to be affected by a small modification to the transfer conditions between the islet and the arteriole, the kinetics of insulin were extremely sensitive to such conditions. The insulin available for diffusion in the vascular system was considerably reduced as the islet to arteriole wall distances increased, or when the diffusion coefficient between the islet and the arteriole decreased.

49.4.2.2.2 Models with Cell Growth A transient mathematical model describing animal cell growth in microcapsules has been developed and compared to experimental data (285,395,399,400). The modeling study was based on the scenario in which microcapsules with fluid intracapsular liquid are used in stationary culture, that is, cells initially settle to the bottom of the capsules and the cell population expands from the bottom up during the culture period. The model described (i) material transport from the bulk to the interior phase of the microcapsule and (ii) mass transfer and cell growth kinetics in the intracapsular region. An unstructured model was used to describe animal cell growth:

$$\frac{dC_X}{dt} = u(t - t_{lag}) \left[\mu C_X + \lambda \int_0^t C_X(r) dr \right] \qquad (49.70)$$

where

$$u(t - t_{lag}) = \begin{cases} 1 & \text{if} \quad t > t_{lag} \\ 0 & \text{if} \quad t < t_{lag} \end{cases} \qquad (49.71)$$

and where λ is the death constant and t_{lag} is the lag time which has to be determined experimentally. The specific growth rate (μ) depended on the rate limiting substrate concentrations (C_i) according to a Monod relation and the cell density was controlled according to a contact-inhibition model developed originally by Frame and Hu (401). The complete expression for μ was therefore proposed as follows:

$$\mu = \mu_{max} \prod_{i=1}^{m} \left(\frac{C_i}{K_{M,S} + C_i} \right) \left[1 - \exp\left(-B \frac{C_{X_{max}} - C_X}{C_X} \right) \right] \qquad (49.72)$$

where C_{Xmax} is the maximum density physically allowable in a microcapsule and B is an adjustable parameter. The numerical "control-volume" method was used to solve the model equations. This approach involves setting up one or more criteria. If these criteria are met in a certain control volume, the neighboring control volumes will be initialized with a certain cell density. Cell growth in the neighboring control volumes will then be based on these initial cell densities. The distribution of cells and nutrients in the microcapsule illustrated clearly the delicate balance between the supply and the demand of nutrients and oxygen in the microcapsule system. The highest growth rate was found in the boundary region at the top of the cell mass. This region received the most abundant supply of nutrients and oxygen across the membrane and from the upper half of the capsule. The cells at the bottom of the capsule close to the membrane had virtually stopped growing since the maximum cell density was reached, and no more space for cell division was left. The cells at the central region of the population were probably suffering from a lack of nutrients and oxygen, and therefore had only a very low specific growth rate. The simulation results agreed quite well with experimental data.

A three-parameter model, which has been used to describe tumor and bacterial growth (402,403), is the Gompertz model (404):

$$y = a \exp\left[-\exp(b - cx) \right] \qquad (49.73)$$

In order to design and fabricate optimized microencapsulated cell system, the Gompertz model was used and modified to describe the growth, substrate consumption and product formation (405).

The growth of hybridoma cells in alginate-poly-L-lysine microscapsules during cultivation in an air-lift bioreactor has been modeled using a mean field approach expressed as a Langevin class of equations for two different regions, that is the alginate microcapsule core and the annular region between the microcapsule core and the membrane (406). The model successfully predicted the impact of various microenvironmental restriction effects on the dynamics of cell growth and appeared useful for further optimization of microcapsule design in order to achieve higher intracapsular cell concentrations, which resulted in higher amounts of monoclonal antibody production.

49.4.2.3 Effectiveness Factor. The effectiveness factor (η) can be calculated to obtain a numerical measure of the influence of mass transfer on the reaction rate. The effectiveness factor is defined as (325):

$$\eta = \frac{\text{observed reaction rate}}{\text{rate that would be obtained without mass transfer resistance}} \qquad (49.74)$$

Usually, the effectiveness factor only includes the internal mass transfer effect. The corresponding η is called the *internal effectiveness factor* η_i (407):

$$\eta_i = \frac{\text{observed reaction rate}}{\begin{array}{c}\text{rate that would occur if} \\ C_i = C_{is} \text{ everywhere in the particle}\end{array}} \tag{49.75}$$

where C_{is} is the concentration of compound i at the surface of the particle. For reactions, which are affected by both internal and external mass transfer restrictions, a total effectiveness factor η_T can be defined:

$$\eta_T = \frac{\text{observed reaction rate}}{\begin{array}{c}\text{rate that would occur if} \\ C_i = C_{ib} \text{ everywhere in the particle}\end{array}} = \eta_i \eta_e \tag{49.76}$$

where C_{ib} is the bulk concentration of compound i, and η_e the external effectiveness factor defined as

$$\eta_e = \frac{\begin{array}{c}\text{rate that would occur} \\ if\ C_i = C_{is} \text{ everywhere in the particle}\end{array}}{\begin{array}{c}\text{rate that would occur} \\ if\ C_i = C_{ib} \text{ everywhere in the particle}\end{array}} \tag{49.77}$$

From the definition of the effectiveness factor it is clear that one expects that the value of η cannot exceed one. However, this is not the case for a substrate-inhibited reaction. For example, it has been shown that the maltose and maltotriose beer fermentation efficiency for entrapped brewer's yeast in Ca-alginate gel was improved compared to freely suspended cells (i.e. effectiveness factor for maltose and maltotriose was larger than 1), since the uptake of maltose is inhibited by glucose and the uptake of maltotriose is inhibited by glucose and maltose (388,389).

Effectiveness factor calculations can be based on steady state models with the assumption of a homogeneous distribution of cells over the carrier (6,26,84,362,369–372,388,389,408–407), steady state models with a cell profile in the particle (155) or dynamic reaction–diffusion models with the assumption of an initial homogeneous distribution of cells (82,408).

The effectiveness factor for substrate consumption can be mathematically expressed as the volume averaged reaction rate relative to the rate at bulk phase concentration:

$$\eta = (n+1)\frac{\left(D_e \frac{dC'_S}{dz'}\right)_{z'=1}}{r_s(1)} \tag{49.78}$$

or

$$\eta = (n+1)\frac{\int_0^1 z'^{n'} r_s(C'_S)dz'}{r_s(1)} \tag{49.79}$$

where n is a shape factor (0 for planar, 1 for cylindrical or 2 for spherical geometry) and z' is the dimensionless position coordinate; r_s is the substrate reaction rate which is a function of the dimensionless substrate concentration (C_S) (and also of the position in the case of transient effectiveness factor).

FERMENTER/BIOREACTOR DESIGN

MARVIN CHARLES
Lehigh University, Bethlehem, Pennsylvania
JACK WILSON
ABEC, Inc., Allentown, Pennsylvania

50.1 INTRODUCTION

50.1.1 Scope

The scope of this chapter is limited to design of agitated vessels used for aerobic, single-cell (bacteria and yeast), and filamentous (bacteria and fungi) fermentations. It presents general design principles, combining basic concepts with practical matters including regulatory compliance, safety, maintenance, cleanability, ease of use, and cost, all of which are strongly interrelated. It focuses primarily on fermenters used to produce human and animal health products or their precursors, but the general approaches discussed are applicable to other types of products (e.g., industrial enzymes, food products); the primary differences are emphasized.

Included in the presentation are fermenter vessels; agitation; aeration; heat transfer; sterilization; cleaning; and piping systems. Control and data acquisition are discussed only to the extent that they influence the items already noted.

It is assumed that the reader is familiar with the basics of fermentation, general fermenter construction, and nomenclature. Those not having such background are advised to consult basic references (1–3).

50.1.2 Design Philosophy

Our basic philosophy comprises the following simple principles:

1. Each design case has unique requirements and calls for individualized application of the basic design concepts and practices discussed herein. The one-size-fits-all approach usually results in sleeves that drape into your food, arm holes that cut off circulation, pant legs that are made to trip over, or some combination of these features and others. The magic number approach—all problems have simple solutions based on codified numbers such as fixed geometric ratios (4)—leads to the same place.
2. Successful design requires a systems approach. A fermenter is a system that is part of a process system, and the process is part of a plant system. All these systems interact with each other, with real people, with control systems, and with other systems related to regulatory compliance, safety, documentation (including protocols, SOPs, etc.), change control, maintenance, and so forth. Failure to take these interactions into account during fermenter design usually results in considerable pain, not only for those guilty of the omission, but also for innocents who were never asked for planning and/or design input, but who must live with the result. Note that appropriate documentation, protocols, SOPs, change control, and so on should be considered important elements of design and operation of any plant, licensed or not.
3. Compromise is always necessary. Nothing in any project is 100% right, and nothing has to be. He or she who looks for 100% of anything will hold up a

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

project needlessly and will generate a lot of animus. (The words actually used in such cases cannot be used here.)

4. The time to be thinking about all of these points is prior to and during design, not when you're standing on the plant floor trying to validate a continuous mixer that has only one port and no instrumentation.

We discuss next the bases for safety and regulatory considerations, primarily to sensitize readers to these issues early on. They are all too often overlooked during early stages of design, when the focus is on satisfying process requirements (e.g., oxygen transfer). Unfortunately, this frequently leads to important constraints being ignored and hence to designs that require expensive and often cumbersome "fixes."

50.2 SAFETY AND REGULATORY COMPLIANCE

All fermenter designs are influenced by safety and regulatory factors, the extent depends on (1) the nature of the product and its intended use, (2) the process, and (3) the nature and location of the facility. For example, even fermentation products not regulated by the U.S. Food and Drug Administration (FDA) must adhere to safety requirements, which in some cases are very strict. Furthermore, no professional design can escape the effects of a long list of code requirements, for example, the ASME pressure vessel code (5). By the same token, not all products that are FDA regulated are equally affected by safety, regulatory, and code requirements. We must consider each case on the basis of its own unique requirements.

Our objective in the rest of this section is to introduce some of the requirements and to provide some rational bases for their implementation, details of which are discussed later. Much of the discussion is directly applicable to fermenters used for production of human or animal health products or for their precursors, but also applies to other cases to varying extents.

50.2.1 Containment: Worker and Community Biosafety

A fermenter must be an integral part of a system designed to insure safety at three levels: product, worker, and community. Many of the methods used to protect the product also serve to protect the plant personnel and the community (e.g., use of closed systems and HEPA filters); however, there are potential points of conflict (6). For example, some containment practices that call for completely welded hard piping to a contained drain line for any condensate that could be exposed to culture fluid could expose the product to drain line contaminants. One resolution of this problem is to use steam locks in all such lines. All such conflicts encountered to date have been resolved, but not always easily or relatively inexpensively.

Insurance of product safety is tied primarily to compliance with FDA (or similar organizations) regulations. This will be considered in the subsection "Product Safety". Here we deal with worker and community safety.

Protection must be provided against potential ill effects of fermentation products (e.g., cytotoxins, allergens), organisms (e.g., pathogens, whether recombinant or not), fermentation byproducts (e.g., pharmacologically active precursors of the active product), or some combination. The practice of providing such protection is called *containment*, which is defined as insuring that deleterious fermentation components can't be transported to any area inside or outside the plant before they have been rendered harmless. To accomplish this, containment must be exercised at several levels (7). We consider in this chapter only direct or "primary" containment of fermenters; however, one should not lose sight of the fact that the other levels must be considered during fermenter design, if for no other reason than to ensure that the fermenter design and operation will be consistent with the overall containment strategy.

Containment levels have been defined by the National Institutes of Health (NIH) (8), based on the potential danger of organisms. These levels, in increasing order of potential danger are GILSP, BL1-LS, BL2-LS, BL3-LS, and BL4-LS. (BL4-LS must be handled on a case-by-case basis in consultation with the Centers for Disease Control and others. It is, thank goodness, well beyond our scope.) There are other classifications that have been developed in the United Kingdom (9), the European Union (10), and elsewhere, but these do not differ markedly from the U.S. scheme. It is important to know that (1) all of these guidelines address what must be accomplished but not how they should be accomplished, and (2) there is not complete agreement on what is actually required to implement the guidelines. In addition, the guidelines do not address containment of products. Although many of the considerations for product containment are the same or very similar to those for organism containment, there are some very important differences. Here, we confine our attention to organisms; the interested reader should consult the Refs 11–14 for more specific information concerning hazardous products. One also should consult U.S. Environmental Protection Agency (EPA) regulations applicable to microorganisms and their products.

Most existing processes use organisms that require either GILSP or BL1-LS containment; nevertheless, many plants are built to satisfy requirements for BL2-LS (actually, somewhere between BL2-LS and BL3-LS). The reasons for this include satisfying FDA requirements (e.g., safety of the product) and the fact that the additional cost is not large and is relatively cheap insurance. There also

is the oft-stated reason that such a route insures greater flexibility for future operation (15). One might add to this the fact that the rules are not well established and that requirements could change substantially between the time of design and the time production begins. It also is worth noting that there is growing interest in using organisms that do, in fact, require BL2-LS and even BL3-LS containment, which will probably focus greater attention on further development of acceptable implementation practices as well as changes in the guidelines. Note that equipment requirements and cost for BL2-LS and BL3-LS are currently about the same (this probably will change); BL3-LS facilities requirements and cost are very much greater than for BL2-LS.

Finally, it is important to note that containment is nothing new. Highly pathogenic organisms have long been used to produce therapeutics and biological warfare components; hence, there is a considerable body of experience dealing with the subject (11,16). There also is considerable guidance to be had from the nuclear industry; nevertheless, the natures, sizes, and large number of new commercial processes, along with new methods, materials, and so on, will force heightened awareness, scrutinity, review, and modernization or change.

50.2.2 Physical Safety

Most physical safety issues are addressed by U.S. Occupational Safety and Health Administration (OSHA) requirements (17) and by various national codes such as the ASME Pressure Vessel Code (5) and the National Electrical Code. There also are many local construction codes that must be satisfied. Among these are various earthquake-resistant construction codes that are also applicable to containment considerations. And then there are the requirements of the final arbitors: the insurance companies.

50.2.3 Product Safety

We focus here on FDA requirements, but the reader is urged to keep in mind that he or she also must consider those of other regulatory agencies and be aware of the unsettling facts that it is not always clear which agency has jurisdiction, and there often are conflicting requirements.

The primary purpose of FDA regulations is to insure product safety, purity, and efficacy. The legal bases for the regulations and their enforcement can be found in the *Code of Federal Regulations* (CFR) (18) and a number of other FDA documents such as *Points to Consider* (19,20), *Inspection Guides* (21,22), and *Guides to Industry* (23,24). Industrial implementation of all the regulations, along with ongoing improvements, is referred to as current good manufacturing practices (cGMP).

There is an endless stream of writings in professional journals, short courses, and such concerning the regulations and cGMP practice. Unfortunately, there is a great deal that is not covered clearly in writing, and there is a constant proliferation of new and/or revised guidelines followed closely by lots of (frequently conflicting) interpretations and opinions. In addition there has been a problem of nonuniform application. For example, regulatory scrutiny has been far stricter for fermenters used to produce active molecules directly than for those used to produce precursors; there has been considerable variation from product to product within a given class; and manufacture of human drugs has been regulated much more rigidly than manufacture of animal drugs. While understandable to some extent, such nonuniformity has caused considerable confusion. These gaps are beginning to be closed, and this may have considerable influence on the design of fermenters—particularly those used to produce precursors and animal drugs.

In simplest terms, cGMP requires that the combination of fermentation process equipment and operating protocols must consistently yield product that meets acceptable specifications and is capable of being converted/purified consistently to final product, meeting approved product specifications. From this general sense of intent it can be argued that failure to have control over the fermentation puts the final product at risk. Few would argue with this general concept; however, there is considerable debate as to interpretation and extent.

Requirements that flow from the need to have control are based on relatively simple ideas:

1. If an organism is subject to environmental, medium, or other conditions outside the range in which it is known to yield product meeting acceptable specifications and capable of being converted/purified consistently to final product meeting approved product specifications, then we have no guarantee that it does not produce other products with which the recovery system can not cope and that can escape detection by the analytical methods in place.
2. If a fermenter becomes contaminated with other microbes, said microbes could produce toxins that could be carried undetected to the final product. It is possible that this could occur without altering the behavior of the process organism. It also is possible that products of the contaminant could cause the process organism to make toxins that could go undetected into the final product. Given these possibilities, plus the fact that it is not possible to prove that the contaminant will always be the same, evidence of contamination is evidence for lack of control.
3. If a fermenter is not cleaned properly, deleterious microbial or nonmicrobial products could remain to

> contaminate the next batch in such a way that impurities could be carried undetected to the final product. Similar statements can be made about other contaminants introduced via other routes as a result of poor cleaning practices.

Again, it is unlikely that many would argue with these points, but again there is considerable debate as to interpretation and extent.

Requirements 1–3 can be translated to specific requirements for, among other things, controllability and reliability of fermentation conditions, sterilization, and aseptic and cleaning operations. Controllability requires that the fermenter and its subsystems be designed and constructed in ways that make possible control of environmental variables within the operational ranges required. This obviously means that mechanical design must be in harmony with control system design.

Sterilization/aseptic operation translates to (1) destroying any microbial contaminants that may be present in any part of the equipment that might contact process fluids and (2) insuring that no microbes (other than the production organism) can enter after the equipment has been sterilized. The latter embodies the concept of the "sterile barrier." To these ends, the following apply:

- The fermenter and all its ports and direct attachments must be sterilizable.
- All piping that will contact process fluids (including additives) and/or provide paths into the system (e.g., the air exhaust line) must be sterilizable initially. Some (e.g., sampling lines, addition lines) must also be sterilizable at any time during a fermentation.
- Inlet gases (e.g., air, oxygen) and all additives (e.g., medium components, acid, base, antifoam) must be sterilized before they contact any sterile process piping.
- All penetrations (e.g., drive shaft, probe ports) must be sterilizable.

The preferred sterilization method is automatic sterilization-in-place (SIP) with steam. This is discussed at length later.

Clean operation requires, among other things, the following:

- The system must be designed such that any surface that can contact a process stream can be cleaned consistently to a level that insures that the product will be free of soils resulting from a fermentation.
- Nothing in the system that comes in contact with process fluid can introduce unacceptable and unidentifiable materials.

Note (for example) that 21 CFR 211 (Part D) (guidelines for design of equipment for licensed facilities) does not have any specific requirements for fermenter sterilization or cleaning; however, the preceding discussion coupled with the intended use and cGMP concepts makes it difficult to to argue the point. But again, there remain the questions of rational interpretation and extent of application.

Riding along with cGMP is the practice of validation. This is an extensive, expensive, and controversial area for which and about which reams of reams have written. Following is the formal definition of validation:

> Establishing documented evidence that provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes (25).

What this means is that not only does the equipment have to be designed, installed, and operated so as to run consistently within well-defined ranges of process variables to consistently yield product that meets acceptable specifications and is capable of being converted/purified consistently to final product, meeting approved product specifications, but that there must be adequate documentation to prove this before product can be sold. In addition, one must demonstrate that this goal can be achieved under so called worst-case conditions; there is often considerable debate as to what this really means (26). It is beyond our scope to consider validation in detail. Suffice it to say that it can translate to checking and testing every component of the equipment and documenting not only its proper function but also its history. The brave of heart are referred to the bulging literature on the subject; Refs 27–30 provide a start.

All of this means we must take great care to consider *all* the details, such as materials, corrosion issues, machining methods, vendors, welds, and types of steam and water, keeping in mind that all must be considered as part of a system that must interface "seamlessly" with the systems of cGMP and validation. Failure to consider this before and during design is almost always very costly. Design should be done so as to facilitate validation, and subsequently, routine cGMP operation, maintenance, and so forth. "Simple" things such as judicious placement of access valves and piping isolation can go a very long way to ensuring minimum pain and maximum operability. Having said all this, we reiterate that not all fermenters are subject to all these requirements, and even those that are, are subject to them in varying degrees (at least in practice).

50.3 DESIGN BASIS AND OTHER GENERAL CONSIDERATIONS

A design basis for fermentation equipment should derive from a facility/process design basis. The latter should

include (among other items) the general nature of the facility (e.g., research and development vs. production, single product vs. multiuse); product(s) specifications; regulatory, containment, and other requirements; level of automatic operation; general processing scheme (e.g., batch); nature of individual process steps; productivity, concentrations, and so forth; cleaning requirements; special considerations (e.g., earthquake-proof construction); critical valving and instrumentation; staffing requirements and constraints; architectural and general floor plan constraints; and utilities. Most of these will have some influence on fermenter design—some in more subtle ways than others.

It is difficult to overstate the importance of the initial definition that will derive from the design basis. Obviously, a rational design basis for a fermenter must also be based on fermentation characteristics as well as operating cycle and productivity required (which should derive from the overall process design basis). From these will flow the sizes and number of vessels, and definitions of oxygen transfer, heat transfer, power, and bulk mixing requirements. The design must satisfy these but must also satisfy requirements for regulatory compliance, safety, cleaning, facile operation, and maintenance. All of these factors are highly interactive (e.g., design for oxygen transfer affects design for cleaning); hence, responsible design will almost always require several iterations to ensure the greatest probability of success and to minimize lost time caused by installation, operation, and various problems. The iterative nature of the design (and, unfortunately, construction) process makes most important the existence of a well-crafted, well-implemented, and well-documented change control process. Finally, as with any engineering project, failure to have a solid basis of design, a complete scope, accurate process flow diagrams and piping and instrumentation diagrams (P&IDs), and accurate process timing will almost certainly result in added cost, lost time, and worse.

50.4 PROCESS REQUIREMENTS: BASICS

One of the first steps in fermenter design is translation of process demands to oxygen transfer, heat transfer, bulk mixing, and power requirements—the so-called transport processes (TPs). Sound translation is not straightforward because the TPs interact not only with each other, but also with vessel geometry and other design factors. The nature of each TP and the relationships among them vary with the process requirements. They also vary significantly with the basic nature of the organism and the culture broth. The major factors here are the rheological nature of the broth and the sensitivity of the organism to fluid mechanical forces. In some cases, sensitivity of the organism to temperature and other environmental factors, such as pH, impose tighter constraints (e.g., wall temperature control, uniformity of mixing).

Single-cell organisms (most bacteria and yeasts) tend to tolerate fluid forces very well (there are a few exceptions) and tend to have low-viscosity, Newtonian broths. Mycelial organisms (fungi and some mycelial bacteria such as streptomycetes) tend to be more prone to damage by fluid mechanical forces than are single-cell organisms and tend to have high-viscosity, non-Newtonian broths. Detailed discussion of all these factors is beyond the scope of this chapter; however, we now discuss a few points concerning rheological behavior, and point to fluid effects wherever appropriate in the remainder of the chapter.

50.4.1 Broth Rheology and Its Effects on Transport Processes

Newtonian viscosity depends only on composition and temperature; the nature of the fluid motion does not affect it. Non-Newtonian viscosity does depend on the nature of the fluid motion. This dependency is usually expressed in terms of fluid shear rate (a measure of how rapidly fluid velocity changes from one point to another point close by).

There are several types of non-Newtonian behavior (e.g., pseudopalstic, Bingham) that can be described quantitatively by a host of mathematical models. One model used frequently to describe non-Newtonian fermentation broths (31–33) is the so-called power law:

$$\eta = K\gamma^{(n-1)} \tag{50.1}$$

where η is viscosity, γ is shear rate, and n and K are constants. Such relationships can be useful if one has rheological data for the subject broth and if the design correlations used incorporate rheological properties in a meaningful and accurate way. It is seldom that either of these conditions is satisfied, and almost never that both are satisfied. Also, there is a considerable amount of misleading and/or inaccurate information in the literature concerning broth rheology, its measurement, and its use; the reader is cautioned to tread carefully in this area (4,34). If accurate viscosity information is available, it can be a valuable qualitative and sometimes semiquantitative guide, if interpreted and used properly.

Mass transfer (oxygen), heat transfer, and bulk fluid motion all depend strongly on rheological characteristics. Generally, all are poorer in non-Newtonian than in Newtonian broths; indeed, the rheological characteristics of mycelial broths can and do impose severe constraints. Two of many examples are the following:

1. Heat and oxygen transfer rates tend to be anywhere from 50 to 5% of what they would be for typical (e.g., *Escherichia coli*) bacterial fermentations.

2. Bulk mixing quality (homogeneity) is much poorer than in typical Newtonian broths; therefore, accurate monitoring and control are much more difficult.

Difficulties associated with viscous, non-Newtonian rheology also extend to other areas such as cleaning.

50.4.2 Oxygen Transfer/Aeration

Please note that in this and subsequent sections we include design and operating rules of thumb based on our experience and the experiences of others. They are intended to be helpful guides, not edicts.

50.4.2.1 Requirements. Oxygen transfer rate (OTR) requirements are usually dictated by conditions during the most active part of the growth phase (other phases require oxygen, but supply rate usually is not as high). The requirement is calculated from

$$\mathrm{OTR} = (Y_{x/\mathrm{o}})^{-1}(\mu X)_{\max} \tag{50.2}$$

where μ is the specific growth rate (h^{-1}), X is the cell mass concentration (g/L dw), and $Y_{x/\mathrm{o}}$ is the cell yield coefficient on oxygen (g cells dw/g O_2). Note that the maximum growth rate and maximum cell mass are not always reached simultaneously.

50.4.2.2 Satisfying the Oxygen Material Balance: Gas Flow and Linear Velocity. The very first thing we must do in satisfying an OTR requirement is to insure that we have a closed oxygen material balance. For most practical operating conditions, the rate of change of oxygen inventory in a fermenter is very small compared to oxygen flows in the inlet and outlet and to the OTR. It also can be demonstrated easily that the total molar flow rate of gas does not change enough to cause any loss of sleep. Given these practical realities, the oxygen material balance is

$$\mathrm{OTR} = (1,000 \times 60)\mathrm{F}(y_{\mathrm{in}} - y_{\mathrm{out}})/V_{\mathrm{L}} \tag{50.3}$$

where, F is the gas flow rate (mol/min), y is the mole fraction of oxygen in the gas, and V_{L} is the liquid volume (L). Note that the usual units for OTR are millimoles per liter per hour and that the factors of 1,000 and 60 in equation 50.3 are conversion factors needed to keep unit consistency.

The material balance also can be expressed as

$$F = \mathrm{OTR} \times V_{\mathrm{L}}/(1,000 \times 60\ \varepsilon y_{\mathrm{in}}) \tag{50.4}$$

where ε is the oxygen transfer efficiency and y_{in} is the oxygen mole fraction in the inlet gas. Equation 50.4 is a more useful form because we know that under practical conditions ε will be between 0.15 and 0.35 for typical Newtonian broths, and between 0.05 and 0.15 for typical non-Newtonian broths.

As a general rule, heroic efforts will be required to get OTRs over 300 mmol/(L h) in large fermenters (>5,000 L). Even if the effort is expended and it is successful, it will usually create heat transfer problems (see later) that will require even greater effort to overcome. Our advice is to consider other options very seriously.

The material balance provides information about the gas volumetric flow rate, which often is expressed as the standard flow, v_{std}, in units of standard liters per minute (SLPM):

$$v_{\mathrm{std}} = 22.4F \tag{50.5}$$

This is useful because most flow meters are calibrated in terms of standard flow; however, actual flow is more useful for fermenter design purposes. One problem encountered in calculating the actual flow is that it increases from the bottom to the top of the broth because of pressure change. As a practical matter, however, it is usually adequate to use the average pressure in the tank:

$$v_{\mathrm{act}} = v_{\mathrm{std}} \times (1/P_{\mathrm{avg}})(T_{\mathrm{f}}/298) \tag{50.6}$$

where v_{act} is the gas flow at average pressure (L/min), P_{avg} is the average pressure (atm, abs), and T_{f} is the fermentation temperature (K). One might want to revisit this for very tall vessels.

The standard gas flow rate also is expressed in standard gas volumes per liquid volume per minute (VVM).

Among the important information that can be obtained from v_{act} is the gas linear velocity, V_{S} (cm/min):

$$V_{\mathrm{S}} = 4 \times 1000\ v_{\mathrm{act}}/(\pi \times D_{\mathrm{t}}^2) \tag{50.7}$$

where D_{t} is the inside diameter of the fermenter. V_{S} affects mass transfer, deliverable power via the impellers, foaming, gas holdup, and aerosol formation. As a rule of thumb, V_{S} should be held below 200 cm/min to avoid problems associated with excessive gas holdup, foaming, and aerosol formation. These effects are discussed later.

50.4.2.3 Mass Transfer. The rate at which oxygen can be transferred is dictated by three factors: the driving force, the resistance to transfer, and the contact area between the gas and liquid phases. This is usually expressed as

$$\mathrm{OTR} = K_{\mathrm{g}}a(\Delta P)_{\mathrm{LM}} \tag{50.8}$$

where K_{g} is the mass transfer coefficient ([mmole M]/[L h atm]), and a is the interfacial area per unit volume (M^2/M^3). $(\Delta P)_{\mathrm{LM}}$ is the log mean pressure driving force, defined as

$$(\Delta P)_{\mathrm{LM}} = \left(P_{\mathrm{O,in}} - P_{\mathrm{O,out}}\right) / LN\left[\left(P_{\mathrm{O,in}} - P_{\mathrm{O}}^{*}\right) / \left(P_{\mathrm{O,out}} - P_{\mathrm{O}}^{*}\right)\right] \tag{50.9}$$

where $P_{O,in}$ is the partial pressure of oxygen in the gas inlet (atm, abs), $P_{O,out}$ is the partial pressure of oxygen in the gas outlet (atm, abs), and P_O^* is the partial pressure of oxygen that would be in equilibrium with the dissolved oxygen concentration in the existing liquid (atm, abs). Note that use of the log mean driving force assumes that the liquid is mixed perfectly (homogeneous liquid phase) and that the gas moves in plug flow through the fermenter. These assumptions are acceptable for most low-viscosity Newtonian broths, but they can be quite poor for high-viscosity, non-Newtonian broths. Unfortunately, no useful alternatives have yet been proposed; therefore, extra caution should be exercised in interpreting calculated results for non-Newtonian broths.

Other mass transfer coefficients are used for driving forces other than $(\Delta P)_{LM}$. The most common among these is $k_l a$ (min^{-1}), which is used in conjunction with a dissolved oxygen concentration driving force. The reader is cautioned that $K_g a$ and $k_l a$ are sometimes confused with each other—even in the literature.

A given OTR requirement can be satisfied by various combinations of driving force and mass transfer coefficient. It is important to note, however, the following:

- Factors that influence driving force also can influence $K_g a$.
- Each combination will have different effects on the ultimate design of the vessel, piping system, and support systems, as well as on operational factors related to regulatory compliance cleaning, maintenance, and so on. Such effects are discussed as we proceed.

Driving force is affected by total pressure, gas inlet oxygen mole fraction, total gas flow rate, and the dissolved oxygen concentration. Total pressure and oxygen mole fraction affect the oxygen partial pressure directly. The effect of total gas flow is a bit more subtle. For a given oxygen transfer rate, increasing the total gas (fixed inlet conditions, pressure, etc.) increases the mole fraction of the outlet gas flow, thereby increasing the average mole fraction of oxygen in the gas; hence, the average driving force is increased. This can be seen quantitatively via an oxygen material balance which gives

$$P_{O,out} = P_{O,in} - OTR \times P/(1,000\ F) \qquad (50.10)$$

where P is the total absolute pressure (atm) and F is the total molar flow (mmol/h) of gas.

The characteristics of K_g and a are complex and not completely understood. Our first clue to this is that $K_g a$ is expressed as a product in terms of empirical correlations (we don't understand enough about them to get reliable quantitative guidance from first principles). Typical correlations have the form

$$K_g a = \delta \times \left(P_g/V_L\right)^{\varphi} (V_S)^{\kappa} \qquad (50.11)$$

where P_g is the power delivered to aerated broth (HP), V_L is the unaerated liquid volume (L), and δ, ϕ, and κ are usually advertised as constants. There also a several variations on this form. A discussion of all the fine points of such correlations is beyond our scope; however, the the reader should take note of the fact that published correlations usually cannot be relied upon to provide accurate predictions. They should be used as qualitative or semiquantitative guides only. Reasons for this caveat include the following:

- They are usually applicable only under conditions at or near the ones used to develop them. Unfortunately, most are developed at scales and under conditions that are not realistic for production.
- They can have pronounced dependence on fermenter geometry.
- They do not scale up well, or at all. The "constants" in equation 50.11 and its relatives usually aren't constant.

These caveats should be made more emphatically for viscous non-Newtonian broths than for Newtonian broths because non-Newtonian rheological characteristics can have profound effects on $K_g a$ (as well as the other transport properties). Most $K_g a$ correlations do not account for broth rheology. Those that do, usually do so inadequately or in ways valid only for a particular broth. It also is important to note that the broth rheology can vary dramatically during a fermentation and that the rheological characteristics can be affected by the fermentation conditions, ranging from the nature of the inoculum to the history of the agitation speed.

As noted earlier, we can get some qualitative guidance from the form of equation 50.11. We'll do that, but please keep in mind that the relationships are highly nonlinear, the factors that influence $K_g a$ are dependent on each other in practical operation, and it is not always possible to control variables at the levels you would like. For example, equation 50.11 predicts that increasing power input per unit liquid volume will increase $K_g a$. This usually turns out to be true in practice if the power can actually be delivered to the fluid and delivered in a manner that will contribute to $K_g a$. Such might not be true in any given case.

The fact that a drive's power rating is 100 hp doesn't mean that 100 hp can be delivered to the broth. Deliverability depends on, among other things, geometry (vessel and agitator), rheology, agitator speed, and gas linear velocity (see later). The effects of all are complex and interactive; the interrelations are more complex for non-Newtonian broths than for Newtonian broths. The manner in which

power is delivered depends largely on impeller type and broth rheology. For example, oxygen transfer rates to highly viscous, non-Newtonian mycelial broths have been shown to be larger for A-315 (hydrofoil) impellers than for Rushton (disk turbine) impellers delivering the same power (35). There appears to be no meaningful difference for Newtonian broths.

The bottom line is that one should try to obtain experimentally determined correlations for the subject organism and broth at meaningful scales. Failing that (which usually is the case because of time and resource constraints), one should try to use correlations developed for systems as similar as possible to the one at hand. Considerable art is involved here.

The reader can find more about $K_g a$ in the literature (35–38).

50.4.3 Power

Power delivered to the broth is used for micromixing and gas dispersion, which are related to mass transfer, and macromixing, which provides overall homogeneity (discussed later). Agitated vessel power is delivered via two mechanisms: direct mechanical power from the impellers and gas expansion. The bulk (>90%) of the power comes from the impellers as long as the fluid motion is under their control, a condition that prevails so long as the impellers are not flooded. There are reasonably reliable correlations available to determine flooding conditions for Newtonian broths (39); however, flooding usually is not a problem under typical conditions used in most Newtonian broth fermentation. Flooding is more likely in highly viscous, pseudoplastic broths typical of mycelial and polysaccharide fermentations because the viscosity near the impeller is much lower than in the rest of the broth. As a result (assuming air is introduced under the impeller), air tends to channel toward the impeller, thereby enshrouding it and decreasing the deliverable power (4). This can dramatically decrease overall mass transfer (and heat transfer) rates and quality of bulk mixing quality (see later). Reliable flooding correlations for non-Newtonian broths have not been published, but some companies have accumulated a considerable amount of data for the fermentations they practice.

Calculation of power input relies on empirical correlations. As with $K_g a$, many correlations have been published (see for example Refs 40–42), but they are not particularly reliable for many of the same reasons given for the unreliability of $K_g a$ correlations; therefore, we give the same advice here as we did for $K_g a$.

Among the more popular approaches used is the one that relies on the aeration number, N_A (dimensionless), defined as

$$N_A = v/N D_i^3 \tag{50.12}$$

where v is the gas volumetric flow rate (m^3/min), N is the agitation speed (min^{-1}), and D_i is the impeller diameter (m). Published correlations give the ratio of gassed power to ungassed power as empirical functions of N_A:

$$P_g/P_{ug} = \text{Func}\,(N_A) \tag{50.13}$$

where P_{ug} is the power delivered to the same broth agitated under the same conditions but unaerated.

Each such correlation pertains to a specific impeller type, a single fermenter geometry, and a fairly narrow range of operating conditions. In some such correlations (40), a unique function is presented for each impeller type (Fig. 50.1). In others the relationship is shown not to be unique (43). In most cases, the correlations are for a single aerated impeller. The situation is more confusing for non-Newtonian broths.

Obviously, to use equation 50.13 one must be able to calculate the ungassed power. This can be done via other empirical correlations that give ungassed power in terms of the dimensionless power number (N_P), defined as

$$N_P = P_{ug} \times g_c/N^3 \times D_i^5 \times \rho \tag{50.14}$$

where g_c is Newton's law conversion factor, and ρ is the ungassed broth density (lb/ft^3). There are published correlations that give N_P as a function of Reynolds number for a wide range of single impellers (44). Each is specific to a particular vessel geometry, liquid height, and so forth. Interestingly enough, there are fairly reliable correlations for Newtonian and non-Newtonian fluids so long as the constraints of the correlations are observed.

It is important to note that some impellers that have high power numbers under unaerated conditions can "unload" considerably under aerated conditions. For example, it is fairly typical for a Rushton turbine to deliver, under aerated conditions, only 40% of the power it can deliver when unaerated. On the other hand, the

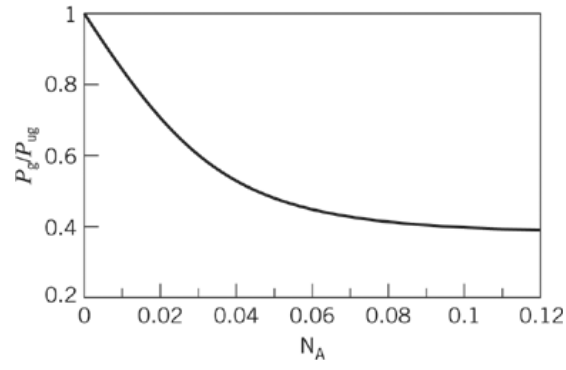

Figure 50.1. Power ratio as a function of aeration number for a Rushton turbine.

SCABA 6SRGT (45), which is a curved-blade disc turbine, does not tend to unload at all. Some hydrofoils also exhibit very little unloading. This is an important consideration when one is trying to rank impellers in terms of how much power they can deliver for oxygen transfer purposes. (Often the ranking tends to be done qualitatively or "semiquantitatively.")

50.4.3.1 Multiimpeller Systems. Most fermenters are equipped with more than one impeller. The reasons for this are to improve bulk mixing (see later) and power distribution and to avoid the need for very large impellers and/or very high agitator speeds. Impeller size is limited practically not only by vessel internals but also by the following:

- *Torque transmitted to the drive shaft*. The larger the torque, the stronger and thicker the shaft must be. This also translates to higher torque and more expensive gear boxes.
- *The size of the vessel manway*. This is particularly important if the impellers must be single piece for better cleaning/sterilization characteristics.

Agitator speed is limited by the natural frequency of the agitation system (4). This is because severe and potentially dangerous vibrations will occur if the rotational speed of the agitator approaches the natural frequency. We recommend that the maximum shaft speed not exceed 70% of the natural frequency.

Having said all this, we are left with the problem of doing the power calculations. This usually involves an iterative calculation in which the parameters are (assuming we have selected impeller types) number of impellers, impeller diameter(s), and shaft speed. (There are other considerations we discuss later.) To do this we use the power correlations already noted. But these usually apply only to single impellers. In most cases, they apply to the lowest impeller, which is the one under which inlet air is introduced. Several approaches have been suggested. The simplest is to treat all the impellers as though each is the only one present. Among other things, this assumes that the impellers do not interact with each other. There is empirical evidence (46 pp. 264–266) that Rushton turbines will not interact substantively in Newtonian broths if they are spaced at least an impeller diameter apart. Obviously, the assumption of noninteraction is not meaningful for impellers that produce significant axial flow (see later).

Another approach used frequently, but not recommended by the authors, is to use the correlations for the lowest impeller but to use them for the upper impellers:

$$P_g/P_{ug} = (1 + \mathrm{HU})^{-1} \tag{50.15}$$

where HU is the gas holdup. You guessed it: there are empirical correlations for HU. One example for Newtonian broths is (47)

$$\mathrm{HU} = 1.8\left(P_g/V_L\right)^{0.14} V_S^{0.75} \tag{50.16}$$

The usual caveats apply.

Typical values for gas holdup range from about 0.1 to 0.3; therefore, equation 50.15 predicts about 10–20% unloading for the upper impellers. Aeration number correlations predict around 50–60% unloading. Given the uncertainty in all this, and assuming that no other (reliable) information is available, we suggest the more conservative approach of applying the aeration number correlation to each impeller independently.

The added cost for the larger drive will not be a major factor for vessels up to about 5,000 L; this is fairly cheap insurance. One should do pilot agitation studies at a meaningful scale for much larger vessels.

50.4.3.2 Organism Sensitivity to Fluid Mechanical Forces. Finally, an additional constraint must be imposed if the organism is sensitive to fluid mechanical forces. This is seldom true of unicellular organisms. There are, however, some mycelial organisms that are sensitive. The extent of sensitivity and the nature of the forces that cause damage should be determined experimentally. One also should keep in mind that the character of fluid forces changes significantly with scale. For example, some turbulent forces that are negligible at small scale can be large and potentially destructive at large scale. Reliable guidance in this area is almost nonexistent. There is, however, a rough rule of thumb that states that damage will occur if impeller tip speed exceeds 1,500 ft/min. Bear in mind that this rule was developed almost 50 years ago and was based on information for organisms used at that time in vessels that had working volumes in the 30,000 to 50,000-gal range. It is clear that many factors (including broth rheology) will affect the potential for damage. Unfortunately, most of the information is seldom available when needed. In such cases, the "any port in a storm" approach to design usually becomes operable. Fortunately, we seldom encounter a circumstance in which the rule of thumb must be violated.

50.4.4 Bulk Mixing

Good bulk mixing is needed to insure homogeneity, which is required for reliable data acquisition and control. There are several important factors that affect mixing quality.

Broth rheology. This is the primary factor affecting our ability to provide good mixing quality, but we seldom have any control over it. We simply must recognize that we will have to go to greater and greater lengths as the

broth becomes more viscous and non-Newtonian. Also, one must bear in mind that the nonlinear behavior of most non-Newtonian fluids often results in nonobvious responses to various actions. For example, increasing agitator speed in a highly non-Newtonian, pseudoplastic broth often leads to a decrease in power input and a decrease in bulk mixing quality.

Type(s) of impeller(s). Impeller types fall into three basic categories: radial flow (e.g., Rushton turbine), axial flow (e.g., marine propellor), and mixed axial and radial flow (e.g., Lightnin' A-315). Radial flow impellers tend to deliver the high power required to enhance micromixing and mass transfer but do not promote top-to-bottom mixing; therefore, they are not the best choice for promoting homogeneity. Multiple radial flow impellers often are used in an attempt to compensate for poor bulk mixing. This can work fairly well for low-viscosity Newtonian broths when the ratio of liquid height to tank diameter does not exceed 1.7–2, but it is a very poor solution when the broth is very viscous and highly non-Newtonian. Anyone who has observed classical streptomycete or xanthan gum fermentations can attest to this fact. Pure axial flow impellers do not deliver much power but do tend to promote good top-to-bottom mixing and hence contribute significantly to bulk homogeneity. They do not, however, contribute much to mass transfer. Some mixed flow types appear to provide a good balance between bulk mixing and mass transfer requirements, particularly for non-Newtonian broths. We recommend that they be considered seriously for such cases. We also have had considerable success with combination systems, for example, those with turbines as the lower impellers and a hydrofoil on top. This appears to work well for Newtonian and non-Newtonian broths.

Impeller size(s). In most cases, large-diameter impellers distribute power better and promote bulk mixing better than do small-diameter impellers. As a rough rule of thumb, based on considerable empirical evidence, we recommend D_i/D_t ratios of between 0.4 and 0.5 unless some other constraint (e.g., torque) is violated. Exceptions to this are some cases in which an axial flow impeller is the top impeller. In such cases, the ratio should not exceed 0.35 to avoid the risk of vortexing. This is particularly true for low-viscosity Newtonian broths.

Vessel geometry. We suggest that the ratio of the aerated liquid height to the tank diameter be kept below 2.0 to minimize bulk mixing problems. This must be reconciled with impeller diameter and impeller spacing requirements (see later) and with architectural, shipping, and other constraints.

Impeller spacing. As noted earlier, there is a body of empirical evidence (48) that supports the spacing of Rushton turbines 1–1.5 impeller diameters apart in Newtonian broths. This spacing appears to provide a balance between preventing impellers from interfering with their neighbors and at the same time avoiding dead zones between them. The same sources of empirical data support placing the lowest impeller one impeller diameter from the bottom of the vessel (assuming a standard dished head) and placing the uppermost impeller one impeller diameter below the liquid surface. We have found these rules to work reasonably well for Newtonian broths and a few non-Newtonian broths, and for radial flow impellers other than Rushtons. Please note that these conclusions are based on limited observations. Finally, keep in mind that one cannot avoid interaction among impellers when at least one of them is an axial flow type or has a significant axial flow component, and that spacing effects in highly non-Newtonian broths are not well understood.

Baffling. Baffles are placed in vessels to minimize fluid swirling and vortex formation (see Ref. 48 for flow pattern diagrams). The usual approach is to use four baffles on 90° centers, each baffle having a width equal to 0.1 of the D_t. Baffling tends to increase transmittable power and to improve mixing (except for the dead spots, which tend to form behind the baffles). Elimination of significant vortexing is important for safety as well as for improved bulk mixing. A vortex can reach down to the impeller in an unbaffled vessel. When this happens, a sizable portion of the impeller becomes air enshrouded, thereby decreasing resistance on the impeller. This tends to drive up the impeller speed, at least briefly (or the speed may be increased intentionally in an attempt to increase the power input). Unfortunately, vortices are unstable and can collapse shortly after formation, resulting in very large and potentially catastrophic stresses (impulse) on the impeller, particularly if the impeller speed is increased significantly while it is enshrouded.

Gas flow. Gas flow has a complex effect on bulk mixing. The flow alone does tends to promote bulk mixing (as in bubble tanks), but it also tends to decrease the effect of the impellers, particularly at high values of gas linear velocity. Fortunately, this is not a major problem in most cases, but it can be for very large fermenters and for highly viscous non-Newtonian broths.

50.4.5 Gas Holdup, Foaming, and Aerosol

There are several problems that can interfere seriously with a fermentation. Gas holdup (discussed earlier) decreases the effective volume of a fermenter. Foaming and aerosol formation can constrain operation, cause major cleaning and asepsis problems, and in the extreme cause termination of a fermentation. All three are dependent on broth characteristics, power input, and gas flow rate. There is some information in the literature, but these points have not been given the attention that even begins to reflect their importance. In general, all one can say is that all three become bigger problems for a given fermentation as gas flow and power

input increase. Beyond that, each case is a new adventure. More will be said about the practical aspects later.

50.4.6 Heat Transfer

50.4.6.1 Heat Loads. Heat transfer is required during fermentation to maintain constant temperature conditions, and at other times (i.e., sterilization, induction) to increase or decrease broth temperature. In most cases, cooling is required during most of an active, aerobic fermentation. A good approximation to the total heat load, Q_{tot}, during such fermentations in which the primary carbon source is glucose or a similar carbohydrate is (49)

$$Q_{tot} = Q_{metab} + Q_{mech}$$
$$Q_{tot} = 0.48(\text{OTR})V_L/Y_{x/o} + 2545P_g \quad (50.17)$$

where Q_{metab} is the heat generated by metabolism (Btu/h), Q_{mech} is the heat generated by power input (Btu/h), and $Y_{x/o}$ is the yield of cells on oxygen (g dry wt cells per g oxygen consumed). Heat transfer can be more of a limiting factor in aerobic fermentations than is oxygen transfer—particularly in large fermenters. The major heat transfer demand is usually during the maximum growth period (i.e., when μX is greatest). It is always wise, however, to check other loads. For example, rapid cooldown after an induction phase could put enormous demands on the cooling system. Cooling a 10,000-L (wv) fermenter from 38°C (104°F) to 10°C (50°F) in 30 min would require an average heat transfer rate of approximately 2.4×10^6 Btu/h. The same heat transfer rate would support an oxygen transfer rate of approximately 495 mmol/L(h), which is very high by almost anyone's standards. Similarly, one should check other potentially high loads such as cooldown after sterilization (see later). In any case, careful thought and solid, empirical facts (e.g., product thermal degradation rates) should form the basis of any specification that will require extraordinary transfer rates.

50.4.6.2 Heat Transfer Rate. The rate at which heat can be transferred is dependent on (1) the driving force for heat transfer, (2) the area across which transfer must occur and, (3) the resistance to heat transfer:

$$Q = (1/\text{resistance}) \times (\text{area}) \times (\text{driving force}) \quad (50.18)$$

The driving force for agitated vessels is usually taken to be the log mean temperature difference, ΔT_{LM}, defined as

$$\Delta T_{LM} = (T_{c,o} - T_{c,i})/LN[(T_f - T_{c,i})/(T_f - T_{c,o})] \quad (50.19)$$

where $T_{c,o}$ is the coolant outlet temperature (°F), $T_{c,i}$ is the coolant inlet temperature (°F), and T_f is the fermentation temperature (°F). Note that use of equation 50.19 assumes that the broth is homogeneous and can be characterized by a single temperature.

The transfer area, A_{JA}, is the actual contact area (not necessarily the same as the available area) between the broth and the heat exchange surface, which is usually a jacket and/or an internal coil. The actual area can be found if the height of aerated liquid in the tank is known, along with the geometry of the jacket and any internal exchange area (e.g., a coil). The aerated liquid height measured along the centerline of the vessel, h_{LA} (ft), is

$$h_{LA} = [(1 + \text{HU})V_{LU} - V_D]/(0.785D_t^2) + \text{IDD} \quad (50.20)$$

where V_{LU} is the unaerated liquid volume (ft^3), V_D is the lower dish volume (ft^3), IDD is the inside depth of lower dish (ft), and D_t is the tank inside diameter (ft).

The resistance to heat transfer is a little more complicated. It is composed of five resistances in series and is expressed as

$$1/U = 1/h_i + 1/h_o + 1/h_{fi} + 1/h_{fo} + t/k \quad (50.21)$$

where U is the overall heat transfer coefficient (Btu/[h°F ft^2]), h_i is the broth film heat transfer coefficient (Btu/[h°F ft^2]), h_o is the jacket fluid heat transfer coefficient (Btu/[h°F ft^2]), h_{fi} is the broth fouling factor (Btu/[h°F ft^2]), h_{fo} is the jacket fluid fouling factor (Btu/[h°F ft^2]), t is the fermenter wall thickness (ft), and k is the fermenter wall thermal conductivity (Btu/[h°F ft]). The resistance of the tank wall can be predicted accurately because both k and wall thickness are known accurately. It should be noted that the k for stainless steel is very low (about 10 Btu/[°F h ft]). This means that the tank wall should be kept as thin as possible to minimize its contribution to heat transfer resistance (see later).

Correlations for h_o can be found in the literature (46 pp. 282–283) but are seldom as reliable as those available from vendors for the specific jackets they fabricate.

The problem in predicting U is in predicting reliable values of h_i, h_{fi}, and h_{fo} Published correlations (50) for h_i values for aerated, Newtonian fermentation broths have been published but are not very reliable. Correlations for non-Newtonian broths have also been published (51), but as was the case for mass transfer coefficients, h_i is strongly dependent on broth rheological characteristics. Unfortunately, existing correlations do not do a very good job of accounting adequately for broth rheology, a problem exacerbated by the fact that good rheological information is seldom available. Finally, the fouling factors are essentially impossible to predict. The best one can do is keep fouling to a minimum by means of good cleaning practices and proper filtration of coolants. Effects of individual resistances on U are illustrated in Fig. 50.2.

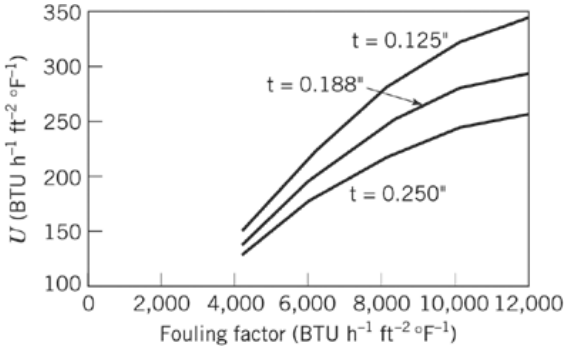

Figure 50.2. Effects of metal thickness and fouling resistances on the overall heat transfer coefficient.

The following rough guides (based on many years of experience) are offered because the authors are unable to offer any collection of reliable prediction tools:

1. U values for simple, low viscosity Newtonian broths usually range from about 120 to 150 Btu/(h°F ft^2) for new, clean stainless steel tanks.
2. U for viscous, non-Newtonian broths ranges from about 30 to 60 Btu/(h°F ft^2)

It also should be noted that U's for heating usually are a bit higher than U's for cooling.

The heat transfer rate can now be expressed as

$$Q = UA\Delta T_{LM} \tag{50.22}$$

Similar equations can be developed for heat transfer via an internal coil. The only difference is that the heat transfer coefficients for coils are usually a bit higher than those for jackets. That having been said, we will try everything possible to discourage you from using internal coils. The reasons relate primarily to mechanical and cleaning considerations and are discussed later.

In applying the preceding, we suggest that the reader consider the following suggestions:

- Avoid the use of internal cooling surfaces (e.g., coils). They make cleaning difficult to impossible, are potential sources of contamination (leaking of coolant), put a lot of mechanical strain on the vessel, and can cause deterioration of bulk mixing (particularly for viscous non-Newtonian broths).
- Avoid subfreezing coolant. Sooner or later, subfreezing coolant will cause severe valve freeze-up and worse.
- Try to keep coolant flow rates low enough to avoid pipe diameters greater than 3 in.; cost increases considerably and availability of fittings and so forth decreases as size increases.

Finally, there are some cases in which high wall temperatures have been cited as causing problems with temperature-sensitive organisms. The wall temperature, T_w, depends on the temperatures of the broth and of the jacket fluid, as well as on the relative values of the heat transfer resistances. A simple energy balance across the heat transfer path yields

$$T_w = (T_f + \beta T_j)/(1 + \beta) \tag{50.23}$$

where

$$\beta = k/h_i/(t + k/h_o) \tag{50.24}$$

Note that this does not account for locally high wall temperatures that would be caused by steam applied to steam locks during fermentation.

50.4.7 Sterilization

50.4.7.1 Introduction. Sterilization and aseptic operation taken together (as they must be) have a much greater influence on fermenter design and operation than does any other requirement.

In theory (1) sterilization destroys or removes all foreign organisms in all process equipment (including piping, seals, etc.) that might come into contact with the process fluid, and (2) aseptic operation insures that *no* contaminating organisms enter the fermenter after sterilization. These ideals are not attainable in practice because (among other reasons) (1) there is a finite probability that a very low concentration of contaminating organisms will not be captured in a sample used to test for contamination, and (2) there is a finite probability of false positives due to sample contamination and so forth. It also is important to note that there is a continuing debate concerning the definitions of pure culture and sterility (6,51).

The driving forces for sterilization and aseptic operation range from minimizing product losses to insuring strict compliance with regulatory requirements. Among the many specific problems that contamination can cause are the following:

- Production of a toxin that can't be removed by the purification system
- Production of an enzyme that degrades the product
- Decreased product yield due to use of substrate by contaminants
- Production of toxins that inhibit the producer strain
- Production of compounds (e.g., polysaccharides) that interfere with the operation of recovery and purification equipment

Which specific problems will exist and where in the spectrum a particular case will lie depend primarily on the product, its economic value, whether it is regulated, and how it will be used. Given all these variables and the fact that absolute sterility is an unachievable abstraction, the extents to which one should go should be considered on a case-by-case basis. As a practical matter, sterilization has to be interpreted as "effective sterilization," meaning that the design and procedures (including sampling and detection) are suitable for the specific case. For example, sterilization of fermenters used to produce parenterals should be held to a much higher standard than sterilization of fermenters used to produce amylases for starch hydrolysis. Unfortunately, there remains a lot of room for disagreement among well-intentioned people (see also the section "Product Safety").

50.4.7.2 Quantification of Sterilization. Mechanical details and other practical considerations of sterilization and aseptic operation are discussed in the subsection "Sterile Piping Systems".

Several methods have been developed to quantify sterilization. The simplest is based on the empirical observation that the death kinetics of many vegetative organisms and spores can be described by a simple first-order expression

$$dN/dt = -kN \tag{50.25}$$

where N is the number of viable organisms (or spores) at any time, t, and k is the thermal death constant. k is a function of most environmental variables but is most strongly affected by temperature. This dependence is very often expressible as an Arrhenius relationship

$$k = A \exp(-E_A/RT) \tag{50.26}$$

where A is the preexponential factor (min^{-1}), E_A is the thermal death activation energy (cal/mol), T is the absolute temperature (K), and R is the gas constant. The effect of temperature on k is pronounced for most organisms because their E_A's are so high (e.g., 65,000 cal/mol for *Bacillus stearothermophilus* spores).

Among other methods of quantifying sterilization concepts are the following:

- *Probability-based theories* (52). These are conceptually different from the first-order model, but give essentially the same results for the levels of kill that must be achieved practically.
- *Methods based on the "decimal reduction factor," D*. These are used widely (53). It is important to note, however, that the nature of temperature dependence has no rational, physical basis and differs considerably from an Arrhenius relationship: it is based primarily on an empirical observation for relatively small temperature ranges.

We use the first-order model for the rest of the discussion.

50.4.7.3 Medium Sterilization. The primary design basis for sterilization systems and procedures is usually the level of sterility that must be achieved. This is most frequently expressed in terms of the probability of sterilization failure (i.e., the probability that a single organism will survive). In most instances probabilities of 10^{-3} to 10^{-4} are quite adequate. This means 1 failure in 1,000 or 10,000 sterilization operations, respectively. It also is important to note that the probability of failure is numerically very close to the value of N in the first-order model.

The reader should also take note of the fact that in some quarters, sterilization criteria are stated in terms of "logs of kill." That is to say, a fixed number of logs (e.g., 12) is taken to be adequate. This is meaningless in that it does not take into account the initial contaminant loading.

Now we consider prediction of requirements for batch sterilizing a fermentation medium as part of the fermenter design process to ensure that we'll have adequate heating and cooling capacity. It should also be done as part of the process design to ensure adequate timing. Batch sterilization involves heating the medium in the fermenter to sterilization temperature (T_{ster}), holding the medium temperature constant at T_{ster} for an adequate time, and then cooling the medium down to fermentation temperature (see the section "Mechanical Design" for additional details). The medium is kept in the fermenter throughout.

It is assumed in what follows that (1) heating and cooling are via the jacket only, and (2) the energy and condensate contributed by the small amount of steam that flows into the vessel as a result of sterilizing piping, air filters, and so on is negligible for energy balance purposes.

The rate of kill at any instant during the sterilization process is

$$dN/dt = -kN = -A \exp(-E_A/RT)\, N \tag{50.27}$$

therefore,

$$N/N_o = A \int \exp(-E_A/RT)\, dt \tag{50.28}$$

where N_o is the number of contaminating organisms initially present. The integration of equation 50.26 must be performed over heating, hold, and cooling phases of sterilization. This is done by numerical integration of equation 50.28, coupled with the equations that describe broth temperature as a function of time.

For heating

$$T_f = T_{ST} - \left(T_{ST} - T_{F,O}\right) \exp\left(-U^* A^*_{JA} t / M^*_F C_{P,m}\right) \tag{50.29}$$

where T_f is the medium temperature (°F), T_{ST} is the steam temperature (°F), $T_{F,O}$ is the initial medium temperature (°F), A_{JA} is the active jacket area (ft^2), t is the time since beginning of heating (h), M_F is the medium mass (lb), and $C_{P,m}$ is the medium heat capacity (Btu/[lb°F]).

For cooling

$$T_f = T_{C,i} + (T_{ster} - T_{C,i}) \exp\left(t \left(W_J C_{P,c} / \left(M_F C_{P,m}\right)\right)\right) \cdot \left(\exp\left(U A_{JA} / \left(W_J C_{P,c}\right)\right) - 1\right) \tag{50.30}$$

where $T_{C,i}$ is the inlet coolant temperature (°F), T_{ster} is the sterilization temperature (°F), t is the time from beginning of cooling (h), W_J is the coolant flow (lb/h), and $C_{P,c}$ is the coolant heat capacity (Btu/[lb°F]). Equations 50.29 and 50.30 can be derived via energy balances.

One chooses times and temperatures such that the desired kill, N/N_o, is achieved. Unfortunately, one usually does not know the level of contamination or the nature of the contaminants. Indeed, it is very unlikely that contamination will remain constant from one fermentation to the next. The usual practice, therefore, is to design for what is thought to be the "worst case." This usually gives results that are quite satisfactory for design specifications. A "typical" worst case is a loading of 5×10^6 spores/mL of the organism *B. stearothermophilus*. Such spores are highly resistant and have the added advantage of being used widely to validate sterilization operations (see later). It is important to note that the purpose of the calculations is to provide a rational basis for obtaining reasonable design information and ensuring a high probability that the desired level of sterilization can be achieved over the whole range of anticipated operating conditions.

Fig. 50.3 illustrates the results of such calculations for the following case:

- Medium volume = 15,000 L
- Initial spore load = 5×10^6/mL
- Initial medium temperature = 70°F
- Steam temperature = 300°F
- Coolant temperature = 35°F
- Coolant flow rate = 100 gpm
- Fermentation temperature = 86°F
- Active jacket area = 225 ft^2
- U = 150 Btu/(h°F ft^2)
- $A = 2.1 \times 10^{36}$/min
- E_A = 65,000 cal/mol
- N (probability of failure) = 0.0001

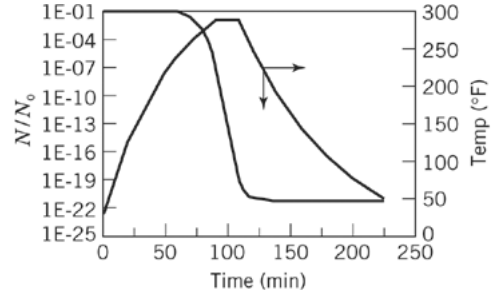

Figure 50.3. Temperature profile and kill ratio for a batch sterilization.

As seen in this example, heating and cooling phases usually contribute only a small fraction of the total sterilization kill, but they do affect turnaround time significantly. Long heating and cooling times can also have other effects:

- Cause damage to the fermentation medium to the extent that the fermentation can be compromised. The seriousness of this depends on some combination of economics and regulatory compliance.
- Cause medium changes that have negative effects on recovery and purification without causing fermentation problems. This includes the possibility of introducing foreign materials that may pass undetected into the final product.

The example also shows that cooling time is considerably longer than heating time. This results primarily from the lower temperature-driving forces during cooling. The problem is exacerbated considerably when the heat transfer coefficient is very low as is the case for viscous non-Newtonian broths. Another method used for batch sterilization is direct steam injection: live steam is injected directly into the medium as the main source of thermal energy. This decreases heating time as well as the overall steam requirement. It also increases the medium volume by about 20% (as a result of steam condensation), which can cause some problems, including the following:

- *Increased cooling time*.
- *Medium dilution*. This will be a significant problem if the initial medium cannot be made concentrated enough to account for the dilution. Some reasons include low solubility of medium components, increased viscosity, and increased reaction rates among medium components at elevated temperatures.
- *Introduction of impurities*. This depends primarily on the quality of the injected steam. In some cases plant steam is acceptable if boiler cleaning agents do not cause problems. At the other extreme is the requirement to use clean steam (WFI quality). It should be noted with regard to this point that some steam will

be injected directly even when jacket heating is used as the main energy source; therefore, one will always be in the position of having to evaluate the effects of contaminants carried by the steam.

For cases in which sterilization times are too long or medium alterations cause too many problems, one might consider continuous sterilization. The interested reader is directed to the literature for additional information (54 pp. 159–176).

50.4.7.4 Piping System Sterilization. Heating and cooling times are not usually significant issues for sterilizing piping; however, there can be some serious heat transfer problems related to piping length, diameter, and orientation. Some of these are discussed in the subsection "Vessel Design". The reader is also referred to literature reports of some practical experiments and theoretical analyses (55,56).

50.4.7.5 Air Sterilization. Theoretical aspects of air sterilization are not discussed here. Suffice it to say that modern filters, if sized, installed, and maintained properly, will provide very reliable results. We'll discuss some of these practical aspects in the section "Mechanical Design". See Refs 54 pp. 176–183 and 57 for additional information.

50.4.8 Cleaning

Scrupulous cleaning is necessary to decrease nonbiological contamination and prevent cross-contamination of batches. Experience also has shown that reliable sterilization is difficult or impossible to achieve in the absence of rigorous cleaning.

As noted earlier, fermenter cleaning is not mentioned specifically in 21 CFR, but the basis is provided in section 211.67, which requires equipment be cleaned as per a defined plan and by trained people. Furthermore, the FDA has made clear the importance it attaches to cleaning not only in various agency publications (58), but also in more stringent enforcement. This is particularly true in multiproduct facilities (a key issue for most modern biotech plants). This agency initiative and the desire to generally improve operation have caused the industry to develop more reliable cleaning systems and protocols and to move to fully automated cleaning-in-place (CIP) systems, which provide greater assurance of successful validation and long-term compliance.

Developing and designing reliable fermenter cleaning systems is not as straightforward as it might appear, and considerable controversy continues. Among the reasons for this is that while much is known about the basic science of cleaning in general, very little is known about the basic science of cleaning fermenters and little has been published. The approach taken is based primarily on experience derived from the dairy, food, and beverage industries. Such information is useful but is not directly applicable in general to pharmaceutical and biotech processes where soils are different and the cleaning requirements are far more stringent. What meager information there is concerning pharmaceutical and biotech soils has been obtained from experiments done on single soil components and/or studies done under conditions not truly representative of the process conditions (59,60). There have been no significant attempts to develop systematic analyses based on experiments done with complex mixtures typical of real fermentation soils under conditions found in real processes. As a result there are no reliable general methods, tools, or correlations on which to base the development of cleaning agents, protocols and CIP system design; decisions tend to be made based on arbitrary criteria (e.g., coupon bake on studies). In keeping with our general design philosophy, we think it important that such arbitrariness be avoided and that cleaning protocols be developed along with the fermentation. It is clear that this will help to ensure not only proper design but will also minimize cleaning validation studies and any questions concerning the presence of contaminants and/or cleaning residues in the commercial product that could not have been present in clinical trial material.

The selection of fermenter cleaning agents and protocols should be based not only on the specific soil but also on the materials of construction, surface finishes, and so on. In addition, one should consider the issues of (1) compatibility of each material with the cleaning agents and protocols, and (2) potential materials interaction during cleaning. These are decisions that usually are made during the design phase, but really should be defined much earlier. These issues are discussed in the subsection "Agitation Systems".

Fermenter cleaning validation is beyond the scope of this chapter; however, the design must be done so as to minimize validation problems and ensure maximum ease in ongoing compliance. The design team must therefore be aware of the procedures that will be used for validation and recognize that this is an issue that has not yet been resolved in the general community.

50.4.9 Putting It Together: Preliminary Design Calculations

We now begin to see some of the interactions that can arise among the transport processes, and between them and the operating variables. This is a necessary step in developing sound designs, and a precursor to preliminary design calculations. As an example, consider a case in which we are trying to find ways to increase the OTR above some base value. One approach would be to increase the gas flow rate (ν) keeping other variables constant:

- The overall driving force tends to increase (equation 50.10).

- V_s increases (equation 50.7).
- Increased V_s tends to increase $K_g a$ (equation 50.11).
- Increased v also increases N_A (equation 50.12).
- Increased N_A tends to decrease power input (Fig. 50.1).
- Decreased power input tends to decrease $K_g a$ (equation 50.11).

As another example, consider increasing the vessel pressure while keeping other variables constant:

- The overall driving force tends to increase (equation 50.10).
- The actual gas volumetric flow rate (v) tends to decrease (assuming constant molar flow rate) (equation 50.6).
- V_s tends to decrease (equation 50.7).
- The decrease in V_s tends to decrease $K_g a$ (equation 50.11).
- The decrease in v also tends to decrease N_A (equation 50.12).
- This tends to increase power input (Fig. 50.1).
- Increased power input tends to increase $K_g a$ (equation 50.11).

Such complex interrelationships develop regardless of what steps are taken to increase OTR. The nature of these will change depending on the approach taken and the system being considered. There will also be additional pluses and minuses related to factors such as cost, safety, cleaning, and regulatory compliance. For example, using pure oxygen to increase the driving force carries with it very distinct cost and safety problems. Many of these more practical implications are be discussed in the section "Mechanical Design".

Now let's carry the second approach a little further. We do this because increasing pressure is usually the easiest and seemingly least expensive way to increase OTR. The decrease in V_s caused by the increased pressure has the positive effects of decreasing foaming, aerosol formation, and gas holdup. But it has the negative effect of requiring thicker tank walls, thereby increasing heat transfer resistance in the face of an increased heat load due to increased metabolic activity. This will become a significant problem when the pressure desired is greater than that required for vessel sterilization. The larger the tank diameter, the greater the possible problem. It should also be noted that thicker walls can make it more difficult to get a good surface finish and therefore increases the possibility of cleaning problems. In addition, the higher the pressure and thicker the walls, the shorter the list of qualified vendors.

This type of reasoning process is applicable to any of the many permutations possible. We extend it after we consider some additional basic concepts, mechanical design practices, and a few more important practical constraints.

We now consider two examples of preliminary design calculations, the objectives of which are to, first, define vessel geometry to ensure that it will not violate architectural constraints and be able to satisfy general rules of thumb for good bulk mixing, impeller spacing, and so forth. Some of this will require checking calculations done later (see later) and may require some iteration.

The second objective is to establish ranges of air flow, pressure, oxygen enrichment, and power that will accomplish the following:

- Satisfy the design basis maximum OTR requirement.
- Keep V_S low enough to avoid foaming, holdup, and aerosol problems. We have found a limit of 200 cm/min to be a safe guide; however, there are cases (Newtonian broths) in which considerably higher values up to 300–350 cm/min tolerable and others (very viscous, highly non-Newtonian broths) in which it is not wise to go beyond 75–100 cm/min.
- Not violate compressor and other component constraints.
- Not require heroic efforts (e.g., extremes in pressure, power, etc.).

Please note that we are trying to establish reasonably broad ranges for each of the variables within which we can satisfy the requirements with a reasonable degree of comfort (based on experience). This is important because the correlations usually available have questionable accuracy, and it allows some breathing room for process improvements and so forth.

The third objective is to define impeller type(s), sizes, and speed that will do the following:

- Provide the power required
- Provide good bulk mixing
- Satisfy impeller spacing rules of thumb
- Not violate constraints related to the sensitivity of the organism
- Make possible single-piece impeller construction and so forth (see the section "Mechanical Design" for consideration of mechanical constraints)
- Not violate any other constraints specified

The fourth objective is to define heat exchange area and coolant flow and temperature that achieve the following:

- Satisfy peak heat transfer requirements

- Not violate coolant temperature and flow constraints and such
- Avoid internal heat exchange area
- Not require subfreezing coolant or flow that will require very large pipe diameters

(*Note*: One should check to make sure that other heat loads [e.g., cooling after fermentation] are not greater than the load during maximum growth activity. We assume that to be the case here.)

The fifth objective is to use the results of the calculations not only to define mechanical details (see the section "Mechanical Design"), but also as a basis for recommendations for rational changes in design basis.

Please note that experimentally derived correlations for the subject cases are used in the examples (this is a design gift as rare as hen's teeth). All were obtained at 500-L scale, and we are just within our comfort range concerning their scalability to 15,000 L (design scale). The reader is cautioned, however, that there is no basis to believe that the correlations would be applicable to other cases, nor would we recommend extrapolation to much larger scales. It also is worth noting that there are some good examples in the literature that might be applicable to the problems at hand or to others; however, one must exercise considerable caution if the conditions specified in the reference differ significantly from those for the case being analyzed. Unfortunately, it is often not possible to determine if significant differences exist.

50.4.9.1 Case 1.

Product	Intracellular protein
Organism	*E. coli*
Final broth volume	15,000 L
Maximum OTR	234 mmol/(L h)
Dissolved oxygen requirement	10% relative to atmospheric conditions
Broth rheological type	Newtonian
Maximum broth viscosity	5 cp
Regulation	CBER
Containment	BL2-LS
Maximum coolant flow	250 gpm
Minimum fluid temperature	35°F
Internal coils	No
Compressor max press/max flow	50 psig/25,000 SLPM
Minimum heat transfer coefficient	150 Btu/(h°F ft^2)
Ceiling height	336 in.
Floor space	1000 ft^2, unobstructed

The following experimental correlations are applicable:

$$K_g a = 108\left(P_g/V_L\right)^{0.6} V_S^{0.2}$$

$$P_g/P_{ug} = 1.0 - 18.56N_A + 215.64N_A^2 - 1082.66N_A^3 + 1859.68N_A^4$$

$$\mathrm{HU} = 0.0133\left(P_g/V_L\right)^{0.4}\left(60V_S/^{0.5}\right) - 0.0333$$

These were developed under the following conditions for single Rushton turbines:

- $0.8 < P_g/V_L < 2.9$ hp/100 gal
- $100 < V_S < 200$ cm/min
- $0 < N_A < 0.1$
- $0.33 < D_i/D_t < 0.45$

Vessel geometry calculations are the same for both cases. We start by assuming a vessel diameter and wall thickness. (Note that the thickness will probably be changed a bit later to satisfy code requirements. This will not have a significant effect on height and volume calculations to follow.) In this case we assume a 96-in. outside diameter and a 0.25-in. wall thickness. By straightforward geometry and using tabulated values of volumes and inside depth of dish (IDD) for standard ASME heads, we get the following:

Liquid height	134.2 in.
(Liquid height)/tank diameter	1.41
Total tank height	192.5 in.
Total volume	21.1 L
Percent fill (unaerated)	71.1%

This satisfies rules of thumb concerning liquid height-to-diameter ratio and fill percent. If we add about 72 in. for legs and 30 in. for opening the manway, we get a total height requirement of 294.5 in. We should be able to satisfy the maximum height limit.

The results of oxygen transfer calculations for several operating conditions are given in Table 50.1. From these results we conclude that the following will satisfy the OTR required and give us a reasonable amount of "breathing room."

Gassed power	100 hp (includes transmission efficiency)
Maximum operating pressure	40 psig
Maximum air flow	10,000 SLPM

We do not recommend oxygen enrichment at this point, but we do suggest that the "holes be punched" to facilitate future installation of an oxygen system. The agitation

Coolant flow (GPM)	190	210	235	200

system calculations are based on the assumption of using two 40-in. diameter Rushton turbines. The results are given in Table 50.2. A maximum speed of 150 rpm should be adequate. Note also that the impellers can be spaced to satisfy the rules of thumb for bulk mixing rules discussed previously. Although this should give satisfactory results for such a low viscosity broth, we recommend consideration of a slightly larger turbine as the lower impeller and a hydrofoil (e.g., A-315) as the top impeller.

The results of the heat transfer calculations are given in Table 50.3. A minimum coolant temperature of 35°F was used in all cases. The results show that the heat loads can be handled, but the conditions are uncomfortably tight. For example, in no case will increasing the coolant flow to the maximum make up for a 10% decrease of the heat transfer coefficient. The potential consequences of inadequate heat transfer in this case should be considered seriously before final design commitments are made. Alternatives (e.g., lower coolant temperature) should be explored.

50.4.9.2 Case 2.

Product	Antibiotic
Organism	*Streptomyces* sp.
Final broth volume	15,000 L
Maximum OTR	50 mmol/(L h)
Dissolved oxygen requirement	10% relative to atmospheric conditions
Broth rheological type	Non-Newtonian (pseudoplastic)
Maximum broth viscosity	1,000–1,500 cp
Regulation	CDER
Containment	BL1-LS
Max coolant flow	250 gpm
Min fluid temperature	35°F
Internal coils	No
Compressor max press/max flow	50 psig/25,000 SLPM
Min heat transfer coefficient	40 btu/(h°F ft^2)
Ceiling height	336 in.
Floor space	1000 ft^2, unobstructed

The following empirical equations are applicable:

$$K_g a = 8.0\left(P_g/V_L\right)^{0.5} V_S^{0.4}$$

$$P_g/P_{ug} = 1.0 - 26.99N_A + 417.37N_A^2 - 2789.43N_A^3 + 6643.30N_A^4$$

$$\mathrm{HU} = 0.012\left(P_g/V_L\right)^{0.3}(60V_S/100)^{0.52} - 0.029$$

TABLE 50.4. Oxygen Transfer Calculation Results (Mycelial)

Pressure (PSIG)	35	25	20	10
Oxygen transfer eff (%)	6	6	6	6
O_2 mol % in	21	21	40	40
Gas flow IN (SLPM)	22,222	22,222	11,667	11,667
VVM	1.48	1.48	0.78	0.78
Average V_s (cm/min)	154	172	102	140
hp/100 gal required	1.7	2.0	1.0	1.6
Theoretical Pg	60.9	79.9	41.7	61.8

These were developed under the following conditions for single Rushton turbines:

- $1.0 < P_g/V_L < 2.3$ hp/100 gal
- $60 < V_S < 130$ cm/min
- $0 < N_A < 0.1$
- $0.36 < D_i/D_t < 0.42$

The results of oxygen transfer calculations for several operating conditions are given in Table 50.4. From these results we conclude that the following will satisfy the OTR required.

Gassed power	100 hp (includes transmission efficiency)
Maximum operating pressure	40 psig
Maximum air flow	25,000 SLPM

Oxygen enrichment should be considered in this case despite the fact that the calculations show that it is not necessary. The reason is that the gas flow rate, and hence V_S, is quite high without enrichment. This results primarily from the very low oxygen transfer efficiency typical of very viscous non-Newtonian broths. Although it is true that we haven't broken the rule of thumb for holdup, foaming, and aerosol we should take note of the fact that high air flows in pseudoplastic broths can exacerbate impeller unloading and cause flooding more readily than for non-Newtonian broths. It also is generally true that our correlations become less reliable as conditions become more extreme and further removed from the conditions under which they were developed. Note in particular that our correlations were not developed for the high values of V_S found in the calculations. It also is clear that we should specify higher pressures than shown in the results in Table 50.4. Additional calculations show that 40–45 psig would bring the V_S into a comfortable range. We suggest, therefore, the following:

Gassed power	100 hp (includes transmission efficiency)
Maximum operating pressure	45 psig
Maximum air flow	25,000 SLPM
Oxygen enrichment	40% oxygen in inlet stream

The agitation system calculations are based on the assumption of using two 40-in.-diameter Rushton turbines. The results are given in Table 50.5. A maximum speed of 140 rpm appears to be adequate. Note also that the impellers can be spaced to satisfy the bulk mixing rules of thumb discussed previously.

That's very nice, but we have significant reservations about the results. An alternative should be given serious consideration because of the rheological nature of the broth, the profound effect this can have on mixing, and the issues of scalability for such broths. At the very least, the lower turbine should be replaced by one having a D_i/D_t approaching 0.5, and the upper turbine should be replaced by a hydrofoil. The reader should understand that this is based on experience only: we have no solid correlations for this case. The best route to take would be to do a few pilot mixing studies in as large a vessel as possible with the real broth.

The results of the heat transfer calculations are given in Table 50.6. The minimum coolant temperature of 35°F was used in all cases. The results show that the heat loads can be handled. It also appears that we are well below the maximum available coolant flow. This may be comforting, but the reader should realize that there is not a lot of breathing

TABLE 50.5. Agitation System Calculation Results (Mycelial)

Shaft speed (rpm)	124	137	107	124
Ungassed hp	159	214	102	159
Aeration number	0.049	0.055	0.042	0.049
Gassed hp	61	80	42	62

TABLE 50.6. Heat Transfer Calculation Results (Mycelial)

Heat load (MMBtu/h)	0.533	0.560	0.463	0.515
Gas hold-up	0.202	0.230	0.124	0.182
Jacket area (ft^2)	298	306	276	292
UJKT [(Btu/ft^2 h°F)]	40	40	40	40
Coolant temp in (°F)	35	35	35	35
Coolant flow (GPM)	190	210	235	200

room for process improvement. In particular, an increase in OTR up to 60–65 mmol/(L h) would put us over the top even if there were no deterioration in heat transfer coefficient. Again, one should give this serious consideration before committing to a final design.

We trust that the discussion and examples in this section have helped the reader to understand not only the many interactions that must be considered, but also the nature of preliminary design calculations and their limitations. The results obtained here must now be translated into a mechanical design that must also take into consideration the items to be discussed in the next section.

50.5 MECHANICAL DESIGN

50.5.1 Mechanical Design Basis

Much of the mechanical design follows from the results of calculations discussed in the previous section Process Requirements: Basics; however, these must be tempered by other considerations that should be included in the process and/or facility design basis. Some of these (e.g., regulatory compliance, containment) have already been discussed and are revisited in greater detail in this section. Other items that should be included and will affect fermenter design include the following:

- *Extent of automation, nature of plant wide control system, etc.* Such items affect not only the instrumentation (beyond our scope) and similar factors, but also valving, piping, vessel ports, and so forth. Among some of the major issues here are identification of critical (as defined by cGMP requirements) valves and other components. It must be kept in mind that failure to identify critical instrumentation and control components frequently leads to very complex valving systems in which the failure of a single switch can bring everything to a grinding halt. Unfortunately, there are too many people who do not think this through (as a system) before final design begins. Much of this results from the human tendency to rationalize and/or push "problems" downstream, the kind of thinking that results in the thought "Why worry? We'll get it whether or not we need it." Such thinking is in no one's best interest (buyer or seller).
- *Staff requirements and the anticipated nature of the operating staff*. This can influence the complexity and physical layout of (among other things) the piping system(s).
- *Plant location*. This will have some affect on overall design and component selection if for no other than service issues.
- *Available utilities*. This can influence such things as the designs of the cooling and aeration systems.
- *Architectural constraints*. These can have profound effects on the ways in which process requirements will be satisfied. Floor space and ceiling height constraints often require that a fermenter be designed in such a way that it violates some or most or even all of the rules of thumb mentioned in the previous section. This is not good but is better than building a vessel that does not fit into the plant.
- *Transportation constraints*. The fermenter has to be moved from the fabricator's shop to the plant—at a cost not greater than the total project budget. This may require some thumb bending or breaking. In extreme cases it may be better to fabricate the fermenter on site; however, this can carry large penalties, particularly in licensed facilities.
- *Maintenance*. Many design decisions can have major effects on the ease of maintenance. It is also often true that some of the design features that ease maintenance are more costly than those that do not. In most cases, the savings in capital expenditure will not come near paying for losses that will result later because of maintenance problems. This is particularly true in licensed facilities where regulators view good, facile maintenance as an integral, indispensible part of cGMP operation.
- *Definition of standards*. Standards for welds, finishes, and so on should be standardized for all parts of the equipment that will contact process fluid. It does not, for example, make sense to call for a high-quality vessel finish (e.g., 320 grit, EP) and at the same time accept unpolished tubing and valves in inoculation and medium addition lines.

Finally, there are a few recurring themes that are encountered in fermenter design:

- *Building-in "versatility."* The types of versatility desired range from wanting a fermenter that can operate well over a very wide range of conditions but with a narrow range of organisms, to wanting a convertible bioreactor that can handle microbes, mammalian cells, and maybe (someday) transgenic animals. Most people understand the value of versatility, but many do not understand the attendant problems and costs. As a general rule, converting laboratory glassware directly into large, stainless steel equivalents usually costs more than any rational person should be willing to pay. Also as a general rule, versatility should decrease as a process goes from the lab to the production floor. Versatility in the laboratory is almost a requirement because change is in the nature of laboratory work. Versatility on the plant floor, however, leads to more procedures, more paper work, more testing, and more confusion, particularly when equipment modifications are required to achieve the versatility; change is not in the basic nature of most plant work. Equipment capital savings can justify the added costs of all the preceding for many cases in which the equipment is designed to handle multiple, similar fermentations on a campaign basis and without significant equipment modification. This statement becomes less true as the fermentations become less similar, as more modifications are necessary, and as regulatory scrutiny increases. Bottom line: analyze very carefully any inclination to want versatility built into plant equipment (or even pilot equipment, in some cases).
- *Retrofitting existing equipment*. The usual thinking is that capital and time savings can be had by refurbishing "old faithful." Just how true this is depends not only on the condition of the existing equipment but also on the intended application(s) of the reborn version. Comments similar to the ones made for versatility apply here. The chances of success decrease as one goes from a lab to licensed production facility. There are ample, expensive corpses to prove this point.

50.5.2 Vessel Design

Please note that Figures 50.4 and 50.5 are simplified vessel and piping diagrams intended to assist the reader in the discussions to follow.

50.5.2.1 Materials of Construction. The major choices that must be made are (1) the type of metal to be used for the vessel and nozzles, and (2) the type of elastomer to be used for static seals (see later for rotating seals). The selections should be based on compatibility with the organism, compatibility with the product, corrosion resistance, cleanability (also related to finish), welding characteristics, and cost and durability. All of these should be determined during process development but seldom are. In almost all cases, the metal selected will be some grade of stainless steel (usually SS304, SS304L, SS316, or SS316L). The choice is usually associated with the nature and value of the product, although some of the other factors noted earlier may be considered. SS304 is usually good enough for lower-value, unlicensed products, whereas SS316L is the material of choice for high-value, licensed products. L-grade is selected when better corrosion resistance and good multipass welding characteristics are required; it adds about 15% to the cost of the vessel.

It is important in making metal selection to keep in mind that clean steam, purified water, and WFI are all highly corrosive. The reader should note that there is considerable controversy concerning metal selection and is directed to Refs 61–63 for additional information and opinion.

Static seal (O-rings and gaskets) materials are usually limited to silicone, EPDM, Viton, or Teflon. Silicone and EPDM are the materials of choice for headplates and elsewhere, respectively. (The reader should be alert to the fact that there are several grades of both, not all of which are FDA approved.) Teflon has much better temperature resistance than either silicone or EPDM, but it doesn't stretch, and it cold flows. Viton hardens on use.

Finally, one should be aware of that some O-ring/gasket-forming processes can leave very small quantities of metals in the seals. These may not be enough to cause fermentation or product problems per se, but they can be the cause of considerable corrosion.

50.5.2.2 Finish. In most instances, the need for a high-quality finish is closely related to the need for high-quality cleaning: there is little question that CIP systems function better when surfaces are smoother. Smoothness is expressed on several scales, two of the more common being grit number and surface R_A. Grit number is related directly to the abrasive used to achieve the finish (mechanical); surface R_A is the actual surface roughness as measured by means of a profilometer and expressed in microns:

Grit	R_A (μm)
120	3.2
220	0.8
320	0.4

The two most common ways of achieving smoothness are mechanical polishing and electropolishing. Mechanical polishing is done by means of a series of continually decreasing abrasive particle sizes (grits). Electropolishing is achieved

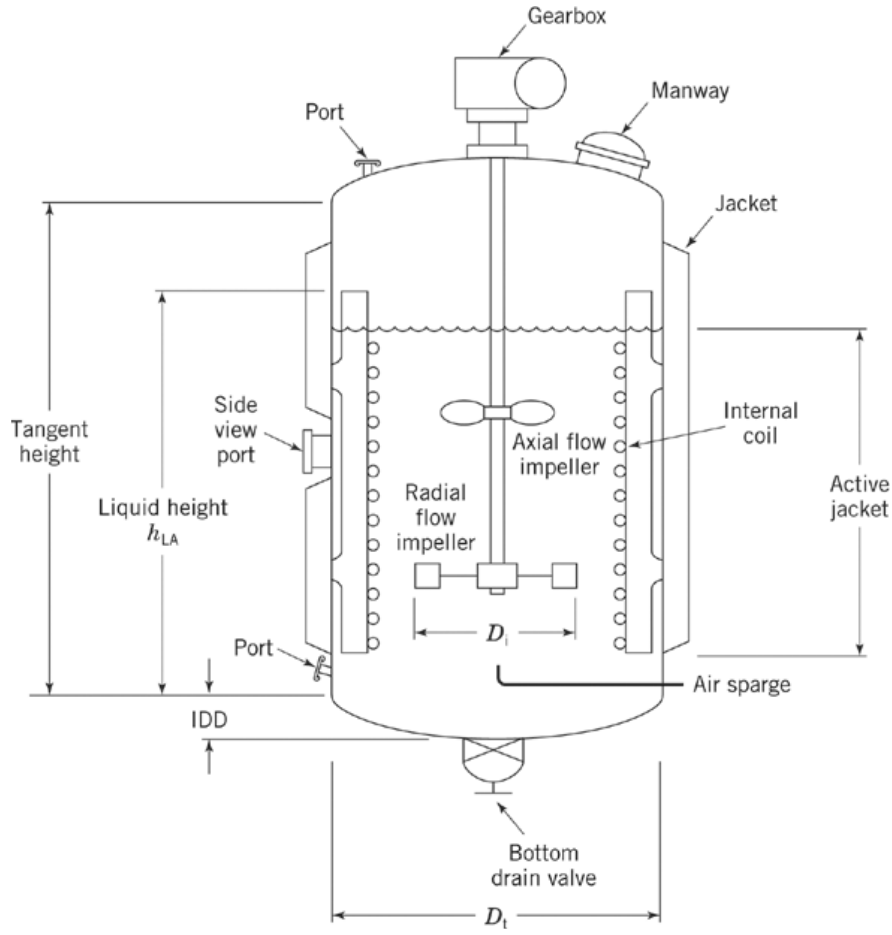

Figure 50.4. Fermenter vessel schematic and terminology.

by electrochemical removal of metal from high points on the surface. One is usually best advised to electropolish only after getting a good mechanical polish (240-grit minimum). It has long been held that the very good finishes required for vessels where cleaning is critical could be achieved only by electropolishing a 320-grit mechanical finish (although 240-grit EP is the most common practice). There is some evidence in the literature (62,63) to support this, but it is not overwhelmingly convincing. It also is important to note that recent advances in mechanical finishes have produced surfaces that easily rival the appearance of any electropolished surface (Lee Industries, personal communication, 1996).

It should be (but is not always) evident that cost increases with surface smoothness. It is also important to note that just because a surface is almost perfectly smooth does not guarantee that it will be easy to clean. Cleanability will also depend on the nature of the interaction between foulants and the surface material. The only way to know for sure is to try your broth on various surfaces and then make a specification based on rational evaluation of the experimental information. Surface material and finish, cleaning agents, and cleaning protocols must be considered together—preferably before design.

Passivation must also be considered. This is a treatment that restores oxides that protect stainless steel from corrosion but can be removed during vessel fabrication (primarily welding). The process is rather simple, but the surface chemistry is not and is not completely understood (64,65); hence, there is controversy as to which method is best and whether it is really as necessary for fermenters as it is for high-purity water systems where rouge formation is a serious problem (66). Two methods are in common use: (1) treatment with sodium hydroxide, citric acid, and nitric acid; and (2) treatment with chelating agents. The second is much milder and does not generate the noxious waste of the first. Both appear to be equally effective; hence, the chelating method is becoming more popular.

50.5.2.3 Nozzles. Ports for additions and probes must be designed to be sterilizable and cleanable. Among other things, this means they must have reliable seals and be free draining. The major debate here usually focuses on the choice between Ingold ports and those designed

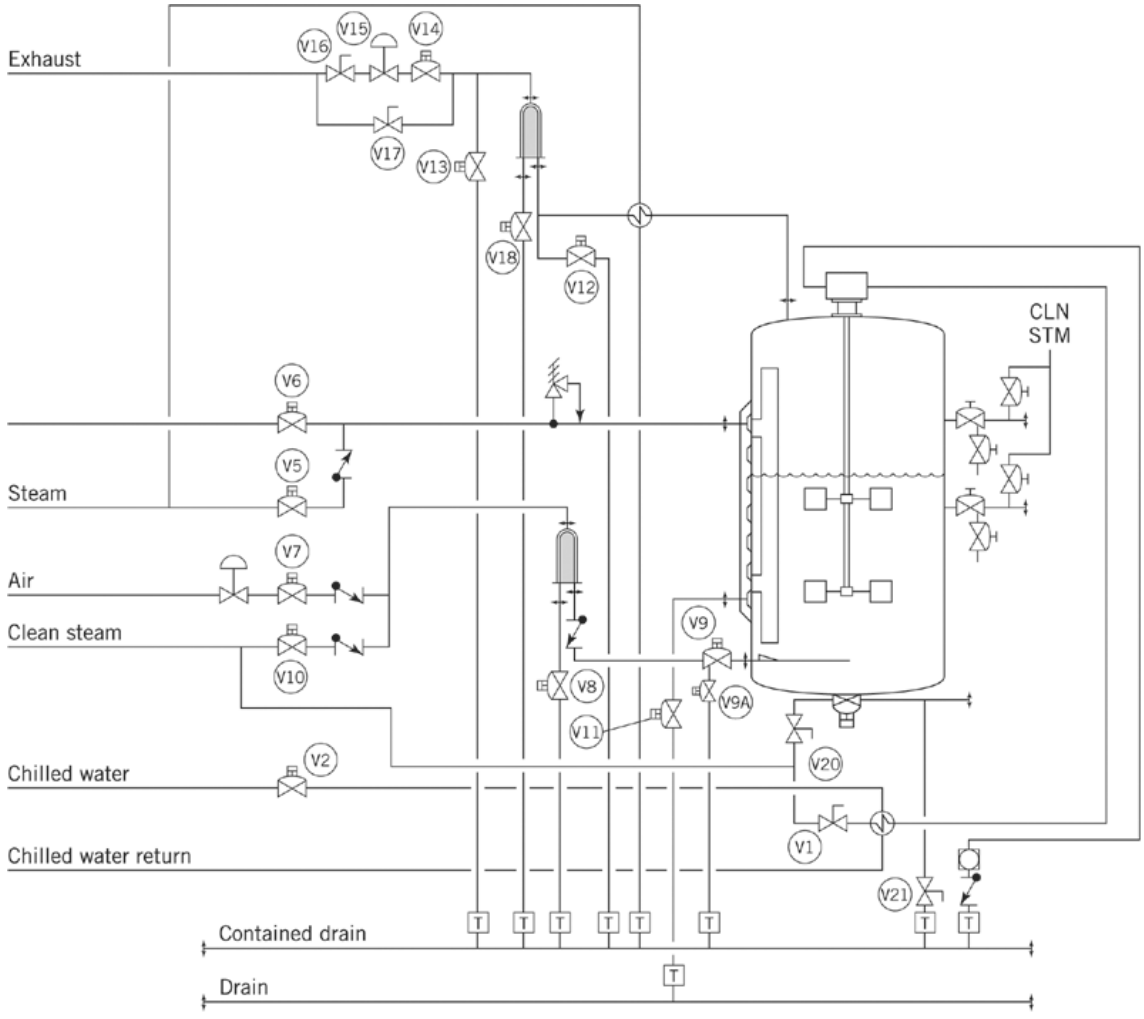

Figure 50.5. Simplified fermenter piping diagram.

for sanitary clamp connection (Fig. 50.6). There have been sterility problems with Ingolds, most of which have been traced to the ports being out of round as a result of distortions caused by welding. Such distortion causes obvious problems with the O-ring seals. This problem can be corrected quite easily by making the nozzle thick enough to avoid distortion. Our experience has been that such a correction yields nozzles that are just as reliable and more easily cleaned than are sanitary fittings when both are mounted at the usual 15°.

50.5.2.4 Side View Ports. The first word that comes to mind is "don't." Side view ports let the bugs see out more than they let you see in. The little that's gained by being able to see less than 1% of the total action does not seem to justify the expense, the jacket coving, and the cleaning and sterility problems caused by these little gems. If you must have one, we suggest the circular Metaglas™ type (Fig. 50.7) attached to the vessel with sanitary clamps; the glass is bonded directly to the metal, which avoids the sealing problems encountered with other types. It does, however, have the disadvantage of having a smaller viewing area than does a standard, circular view port, and it is more expensive. We recommend avoiding long rectangular view ports, which are very difficult to keep clean and free draining, and types in which the glass has to be sealed with gaskets and/or O-rings on both sides (Fig. 50.8). Keep in mind that tolerances for glass are measured in fractions of an inch, not thousandths. That, coupled with the fact that the gaskets will compress means that the probability of repeatedly achieving a good seal and good cleaning is lower than your odds of winning more than once at Atlantic City.

50.5.2.5 Baffles. Baffles are usually required in high-power systems to prevent swirling and vortexing, thereby increasing the power that can be delivered to the fluid. The usual practice is to use four baffles on 90°

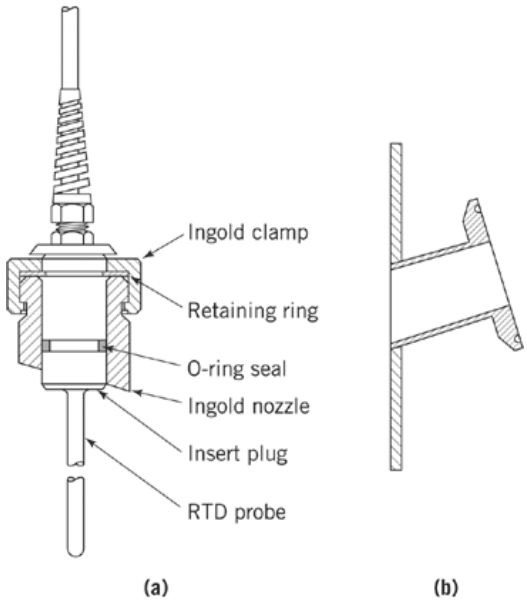

Figure 50.6. Ingold and sanitary clamp fittings.

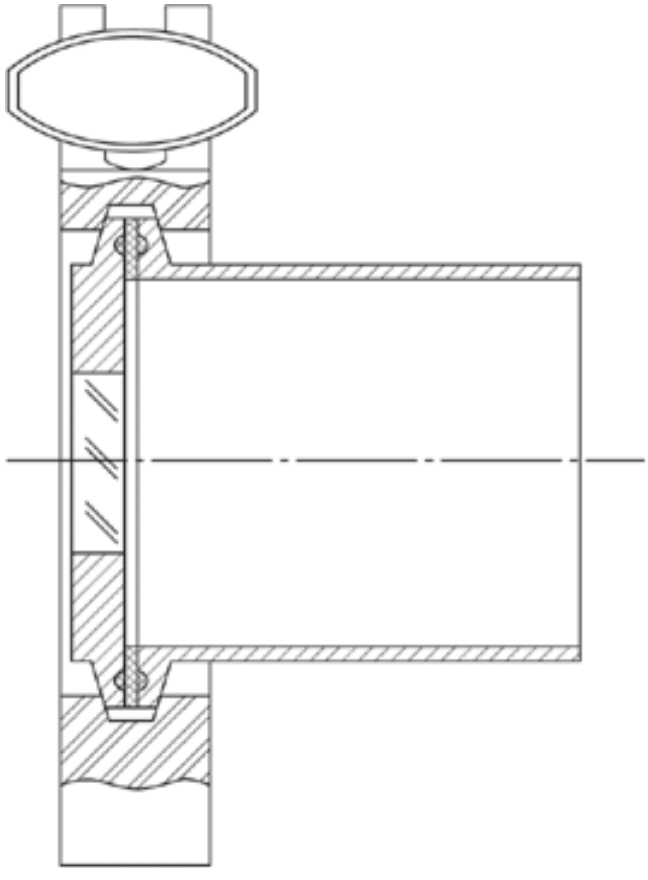

Figure 50.7. Metaglas™ side viewport.

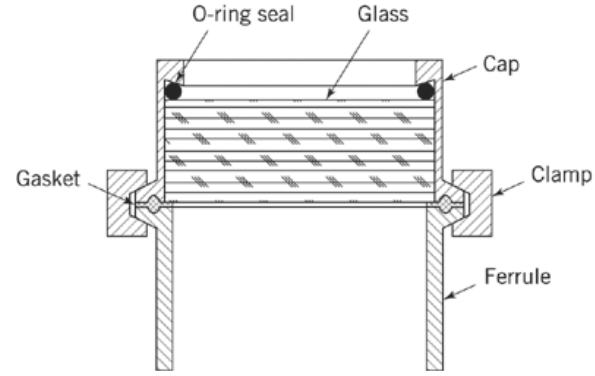

Figure 50.8. Side viewport with separate glass piece sealed by two gaskets.

centers welded directly to the wall. Each baffle should have a width equal to 10% of the tank diameter and should have long slots cut out of the edge facing the wall so as to prevent solids build up and to make cleaning easier. Removable baffles are used in some cases; however, we discourage this practice, particularly in cases where cleaning is a critical issue, simply because unsealed joints resulting from baffle removal make cleaning more difficult.

50.5.2.6 Jackets. Several types (67) of jacket are used on fermenters; the choice of type is usually not critical for heat transfer purposes and is best left to the vessel fabricater. In some cases, however, a jacket type (e.g., half pipe) may be chosen to increase the vessel pressure rating. The following have proven to be useful practices:

- The jacket should extend from the probe ring (about 2 in. above the bottom tangent line) to the top tangent line and should be zoned. This allows additional active surface area to come in contact with the broth as the volume increase due to additions and to increasing gas holdup, minimizing cooling-loop pressure drop, and minimizing medium bake-on.
- Connections to the jacket should be via sanitary clamps or flanges, not by screwed fittings. This minimizes possible damage to jacket welds when cooling lines are connected or disconnected.
- Coolant should be filtered to avoid solids buildup and/or jacket fouling.
- Bottom jackets should be considered only for vessels larger than 5,000 L. The additional area will be about 10% of the straight side jacket area (allowing for bottom drain, etc. and will add about 5% to the cost of the vessel). In cases where there is an internal coil, bottom jacketing isn't necessary or desirable.
- Jacket coving to accommodate view ports, decreases jacket area and effectiveness and increases cost considerably. It should be avoided.

50.5.2.7 Internal Cooling Surfaces. Coils are the most common internal cooling surfaces, although there are other types (68). They can easily double the available heat transfer area and tend to be more effective than jackets; however, they can have big disadvantages:

- They make cleaning very difficult.
- They can cause additional bulk mixing problems, particularly for very viscous non-Newtonian broths.
- They will eventually leak nonsterile coolant into the broth.
- They can add up to 25% to the cost of the vessel.

We recommend that every other alternative (including slight decreases in growth rate and/or cell mass) be considered before yielding to the temptation to use coils. Keep in mind that, once installed, they will be there for the life of the vessel. If you absolutely, positively must use a coil, there are several points to remember:

- Mount it in a way that will insure minimum stress during heat-up and cooldown.
- Weld cladding over the butt welds used to join the coil pipe sections.
- Leak test (69) after construction and build in design features that will simplify leak testing on a regular basis thereafter.
- Space coil turns at least 3 in. apart. Anything closer will insure major cleaning problems.

50.5.2.8 Spargers. There has been a lot of discussion concerning the pros and cons of ring and single-orifice spargers, and the details of design of each. We have seen both work well and have not found any evidence for the validity of claims concerning the importance of hole size (for example) for oxygen transfer per se. The primary focus should be on gas distribution (which will depend on other aspects of the agitation system) and on aseptic operation. We usually favor single-orifice spargers.

There also have been advocates of porous (frits) spargers. The rationale presented has focused primarily on the small bubble size such spargers produce. There is some basis for these claims in cases where little mechanical energy is available for bubble breakup (e.g., in mammalian cell systems). There might also be some value in cases for which bubble coalescence is not a problem (far and few between in practical systems). They can be extremely difficult to clean, particularly for mycelial organisms. We usually suggest they not be used except in very special cases, as just noted.

Finally, it is important that the sparger be made and mounted in such a way that it can be removed easily for cleaning.

50.5.3 Piping and Valving

Design and construction details of the piping system depend on process, sterility, cleaning, and containment requirements, taken together.

50.5.3.1 Service Lines for Non-Process-Contacting Fluids. All lines providing fluids that cannot contact process fluid surfaces (e.g., coolant lines, plant steam lines for heating only) fall into this category. Satisfactory service is provided by either copper or stainless steel piping along with a rational combination of welded and compression fittings. Durability, servicability, cost, and corrosion resistance are major considerations. Ball valves are satisfactory on lines not turned on and off frequently (diaphragm valves tend to withstand a greater number of on–off cycles prior to failure).

50.5.3.2 Sterile Piping Systems. Before we discuss design of sterile piping systems, we reiterate the importance of a systems approach to integrating vessel and piping design. Independent design almost always results in a lot of aggravation, as well as higher cost and lost time.

A sterile piping system can usually be divided into five major subsystems: process, steam/condensate, air, harvest, and seal lubrication. Each has specific requirements dependent on its unique functions as well as the specific demands of the process. None of these systems is completely independent of the others, and all share common components. All also interact with the CIP piping system, which is discussed later.

Details of each of these subsystems follow a simplified description of sterilization procedures (Fig. 50.5). The reader is advised that the procedure is one of several commonly practiced; there are, for example, different opinions as to when live steam to the air inlet line should be turned on.

Phase 1 . After the vessel is filled with set medium, steam flow is started through the jacket. The agitator is run at low speed, and particulate free steam lubricates the shaft seal. The exhaust line is open for venting to the atmosphere. All other valves are closed. During this time not only are the vessel and the set medium being heated, but air is being purged from the medium. If the air is not purged, the vessel pressure during sterilization can become dangerously high, and there will not be a reliable correlation between pressure and temperature. Phase 1 continues until the medium temperature reaches 100°C.

Phase 2 . Steam continues to flow through the jacket. The air exhaust line is closed; the only path out is via steam traps. Steam is now admitted through the air inlet line to sterilize the inlet filter; steam leaving the vessel through the air exhaust line sterilizes the exhaust line piping and the exhaust filter. Steam flow is started through subsurface

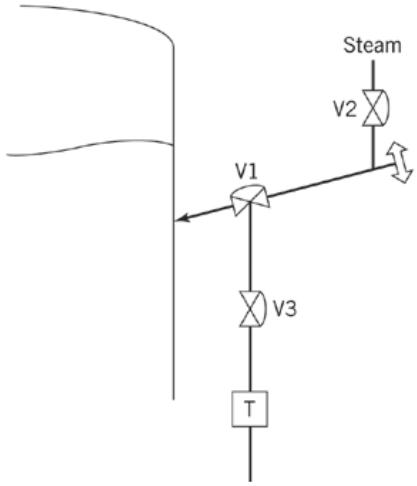

Figure 50.9. Sterilization of subsurface ports.

ports via steam lock assemblies (Fig. 50.9). (See later for further discussion of steam locks.) Ports above the liquid surface are sterilized by steam escaping through them from the vessel and then to condensate lines. Steam flow also is started through the bottom drain valve. All steam flows continue until the cooldown begins. Phase 2 continues until the medium temperature reaches 121°C.

Phase 3. Steam flow to the jacket is throttled to hold sterilization temperature constant until cooldown begins.

Phase 4. Cooldown. This is not discussed here.

50.5.3.2.1 General Principles. There are several general principles that should be applied to all sterile piping:

- Make all piping system components free draining. This requires special attention to the details of pipe pitches, valve orientations, and so forth
- Design all components and the piping layout so as to eliminate nooks and crannies where contamination (biological and nonbiological) can hide so as to escape cleaning and/or sterilization. Frequently overlooked problems include such things as deadlegs and ridges formed by welding operations.
- Make steam and condensate piping at least 3/8 in. diameter to insure proper steam flow and condensate draining.
- Make all piping lengths as short as possible without interfering with good fabrication practices (GFP), operability, and maintenance.
- Use check valves only when no other solution is possible (e.g., in overpressurized lines).
- Do not use sight glasses in condensate drain lines except in the seal lubricant drain line.
- Pay careful attention to piping orientation to avoid the possibility of air traps and inadequate heating (55,56).
- Make sure that bottom drain valves are flush-mounted diaphragm valves capable of being steamed in the closed position (Fig. 50.10). They must be free draining.
- Avoid dip tubes unless there is no other way (there almost always is).

Finally, the design should take into consideration the methods that will be used for validation of sterilization operations. These will vary considerably with the product and the organism. At one extreme is virtually no validation; at the other extreme is temperature mapping of the vessel and all the trap lines, as well as the use of spore strips and/or spore ampules in the vessel and in the trap lines. In some cases, tee sections have been included in drain lines for insertion of spore strips.

50.5.3.2.2 Welds. Orbital welding of the piping system produces the most reliable results with regard to aseptic operation and cleanability; it is essentially a requirement for many classes of regulated products, particularly those regulated by Center for Biologics Evaluation and Research (CBER). It also is the most expensive to build and to maintain. There are, however, many processes for which an economic combination of welded and compression fittings is acceptable. These can be operated quite satisfactorily if proper attention is paid to cleaning, sterilization, and maintenance protocols. The fact is that such systems have been used for many years to manufacture regulated products safely and efficaciously.

50.5.3.2.3 Valves. Diaphragm valves have become essentially required for most classes of regulated fermentation products. There is little argument that their design provides the greatest reliability for clean, aseptic operation. They have the added advantage of integral sterile access ports, which permit very short piping runs, particularly in valve clusters. Historically, diaphragm valves have been more expensive than have ball valves, but this has changed recently, particularly for some materials (e.g., SS316L). It therefore makes sense to use diaphragms for most applications. The primary exceptions are steam lines or other applications in which diaphragm life is a problem; in those cases one should consider ball valves or plug valves, as appropriate.

Another important consideration is the extent to which one uses valve actuators and position indicators. Obviously, this will depend in large measure on the nature of the control systems employed. In any event, one should consider very seriously the problems (e.g., space and orientation constraints, reliability) associated with valve "extras" while control system decisions are being made.

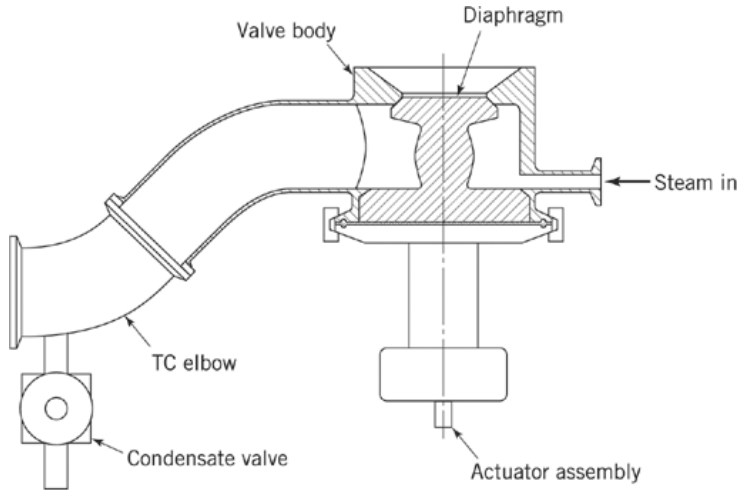

Figure 50.10. Bottom drain valve.

50.5.3.2.4 Steamlock Assemblies. The primary purpose of steamlocks (also known as block and bleed) is to allow sterilization of ports and process piping at any time during a fermentation in such a way that connections can be made and broken without risk of breaching the sterile barrier and/or the containment barrier. A basic steamlock assembly is illustrated in Fig. 50.11. In this case, vessel T1 contains presterilized nutrient that must be added at some time during the fermentation. T1 is connected to the fermenter by means of sanitary clamps (other means are possible). Steam flow is then started (open V1, V3, and V5) so as to sterilize the connecting hose and all the valving not previously sterilized. Condensate goes to drain (sanitary, if necessary) via V3 and V5. The steam and condensate valves are closed after sterilization is complete; process valves V2 and V4 can be opened anytime thereafter to make the sterile transfer. Note that the diaphragm valve sterile access ports make it much easier to sterilize the steam side of the valves than is possible with other valve types. Variations on this theme are better suited to cases involving long transfer lines or having other special requirements.

50.5.3.2.5 Air Inlet and Outlet. Fig. 50.12 is a simplified diagram of a "typical" air inlet/outlet system. The major problems for this system are related mainly to the filters. Chief among these (other than outright failure) is wetting of both filters caused by condensate during sterilization, and wetting and clogging of the exhaust filter by condensate and/or aerosol during fermentation. These problems are not all easy to resolve and should be dealt with most seriously during design. Wetting and/or clogging of the inlet filter by condensate and/or compressor oil during fermentation also can be a problem but is usually the result of not using proper quality air, having no or improper prefilters in the air inlet

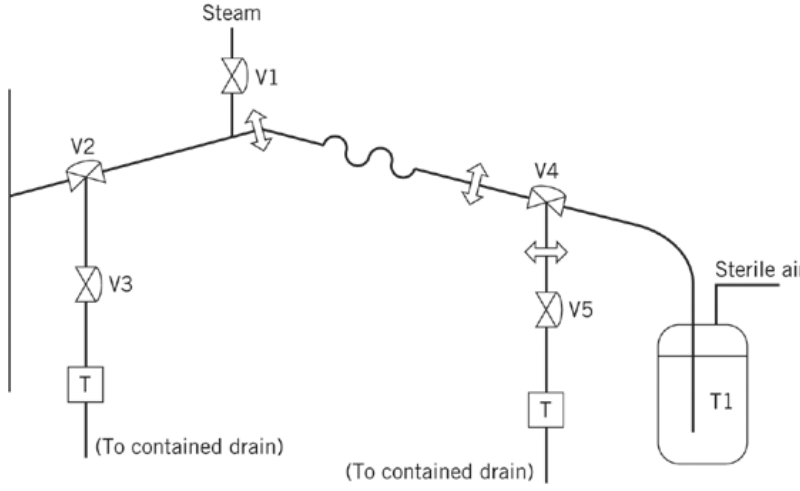

Figure 50.11. Steam lock assemblies for transfering sterile medium.

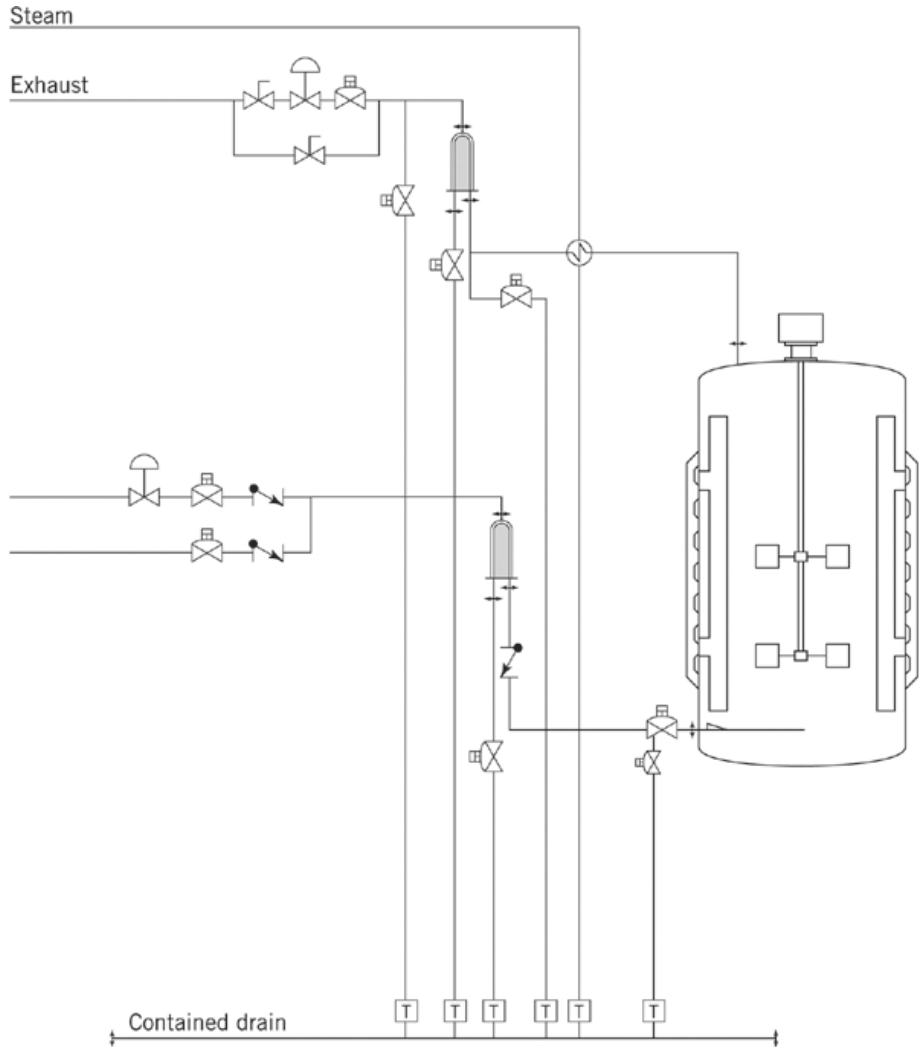

Figure 50.12. Simplified piping diagram illustrating air inlet and outlet systems.

line, and/or poor maintenance (e.g., of the compressor). All of these are easily remedied.

The extent of condensate problems during sterilization can be remedied best by ensuring that whatever condensate does form can drain freely. This can be complicated by the fact that it is undesirable to have the sterile side of the filter connected directly to the drain line. Another approach is to steam heat the filter housing such that condensation cannot occur. This is effective but has the disadvantages of adding cost and decreasing filter life.

Other factors that can affect condensate problems are the positioning and orientation of the housing. There are differing opinions concerning these; one is best advised to consider the advice the filter and the fermenter vendors for specific cases.

Plugging of the exhaust filter by condensate and aerosols during fermentation require special consideration. Air leaving the fermenter will be essentially saturated with water vapor at fermentation temperature. The exhaust line, filter, and so on usually are colder than the fermenter; therefore, condensation is inevitable. The amount of condensation will depend on temperature differences, air flow rate, and the nature of the surfaces of the components in the exhaust line (the maximum potential is easily calculable). Approaches that have been used to deal with these problems include (70):

- Condensers
- Heat exchangers; used before the exhaust filter to avoid condensation from the fermenter off gases and after the pressure control valve to prevent reflux from the exterior exhaust line
- Steam-heated filter housings
- Heated exhaust lines
- Coalescers
- All of the above

None of these is completely successful, and each has its proponents and detractors. Suffice it to say that each case should be considered on its own merits (e.g., fermentation temperature, duration, and air flow) and that combinations of the approaches should not be ignored.

The condensate problem is exacerbated by the aerosol problem. Aerosols will form in any aerobic fermentation and will carry liquid along with dissolved solids and particulates (including organisms) to the exhaust line. The only questions are how much and what problems they will cause. Among the problems are deposition of dissolved and particulate solids, not only on the filter, but also on heated surfaces or condenser surfaces. Among the problems deposition causes is reduction in heat exchange effectiveness, which reduces the capabilities of the previously mentioned devices to eliminate condensation. In severe cases, exhaust line blockage can lead to other problems related to pressure buildup and/or higher linear velocities in the exhaust line. The problem should be dealt with on a case-by-case basis during process development and fermenter design.

Provisions should be made for in situ integrity testing of sterile filters. This can be done by means of any of several commercial electronic testing devices that are based on liquid intrusion, diffusion, or some other well-established method for testing membrane filter integrity (71–73). One example of the piping necessary to perform the test on an exhaust filter is shown in Fig. 50.13.

Finally, two pressure control valves are required in the case of constant pressure sterilization (continuous flow of steam into the vessel and out to atmosphere). The reason is that the steam flow will be very much lower than the air flow during fermentation; hence, the valve C_v required to maintain steam pressure accurately will be far too small to control air pressure accurately.

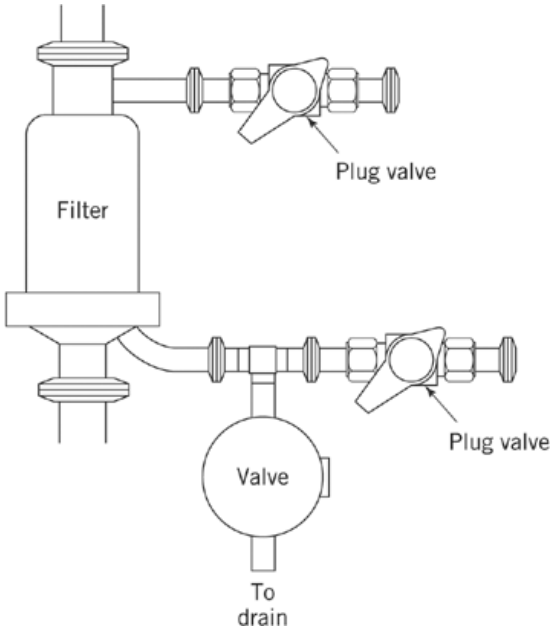

Figure 50.13. Piping diagram for in situ air outlet integrity test.

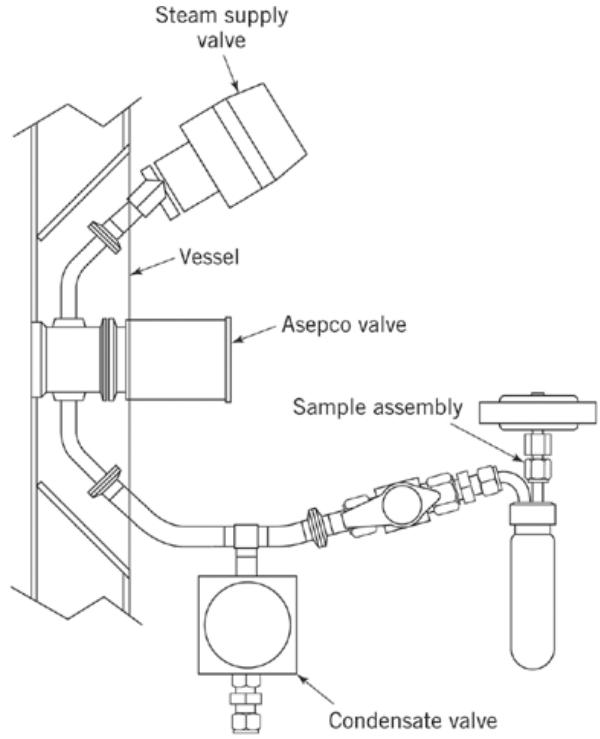

Figure 50.14. Aseptic sampling system.

50.5.3.2.6 Sampling Systems. One example of a simple aseptic sampling system is illustrated in Fig. 50.14. The sample vial, vent filter, and valve V1 are sterilized as a unit in an autoclave. The unit then is connected to the fermenter piping via a sanitary clamp. After the connection is made, steam is introduced via V3 and passes across the nonsterile sides of V2 and V1 and then to trap via V4. Once the valves and line are sterile, the steam and condensate valves are closed. Samples may be taken any time after the sampling system cools. Samples are taken via V1 and V2. Lines and valves are resterilized before the sanitary connection is broken.

The valves selected for this system will depend on the class of service required. We suggest that vessel sampling valve V3 be a flush-mounted diaphragm valve (e.g., Asepco™, NovaSeptic™) designed in such a way as to minimize dead volume and piping lengths; it is an excellent choice for service requiring very high levels of asepsis and cleanability. Less expensive valves can be used for less-demanding service, but we think that the initial extra cost will more than pay for itself. Diaphragm valves are suggested for V1, V3, and V4 in cases of demanding cGMP or containment requirements. This is not required for all classes of service; indeed, it is usually satisfactory

to use plug valves for steam and condensate lines even in many demanding circumstances. It should be noted, however, that you may encounter a perception problem if you use them for applications deemed to be sensitive.

There are several other designs that have been used successfully. A few have been designed specifically for systems requiring BL3-LS containment or higher. These are discussed later. Finally, please note that addition system design and operation are very similar to those for sample systems and are not discussed here.

50.5.4 Agitation Systems

Agitation can be done by direct mechanical coupling of the shaft to the drive or by magnetic coupling. The latter has been recommended for cases where high levels of containment are required (74). There also is the perception that magnetic drives are more suitable for maintaining more stringent levels of asepsis and cleanliness than is possible with direct drive. Neither claim has any substantive basis; indeed, there is good reason to believe that existing magnetic drives may present greater cleaning difficulties because of the manner in which the driven magnet must be mounted at the bottom of the vessel. In addition, power transfer by magnetic drive is quite low.

Direct drive is the predominant current choice at almost any scale of operation. The major mechanical decisions that must be made in this case (other than power) have been discussed at length elsewhere (4,75). The major arguments for bottom drive are ease of maintenance, shorter shafts, less support structure, and lower overall height. The arguments against bottom (and for top drive) focus primarily on the potential of catastrophic spills resulting from bottom seal failure, seal grinding as a result of broth particulates working into a bottom seal, and greater cleaning difficulties. If the seals are designed and maintained properly, none of these is a problem. We have seldom seen any real difference in aseptic operability between top and bottom drives, and we are reasonably certain that the organisms don't care. The choice probably will continue to be driven primarily by personal preference.

There are very few cases in which double mechanical seals are not (or should not) be used in fermenters. The major debate focuses on seal orientation and the details of individual seal designs. There are basically two orientations used: inline (Fig. 50.15) and back-to-back (Fig. 50.16). The

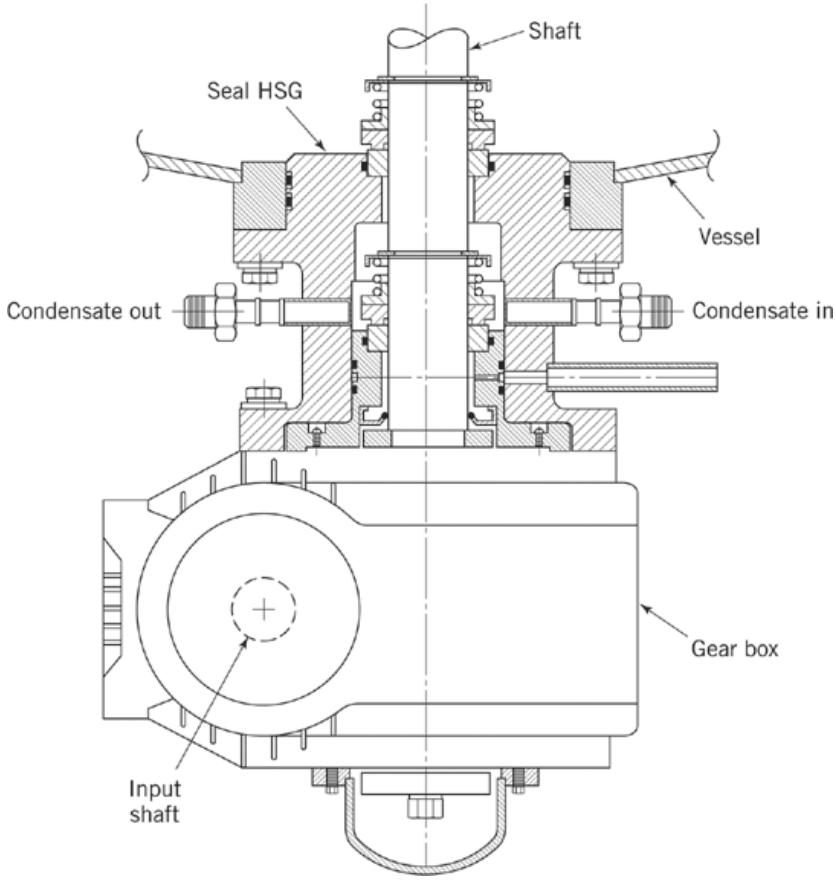

Figure 50.15. In-line double mechanical fermenter shaft seal.

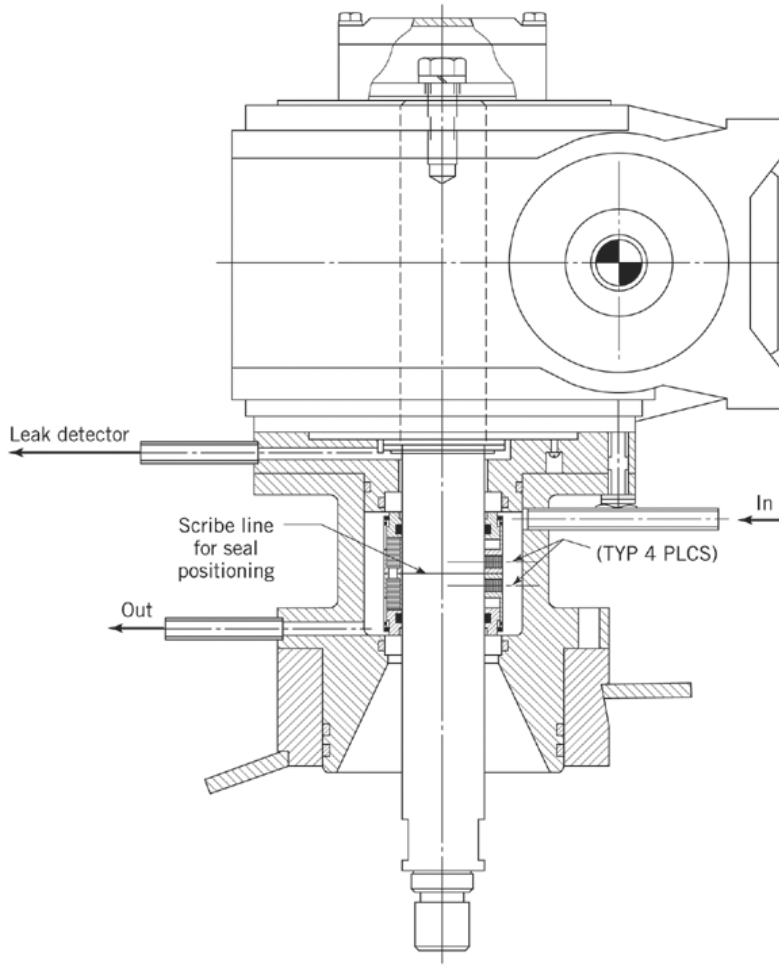

Figure 50.16. Back-to-back double mechanical fermenter shaft seal.

details are discussed in Refs 4 and 75. We recommend in-line design because we have found it to operate more cleanly and require a simpler sterilizing/lubricant system (4,75).

Seal lubrication is usually provided by means of sterile steam condensate. It is extremely important that this condensate be free of particulates: their presence guarantees rapid seal failure, contaminated fermentations, and a hyperactive maintenance program. It is also important to note that during sterilization live steam flows through the seal housing. There are some who insist on keeping the steam flowing throughout the fermentation. (Obviously, they have no faith in the seals.) The one thing this will guarantee is much more rapid wearing of the seals (perhaps supporting the lack of faith in the seals).

One must also decide on the means for controlling lubricant flow rate. Most use a valve for this purpose. We suggest an orifice sized to deliver the proper flow. This avoids the cost and maintenance of a valve and insures fiddle-proof operation. It does, however, require the use of particulate-free condensate, but then so does proper operation of the seals. We also recommend including a sight glass in the lubricant drain line as well as a seal leak detector (Fig. 50.17). Other more complex detection systems might be considered for specific circumstances (e.g., severe containment requirements).

Finally, preventing shaft vibration is another important factor in agitation system design. Shaft vibration is a safety hazard. It will also cause premature seal failure and other costly mechanical damage. Details have been presented elsewhere (4).

50.5.5 Cleaning Systems

As noted earlier, specific requirements for cleaning depend on several factors including the nature of the fermentation

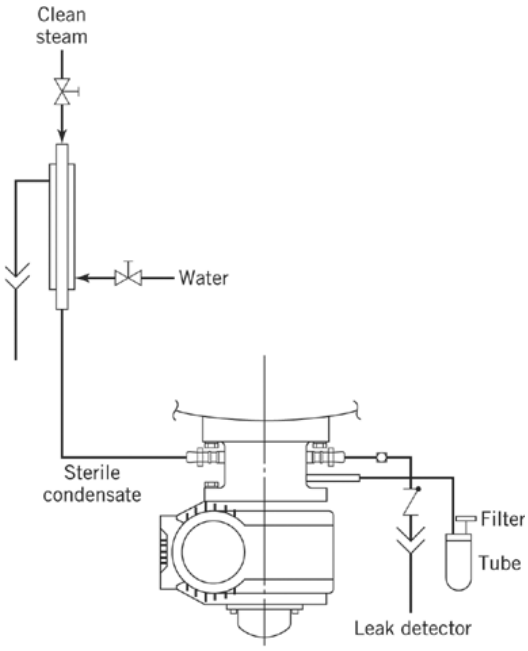

Figure 50.17. Piping diagram illustrating lubricant flow sight glass and seal leak detector.

broth. There is a major difference between most microbial broths and most mycelial broths. Single-cell microbial broths, with the exception of those containing a lot of undissolved particulates and high viscosity components (e.g., xanthan broths), tend to be free draining and readily amenable to cleaning based primarily on the physicochemical action of the cleaning agents. Many fungi and mycelial bacteria, on the other hand, tend to cling to fermenter internals and may require mechanical action (e.g., high-velocity jets) in addition to cleaning agents.

The following guidelines are applicable for most systems. These principles must be applied in light of the actual cleaning agents and protocols to be used:

- Eliminate internals and nooks and crannies to the greatest extent possible in the vessel and throughout the piping system. This practice is consistent with design for aseptic operation.
- Drill and position sprayballs to insure complete coverage of all surfaces inside the vessel. This usually requires an empirical approach. Coverage can be tested by means of the riboflavin test. The reader is cautioned, however, that complete coverage is a necessary but not sufficient condition for cleaning. Also, please note the following:
  - Spray balls designed for sanitary operation are self-draining and self-cleaning. They can be sterilized in situ. There is, however, considerable debate concerning whether they should be removed prior to fermentation.
  - High-velocity, rotating devices that may be necessary when large clumps of sticky residue must be removed (e.g., as with a fungus) are not designed to be inherently self-cleaning, self-draining, or sterilizable. They should not be mounted permanently.
- Eliminate deadlegs in piping and deadspaces in valves, fittings, and other system components. This is also consistent with design for aseptic operation.
- Specify the same materials and finishes for process and CIP piping as are specified for the fermenter. Obviously, these must be compatible with the cleansers and conditions used.
- Avoid threaded joints. A completely welded system is best, but compression fittings can be satisfactory when cost is a major consideration, particularly for nonregulated products.
- Make CIP piping as simple as possible. For example, make dual use of process and other piping as much as possible.
- Avoid complex, expensive transfer panels wherever possible. Use swing elbows wherever practical.
- Design and construct the system to facilitate validation and on-going testing for removal of contaminants, including the cleaning agents. This design should provide for swabbing, obtaining rinse samples, or whatever else the cleaning protocol requires.

A portion of one approach to integral CIP piping is illustrated in Fig. 50.18.

There are many cases for which a portable CIP system is preferable to an integral system. For such cases, the fermenter and the portable unit should be designed to allow simple mechanical attachment of the necessary hoses between the two units and with utilities, and a straightforward means for interfacing the instrumentation, logging data, and controlling the systems of the two units.

Finally, we note that classical CIP systems rely on continuous cleanser flow and the maintenance of a shallow puddle in the bottom of the fermenter. To achieve this they rely on special pumping devices such as eductors (74). Aside from the design, control, and other operating problems this causes, it has been observed in some facilities that the stable pool leads to the formation of "cleaning rings" at the bottom of the fermenter. These rings may not be real problems (additional evidence is still required), but they do cause perception problems. We suggest the use of a pulsed-flow system to overcome not only the need for special pumping devices but also the "cleaning ring" problem. Such pulsed systems have been found to accomplish both objectives in practice.

Additional details concerning fluid velocity, vortex elimination, and many other aspects of CIP system design and operation are described elsewhere (59).

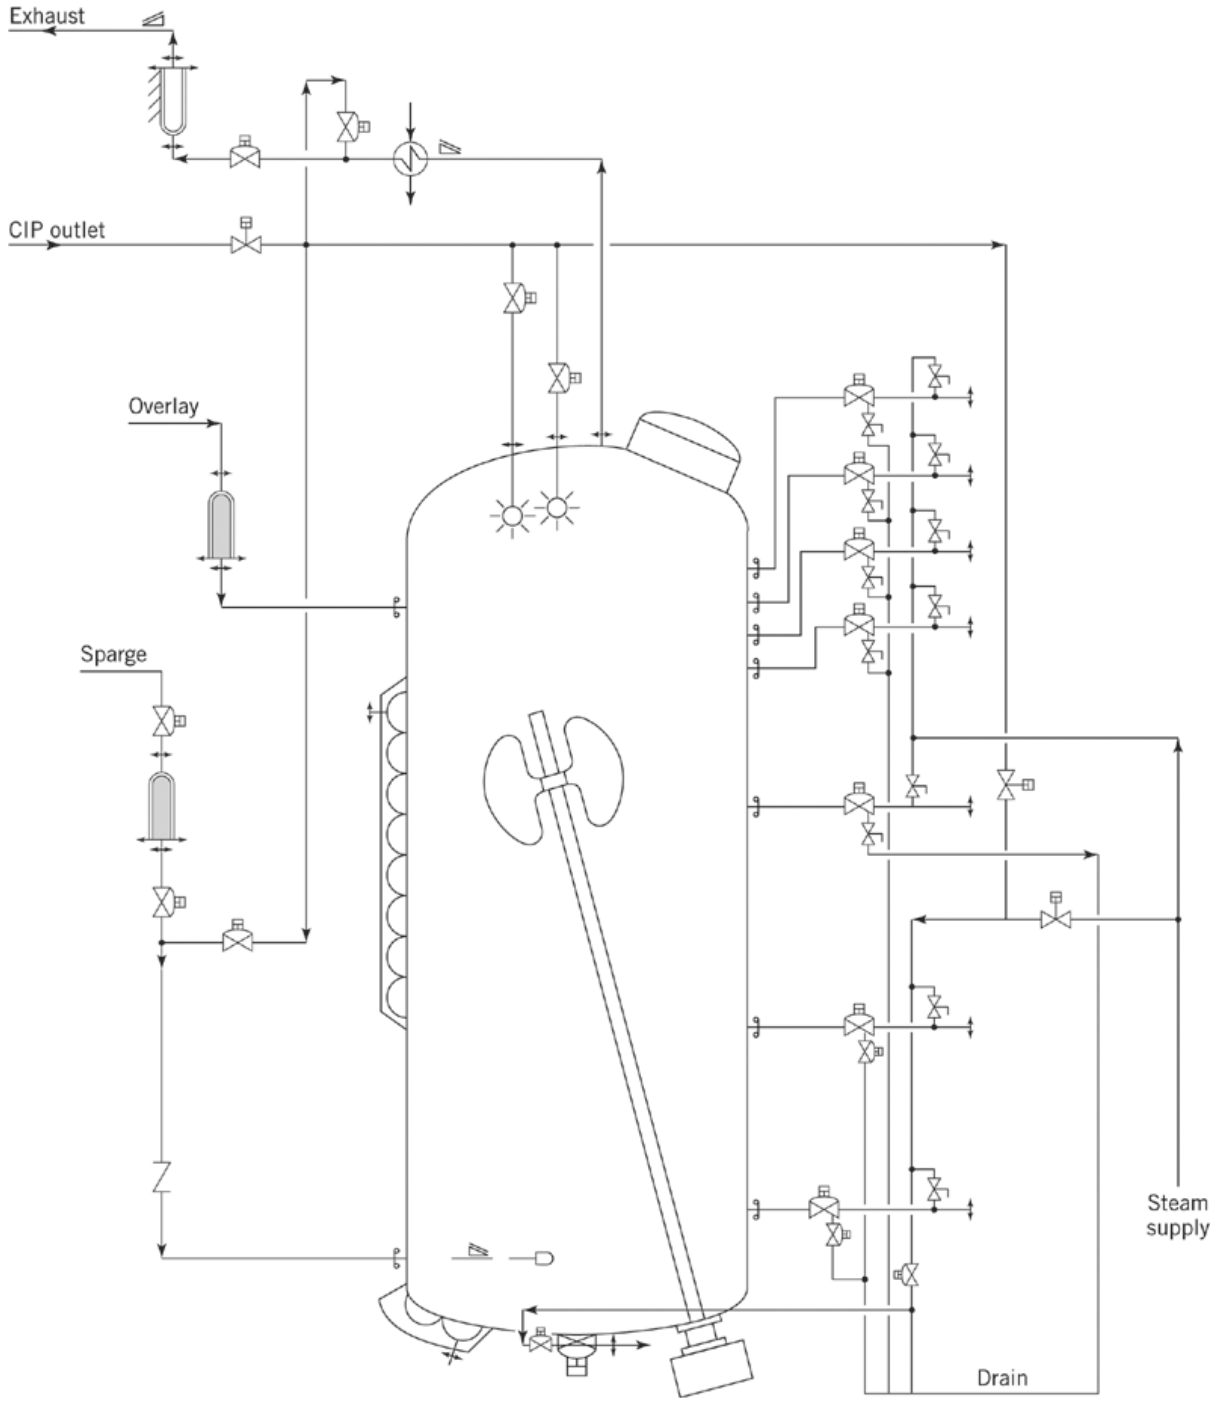

Figure 50.18. Simplified CIP piping diagram.

50.5.6 Containment

Our scope is limited to containment of fermenters; however, we reiterate here the importance of making certain that the equipment, the facility, and the operating protocols be considered simultaneously to ensure compatibility with regard to containment (just as in the cases of sterility and cleaning). As noted earlier, most new facilities for regulated products are being built to satisfy BL2-LS facility requirements and (in most cases) BL3-LS fermenter containment requirements. With few exceptions (about which there is no agreement) there is no difference with regard to the equipment containment requirements at the two levels—at present.

The guidelines require that BL2-LS/BL3-LS fermenters be designed and constructed to prevent organism release (primary containment) from the vessel and from any of the subsystems noted earlier; hence, they must be built as closed systems. (Note that it also is possible to enclose a fermenter in a biosafety "cabinet," but this is not usually practical or necessary.) Some areas that have been subject to greater scrutiny than has been required for cGMP compliance are as follows. In evaluating the discussion, the reader should bear in mind that there is not much information readily available concerning containment reliability data. Some progress is being made via the Industrial Biosafety Project in the United Kingdom.

- *Static seals*. It has been suggested that double static seals (e.g., in headplates) be used for BL2-LS and that double static seals with a steam trace between the seals be used for BL3-LS (76). There has been little to demonstrate that these are either needed or desirable. Indeed, there have been substantive arguments made against using such devices (76). There is as yet no consensus.
- *Rotating seals*. Arguments have been made in favor of using magnetic drives at anything higher than BL2-LS. This was discussed earlier. There are many who argue that only top drive be considered for BL2-;LS and above. Their reasons have mainly to do with avoiding the possibility of large spills in the event of catastrophic seal failure. Such a circumstance is possible but highly unlikely. Leak detectors (which would normally be installed for cGMP requirements) would almost certainly indicate a leak long before there was the remotest possibility of catastrophic failure. One also should consider that a leak in top drive seal might be more difficult to detect and could lead to release of a more insidious nature. Again there is no consensus. Finally, it has been suggested that a low-pressure sensor or flow sensor be used to detect lubricant flow failure. This could help to avoid seal failure (77).
- *Sampling systems*. One system recommended (78) for contained sampling is illustrated in Fig. 50.19. Note that it is similar to the system in Fig. 50.14 recommended for cGMP compliance. It is a bit more complicated and may provide some incremental benefit; however, this might be outweighed by the greater likelihood of operator error. There have also been more complex systems suggested that involve more intricate valving and/or biosafety cabinets. It is apparent that this is an area that needs considerably more development work.
- *Air exhaust system*. It has been suggested that two in-series sterile filters or a sterile filter followed by an incinerator be used at BL2-LS and higher. All other aspects are covered by the earlier discussion of exhaust lines.
- *Pressure relief*. This is an area of some controversy because of the need to satisfy physical and biological safety requirements simultaneously. It has been suggested by many that relief venting be done via a large kill tank protected by a HEPA filter; however, this could be in conflict with physical safety codes that require there be no devices in the relief path (79). We do not have anything approaching universal agreement here; however, it does seem fairly apparent that limiting the supply pressure would help to minimize the risk. There does appear to be agreement on the use of rupture disks rather than pressure relief valves; this is consistent with accepted practice for cGMP compliance. Rupture disks are cleaner and are not prone to sticking.

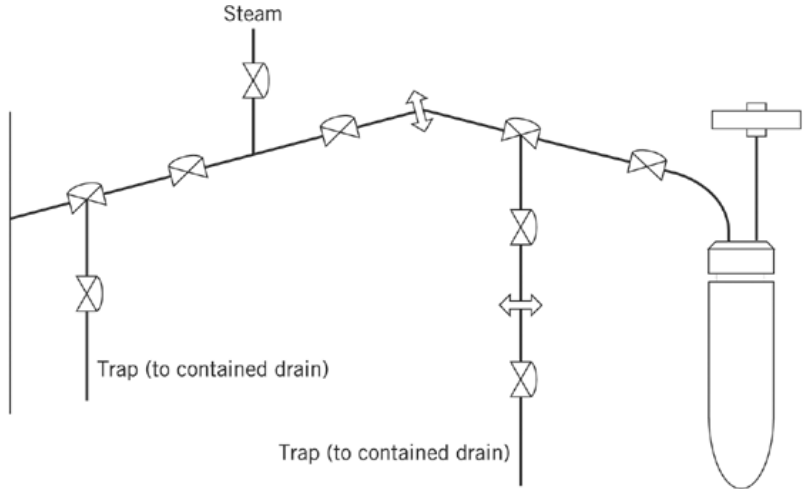

Figure 50.19. Contained sampling system. *Source*: Adapted from Van Houten (78).

Finally, HAZOP evaluations for fermenter containment have been recommended. Such analyses would evaluate potential hazards that might be caused by a wide range of incidents (e.g., fire) not limited to normal operation.

50.6 CONCLUSION

Our intent has been to present a balanced view of stirred-tank fermenter design and construction for microbial and and mycelial organisms. There are, however, several important aspects that space and scope considerations prevent us from considering in the depth they warrant. In particular, we would like to have included more information related to overall process considerations, instrumentation, and control; however, we believe that these are addressed elsewhere in this volume. We trust that we have conveyed the sense that fermenter design is very much an art and that we have convinced you to consider each case separately.

GAS-HOLDUP IN BIOREACTORS

Christian Sieblist and Andreas Lübbert
Institute of Biotechnology; Centre of Bioengineering, Martin-Luther-University Halle-Wittenberg, Weinbergweg, Halle (Saale), Germany

51.1 BASIC DEFINITIONS

The gas holdup ε_G is an important bioprocess design variable, as it determines the maximal liquid culture volume $V_{L\,max}$ that can be processed in a given bioreactor of total vessel volume V_T.

Most production processes in biotechnology are performed as submerged cultures, where cells are suspended in a liquid medium of volume V_L. In order to support aerobic cultures with oxygen and to remove the carbon dioxide formed at sufficient rates, air is dispersed into the liquid medium. The total volume V_G of gas within the entire volume V_D of the dispersion is most often represented as its volume fraction ε_G. This is referred to as the gas holdup (Eq. 51.1).

$$\varepsilon_G = \frac{V_G}{V_L + V_G} = \frac{V_G}{V_D} \tag{51.1}$$

Dispersed gas also appears in anaerobic cultures, for example during beer fermentation. There, the gas holdup is made up by CO_2 bubbles. This gas is one of the main metabolic products during beer fermentation.

Obviously, the larger the gas holdup ε_G, the larger is the dispersion volume V_D occupying the total reactor or tank volume V_T. Particularly from this point of view we must distinguish two forms of gas–liquid dispersion within a bioreactor. The first is the dispersion of bubbles in the bulk of the culture, where bubbles rise relative to the liquid. The other is the foam that most often develops on top of the culture (1–3). Again, foam consists of gas dispersed within the continuous liquid phase, even though the gas bubbles no longer rise relative to the liquid. On the contrary, the liquid drains out of the foam, down into the bulk of the liquid. In foam, the gas holdup is quite high, sometimes larger than 99% of the total volume.

The gas volume fraction in the bioreactor is not homogeneously distributed across the bioreactor volume (27). Hence it is straightforward to distinguish between local gas holdup ε_{Gl} and the integral or total gas holdup ε_{Gt}. Whenever not directly specified, we mean the global or total gas holdup $\varepsilon_G = \varepsilon_{Gt}$. The local gas holdup, ε_{Gl}, is defined by the differential quotient (Eq. 51.2).

$$\varepsilon_{Gl} = \frac{dV_G}{dV_D} \tag{51.2}$$

In this case, we assume that we are allowed to speak about the dispersion as a quasi-homogeneous fluid. This is a reasonable assumption when we speak about technical bioreactors where the bubbles are generally very small as compared to the reactor dimensions. Of course, when we discuss effects on small scales, we should keep in mind that the gas-phase in gas–liquid dispersions is composed of individual bubbles of volume V_j. But when we are looking for effects on scales in the order of the mean bubble size, it does not make sense at all to speak of gas holdup. On such small scales, the gas–liquid two-phase flow system must be treated in a discontinuous way. In conclusion, discussions about the gas holdup in bioreactors are more or less restricted to scales which are large as compared to the bubble size.

With respect to the foam layer, we must discuss the foam formation and the stability of the already formed foam. Both

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

are of considerable practical relevance to the gas holdup in the fermenters used in bioprocess engineering. Foam formation is related to gas sparging or bubble generation. Only where bubbles are formed, can foam develop. When the bubbles rise in the continuous liquid phase they finally approach the upper surface of the dispersion. There they are slowed down before they can disengage from the dispersion. When the disengagement process is retarded, we observe a traffic jam effect, that is, a high bubble density. From this region, the liquid flows down and the gas holdup rises. Finally, the liquid phase forms only thin layers which separate the bubbles. Then we speak of foam: it is important to recognize that in a bioprocess with a foam layer on top of the dispersion, the local gas holdup rises from the upper part of the dispersion into the foam. In other words, in an actively aerated bioreactor we do not observe a sharp boundary layer between the bulk of the dispersion and the foam.

The bubbles in the foams which we are dealing with in bioreactors, are more or less stable. Usually, the bubbles coalesce after a shorter or longer time. When the number of bubbles entering the foam is smaller than the number of bubble coalescence processes, the foam layer will rise. Stable foams are persistent even if no bubbles are entering the foam layer from below. On the average, however, roughly the same amount of gas that arrives at the foam layer during cultivation processes is disappearing from the upper surface of the foam. Otherwise, the foam on top of a microbial culture, aerated with a gas flow rate of about 1 (vvm) would enter the reactor's vent line after a few seconds. There it would clog the off-gas filter so that the process would have to be stopped. In practice, foam layers increase comparably slowly so that there is time to act against foam stabilization.

51.2 BIOTECHNOLOGICAL RELEVANCE

51.2.1 Gas Holdup for Mass Transfer

One main reason for the importance of the gas holdup results from the reason why a gas holdup is established during gas–liquid mass transfer.

Most important to aerobic cultivations is the oxygen transfer from the dispersed air (in some cases enriched with oxygen), into the continuous liquid phase. It is essentially determined by the diffusion of oxygen across the liquid-side boundary layer around the bubbles, which is driven by the oxygen concentration difference O^*-O between the bulk concentration O and the concentration O^* directly at the physical interfacial area. With the corresponding volumetric transfer coefficient k_La, the corresponding transport law, the oxygen transfer rate (OTR) reads as given in Equation 51.3:

$$OTR = k_La(O^* - O) \tag{51.3}$$

A more detailed analysis shows that the coefficient k_La is composed of two factors, k_L and a. The first, k_L, considers the mean conductance of the boundary layer, around the bubble. The second, a, is the transport cross-section provided per unit volume.

The gas holdup is related to both factors: the size of the mass-transfer cross-sectional area per dispersion volume, a, and via the mean equivalent bubble diameter d, to the boundary layer conductance and thus k_L. The equivalent diameter d_j of the j-th bubble is defined as the diameter of the sphere of the volume V_j of the bubble gas. It is the preferred bubble size measure because it is more intuitive than the bubble volume V_j. The total gas volume V_G is composed of all individual bubbles (Eq. 51.4).

$$V_G = \sum V_j = \frac{\pi}{6}\sum d_j^3 \tag{51.4}$$

Using this bubble size definition, the integral transport cross-sectional area A for gas–liquid mass transfer can also be divided into the contributions from individual bubbles (Eq. 51.5):

$$A = \sum A_j = \pi \sum d_j^2 \tag{51.5}$$

where A_j is the surface area of the j-th bubble. In biochemical reaction engineering, one prefers to discuss the transport cross-section as a specific property of the dispersion. In this particular case it is a volume-related quantity. The specific interfacial area, a, is defined as the transport cross-section per unit volume of the culture (Eq. 51.6):

$$a = \frac{A}{V_D} = \frac{\sum A_j}{V_D} = \frac{\pi \sum d_j^2}{V_D} \tag{51.6}$$

With these definitions we are able to relate the gas holdup to the quantities of primary interest in biochemical reaction engineering. Starting from the definition (1), we get Equation 51.7.

$$\varepsilon_G = \frac{V_G}{V_D} = \frac{AV_G}{V_DA} = \frac{A}{V_D}\frac{\frac{\pi}{6}\sum d_j^3}{\pi \sum d_j^2} = a\frac{\frac{\pi}{6}\sum d_j^3}{\pi \sum d_j^2} \tag{51.7}$$

Since the bubbles in biotechnologically relevant dispersions are not of uniform diameter d_j, such expressions are of little practical use. It is straightforward to characterize the bubbles by a mean equivalent bubble diameter. In the light of the preceding discussion, it is convenient, as proposed by Sauter, to take the quantity d_s as such a (special!) mean of the bubble diameters (Eq. 51.8):

$$d_S = \frac{\sum d_j^3}{\sum d_j^2} \tag{51.8}$$

The sums are drawn over all bubbles j. In literature, d_s is referred to as the Sauter diameter.

An advantage of this definition of the Sauter diameter d_s is that we obtain a very simple relationship for the relevant gas-phase characteristics of bubble dispersions, as given in Eq. 51.9:

$$\varepsilon = a\frac{d_S}{6} \text{ or } a = \frac{6\varepsilon}{d_s} \tag{51.9}$$

This essentially says that the specific interfacial area a, the key quantity for mass transfer, increases proportionally to the gas holdup ε. The proportionality factor depends in a most simple way of the Sauter mean bubble diameter d_s. In other words: The specific interfacial area a, is formed by establishing a gas holdup ε and one is more effective, when the mean bubble size is kept smaller.

Only at first glance, the specific interfacial area, a, appears to be of primary importance to mass transfer. When, at the same gas holdup, ε_G, the mean bubble size d_S is too small then, although a large specific interfacial a appears and the bubbles do not have enough relative motion with respect to the continuous liquid phase. When they will stay within the dispersion, and after they became exhausted, they can no longer contribute to oxygen mass transfer. Then, in the same way as the foam, they must essentially be considered as dead volume that reduces the productivity of the reactor.

In practice, ε is primarily increased by increasing the aeration rate or gas throughput Q_G. The latter is often represented relative to the cross-sectional area A_{RCS} of the reactor. This quantity is referred to as the superficial gas velocity w_{sg} (Eq. 51.10), since it formally has the dimension of a velocity.

$$w_{sg} = \frac{Q_G}{A_{RCS}}[m^3/h/m^2 = m/h] \tag{51.10}$$

At lower superficial gas velocities of about $w_{sg} < 8$ [cm/s] the bubbles form a homogeneous dispersion with a narrow bubble size distribution, and they rise with a more or less constant velocity within the liquid phase. At superficial gas velocities larger than about 8 cm/s the bubble flow becomes heterogeneous. Additional larger bubbles are formed that rise with an enhanced velocity and the overall flow becomes turbulent. Then, one speaks of a churn-turbulent flow regime.

In bubble columns, the gas holdup ε shows a small decrease with increased column diameter. This effect is due to increased liquid recirculation with increasing scale. The volumetric mass-transfer coefficient, k_La, closely follows the trend in gas holdup (4). In the heterogeneous flow regime, that is at $w_{sg} > 8$ (cm/s), the value of k_La/ε was found to be practically independent of column diameter and superficial gas velocity w_{sg} (4).

51.2.2 Gas Holdup Determining Mixing

The second main aspect, influenced by the gas holdup, is the mixing of the dispersion. Mixing of the continuous liquid phase is a very important task for every bioreactor.

For mixing, the local gas holdup ε_{Gl} is important. This can most easily be understood, considering the important group of bubble column bioreactors. They are the preferred reactors for very large production processes such as citric acid production ($V_D > 500$ (m^3)). In bubble columns the gas is dispersed at the bottom by means of a sparger. The correspondingly enhanced local gas holdup in the sparger region leads to a reduced density ρ_D of the dispersion, which can be represented as a linear function of the local gas holdup ε_{Gl} (Eq. 51.11) where ρ_L is the density of the liquid phase:

$$\rho_D = (1 - \varepsilon_{Gl}) \cdot \rho_L \tag{51.11}$$

This immediately leads to convective flows by which the dispersion tries to counteract, that is, tries to degrade the density inversion. When the gas flow rate into the bioreactor becomes higher, the density around the sparger becomes even lower. Finally, the resulting convective flows become turbulent over the entire dispersion in the bubble column and this turbulence is required for an efficient mixing.

According to Freedman and Davidson (5) the mean fluid flow acquires the appearance of a gulf stream. This model shows a region of higher local gas holdup in the surroundings of the column axis where the mean flow velocity is rising. Corresponding to this flow, a downward-directed flow near the wall is compensating the rise. This is important for the top-to-bottom mixing in these bioreactors.

In airlift tower loop reactors (e.g. Bello *et al*. (6)) the gas holdup difference between the riser and the descender part is essential for the reactor to work, that is, to globally circulate the culture around the loop.

When the mean axial bubble velocity in the laboratory coordinate system is w_{bl} which is given by (Eq. 51.12):

$$w_{bl} = \frac{H_D}{\tau_B} \tag{51.12}$$

where τ_B is the mean residence time of the bubbles in the reactor, and Q_G is given by Equation 51.13.

$$Q_G = \frac{V_G}{\tau_B} \tag{51.13}$$

Then we get Equation 51.14:

$$\varepsilon_G = \frac{V_G}{V_D} = \frac{V_G}{A_{RCS}H_D} = \frac{V_G\tau_B}{\tau_B A_{RCS}H_D} = \frac{w_{sg}\tau_B}{H_D} = \frac{w_{sg}}{w_{bl}} \tag{51.14}$$

In other words, the gas holdup ε_G is proportional to the superficial gas velocity, the proportionality constant being the reciprocal value of the mean bubble rise velocity in the laboratory coordinate system. The superficial gas velocity w_{sg} is usually taken as the primary manipulated variable since, as will become clear soon, most important variables of gas–liquid reaction systems are primarily influenced by w_{sg}. The other important quantity in Equation 51.14, the effective bubble rise velocity, w_{bl}, depends on the fluid dynamic properties within the reactor as well of the broth rheology. Equation 51.14 has some practical consequences that will be discussed later.

The gas residence time distribution in the reactor may be influenced by the geometry of the reactor. The gas throughput and, where installed, the impeller system inducing re-circulated flows within the reactor. In order to estimate the mean gas residence time, the mean bubble rise velocity allows a first estimate. Correlations are only available for the rise velocities of single bubbles in a large basin (e.g., Clift *et al*. (7)). They must be corrected for bubble-bubble interactions in bubble swarms. Such corrections primarily depend on the gas holdup. Kendoush (8) presented a simple correction term (Eq. 51.15):

$$\frac{v_B}{v_{Bs}} = (1 - \varepsilon)^3 \tag{51.15}$$

An additional mixing effect, resulting from the gas holdup, is the local mixing made by individual bubble wakes. When bubbles rise, they carry along within their wakes some amount of liquid through the dispersion, relative to the liquid bulk. Of course, there is some liquid transfer between the wake and the bulk, but on the average, the rising bubbles carry the liquid for some seconds. This results in liquid displacements in the order of several decimeters. When the wake is roughly half the bubble volume, this means at a gas holdup of 20%, roughly 10% of the entire liquid is steadily being shifted relative to the bulk motion, by means of the bubbles. Hence, the local mixing due to the bubbles is primarily a function of the gas holdup.

In the most important bioreactors, the stirred tank reactors, the situation is not very different. Only when the impeller system works, it superimposes an additional mean flow on the bubble column flow. But in stirred tank bioreactors the gas holdup has another indirect influence on mixing: The larger the gas holdup, the lower the power that can be transferred from the agitator into the dispersion at the same stirrer speed. This results from gas cavities developing behind the impeller blades due to the lower pressures at these places which attract bubbles. The gas cavities reduce the effective flow resistance of the impeller blades and thus, at a predefined stirrer speed, less mechanical power will be transferred into the flow.

Another aspect to note is that the gas, which is sucked into the cavities behind the impeller blades, is redispersed into the bulk of the dispersion such that there is a constant gas flow through these cavities. The mean size of these secondary gas bubbles is determined by the impeller geometry, the stirrer speed, the gas holdup and the rheological properties of the fluids. The amount of gas redispersed in this way is larger than the gas delivered by the primary gas sparger, because it will be recirculated several times through the cavity system. Hence, in stirred tank reactors the mean bubble size and the gas holdup is determined more by the impeller system than by the sparger (25). From the practical point of view this means that it does not make much sense to optimize a sparger construction for stirred tank reactors with respect to small primary bubble sizes. Thus, in many production-scale bioreactors, an open tube is used for gas supply to the cultures.

51.2.3 Gas Holdup and Foam

The key problem with a foam layer on top of the dispersion is that when it becomes too high, it enters the vent line and reaches the off-gas sterile filter. After a short time, the filter will clog and finally prohibit the gas throughput. Foaming is not completely predictable. In order to avoid such situations, the headspace chosen must be quite large, allowing the development of rather large foam volumes before the foam can enter the vent line. This obviously restricts the culture volume, which can be operated in the vessel, to rather low values. In production-scale baker's yeast cultivations for instance, the average dispersed gas and foam sum up to roughly 30% of the liquid volume. Moreover, additional 10–20% must be reserved for situations in which extraordinary amounts of foam are being formed.

From the reactor design perspective, both parts, the dispersed bubble part and the foam layer on its top, influence the process performance in different ways. However, both must be discussed in the same context for a number of reasons:

(i) The size of the culture that can be operated in a given bioreactor is determined by both.

(ii) During the main cultivation phases both parts cannot sharply be separated from each other. In most reactors, their relative volumes can neither be determined nor controlled.

(iii) Most measures affecting one part immediately influence the other one. Antifoam agents, for example, reduce the foam but also the gas holdup in the bulk of the culture.

There are a few more important aspects where culture and foam interact. By virtue of their surface properties, some cells have the tendency to concentrate at gas–liquid

interfaces. There, they can be separated from fermentation broths by flotation into the foam. Factors affecting cell flotation include bubble size, aeration rate, pH, and cultivation conditions. Hydrophobicity of the cell surface has been found to be a significant parameter in a number of studies.

51.3 WHAT DETERMINES GAS HOLDUP?

In practical bioprocess engineering, we are primarily interested in the influences of the manipulatable or adjustable process variables on gas holdup.

51.3.1 Physical Influences

The height of a gas holdup in a culture is most easy to understand in terms of the gas residence time τ_b. When the bubbles are considered as vehicles moving the gas from the sparger or gas distributor into the headspace of the reactor, a slower rise, that is a longer mean residence time, leads to a higher gas holdup. At low bubble rise velocities we observe traffic jam or traffic holdup effects. If the bubbles are restricted to move at slow speeds, the bubble density and, thus, the gas holdup become high.

The bubble size is the most important variable affecting the resident time distribution. The primary bubble size, which is the size which is generated at the gas sparger, depends on many variables (26). Most important for the liquid properties are the surface tension σ, the density ρ_L, the viscosity μ, and the direct sparger properties. The key operating variable is the superficial gas velocity w_{sg}. Pohorecki *et al*. (9) proposed for Sauter's diameter d_s, the following equation (Eq. 51.16):

$$d_s = 0.889\rho_L^{-0.552}\mu^{-0.048}\sigma^{0.442}w_{sg}^{-0.124} \qquad (51.16)$$

Upon the appearance of surfactants, the bubble size in such solutions is smaller than in pure water, as the surface tension σ is usually reduced by these compounds.

The mean bubble size d_s immediately influences the bubble rise velocity, hence $w_B = w_B(d_s)$. Larger bubbles usually do rise faster than smaller ones (e.g., Abou-El-Hassan (10)). However, $w_B(d_s)$ is not a linear but a rather complex function of d_s.

The bubble rise velocity is also influenced by the mobility of molecules at the surface of the bubbles. The liquid media which are used in biotechnology most often contain surfactants and also most proteins work as surface-active substances. They reduce the surface mobility and thus lead to smaller bubble rise velocities.

Most importantly the gas hold in bioreactors is affected by the coalescence of smaller gas bubbles and redispersion of larger ones. These processes immediately change the bubble size, rise velocity, and number density. In real cultures coalescence and redispersion are rather complicated processes that are not yet completely understood. Both are dependent on a number of aspects such as composition of the liquid and the gas phase, motion of the liquid phase, process time, etc.

The basic physical process leading to bubble coalescence can be divided into three steps:

- Bubbles must come into *contact* and form a film of 1–10 μm thickness. This is mostly controlled by the hydrodynamics of the bulk liquid.
- Thinning down the films. The rate of *thinning* is controlled by the hydrodynamics within the liquid film.
- *Rupturing* occurs once the film is sufficiently thin.

The rupturing process is faster than the other two steps but will not occur if the contact time is shorter than the thinning process. So we can consider that rate of thinning in the liquid film is the rate-controlling step.

However, the coalescence repression may appear when the thinning process is retarded by changes in the rheology of the liquid, close to the surfaces or when the bubble collision frequency is reduced, for example by electrostatic repulsion of the bubbles in cases where polarization effects appear with the surfactants at the bubble surface.

During fermentation some of the metabolites and particularly, the components of lyses organisms may change the bubble surface properties and thus the frequency of coalescence and redispersion processes develops, with time, in a practically unpredictable way.

In stirred tank reactors, gas can also be drawn into the dispersion by an impeller. This is an important effect when the vessel does not wear baffles because then, whirling occurs at higher stirrer speeds. However, such operational modes are generally avoided in industrial bioreactors. Hence, when there is no active aeration, then the gas holdup is negligible.

Practically, the gas holdup within a biotechnical cultivation broth is first of all a function of the superficial gas velocity w_{sg}. One usually describes the relation in terms of the folllowing engineering correlation (Eq. 51.17):

$$\varepsilon_G = a \cdot w_{sg}^b \qquad (51.17)$$

The free parameters a and b are determined from experiments. Values are published for simple model media only. For tapwater typical values are $a = 0.6$ and $b = 0.7$ for the case that w_{sg} is measured in m/s. Chisti (11) found that parameters were dependent on the flow regime and flow behavior index of the fluid.

McManamey and Wase (12) proposed to relate volumetric mass transfer coefficients to gas holdup by

Equation 51.18:

$$k_L a = 0.2883 \cdot \varepsilon^{0.9562} \tag{51.18}$$

McManamey and Wase (13) and Prokop *et al*. (14) found that the exponent can vary between 0.8 and 1.1 depending on the medium properties. It is well known (11) that logarithmic scale plots of $k_L a$ vs. (ε/(1-ε)) for any particular data set should have a unit slope as given in Equation 51.19:

$$\ln k_L a = \ln\left(6\frac{k_L}{d_B}\right) + \ln\left(\frac{\varepsilon}{1-\varepsilon}\right) \tag{51.19}$$

where k_L is the mass-transfer coefficient and d_B is the bubble diameter.

In mechanically stirred bioreactors, which are the most used devices in biochemical engineering, a second influence parameter gains importance This is the mechanical power P_D transferred into the dispersion per culture volume. For this practically important case, Equation 51.20 was formulated as an experimental or engineering correlation.

$$\varepsilon \propto \left(\frac{P_D}{V_D}\right)^{0.47} w_{sg}^{0.53} \tag{51.20}$$

Both, (P_D/V_D) and w_{sg} represent power inputs to the dispersion. w_{sg} is related to the power P_c released by the rising bubbles (Eq. 51.21). This power is supplied by the air compressor against the static pressure of the liquid at the sparger location.

$$P_C = Q_G \cdot \Delta_p = w_{sg} \cdot W \tag{51.21}$$

Δp is the pressure difference between the surface of the dispersion and the position of the sparger. W is the weight of the dispersion above the sparger, i.e. essentially the weight of the liquid phase. The point to note is that the mechanical power, pneumatically introduced with the bubbling gas into the dispersion, is proportional to the superficial gas velocity w_{sg}. In bubble column bioreactors this is the only way of bringing mechanical power into the liquid.

What is the reason for the power dependency of the gas holdup? With the mechanical power input, two additional fluid mechanic effects become relevant to the gas holdup:

– The first effect is that with higher energy inputs, the velocities of the circulatory fluid flows within the reactors become more intense. That is why a larger part of the bubbles within the flow get recirculated. Thus, the mean residence time and, consequently, also by Equation 51.16, the gas holdup increases. In particular, intensive eddy motions with high local flow velocities may trap some smaller bubbles within the dispersion for some time.

– The second effect supports the first one. At higher power input levels, the chaotic eddy flow motions lead to higher shear rates in the liquid phase on the scale of the bubble size. This reduces the mean bubble diameter as characterized by the Sauter diameter due to redispersion. Consequently, even more bubbles closely follow the liquid motions and thus the gas holdup increases.

51.4 PHYSICO-CHEMICAL EFFECTS

51.4.1 Pure Versus Solutions

In pure liquids bubbles are prone to coalesce. Small impurities may suppress the coalescence probability considerably. The impurities may change the bubble–bubble interaction forces, for example by repulsing electrical surface charges, or by stabilizing the boundary layer around the bubbles, or both.

51.4.2 Solutions of Organics

It was shown by many investigators that contaminants had a significant impact on the gas holdup. Usually this effect is so high that it considerably overshadows the effect of many other physical influence variables (15).

The size of a spherical bubble, which contains a fixed amount of a gas, depends on the surface tension which is determined by pressure created by the surrounding liquid. Therefore we can say, the size depends on the gas compression within the bubble.

This, however, is not so relevant to the bubble size in technical devices, as the bubble sizes generated by a sparger are most often practically independent of the surface tension. It is more dependent on the viscosity of the liquid and the fluid flow conditions at the sparger's orifices. The reason is that these conditions significantly influence the coalescence and redispersion events of the bubbles after their release from the sparger. Coalescence effects increase the bubble size and redispersion effects, for instance, by means of the impellers in a stirred tank reactor they reduce the primary bubble size.

Hu *et al*. (16) showed that a marked minimum bubble size can be found at low concentrations of solutions of hydrophilic organics in water. These concentrations depend on the particular organic. With miscible hydrophobic or hydrophilic organics, a minimum bubble size could not be found.

51.4.3 Salt Effects

It has long been recognized that electrolytes influence bubble coalescence. Further, different electrolytes give rise to the coalescence behavior. Some electrolytes such as NaCl

or KNO_3 solutions inhibit bubble coalescence, while others such as sodium acetate or HCl do not. Where coalescence inhibition is observed, a transition between no inhibition of bubble coalescence and a constant inhibition appears over a narrow concentration range. Typically 0.01 *M* solutions show no effect relative to pure water, and coalescence inhibition reaches a maximum by 0.2 *M*.

Craig *et al*. (17) systematically investigated a large number of electrolytes and developed simple rules which can predict the bubble coalescence behavior for different electrolytes on the basis of assigned properties of the individual ions.

When free surfaces approach each other in pure water, very high surface free energy leads to an attractive interaction. In electrolyte solutions where both anions and cations are attracted to the surface (like H^+ and Cl^- in HCl solutions), van-der-Waals-attraction facilitates approach of the surfaces and the coalescence of air bubbles (18). When only one type of an ion, an anion or a cation, is attracted to the surface (like Cl^- in NaCl solutions), an electric double layer is formed. This results in repulsive interactions between free surfaces. This inhibits coalescence events.

The change of surface tension with concentration correlates weakly with the inhibition of coalescence (e.g., Marcelja (18)). Two features of the inhibition of coalescence point to the controlling role of the ionic contribution to the interaction between free surfaces. The effect is strongly ion-specific, and the transition concentration is well-defined.

51.4.4 Stabilizing Surfaces

A third class of substances, most important to gas holdup, is surfactants. Surfactants are chemical compounds which are preferentially adsorbed on an interface when they are dissolved or dispersed in a liquid. The molecules of the tenside surfactants have a hydrophobic (= lipophilic, i. e. water repellent = oil attracting) organic residual part, and a hydrophilic (= lipophobic, i. e. water attracting = oil repellent) group. The surfactant molecules settle on the water–air interface in such a way that the hydrophilic part of the molecule is in the water, and the hydrophobic part in the air. A monomolecular layer is formed—that is a thin film—of surfactant molecules. Due to reduction in the surface tension upon the appearance of surfactants, the bubble size in such solutions is smaller than in pure water (19).

This layer (film) is the precondition for the formation of stable foams. The high concentration at the water–air interface means that frequently, only very small quantities of surfactant (foaming agent) in relation to the total quantity of water, are sufficient to bring about considerable foam formation.

Most suspended microorganisms produce foam-producing agents by themselves. These agents include, for example:

- Proteins (e.g. gelatin, caesin and albumin)
- Polysaccharides (e.g. starch, pectins)
- Cellulose derivatives (e. g. cellulose ethers and carboxy-methyl-cellulose)
- Humic acids

Particularly when these compounds are part of the substrate, problems with foam are to be expected. In some cases extremely high stabilization of foams can be obtained by these substance components. These obstinate, stable and elastic foams are the so-called microbubble foams.

51.4.5 Antifoam Agents

Foam can be combated mechanically or chemically by means of antifoam agents (20,21). The mechanical approach usually applies turbines that fling the foam onto the reactor wall in order to break the lamellae between the foam bubbles. The chemical antifoam agents destabilize the lamellae. Defoamers must be specially chosen for each fermentation system. Screening and selection of suitable antifoam agents is a complex empirical task.

Antifoam agents do not only influence the main foam layer but also the bubbles in the bulk of the culture. In this respect, the principal disadvantage associated with chemical antifoams is a significant reduction in the gas–liquid mass-transfer coefficient. Two obvious mechanisms for this are:

(i) The average bubble size in the broth increases and gas holdup decreases due to antifoam-induced bubble coalescence. The consequence is a lower specific interfacial area, which in turn gives lower oxygen transport rates.

(ii) Surfactants from the defoamer are distributed as a spread film on the bubble surfaces, inhibiting oxygen diffusion.

Foaming tendencies and properties of biomedia vary considerably. Moreover, the surface properties of antifoam agents are not constant. Hence, foam suppression requires a balance between various surface-active components in the media including the antifoam agent. An agent capable of destroying foam in one case may well act as a foam stabilizer in another one (22). So we can note that screening is required for an effective antifoam agent.

Antifoam agents may also complicate downstream processing as these surface-active substances may interfere with filter membranes and the beads in chromatographs.

51.5 MEASUREMENT TECHNIQUES

In order to control the gas holdup, at least in the sense of keeping it below a critical value, it must be measured. Many techniques have been proposed in literature, however only a few of them can routinely be applied in biotechnical production practice (23,24).

The simplest way of monitoring situations in which the entire gas holdup including the foam are within the desired limits, is a foam detector in the headspace of the bioreactor. Conductivity probes, which make use of the fact that biotechnical culture media are electrically conductive, can be used as foam sensors. A single electrode placed at the critical height in the headspace of the bioreactor, connected with some counterelectrode in the dispersion (e.g. the wall of the reactor) via a voltage source, suffices. Only when the dispersion reaches the electrode, the current loop becomes closed. Then the flowing electric current indicates that the gas holdup has reached its maximally allowed value.

The most straightforward way to measure the gas holdup ε_G is to register the difference $\Delta H = H_D - H_L$ in the culture surface height with (H_D) and without (H_L) aeration (Eq. 51.22).

$$\varepsilon_G = \frac{V_G}{V_D} = \frac{\Delta H}{H_D} \tag{51.22}$$

However, since in most real bioprocesses the air supply cannot be switched off and it is not possible to remove the bubbles, the volume of liquid phase must be determined indirectly. The simplest way is to make use of the culture weight, which is often measured even at production reactors and some estimate on the density of the non-gas phase of the dispersion.

The most convenient method to estimate the mean gas holdup ε between two heights in large reactors is the volume expansion method. Measuring the static pressure differences Δp between the two heights of difference ΔH allows to determine the gas holdup (Eq. 51.23).

$$\varepsilon = 1 - \frac{\Delta p}{\left(\rho_l - \rho_g\right) \cdot g \cdot \Delta H} \tag{51.23}$$

The liquid and the gas phase densities ρ_l and ρ_g must be known. Reliable pressure sensors, which are sensitive and also robust enough for measurements in production reactors, are on the market. However, one must make sure that only the static pressure difference is measured.

Another measurement principle for local gas holdups uses point-like probes that can distinguish between gas- and liquid-phase. For instance, a point-like conductivity probe can be used for that purpose. Whenever the point electrode of this probe is within a bubble, the current flow between this and another electrode is interrupted. When the total measurement time t_{tm} was not chosen too short, the ratio of the sum of the time intervals Δt_j that the current is interrupted to the total measurement time t_{tm}, is exactly the local gas holdup. All other point-like sensors, which can distinguish between gas and liquid phase, can be used in the same way, for example, a light reflection probe.

There are other probes for local gas-hold measurements with larger measurement volumes, like the capacitance sensors which measure the local gas holdup by introducing a small capacitor into the dispersion, so that the dispersion forms the dielectric. The dielectricity constant is dependent on the gas holdup within this capacitor. After some calibration, this sensor can be used to monitor the local gas holdup, provided it can be made sure that the holdup between the plates of the capacitor is representative of the holdup in its surrounding.

IMMOBILIZATION OF PROTEINS AND ENZYMES, MESOPOROUS SUPPORTS

Martin Hartmann and Dirk Jung
Advanced Materials Science, Department of Physics, University of Augsburg, Augsburg, Germany

52.1 INTRODUCTION

Immobilization of biocatalysts paves the way for their economic reuse and the development of continuous bioprocesses. For the preparation of heterogeneous biocatalysts, either isolated enzymes or whole cells are immobilized on suitable supports. Immobilization often results in stabilization and allows the use of enzymes under harsh environmental conditions of pH, temperature, and in the presence of organic solvents. Biotechnology is currently considered a suitable alternative to conventional process technology in industrial catalysis, sensing applications, and disease diagnostics. In the light of this development, immobilization of proteins on organic [e.g. polymers (1)] and inorganic support including controlled porous glass (CPG) and sol–gel materials has been extensively studied (2–6).

The encapsulation of enzymes and other proteins into ordered mesoporous inorganic hosts and related materials has attracted considerable attention over the past 10 years. Ordered mesoporous silicas prepared using a surfactant templating approach were discovered in the 1990s and are characterized by high specific surface areas and pore volumes as well as narrow pore size distribution. Their regular pore system consisting of tunable mesopores ($d = \sim 2–30$ nm) offers the possibility of immobilizing large biomolecules within their pores. The distinct order of the channels and cages as well as the possibility to tune structure, pore size and chemical composition over a wide range offers advantages over sol–gel or CPG materials. While the first report on enzyme immobilization on ordered mesoporous supports appeared as early as 1996 (7), the major developments in particular with respect to applications in biocatalysis have only come within the last 5 years. This research has demonstrated that biomolecules immobilized in inorganic matrices retain their functional characteristics to a large extent. These new materials are of interest for applications as (optically based) biosensors and biocatalysts. The present contribution intends to outline the basic principles of protein immobilization on (ordered) mesoporous molecular sieves, summarize the state of the art with respect to the application of the resulting bioinorganic hybrid materials in biocatalysis and highlight potential areas of future development.

52.2 IMMOBILIZATION OF PROTEINS ON MESOPOROUS SILICAS AND CARBONS

52.2.1 Materials

Porous solids have been classified by IUPAC (International Union of Pure and Applied Chemistry) based on their pore size into three groups (Fig. 52.1) (8). Porous solids with a pore diameter below 2 nm are named microporous. Zeolites and related materials with a pore diameter between 0.4 and 1.2 nm belong to this group of materials. Porous solids with a pore diameter between 2 and 50 nm are labeled mesoporous, while solids with a pore diameter above 50 nm are named macroporous. Typical macroporous solids with a broad pore size distribution are silica gel and active charcoal (Fig. 52.1).

The preparation of low density silica materials by hydrolysis of tetraethylorthosilicate (TEOS) in the presence of cationic surfactants, namely, hexadecyltrimethylammonium bromide, was patented by Chiola *et al*. in 1969 (9). However, the structural properties of these materials were not assessed. Di Renzo *et al*. (10) reported in 1997 that the patented preparation indeed results in the formation of mesoporous silicas of the Mobil Composition of Matter (MCM)-41 type, which were later rediscovered by researchers from Mobil Research and Development Corporation.

In 1990, Kuroda and coworkers (11) reported the synthesis of hexagonally arranged mesoporous silicas, which were obtained from kanemite in the presence of hexadecyl trimethylammonium bromide. These materials were prepared by exchange of the sodium ions in kanemite, a crystalline layered silicate, by hexadecyltrimethylammonium cations in aqueous solution and subsequent calcination to remove the organic template. Owing to the proposed synthesis mechanism, the novel materials were named *folded sheet materials (FSM-16)*. The transformation of kanemite in the presence of templates with different alkyl chain length into mesoporous materials with different pore size was later reported by Inagaki *et al*. (12).

The discovery of mesoporous molecular sieves of the M41S family was reported by researchers from the Mobil Research and Development Corporation in 1992 (13,14). The initial members of M41S family consisted of MCM-41 (hexagonal *p6mm* phase), MCM-48 (cubic *Ia-3d* phase) and MCM-50 (a stabilized lamellar phase). MCM-41 exhibits an X-ray diffraction pattern containing three or more peaks below $2\theta = 10^{\circ}$ that can be indexed in a hexagonal *hk*0 lattice (Fig. 52.2). The structure is proposed to have a hexagonal stacking of porous tubes with uniform diameter. MCM-48, the cubic phase, exhibits an X-Ray diffraction (XRD) pattern (Fig. 52.3) consisting of several peaks that can be assigned to the *Ia-3d* space group. The structure of MCM-48 has been proposed by Husson et al. (15) to be bicontinuous with a simple representation of two infinite three-dimensional, mutually intertwined, unconnected networks. A more sophisticated and perhaps more realistic model would be based on the concept of an infinite periodic minimal surface of the gyroid form, Q^{230}, proposed for water-surfactant systems (16). The proposed structure is also shown in Fig. 52.3. The lamellar phase MCM-50 is instable and collapses upon template removal.

In addition to the "classical" [$S^+ I^-$; cationic surfactant (S^+) and anionic inorganic species (I^-)] route to mesoporous molecular sieves such as MCM-41 and MCM-48, new synthesis concepts have been developed, which differ from the original one by the nature of the electrostatic interaction between the organic and the inorganic phases (Table 52.1). The ($S^- I^+$) pathway involves condensation of an anionic surfactant with cationic inorganic species (17). Two other routes were also developed in which the surfactant and the inorganic phase have similar charges, but are separated from each other by small ions with opposite charge: ($S^+X^- I^+$)($X^- = Cl^-$; Br^-) and ($S^- M^+I^-$) with $M^+ = Na^+$ or K^+ (17,18). At the same time, an elegant route to prepare mesoporous silicas at room temperature by a neutral (S^0I^0) templating route was proposed by Tanev and Pinnavaia (19). The materials prepared by using the S^0I^0 approach, so-called hexagonal mesoporous silica (HMS) materials, exhibit single d_{100} reflections accompanied by more or less pronounced diffuse scattering centered

at ~1.8 nm. Compared with the electrostatically templated MCM-41 silicas, HMS materials show a consistently larger wall thickness (1.7–3 nm), but a lower long-range hexagonal order (20).

Further studies led to the discovery of several other types of mesoporous silicas with high specific surface area, high specific pore volume and pores in the mesopores range with a narrow pore size distribution. A cubic phase SBA-1 (Santa Barbara advanced material no. 1), which was synthesized in acidic media, was suggested to have an ordered three-dimensional structure with two types of globular cages forming a continuous porous network (Fig. 52.4) (17,21). SBA-2 was shown to exhibit a three-dimensional periodic hexagonal array of mesoporous cages (21). Moreover, a hexagonal phase SBA-15 with pore sizes ranging from 5 to as large as 30 nm, and a variety of other cubic structures (i.e. SBA-2, SBA-7, and SBA-8) were prepared using oligomers and triblock copolymers as templates (22,23). The highly ordered large-pore mesoporous silica SBA-15, prepared by using the amphiphilic triblock copolymer $EO_{20}PO_{70}EO_{20}$ (Pluronic P123), possesses also a two-dimensional hexagonal structure comparable to MCM-41. However, the pore walls are substantially thicker (~2–6 nm) and the large mesopores are interconnected by micropores. This results in a somewhat higher thermal (>900°C) and hydrothermal stability compared to other mesoporous materials. SBA-15 may exhibit a large variety of morphologies depending on the synthesis conditions. Moreover, the pore size can be adjusted between ~4 and 30 nm by variation of the synthesis gel composition [e.g. addition of the swelling agent tetramethylbenzene (TMB)] and conditions [e.g. temperature (24)]. Stucky and his group also reported the preparation of mesocellular foams (MCF, Fig. 52.5)

TABLE 52.1. Structural Characteristics of Mesoporous Materials Employed for the Immobilization of Biomolecules

Pore System	Crystal System	Symmetry	Typical Material	Typical Template Used
Lamellar (no channel)	Hexagonal	—	MCM-50, KSW-2	Long-chain alkyl trimethyl ammonium salts (e.g. CTAB or CTACl)
Low-ordered channel	(Near hexagonal)	—	MSU-n, HMS, KIT-1, TUD-1	Long-chain primary amine, nonionic poly(ethylene oxide), CTB
1D-channel	Hexagonal	*p6mm*	MCM-41, FSM-16	CTAB; C_nTMA^+ ($n = 14–18$); $C_{16-n-16}$ ($n = 4,6,7,8,10$)
			SBA-3	C_nTMA^+ ($n = 14–18$); $C_{16-n-16}$ ($n = 3,4,6,7,8,10,12$)
			SBA-15	P123 ($EO_{20}PO_{70}EO_{20}$)
	Hexagonal	*c2mm*	SBA-8, KSW-2	Bola surfactant
3D-channel	Cubic	*Ia-3d*	MCM-48	C_nTMA^+ ($n = 14–18$); Gemini surfactants $C_{22-12-22}$ and $C_{16-12-16}$
			KIT-6	P123 ($EO_{20}PO_{70}EO_{20}$), *n*-butanol
3D-cage	Cubic	*Pm-3n*	SBA-1	$C_{16}TEABr$
			SBA-6	$18B_{4-3-1}$
		Im-3m	SBA-16	F127 ($EO_{106}PO_{70}EO_{106}$)
		Fm-3m	KIT-5	F127 ($EO_{106}PO_{70}EO_{106}$) + *n*-butanol
			FDU-12	F127 ($EO_{106}PO_{70}EO_{106}$) + TMB and KCl

employing triblock copolymers stabilized in oil in water emulsions (25). The large-pore system with open pores renders MCF materials that are interesting candidates for the immobilization of large biomolecules. MCF materials resemble aerogels, but offer the additional benefit of a simple and reliable synthesis protocol. Disordered materials such as LMU-1 (Ludwig-Maximilians Universität no. 1) (26) and KIT-1 (*K*orean Advanced *I*nstitute of Science and *T*echnology no. 1) (27) were also reported to have uniform channels.

SBA-16 is a mesoporous silica material with large cage-like mesopores arranged in a three-dimensional cubic-body-centered Im-3m symmetry. Analogous to SBA-15, the synthesis of SBA-16 is conducted under acidic conditions using a nonionic triblock copolymer as surfactant. The mesophase is created using mixtures of Pluronic P123 and F127 ($EO_{103}PO_{70}EO_{106}$) or employing mixtures of water, *tert*-butanol and F127. The cage diameter can be tuned between 5 and 15 nm by changing the composition of the polymer mixture. The structure of

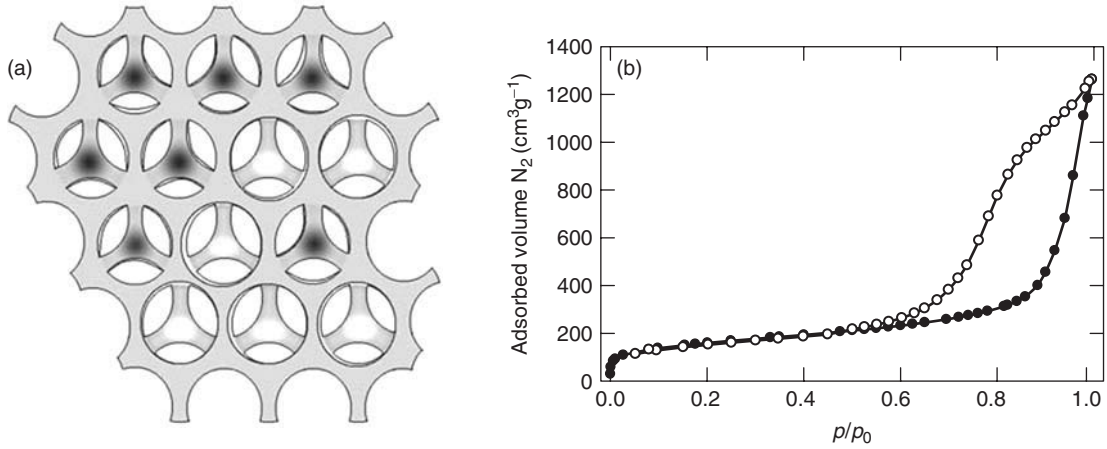

Figure 52.5. Schematic representation (a) of the mesocellular foam (MCF) materials and characteristic nitrogen adsorption isotherm (b).

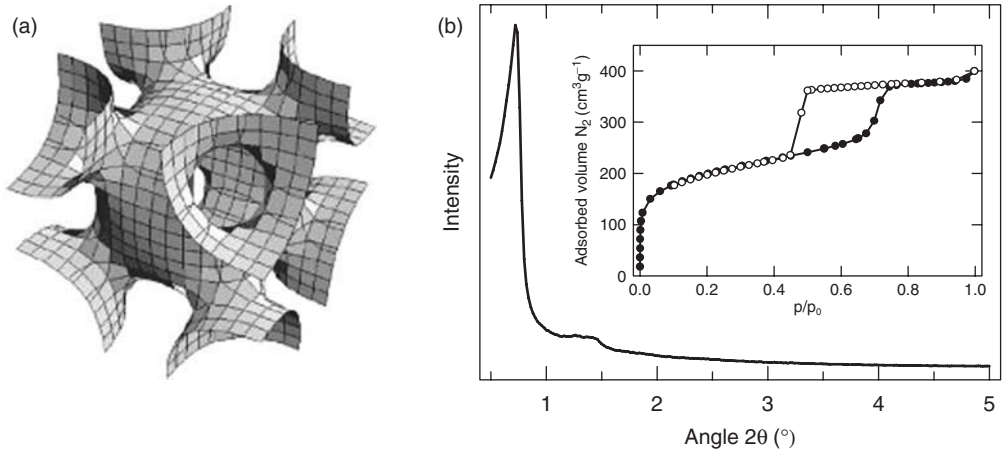

Figure 52.6. Schematic representation of the pore structure (a) and representative powder XRD pattern and nitrogen adsorption isotherm (b) of SBA-16.

SBA-16 is best described by a triply periodic minimal surface names I-WP (body centered wrapped package, Fig. 52.6) (28). As suggested by electron crystallography, each mesopore is connected to eight neighboring mesopores. The size of the pore entrances is significantly smaller than the diameter of the cages and may not exceed 5 nm.

KIT-5 is a porous silica material with properties similar to those of SBA-16; the mesopores are ordered in a cubic face-centered *Fm-3m* symmetry. Similar to SBA-16, KIT-5 is synthesized in a ternary water, *n*-butanol and Pluronic F127 surfactant system with emphasis on a low HCl concentration in aqueous solution (29). In contrast to the triply periodic bicontinuous minimal surface of the SBA-16 mesophase, KIT-5 may be represented by a cubic micellar mesophase. In this case, each mesopore would only be statistically connected to its neighbors, but arranged in a face-centered symmetry. FDU-12 also represents a cubic (*Fm-3m*) mesostructure with a large cavity size of 10–12 nm. Mesoporous silicas FDU-12 were synthesized using the block copolymer F127 or F108 assisted by TMB and inorganic salts, for example KCl (30). It has been reported that the synergistic role of TMB and KCl is critical for the synthesis of this material. Lowering the aging temperature and increasing the synthesis temperature can enlarge the pore sizes from 14 to 22 nm and the entrance diameters from 4 to ca. 9 nm (30,31). The approximate structure of FDU-12 prepared at low temperature can be regarded as face-centered cubic closed packing of spherical cages, each connected to 12 neighboring cages (32). A remarkable difference between the two materials FDU-12 and KIT-5 has been observed in the XRD pattern of the two materials with the same face-centered cubic *Fm-3m* symmetry. FDU-12 displays

strong (311) and unsolved (200) and (400) reflections, while KIT-5 exhibits a strong (220) and weak (200) and (311) diffraction lines. The structural implications to these structural differences are, however, not understood yet and subject to further investigations.

KIT-6 (33,34) is analogous to MCM-48 and possesses a three-dimensional *Ia-3d* structure. Again, the representation of the structure is a gyroid minimal surface as shown in Fig. 52.3. The gyroid structure, which can be interpreted as two interwoven cylindrical channel systems result in adsorption properties very similar to those observed for two-dimensional hexagonal systems. In contrast to MCM-48, these two intertwined systems of relatively large channels in KIT-6 can also be connected through irregular micropores present in the mesopore walls analogous to those present in SBA-15.

Owing to their potential application in various petroleum refining processes, aluminum-containing mesoporous materials have received considerable attention over the last years in both the patent and the open literature (35). In particular, two reviews by Sayari (36,37) give an overview of catalytic applications of AlMCM-41 and an exhaustive list of industrial patents on the catalytic applications of these materials reported until 1996. The degree of incorporation of aluminum into mesoporous silicas as well as the physical properties and stability of the obtained solids strongly depend on the synthesis conditions (38–40). MCM-41 materials with n_{Si}/n_{Al} ratios in the range from 2 to 100 can be obtained and ^{27}Al Magic Angle Spinning Nuclear Magnetic Resonance Spectroscopy (MAS NMR) shows that the aluminum species are exclusively in tetrahedral environment (41,42). The incorporation of aluminum into other phases, for example, MCM-48, SBA-15, and SBA-1, is more difficult and was studied to a lesser extent (43–48). Incorporation of other heteroatoms including Cu (49,50), Zn (49,50), B (51–56), Ga (57,58), Fe (51,59–63), Cr (64–67), Co (68), Nb (69–72), Ni (73), Mn (74–76), Mo (77,78), Ti (79–81), V (64,67,82–85), Sn (80,81), and Zr (86–90) has been widely investigated, however, the potential of these materials for protein adsorption is only rarely explored.

Inorganic-organic hybrid mesoporous materials offer the potential of tuning the chemical composition. There are three general methods of generating functionalized materials, (i) direct functionalization during synthesis, (ii) post-synthesis functionalization and (iii) incorporation of organic moieties into the pore walls using organic molecules possessing multiple alkoxysilane groups (Fig. 52.7). The synthesis of this so-called periodic mesoporous organosilicates (PMO) was independently reported by the groups of Inagaki (91), Ozin (92) and Stein (93). Chemical modification of the pore wall has also been reported (94–97). One of the most fascinating features of certain PMOs is the formation of crystalline pore walls. The first example was reported by Inagaki *et al*. who employed 1,4-bis(triethoxysilyl)benzene as precursor (98). Moreover, the condensation approach can be used to introduce a second functionality (94,99).

At the end of the 1990, the preparation of mesoporous carbon materials using mesoporous silicas as hard templates has been reported [for reviews see e.g. (100,101)]. Kyotani and coworkers prepared ordered microporous carbons using zeolite Y as a template (102,103). This concept has been extended by Ryoo *et al*. to the preparation of ordered mesoporous carbons employing ordered mesoporous silica molecular sieves such as MCM-48, SBA-1, and SBA-15 as templates (104–107). A similar approach was reported independently by Hyeon *et al*. (108,109); the obtained well-ordered mesoporous carbon materials were designated SNU-x. The use of the cubic mesoporous silica MCM-48 as template and sucrose as carbon source result in the formation of the mesoporous carbon CMK-1. SBA-15, which possesses a hexagonal array of cylindrical mesoporous interconnected by micropores, is used for the preparation of CMK-3. It was shown that the pore diameter of the mesoporous carbons CMK-3 can be tuned by using silica templates prepared at different temperatures (110). The use of the face-centered cubic mesoporous silica KIT-5 enables the formation of the more complex carbon nanostructure coined "carbon nanocage" by their inventors (Fig. 52.8) (111,112). The pore dimensions of this material can be tuned by using KIT-5 mesoporous silicas prepared at different temperatures and by variation of the sucrose to silica ratio. An overview of the reported ordered mesoporous carbons generated by nanocasting is given in Table 52.2.

Mesoporous oxides from other elements than silica have been reported as early as 1994. Huo *et al*. (21,113) found that metals such as Sb, Fe, Zn, Pb, W, and Mo also form mesoporous oxides. However, many of the obtained mesophases were lamellar and were not porous after template removal (calcination). Antonelli and Ying reported the transformation of titanium, niobium and tantalum alkoxides into stable mesophases (114–117). Subsequently, mesoporous oxides based on zirconium, hafnium, and manganese have been synthesized [for a recent review on these materials see (118)]. Bagshaw and Pinnavaia (119) prepared mesoporous alumina with worm-like pores and a specific surface area of more than 400 m^2/g. Mesoporous aluminas with surface areas above 700 m^2/g have been reported by Vaudry *et al*. (120).

The morphology of the mesoporous silicates is important for envisaged industrial application in catalysis, separation, and chromatography. In recent years, various morphologies such as fibers, discs, doughnuts, rods, vesicles, and helices have been reported (121,122). It has been found that several factors can affect the morphology of the final materials including hydrolysis and condensation of silicate species, the shape of the surfactant micelles, the interaction between them and the use of additives (inorganic salts, organic swelling agents, cosolvents, and

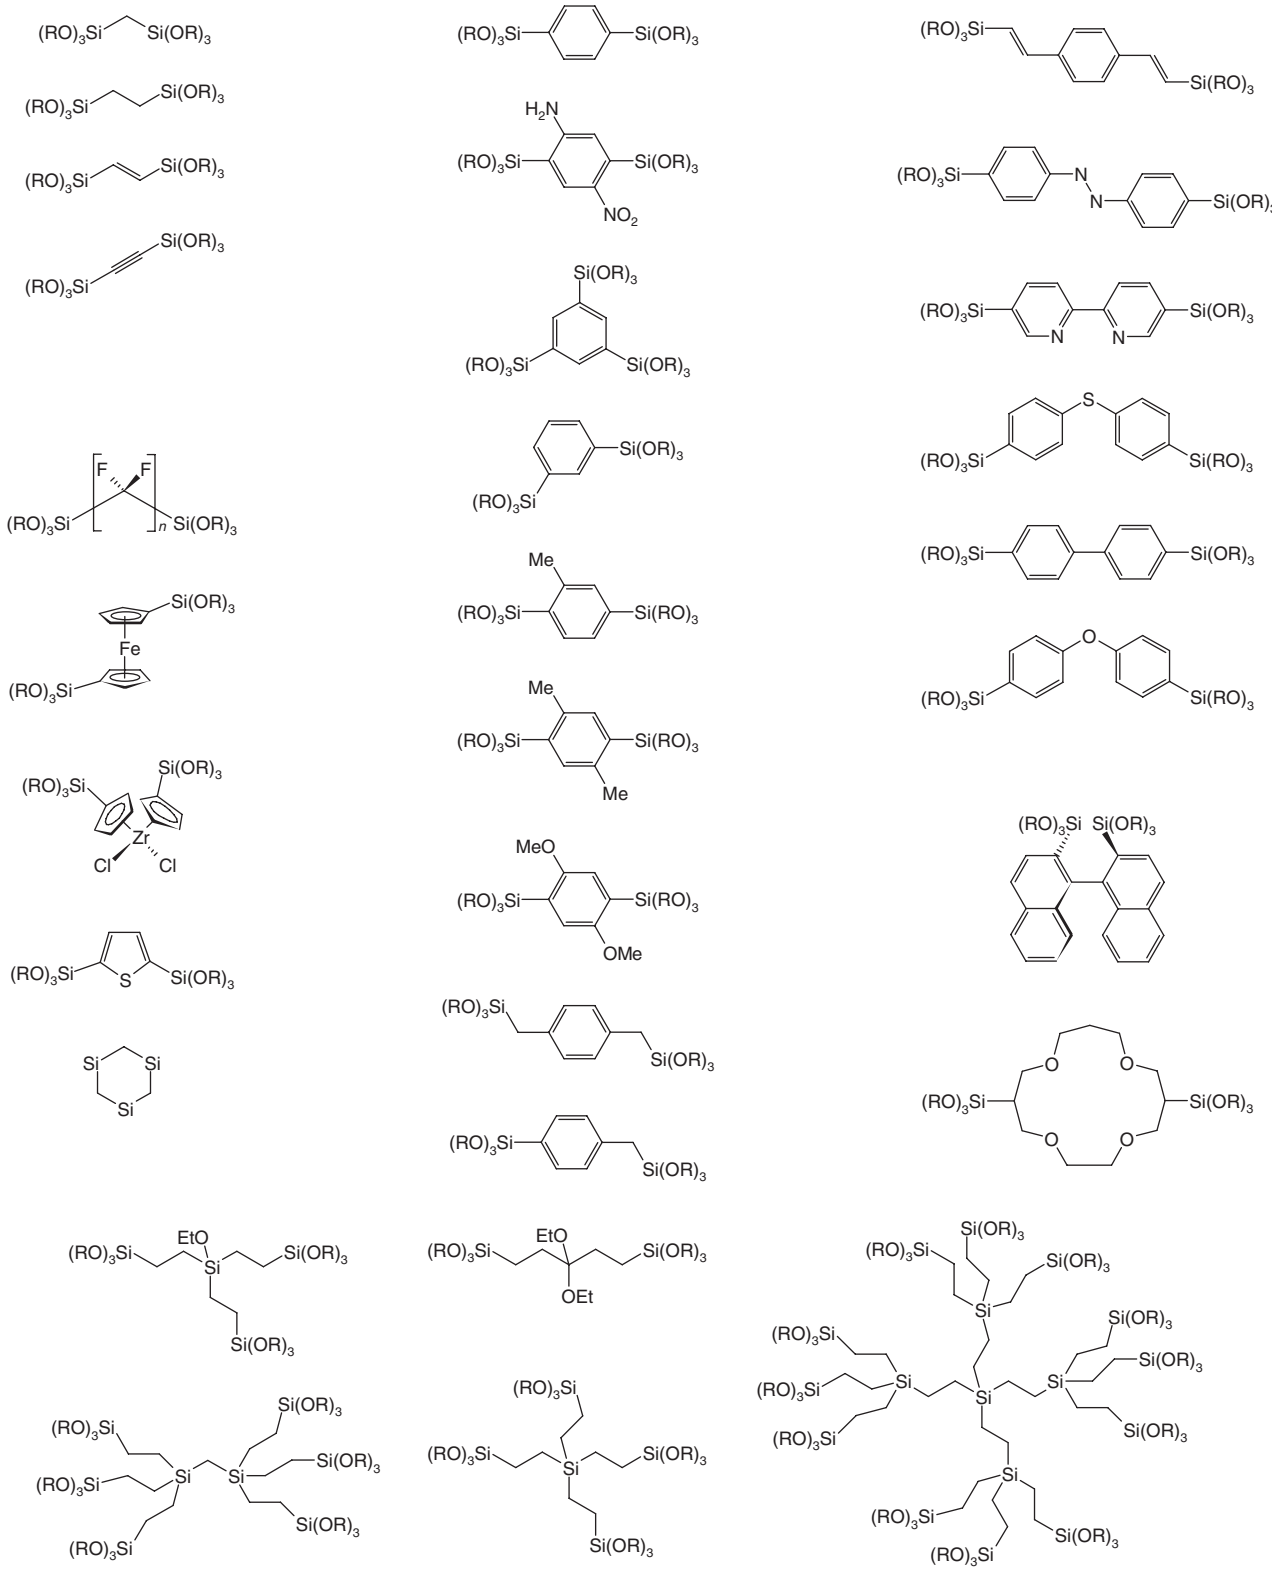

Figure 52.7. Si-alkoxy precursors for the synthesis of PMO materials.

TABLE 52.2. Overview of Reported Ordered Mesoporous Carbons Generated by Nanocasting

Carbon	Space Group	Template	Space Group	Precursor
CMK-1 (SNU-1)	*I4 1/a*	MCM-48	*Ia-3d*	Sucrose, phenol resin
CMK-2	Unknown cubic	SBA-1	*Pm-3n*	Sucrose
CMK-3	*p6mm*	SBA-15	*p6mm*	Sucrose, phenol resign,
CMK-4	*Ia-3d*	MCM-48	*Ia-3d*	Acetylene
CMK-5	*p6mm*	SBA-15	*p6mm*	Furfuryl alcohol
NCC-1	*p6mm*	SBA-15	*p6mm*	Furfuryl alcohol

Carbon nanocage	Unknown	KIT-5	*Fm-3m*	Sucrose

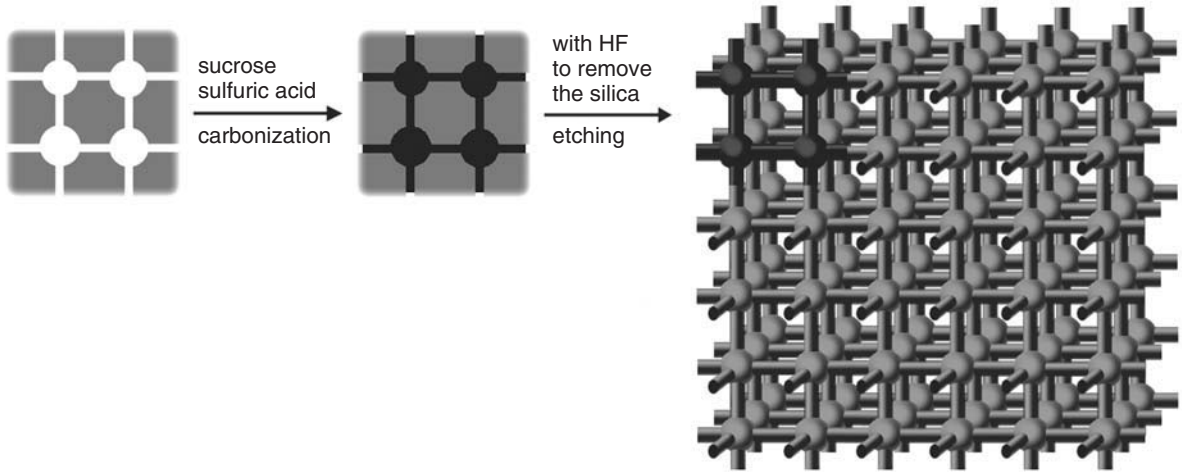

Figure 52.8. Nanoreplication of KIT-5 into carbon nanocage (CNC) material.

cosurfactants). Lamellar silicas with hierarchical vesicular structure are expected to provide optimal access to the pore walls under diffusion limited conditions (123,124). For the preparation of these materials, Pinnavia and coworkers employed electrically neutral and unsymmetrical Gemini surfactants of the type $C_nH_{2n+1}NH(CH_2)_mNH_2$ ($n = 12$, 14 and $m = 3$, 4). However, the achievable pore diameters are too small for the adsorption of larger biomolecules.

The development of tailor-made mesoporous silica supports has significantly advanced in recent years. Based on the understanding that an ordered array of mesopores is not required for the majority of applications in biocatalysis and biosensing, synthesis protocols for high surface area materials with narrow pore size distributions based on silica microspheres have been reported (125–128). Lecithin/dodecylamine mixed-micelles in an alcoholic/water media are reported to form sponge mesoporous silicas (coined SMS) through a self-assembly process between mixed micelles and TEOS (129,130). This synthesis strategy expands the classical sol–gel synthesis allowing to control the mesoporosity. SMS materials feature an isotropic three-dimensional pore structure analogous to SBA-16 but with a lower degree of mesoscopic structural order. Its porosity results from cavities and connecting channels, whose dimensions are controlled by the synthesis parameters (131).

Recently, the design of a novel biocompatible controlled- release motif including silica particles (d = ca. 400 nm) containing hexagonally arranged pores with a diameter of about 2 nm has been reported (132). The porous mesostructure is templated by CTAB (cetyltrimethyl-ammonium bromide) and particles synthesis is accomplished using a base-catalyzed sol–gel procedure. The snap-top consists of a [2] rotaxane tethered to the surface of a nanoparticle in which an α-cyclodextrin torus encircles a polyethylene glycol thread. The ester-linked adamantyl stopper is cleaved by porcine liver esterase and the payload is set free.

For further details on the preparation of mesoporous silicas and carbons, organic-inorganic hybrid materials (PMOs)

and mesoporous thin films, the reader is referred to extensive reviews published recently (133–136).

52.2.2 Nature of the Adsorption of Proteins on Surfaces

The various factors affecting the amount of protein adsorbed on a given (in the case of porous supports curved) surface are inevitably linked to the conformation adopted by the protein in the cages and channels. The reason is that a modification to a more disordered structure contributes to the driving force of adsorption as it increases the entropy of the systems. Thus, the Gibbs energy decreases which is the driving force for spontaneous adsorption. Moreover, the conformational modifications may also affect the maximum quantity of protein adsorbed since those changes may alter the area occupied by a single protein molecule in particular when the available space is restricted in three dimensions.

The adsorption of proteins at constant temperature and pressure leads to a decrease of the free enthalpy of the system according to the second law of thermodynamics (137,138). The change in free enthalpy $\Delta_{ads}G$ depends on the enthalpy (change) $\Delta_{ads}H$, which is a measure of the potential energy (i.e. the energy that has to be supplied to separate the molecular constituents from another) and the entropy change $\Delta_{ads}S$, which is related to the disorder of the system multiplied by the absolute temperature T:

$$\Delta_{ads}G = \Delta_{ads}H - T\Delta_{ads}S < 0$$

As pointed out by Quiquampoix (139), the difficulty in analyzing these processes lies in the fact that enthalpy effects and entropic effects are not totally independent. Enthalpic effects are typically related to intermolecular forces while entropic effects are related to the spatial arrangements of molecules. Moreover, intermolecular forces influence the molecule distribution and the potential energy is also dependent on the molecular structure of the system. Nevertheless, the enthalpic and entropic contributions will be discussed separately.

52.2.2.1 Enthalpic Effects

52.2.2.1.1 Coulomb Interactions. Proteins carry electrical charges resulting from the ionization of carboxylic, tyrosyl, amine, and imidazole groups of amino acid side chains. The electric charges of the mesoporous adsorbent surface may result from the isomorphous substitution of aluminum or other elements into the silica walls or from pH-dependent ionization of silanol or other surface groups. Coulomb forces are very strong and long-range interactions, which may even be as strong as covalent bonds. However, as the thermodynamic cost of an uncompensated electrical charge even in a small unit of volume is high, all charges of a given sign are compensated by an equal number of electrical charges of the opposite sign. Thus, a diffuse double layer is established around the biomacromolecule and the (curved) surfaces. The electrostatic interaction between proteins and the surfaces can be described as an overlap of their electrical double layers. The electrostatic part of the free enthalpy is given by the isothermal and isobaric work of charging the electrical double layer:

$$G_{el} = \int_0^{\sigma} \varphi(\sigma)d\sigma \qquad (52.1)$$

where ϕ is the variable electrostatic potential and σ is the variable surface density during the charging process.

52.2.2.1.2 Van der Waals Interactions. In addition to electrostatic interactions, van der Waals forces act on all molecules even if they are electrically neutral. These forces are composed of three different components and are considered short range forces. The main components are the dispersion (or London) forces, which originate from the instantaneous dipolar moment resulting from the fluctuation of the electrons around the nuclear protons in nonpolar molecules. Thus, an electric field is created that induces a dipole moment in nearby molecules, which in turn creates an instantaneous attractive interaction. The other two components are the induction (or Debye) forces, which are related to the interaction between a polar molecule and a nonpolar molecule, and the orientation (or Keesom) forces related to the interaction between two polar molecules.

52.2.2.2 Entropic Effects

52.2.2.2.1 Hydrophobic Interactions and Solvation Effects. Sometimes hydrophobic interactions are involved when proteins are adsorbed on mineral surfaces. One of the most important factors responsible for the stability of proteins in solution is the shielding of amino acids with a hydrophobic side chain in the core of the protein from contact with water. This phenomenon contributes to the decrease of the free enthalpie of the polypeptide chain that accompanies its folding. The shielding originates from the "hydrophobic effect" which causes water molecules to establish more hydrogen bonds among themselves in the presence of a nonpolar group than in the presence of a polar group. This process maximizes the mutual association of water molecules by hydrogen bonds and results in an increased order of the surrounding water and, thus, a favorable decrease in entropy of the system. It can be inferred that the presence of a surface with hydrophobic properties perturbs the spatial arrangement of nonpolar amino acids, and consequently the adsorption of proteins on surfaces cannot be analyzed without taking into account the interaction of water molecules with both the mineral surface and

the protein. Moreover, a gain in entropy is expected when water does not have to solubilize hydrophobic amino acids.

52.2.2.2.2 Modifications in Protein Molecular Structure. The interaction of proteins with surfaces in confined spaces is a more complex phenomenon than the interaction of ions or small more rigid molecules with surfaces. In the case of protein adsorption an entropic contribution can result from a modification of the protein conformation. This phenomenon is related to an increase in the rotational freedom of the peptide bonds engaged in the secondary structure, that is, α-helices and β-sheets. These ordered secondary structures represent an important part of the densely packed hydrophobic core of the protein. When a protein is adsorbed on a pore surface, internal hydrophobic amino acids can reach more external positions in contact with the surface, since the amino acid remains (partially) shielded from the contact with water molecules of the surrounding solvent phase (139). The breaking of hydrogen bonds that maintain the peptide chain in a given conformation results in an increase of conformational entropy. The gain in conformational entropy, S_{conf}, can be calculated under the assumption that four different conformations are possible for peptide units in random structures as compared with only one in α-helices and β-sheets:

$$\varepsilon\theta\nu\Delta_{\text{ads}}S_{\text{conf}} = R\ln(4^n) \tag{52.2}$$

In Equation 52.2, R is the gas constant and n is the number of peptide units involved in the transfer from an ordered secondary structure to a random secondary structure (140,141).

52.2.3 Strategies for Enzyme Immobilization

Different strategies have been developed for the immobilization of proteins on mesoporous supports. Figure 52.9 gives an overview on the immobilization methods available so far. Several parameters have to be considered when a suitable enzyme-carrier system is selected (Table 52.3). Physisorption of proteins onto oxide surfaces is governed by the interaction of amino acids with the solid surface. Proteins are highly complex and possess a wide variety of chemical properties originating from different surface groups including amines, carboxylates and disulfide bridges. The predominant binding forces of proteins to hydrated silica surfaces are electrostatic interactions, hydrogen bonding, and van der Waals interactions. Electrostatic protein-surface interactions are likely to be dominating when the adsorption is performed at a pH below the isoelectric point (pI) of the protein, that is, the point where the overall charge of the proteins is zero. Then the protein possesses a positive charge, while silica carries negative charges at a pH above ca. 3 (7). The larger the positive charge of the protein, the stronger the interaction between protein and surface, but the repulsion between adsorbed proteins is also increased. At a pH above the isoelectric point, the protein is negatively charged and repulsive interactions between the protein and the negatively charged surface will dominate. Consequently, surface adsorption capacities of proteins are found to vary with pH of the solution according to a bell-shaped curve with the maximum being near the isoelectric point of the protein (Fig. 52.10). Nevertheless, the pH dependence is very much dependent on the protein, that is, compare cytochrome *c* with chloroperoxidase (CPO).

Covalent binding is an extensively used technique for the immobilization of enzymes. The enzymes are covalently linked to the support using the functional groups of enzymes, which are not essential for their activity. The first step is the organic functionalization of the silica surface. The most potentially useful surface functional groups are alkyl chlorides, amines, carboxylic acids, and thiols. Other functional groups such as alkyl, phenyl, and vinyl can be added to modify the environment of the enzyme by increasing the hydrophobicity of the surface. Formation of covalent bonds with functionalized surfaces ensures strong binding and negligible leaching. It is often advisable to carry out the immobilization in the presence of the substrate or a competitive inhibitor in order to protect the active site. Moreover, the covalent binding has to be carried out in such a way that the conformational flexibility of the enzyme is not altered.

Another way of preventing leaching of the enzyme from the mesoporous support is physical encapsulation inside the pores. Several routes have been explored including silanation or coating with microporous silicas or organic layers. First, the protein is adsorbed from the solution and subsequently the pore entrance is reduced in size by, for example, silanation using 3-aminopropyltriethoxysilane (APTES) (142).

Biocatalysts can also be immobilized through chemical cross linking using homo- as well as hetero-bifunctional cross-linking agents. Chemical cross-linking of the enzymes preserves their catalytic activity even under harsh conditions such as high temperature, extreme pH values, the presence of organic solvents and radicals. Glutardealdehyde (GA) reacts with amino groups in a base-catalyzed reaction. GA has been used extensively due to low costs, high efficiency, and stability. Adsorption followed by cross-linking may allow encapsulation of proteins on porous support having a cage-like structure. The advantages and disadvantages of the four preferred immobilization methods are compared in Tables 52.4 and 52.5 (142).

52.2.4 Enzyme Immobilization on Ordered Mesoporous Materials

The unique advantages of ordered mesoporous solids over disordered, high surface area silicas, such as those prepared by sol–gel or aerosol methods, are their narrow pore size distribution and the well-defined pore geometry and connectivity. Diaz and Balkus were the first to publish work on the immobilization of globular proteins (cytochrome *c*, papain, and trypsin) on MCM-41 (7). A clear (almost linear) dependence of the protein size on the achieved loading was found. Since then, research in this area has developed rapidly and more than 200 papers have been published in this area up till now.

Initial adsorption studies were confined to small, stable, and readily available enzymes such as cytochrome *c*, lysozyme, trypsin, and lipase. Typically rather low loadings were obtained, which could only be increased significantly after thorough studies of different factors affecting protein adsorption including pH and ionic strength of the solution, surface charge and pore diameter of the support. Over the years, larger and less stable enzymes such as horseradish peroxidase (HRP) and CPO have also been studied. Recent studies also deal with the adsorption of even larger biomolecules including DNA (142).

Some general trends can be deduced from the adsorption studies published so far. Adsorption is dominated by weak

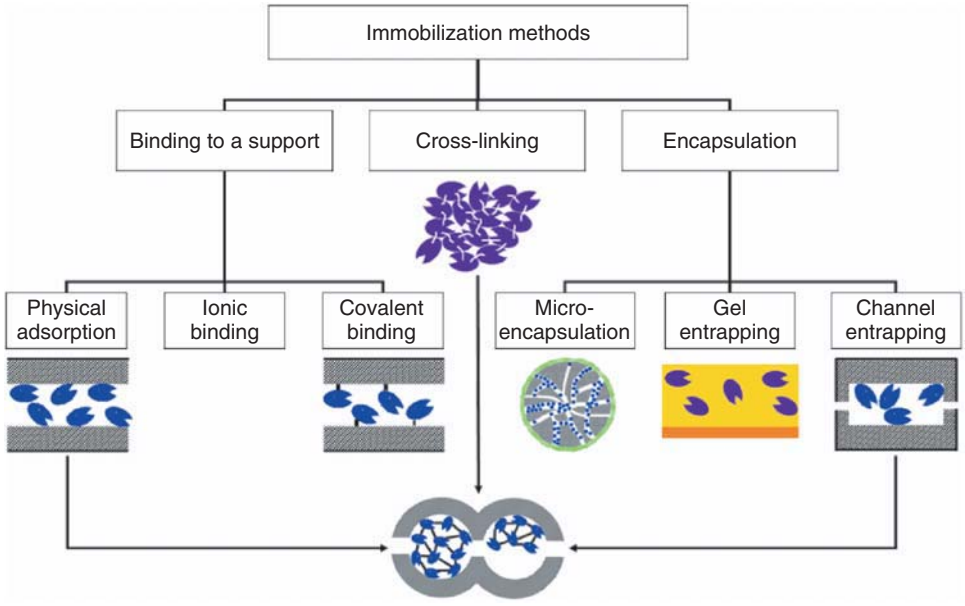

Figure 52.9. Overview of immobilization strategies on mesoporous supports. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

TABLE 52.3. Parameters to be Considered for Enzyme Immobilization

	Parameters to be Considered	Examples
Enzyme	Biochemical properties	Molecular weight, functional groups on the surface, surface charge, purity, isoelectric point (p*I*)
	Kinetic parameters	Specific activity, pH and temperature profiles, solvents; stability against pH, temperature, solvents, contaminants and impurities
Carrier	Chemical characteristics	Composition, functional groups, swelling behavior, surface charge, pore size, stability
	Mechanical properties	Particle size, flow resistance (in case of fixed-bed application), single particle compression behavior, abrasion (for stirred tanks).
Immobilized enzyme	Immobilization methods	Bound protein, yield of active enzyme, intrinsic kinetic parameters
	Mass transfer effects	Buffer effect, film and pore diffusion
	Stability	Operational and storage stability
	Performance	Productivity (space–time yield), enzyme consumption and reuse

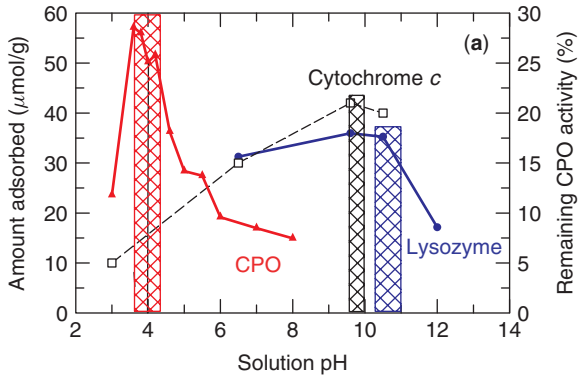

Figure 52.10. Dependence of the maximum of the enzyme adsorption on the pH of the solution. The shaded area represents the range of isoelectric points reported in the literature. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

physical forces, that is, van der Waals or dispersion forces. It is shown in some studies that proteins tend to adsorb better, when strong electrostatic (charge) interactions occur between the (alumino) silica surface and the protein. Near the isoelectric point, the coulomb forces derived from the positive charges of the ionized protein and the negative charges at the silica surface are small. Under these circumstances, hydrophobic interactions between the protein and the adsorbent become more important. It is worth to mention that hydrophobic interactions are believed to be much weaker (by about 1/13 in water) than coulombic forces. These hydrophobic interactions may either originate from attraction of the nonpolar side chains of the amino acid residues on the surface of the protein or from protein–protein interactions between the hydrophobic side chains of neighboring protein molecules. It should be noted that the surface properties of the adsorbent are of paramount importance when adsorption occurs mainly by hydrophobic interactions. More work is needed in this area to gain full understanding and control. Under conditions of physical adsorption, the active site of the enzyme is often unaffected and nearly full activity is retained upon adsorption. However, desorption (leaching) of proteins is a common problem, in particular in the presence of a strong hydrodynamic force, since binding forces are weak. For a given pore size of the adsorbent, smaller proteins generally are adsorbed to a higher degree than larger ones, although the

TABLE 52.4. Advantages and Disadvantages of the Four Preferred Immobilization Methods

Immobilization Method	Advantages	Disadvantages
Encapsulation	Enzyme molecules retained; Enzyme molecules free to move inside channels	Complicated experimental procedure; Reactive species and toxic solvents may denature enzymes; Reduced pore opening may decrease diffusion rate of reactants and products
Physical adsorption	Simple (and cheap) experimental procedure; No toxic solvents; Little or no conformational changes of the enzyme or destruction of its active left	Leaching of enzymes during reaction resulting from changes in pH, temperature and ionic strength
Covalent binding	Enzyme molecules retained; Wide choice of organic linkers available	More expensive and complicated procedure in support preparation; Enzyme molecules immobile inside the channels
CLEA confinement	Concentration inside the pores prior to cross-linking; Size of the CLEAs is restricted by the cage size	Enzyme molecules immobile inside the channels

TABLE 52.5. Comparison Between Different Methods

Characteristics	Physical Adsorption	Covalent Binding	Encapsulation	CLEA Confinement
Preparation	Simple	Difficult	Difficult	Difficult
Cost	Low	High	Moderate	High
Binding force	Variable	Strong	Weak	Strong
Enzyme leakage	Yes	No	Yes	No
Applicability	Wide	Selective	Wide	Not yet known
Running problems	High	Low	High	Low
Matrix effects	Yes	Yes	Yes	No
Large diffusion barriers	No	No	Yes	Yes
Microbial protection	No	No	Yes	Yes

loading in many studies is low and far from complete filling of the mesopores. Moreover, it is unlikely that the proteins are evenly distributed in a given mesopore, but are more likely clustered at the pore entrance. For complete filling of the pore, (slow) single file diffusion (the proteins size is often similar to the pore diameter) might hinder rapid approach to thermodynamic equilibrium. Moreover, little is known regarding the geometry of the adsorption complex on mesoporous supports. Most proteins are somewhat ellipsoidal and might adsorb with either their long or their short axis with comparable probabilities. The molecule may also relax its orientation and may bind more strongly by moving its long axis from perpendicular to parallel. However, the relaxation is dependent on the surface coverage since it cannot take place if the neighboring area into which the molecule could expand is already occupied by another protein molecule. Finally, in many cases, it is furthermore found that adsorption is not completely reversible which also has a number of important implications as outlined in (143). However, more research work is needed to understand the fundamentals of this particular adsorption process. For further improvement of the adsorption process, different goals have been identified:

- Improvement of the adsorption capacity (loading).
- Adsorption kinetics (fast uptake).
- Immobilization rather than reversible adsorption.

The adsorption capacity is mainly dominated by the specific pore volume and the pore diameter, respectively, of a given support. While high loadings would be beneficial for catalysis in terms of reaction rate, the activity of immobilized enzymes is often loading dependent. Typically, the activity (in U/g) of the immobilized enzyme increases with increasing loading and finally reaches a plateau. Often, enzyme loading up to an amount sufficient to form a monolayer is beneficial in order to avoid conformational changes that result in reduced activity. Furthermore, the stabilization of the enzymes is associated with the pore diameter of the host and the size of the enzyme. In this context, different views are expressed in the literature whether the pore size should be significantly larger than the protein to allow for facile diffusion of protein and substrate down the pore or of similar size in order to increase stability and protection of the protein from the external environment. In addition, smaller pore dimensions allow a tight fit of the adsorbed enzymes and may reduce leaching. On the other hand, the use of mesocellular mesoporous silica with very large mesoporous cages connected by smaller mesoporous channels allows the encapsulation of cross-linked enzymes in the pore cavities. By cross-linking enzymes within mesocellular pores the resulting enzyme aggregates were successfully retained in the pores and high loading capacities were achieved (144–146).

A new strategy for enzyme immobilization, that is, the formation of cross-linked enzyme aggregates (CLEAs) was invented by Sheldon *et al*. (147–149). The addition of salts, water-miscible organic solvents or nonionic polymers to aqueous solutions of proteins leads to their precipitation as physical aggregates. Subsequent cross-linking of these physical aggregates make them permanently insoluble while maintaining their preorganized superstructure, and, hence their catalytic activity. The CLEA methodology essentially combines purification and immobilization into a single unit operation that does not require a highly pure enzyme. Since the discovery of CLEAs, this novel route is widely used for the heterogenization of a variety of enzymes ((150,151) and references therein).

Hyeon and coworkers (144,145) developed hierarchically ordered mesocellular mesoporous silica materials (HMMS) as a support for cross-linked enzymes. The final pore structure of HMMS is a combination of MCF pores and one-dimensional SBA-15 channels. α-chymotrypsin and lipase were immobilized in HMMS by enzyme adsorption followed by GA cross-linking. This results in the formation of CLEAs entrapped in the mesocellular pores of HMMS ($d_p = 37$ nm), which do not leach out through the narrow mesoporous channels ($d_c = 13$ nm). The formation of CLEAs of α-chymotrypsin in HMMS enables high enzyme loadings accompanied by significantly increased enzyme stability. No decrease in activity was observed for 2 weeks under rigorous shaking, while adsorbed and free α-chymotrypsin showed rapid inactivation due to enzyme leaching and presumably autolysis, respectively. The CLEAs of lipase in HMMS retained 30% of the specific activity of free lipase, but with significantly enhanced stability.

In a further study, the same authors applied the CLEA approach to enzyme immobilization in SBA-15, which has one-dimensional pores (146). It is not really clear, however, whether the use of SBA-15 instead of materials with bottle-neck pore structure presents an advantage with respect to enzyme leaching. In general, these initial studies demonstrate that the CLEA approach can efficiently be employed for enzyme immobilization resulting in enhanced stability of the immobilized enzymes with high loading and activity. The natural concentration of the enzymes by adsorption in the pores of the mesoporous material without the addition of additives and the restriction of the CLEA size by the pore diameter (thereby increasing the accessibility of the enzymes) are the most important advantages of this novel approach. However, the inherent shortcoming that the crosslinking step can deactivate the enzyme is still not solved. Regrettably, the applications of this approach to catalytic conversions and reaction engineering is still lacking up till now. In extension of the CLEA approach, multifunctional nanocomposites of enzymes and magnetic nanoparticles located in the pores of

HMMS materials were developed by Hyeon and coworkers (152). This approach involves a simple, two-step process comprising the coadsorption of enzyme and magnetic nanoparticles into HMMS followed by GA treatment. α-Chymotrypsin was immobilized via coadsorption of the enzyme and magnetite (Fe_3O_4) nanoparticles followed by cross-linking of the enzymes with GA. Under optimal conditions, the cross-linking of the enzymes resulted in the effective entrapment of the magnetite nanoparticles in the CLEAs. Furthermore, the composites of CLEAs and magnetite nanoparticles in the large mesocellular pores did not leach out from the HMMS through the narrow mesoporous channels. The authors inferred from their study that this ship-in-a-bottle approach for a magnetically separable and stable enzyme biocatalyst can be easily expanded to many other enzymes and has large potential in biotechnology applications such as bioremediation and bioconversion.

Han *et al*. (153) described a pressure-driven method for entrapping enzymes. Instead of stirring the MCF part- icles in the enzyme solution, high pressure (205–345 bar) was used to achieve high enzyme loading within the pores of the support (up to 275 mg/g of silica). The modified mesoporous silica was dispersed in 2-propanol and packed into a high-performance liquid chromatography (HPLC) column. After the 2-propanol in the column was removed thoroughly by washing with water, the enzyme stock solution was cycled through the prepacked silica column for 2 h under high pressure. Compared to the conventional approach, the pressure-driven method resulted in significantly higher enzyme loading on MCF and FDU-12 materials within a shorter period of time. For example, 24 h of stirring led to an enzyme loading of 92 mg/g onto MCF, whereas an enzyme loading of 275 mg/g onto MCF was achieved within 2 h with the pressure-driven method.

In order to reduce leaching, functionalization of the mesoporous silica support is another promising approach. An easy access to organic-inorganic hybrid materials based on SBA-15 is provided by surface modification (154,155). Thereby, surface silanol groups are condensed with an organotrialkoxysilane or with another reactive silane species to generate covalently bound organic moieties. There are two approaches to surface modification (142,156), that is postmodification, also known as *grafting*, and direct synthesis or co-condensation. Grafting is the method more commonly used in performing surface modification by covalently linking organosilane species with surface silanol groups.

However, the grafting method has several shortcomings as follows:

- The pore size is reduced due to the attachment of a layer of functional moieties on the surface.
- It is time-consuming, because two steps are required to accomplish the modification process.
- The number of accessible surface silanol groups on the mesoporous silica materials is limited.
- Difficulties in controlling the loading and position of the organosilane may arise.

In 1996, the co-condensation method was first independently reported by two research groups (157,158). This method allows surface modification of the mesoporous materials in a single step by copolymerization of organosilanes with silica or organosilica precursors in the presence of a surfactant. This approach enables a higher and more homogeneous surface coverage of organosilane functionalities. The disadvantage of the co-condensation is that the functionalized alkoxysilane (e.g. APTES) must hydrolyze at a similar rate as compared to the unfunctionalized alkoxysilane (e.g. tertaethylorthosilicate) otherwise a heterogeneous gel will be formed and, thus, the functional groups will not be homogenously distributed.

A variety of functional groups has been incorporated into mesoporous materials such as aliphatic hydrocarbons, thiol groups, vinyl groups, phenyl groups, amine groups, and perfluoro groups (142,154–159). Surface modification using APTES, producing a terminal amine group ($-NH_2$) has been found to be useful for covalent coupling of proteins to the surface of silica materials (142). An overview of commonly used functional groups for covalent enzyme linking is given in Table 52.6.

Yiu *et al*. (160) showed in their study that there is an essential difference between *in situ* synthesis and postmodification. The method of functionalization is found to be critical for using the resulting organosilica materials as support for trypsin immobilization. Thiol, chloride and acid functionalized solids are more active when the functional group has been incorporated during the synthesis of the mesoporous molecular sieve rather than by postsynthetic treatment. This study also shows that the nature of the functional group is critical. For example, amine-functionalized solids exhibit enhanced leaching characteristics, but the observed catalytic activity of trypsin is strongly reduced. The most promising support for trypsin in this study is a thiol-functionalized SBA-15 which was prepared by direct synthesis. This catalyst, which exhibits negligible leaching in the respective activity assays, possesses a catalytic activity that corresponds to 84% of the activity determined for the free enzyme. The differences between *in situ* synthesis and postmodification concerning the uptake of trypsin are illustrated in Table 52.7. It has to be pointed out that this study only applies to trypsin and may not be generalized. Consequently, this has to be investigated for the particular enzyme under study.

Furthermore, the immobilization of enzymes was affected not only by the functionalization with organo

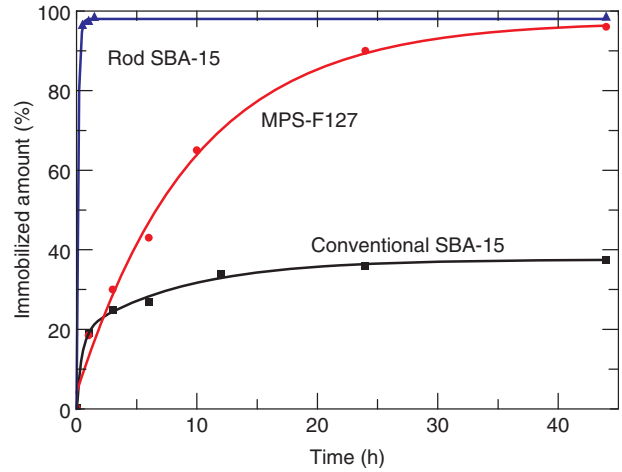

Figure 52.11. Uptake of lysozyme on rod-like and conventional SBA-15 in comparison to MPS-127 which possesses a three-dimensional cage structure (after Fan *et al*. (176)). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

moieties but also the incorporation of metal ions. Aburto *et al*. (171) impregnated SBA-16 with Cs^+ ions which resulted in an increased activity of immobilized CPO compared to a sample prepared by physical adsorption. The authors suspect that the higher activity is due to the proper enzyme orientation on the Cs-doped surface leading to an orientation of the active site of the enzyme away from the silica wall. It cannot be ruled out that the higher activity is due to enzymes which are adsorbed on the outer surface of the material. Interactions between the enzymes and the Cs-doped outer surface may result in an increase in activity because diffusion of the substrate into the pore system is not required. However, a mechanistic understanding has not been achieved so far.

The adsorption kinetics, namely, the uptake rate of the enzyme, is influenced by the macrostructure (i.e. particle size and morphology) of the host material. Fan *et al*. (176) reported a correlation between the macrostructure of mesoporous silica and the rate and amount of enzyme uptake. Smaller particles possess a larger number of pore entrances compared to conventional larger particles, which results in an improved bioimmobilization performance (Fig. 52.11). For rod-like SBA-15, a very rapid (< 10 min to reach equilibrium) and large (up to 533 mg/g) uptake of the protein lysozyme was reported (176).

PMOs represent an exciting class of organic–inorganic hybrid supports. These materials are of interest, because they exhibit well-defined host–guest chemistry. The specific interactions between host and guest can be tuned for a desired application. Therefore, enzyme immobilization onto PMO is of current interest, but only little work was reported in this area up till now. For example, Hudson *et al*. (177) described the immobilization of cytochrome *c* and xylanase onto SBA-15 and a

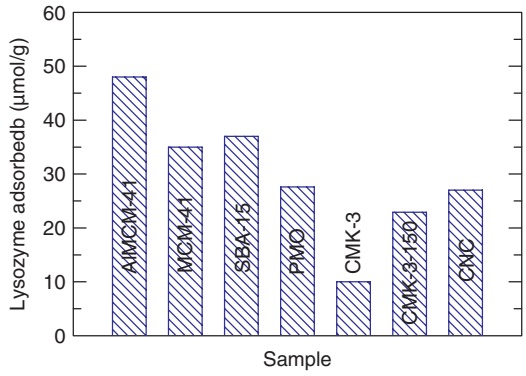

Figure 52.12. Comparison of the maximum lysozyme adsorption capacity for different mesoporous supports. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

1,2bis(trimethoxysilyl)ethane-based PMO. They observed that electrostatic attraction dominated protein interactions with SBA-15, while weaker hydrophobic interactions are more prominent with PMO. The advantage of PMOs is the easy design of a solid support for any protein by simple variation of the organic bridging group. In two similar publications, Qiao *et al*. (178,179) describe the adsorption of bovine heart cytochrome *c* and lysozme onto a 1,2bis(trimethoxysilyl)ethane-based PMO in comparison to conventional SBA-15. As the amounts of enzyme adsorbed decrease with ionic strength of the solution, the authors concluded that the electrostatic interaction between the enzymes and support is much more important than the hydrophobic interaction.

In Fig. 52.12, the adsorption of lysozyme on different mesoporous supports is compared under optimized conditions. While the more hydrophilic silica-based supports still allow higher enzyme loadings, PMO materials as well as specially engineered mesoporous carbons might not be too far behind. However, the vast options in variation of the chemical composition and the possibility to introduce different functional groups will allow extraordinary freedom in tailoring the surface properties of the support.

Wang and Caruso developed a new method for enzyme encapsulation in mesoporous supports. They reported enzyme immobilization and encapsulation in bimodal mesoporous silica spheres (BMS) (180). The enzymes were immobilized in the BMS spheres, and a multilayer shell was then assembled on the sphere surface by the layer-by-layer (LbL) electrostatic assembly of oppositely charged species to encapsulate the enzymes. Nonporous silica spheres and mesoporous silica spheres with a series of pore sizes were used as enzyme immobilization hosts for comparison. Two systems were used to form dense coatings on the enzyme-loaded BMS spheres: (i) a polyelectrolyte (PE) multilayer shell formed through the alternate deposition of poly (diallyldimethylammonium chloride) and poly (sodium 4-styrenesulfonate) and (ii) a composite shell through the alternate deposition of poly (diallyldimethylammonium chloride) and the nonporous silica spheres. The authors described an effective method to encapsulate enzymes by using mesoporous silica particles with pore sizes between 10 and 40 nm and subsequent stepwise coating with nanoscale shells. Enzyme loadings in the range of 20–40 wt.% were obtained for small enzymes (diameter ca. 3 nm) with a high p*I* (>10) and ca. 8 wt.% for larger enzymes such as catalase. The lifetime of catalase was improved by encasing LbL assembled PE shells on the catalase-loaded BMS spheres. The encapsulated catalase can also be recycled 25 times with an associated loss of activity of 30%, which is significantly smaller than the loss in activity observed for catalase immobilized in the BMS spheres (ca. 65%). Additionally, ca. 98% of the activity of the encapsulated catalase was retained when subjected to proteolysis treatment. The enzyme-loaded particles prepared are expected to find future applications in industrial catalysis.

Apart from the studies exemplary discussed above, a large (and still increasing) number of studies is devoted to enzyme immobilization on (ordered) mesoporous supports (Table 52.8). It should be pointed out that characterization after immobilization of both the protein and the porous support after adsorption is very important in order to confirm that the protein and the support are stable under the prevailing immobilization conditions. For a more detailed discussion on enzyme immobilization on ordered mesoporous supports, the reader is referred to recent review chapters (142,181–183).

52.2.5 Biocatalysis

52.2.5.1 General Remarks. The use of enzymes in enzyme-catalyzed reactions is often hampered by three main drawbacks:

- Many enzymes are not sufficiently stable under the prevailing operation conditions and may loose their catalytic activity as a consequence of auto-oxidation, self-digestion, and/or denaturation by the reactants and the solvent or due to mechanical shear forces.
- Enzymes are water-soluble molecules and, thus, their repeated use (which is often required from an economical point of view) requires the recovery of the enzyme from aqueous solutions also containing the reactants.
- The space–time yield (a measure of the productivity of an industrial process) is often low due to the limited tolerance of enzymes to high concentration of the reactants.

Glucose oxidase	Pt/CMK-3	Amperometry	—	249

Depending on the immobilization technique, the properties of the biocatalyst such as stability, selectivity, kinetics, pH- and temperature characteristics may be significantly altered, which may result in (often) reduced or (sometimes) improved performance. However, at present predictions about the influence of the immobilization on the catalytic performance are difficult to make.

It is reasonable to assume that immobilization of the enzyme on a suitable support is a prerequisite for the use of biocatalysts in large-scale processing. Besides achieving retention of the biocatalyst, immobilization is often employed to stabilize the enzyme as translational motion as well as volume enhancing enfolding of enzymes is restricted. Moreover, encapsulation induces a change in microenvironment with respect to pH or hydrophobicity. However, in immobilized biocatalyst systems based on (meso) porous materials, film and pore diffusion might be rate determining instead of the catalytic reaction. It is, therefore, of utmost importance to establish the rate-determining step under the prevailing reaction conditions. Furthermore binding to the mesoporous carrier might cause changes in the active site of the enzyme often accompanied by significant loss in catalytic activity. Even when binding does not alter the enzyme structure, some enzymes may be bound to the carrier surface with the active site oriented away from the substrate solution and toward the surface, thereby hindering access of the substrate to the active site of the enzyme.

Although many cases of successful immobilization of enzymes using ordered mesoporous materials have been reported (cf. Tables 52.6 and 52.7) most of the research published only uses standard activity assays to monitor the catalytic performance. Up till now only a small effort has been made to test biocatalysts immobilized on mesoporous supports in real catalytic reactions. Thus, demonstration of their utility including the possibility to reuse the biocatalyst is of imminent importance. For industrial applications, a major obstacle to overcome is the low space–time yield in comparison to conventional (chemical) catalysts. Significant progress in this area would presumably increase the use of immobilized biocatalyst in industrial practice. Moreover, a unique feature of enzymes is their capability to catalyze reactions with high regio- and enantioselectivity.

The development of novel biocatalyst would be in particular useful for the production of pharmaceuticals and fine chemicals.

In the majority of studies devoted to the application of enzymes immobilize on mesoporous supports in catalysis, the catalytic activity is determined using standard activity assays. In this way, the relevant issues (i) enzyme activity after immobilization, (ii) stability during the reaction, and (iii) reusability after reaction are addressed for a large number of individual systems. Since these aspects have been thoroughly discussed in a recent review (181), here only a few representative examples with respect to potential industrial applications are discussed.

52.2.5.2 Case Studies. Many of the enzymes (e.g. lysozyme, papain, subtilisin Carlsberg, and trypsin) investigated so far are proteolytic enzymes that have large potential in the area of proteonomics owing to their potential to produce characteristic peptides that allow peptide mass finger printing. In particular, trypsin is one of the three principal digestive proteinases, the other two being pepsin and chymotrypsin. In the digestive process, trypsin acts with the other proteinases to break down dietary protein molecules to their component peptides and amino acids. Trypsin is the most discriminating of all the proteolytic enzymes in terms of the restricted number of chemical bonds that it will attack. Good use of this fact has been made by chemists interested in the determination of the amino acid sequence of proteins; trypsin is widely employed as a reagent for the orderly and unambiguous cleavage of such molecules.

Magner and coworkers (250) developed and studied a "nanoporous reactor" based on cyano-functionalized mesoporous silicates for efficient proteolysis employing trypsin. The trypsin-mediated digestion of proteins is reported to occur within its mesochannels. Mesoporous silica (d_p = 18 nm) is used as support for trypsin and rapid *in situ* digestion of the proteins cytochrome *c* and myoglobin is observed. After digestion, the generated peptides were analyzed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS). The authors pointed out that proteolysis by trypsin immobilized in the channels of mesoporous silica is much more efficient than digestion in solution. This observation is ascribed to the nanoscopic confinement and the concentration enrichment of the substrate within the mesopores. Thus, the invented "nanoreactor" combines the advantages of short digestion time with retention of enzymatic activity, thus providing a promising way to advance the development of proteomics.

The hydrolysis of *N*-α-benzoyl-DL-arginine-4-nitroanilide (BAPNA) is widely used for the activity determination of immobilized trypsin (7,160,251). Yiu *et al*. reported the immobilization of trypsin onto a variety of functionalized mesoporous SBA-15 materials (160). The most promising catalyst in this study is trypsin adsorbed on a thiol-functionalized SBA-15 support. The catalytic activity of this solid, which showed negligible leaching in catalytic assays, amounts to about 84% of the activity measured for the free enzyme. It was shown that reuse of the catalysts is also possible, even after a period of several days, although the initial activity of the recycled catalyst (trypsin supported on thiol-functionalized SBA-15) is only two-thirds of that displayed by the fresh catalyst.

Hodnett and his group (197) studied the transesterfication of *N*-acetyl-L-tyrosine ethyl ester with propane-1-ol by trypsin supported on MCM-41 (d_p = 4.5 nm). The catalytic experiments were performed in a batch reactor. The authors reported that the activity of the catalyst is not reduced after the second and third reuse. Under the prevailing experimental conditions, the turnover number (TON) amounts to 600, that is, 600 molecules of ethanol are formed per molecule of trypsin.

In vivo, chymotrypsin is a proteolytic enzyme acting in the digestive systems of mammals and other organisms. In enzymatic catalyzed experiments, chymotrypsin was found to be useful for resolutions of racemic mixtures and in transesterifications. Fadnavis *et al*. (166) immobilized the zymogen α-chymotrypsinogen A onto mesoporous silica MCM-41. After activation of the zymogen with trypsin, the active α-chymotrypsin immobilized on MCM-41 was obtained. The enzyme was tightly bound to the support and can be used in over 100 cycles over 1 week in aqueous as well as reverse micellar media. The immobilized α-chymotrypsin has been used for resolution of *N*-acetyl- DL -amino acid esters. The determination of enantiomeric purity showed that the racemic amino acid is completely resolved giving *N*-acetyl-L-amino acid and the unreacted D-ester with an enantiomeric excess (ee) > 99% and an ee of 98%, respectively.

The kinetic resolution and accordingly the transesterification of racemic (±)-*trans*-4-methoxy-3-phenylglycidic acid methyl ester is an industrially important process since the optically pure (2*R*,3*S*)-*trans*-4-methoxy-3-phenylglycidic acid methyl ester is used as an intermediate for the production of diltiazem, which is an important drug. It was observed that the immobilized α-chymotrypsin shows stereoselectivity toward the (2*S*,3*R*)-isomer, giving *trans*-(2S,3*R*)-*p*-methoxy-3-phenylglycidic acid butyl ester (ee = 75%) and *trans*-(2*R*,3*S*)-*p*-methoxy-3-phenylglycidic acid methyl ester with ee = 65% at a conversion of 45% (Fig. 52.13). Furthermore, the activity of immobilized α-chymotrypsin in aqueous buffer was found to be consistent for at least 100 recycles (20 recycles per day) over 1 week at room temperature and decreased gradually to 15% during the next 10 days. It was confirmed that the inherent properties of α-chymotrypsin do not change after immobilization in the pores of MCM-41 and the resulting

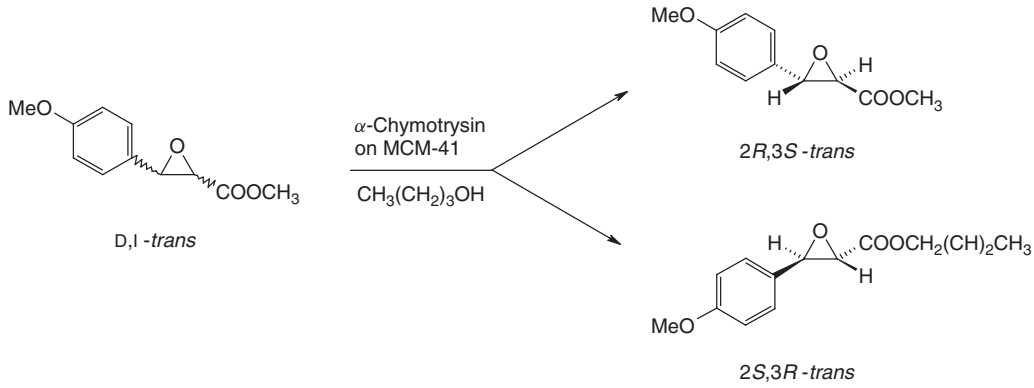

Figure 52.13. Kinetic resolution of racemic (±)-*trans*-4-methoxy-3-phenylglycidic acid methyl ester glycidate with α-chymotrypsin.

heterogeneous catalyst can be used in both aqueous and reverse micellar media for practical applications.

Transesterification reactions using immobilized α-chymotrypsin in organic solvents were conducted by Wang *et al*. (175). α-Chymotrypsin was immobilized by covalent anchoring onto an ordered mesoporous silica support (SBA-15-like with $d_p = 15$ nm) and its activity in the transesterification of *N*-acetyl-L-phenylalanine ethylester and *n*-propanol in hexane, acetonitrile, methanol, and *iso*-octane was tested. Although methanol is a potential reactant for the transesterification, no methylester product peak was detected and, thus, no transesterification with methanol occurs. The authors observed a much higher activity of the immobilized α-chymotrypsin compared to the native enzyme suspended in the same organic solvent. For hexane, a 110-fold enhancement was observed, while the highest activity was determined when *iso*-octane was used as a solvent. In contrast, the apparent activities of immobilized α-chrymotrypsin are usually much lower than those of their free parent enzyme as measured by the hydrolysis reaction.

A broad variety of esterifications is catalyzed by lipases. Lipases belong to the hydrolytic enzymes beside proteases, amylases, amidases, and esterases, which provide the major contingent of enzymes used for industrial processes. Lipases (triacylglycerol acylhydrolases, E.C. 3.1.1.3) have turned bit by bit to key enzymes in the growing biotechnology sector and find usage in a wide array of industrial applications including food technology, detergents, chemical industry, and biomedical sciences. Lipases are hydrolases which cleave the carboxyl ester bonds in triacylglycerols under aqueous conditions to liberate fatty acids and glycerol. The natural substrates of lipases are long-chain triacylglycerols with very low solubility in water. Therefore, the reaction is catalyzed at the lipid–water interface. Under microaqueous conditions, lipases possess the unique ability to carry out the reverse reaction, leading to esterification, alcoholysis, and acidolysis. Besides being lipolytic, lipases also possess esterolytic activity. In order to improve the catalytic potential of lipases and to enhance their utilization in industrial processes and for further applications, several strategies have been developed for efficient immobilization onto mesoporous silicas.

To exploit the lipolytic nature, studies of gas-phase enzymatic reactions catalyzed by supported lipases onto MCM-41 and Al-MCM-41 were carried out. Pires *et al*. (194) examined lipases produced by five different microorganisms in the esterification reaction of acetic acid with ethanol. The used lipases were extracted from: *Rhizopus oryzae*, *Rhizopus niveus*, *Mucor javanicus*, *Pseudomonas fluorescens*, and *Pseudomonas cepacia*. The transesterification of acetic acid catalyzed by free and immobilized lipases was tested in the liquid-phase in a batch reactor. In addition, the immobilized lipases were tested in gas-phase reactions in a continuously operated fixed-bed reactor. In general, Pires *et al*. observed an increase of the turnover number for the liquid-phase reactions carried out with the immobilized lipases compared to the homogeneous catalytic reaction. Although the results showed that the rates of liquid-phase reactions were higher than those measured for the gas-phase reactions, the authors avoided a comparison of the two systems because the concentration of reactants and the amount of catalyst used were lower in the gas-phase experiments. In addition, Pires *et al*. found a higher activity for the lipases immobilized in Al-MCM-41 than for those immobilized in MCM-41.

To enhance lipase activity by coimmobilization of different stabilizing additives was found to be a promising strategy. Soares *et al*. (229) reported that simultaneous immobilization of lipase and nonenzymatic proteins (e.g. albumin and lecithin) on the same mesoporous support enhanced the activity of the resulting catalyst. The solid catalysts were prepared by covalent immobilization of lipase together with albumin and lecithin, respectively. The mesoporous support was functionalized with APTES followed by the reaction

of the pretreated beads with glutaraldehyde and the proteins. The reaction mixture consisting of heptane, *n*-butanol, butyric acid, and immobilized lipase was incubated at 37°C for 24 h with continuous shaking at 150 rpm. The initial esterification activity of immobilized lipase without additive was 161 μmol/g·min, while for the catalyst prepared in the presence of lecithin or albumin the activity increased by about a factor of 2. The authors showed that the lipase catalyzed synthesis of butyl butyrate via esterification can be enhanced by nonenzymatic additives. In Fig. 52.14, the concentration of the synthesized butyl butyrate is plotted against the reaction time. The improved lipase activity was considered to be a consequence of the coimmobilization of lipase with the additives, which presumably prevents enzyme aggregation and increases the accessibility of active sites to the substrate.

A special case of an esterification, which is very common in the synthesis of natural products, is the acetylation. Because of its manifold applications in organic synthesis, the enzymatic catalyzed acetylation using immobilized lipases is also investigated. Here, methyl (±)-mandelate (methyl-α-hydroxyphenyl acetate) was chosen as a model substrate for the lipase-catalyzed reaction (196). This model reaction, shown in Fig. 52.15, was carried out in an ionic liquid as solvent, therefore, lipase PS was immobilized on a methacrylpropyl-modified SBA-15 (252).

Itoh *et al*. (196,252) showed that the acetylation of methyl (±)-mandelate results in the formation of (−)-methyl (*R*)-mandelate with an ee larger than 99%. The acetylation provided the product (+)-methyl (*S*)-α-acetoxyphenyl acetate in 71% yield with an ee of about 22%. This type of reaction is potentially interesting since it allows kinetic resolution of racemic mixtures.

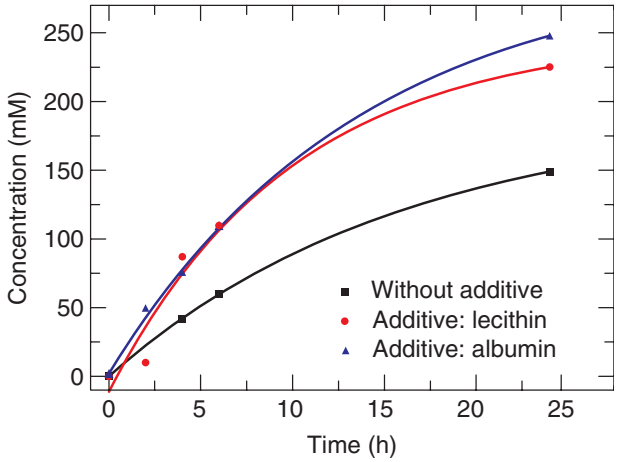

Figure 52.14. Synthesis of butyl bytyrate from butanol and butyric acid using immobilized lipase without (■) and with additives (lecithin (•) and albumin (▲)), respectively. The intial esterification activities for immobilized lipase without additive, with lecithin and with albumin amount 161, 306, and 338 μmol/g, respectively (after C.M.F. Soares *et al*. (229)). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Full resolution of the racemic mixture of 1-phenylethanol to (*R*)-1-phenylethanol and (*R*)-1-phenylethyl acetate was achieved in a packed fixed-bed reactor as described by Han *et al*. (153). A standard HPLC column was filled with a catalyst consisting of lipase *Candida antarctica* lipase B immobilized on modified silica MCF by the pressure-driven immobilization method (described in Section 2.4). The catalyst-packed column was tested for continuous conversion of 1-phenylethanol. The flow rate was adjusted to give full conversion of (*R*)-1-phenylethanol (i.e. 50% conversion of the (*R*)-1-phenylethanol and (*S*)-1-phenylethanol racemic mixture). The activity and enantioselectivity of the reaction remained constant in the beginning and decreased by 9% after 48 h of reaction. Unfortunately, the conversion of (*R*)-1-phenylethanol was 100% at the beginning and so deactivation cannot be detected in the early stage of the reaction. A multitude of experiments was carried in a batch reactor in order to determine the conversion of (*R*)-1-phenylethanol over immobilized lipase prepared by the pressure-driven method as well as the conventional method in comparison to the commercial catalyst Novozyme 435 and free lipase (CALB). After 5 h, a conversion of 50% based on the racemic mixture was achieved over the immobilized lipases, while only 45% were found over the free lipase. After a thermal treatment at 80°C, only the pressure-driven immobilized lipase reached a conversion of 50%. Moreover, leaching of the catalysts was reported to be a problem.

Another versatile and often employed reaction in organic synthesis is the acylation of, for example, amines, amides, and alcohols. A prominent example is the industrial production of the pain-killer aspirin. Thus, there is also an interest in performing lipase-catalyzed acylations under conditions which fulfill industrial requirements. Blanco *et al*. described the acylation of ethanolamine with lauric acid in acetonitrile catalyzed by lipase from *C. antarctica* B (230). The catalyst used was lipase immobilized onto a commercial mesoporous silica (with a surface area of 300–320 m^2/g and an average pore diameter of 30–40 nm), which was modified with octyltriethoxysilane prior to the immobilization step. The N-acylation of ethanolamine with lauric acid was conducted in a stirred-tank reactor, where the lipase-octyl-silica catalyst was added to the acetonitrile solution containing ethanolamine and lauric acid. After completion of the reaction, the solid catalyst was recovered by filtration and a new reaction was started. Following this procedure, the catalyst was reused up to 15 times. The catalyst remained fully active for these 15 cycles at 40°C, thus, exhibiting an excellent operational stability of the immobilized lipase.

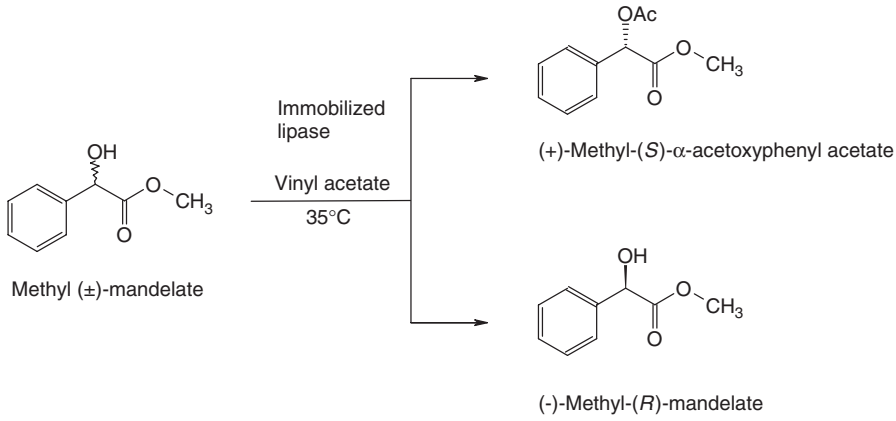

Figure 52.15. Transesterification of methyl (±)-mandelate and vinyl acetate in 1-butyl-3-methylimidazolium tetrafluoroborate or hexafluorophosphate catalyzed with immobilized lipase PS.

The hydrolysis of ethylthiodecanoate with encapsulated lipase was tested by Mureseanu *et al*. (134). The enzymatic catalysis tests were performed in a cuvette. The hydrolysis of the ethylthiodecanoate was selected because the thioethanol formed during this reaction can be easily detected by UV–Vis spectroscopy from the yellow colored product formed in the presence of 5,5-dithiobis(2-nitrobenzoic acid).

In the majority of the studies published so far, the activity of lipase is determined via an enzymatic activity assay, that is, the hydrolysis of olive oil and *para*-nitrophenyl palmitate, respectively. Owing to the lack of correlation between the hydrolytic and synthetic activity of lipases, high activities in hydrolysis reactions do not necessarily go along with high activities in synthetic reactions. Therefore, it is necessary to study more lipase-catalyzed reactions with respect to their applicability in organic synthesis and in industrial areas, for example, the production of pharmaceuticals.

Hydrolysis also plays an enormous role in the breakdown of starch into maltose molecules. Starch is the most common storage carbohydrate in plants. Since it is used by the plants themselves, by microbes and by higher organisms, a great diversity of enzymes is able to catalyze the hydrolysis of starch. Acidic hydrolysis of starch was widely used in the past and is now replaced by enzymatic processes step by step. Thus, there is a large interest in heterogeneous catalysts based on α-amylase to produce dextrin, glue, starchy syrup or other food ingredients such as glucose.

Pandya *et al*. (165) reported the immobilization of α-amylase into SBA-15, MCM-41, and MCF. The immobilization of α-amylase was carried out in a three-step process. In the first step, alkylamine was covalently bonded to the silanol groups of mesoporous silica. Further treatment with glutaraldehyde resulted in an imino function. In the last step, α-amylase was covalently anchored onto the mesoporous material. Owing to the inability of α-amylase to hydrolyze $\alpha(1-6)$ bonds, the actual reaction products are dextrins rather than maltose. The highest starch conversion with a specific activity of 80% of the free enzyme was observed for α-amylase immobilized on MCF possibly due to the higher enzyme loading. Furthermore, the structural features of MCF provide accessibility and more diffusional freedom for substrate and product molecules. Hence, the authors conclude that the two-dimensional pore structure of MCM-41 and SBA-15 might impose diffusional restrictions on substrate and product molecules. In conclusion, it was observed that the stability of immobilized α-amylase was enhanced with increasing pore sizes of the support and the catalyst retains its activity in starch hydrolysis for 140 min.

Vegetable raw materials are not only important for the production of food or food additives, but also for energy generation using biomass. Sulfur-containing compounds of biomass and petroleum are a well-known problem for industry and environment. The oil refining industry is a potential candidate for the use of enzymes in the production of clean fuels including diesel and gasoline in order to meet the present and future rigorous environmental regulations. The technological and economical feasibility of biocatalytic oxidation and subsequent separation of organosulfur compounds by distillation to obtain low-sulfur fuels is insufficient. Up till now, only few papers were published dealing with this topic, which provides an interesting area for future studies. The homogeneous enzymatic oxidation of dibenzothiophene by laccase (253) and the oxidation of 4,6-dimethyldibenzothiophene (4,6-DMDBT) by immobilized CPO from *Caldariomyces fumago* were recently investigated (172,214). CPO was immobilized on amorphous and ordered silica-based materials either by physical adsorption or covalent anchoring using an organosilane derivative; both catalysts were tested in the oxidation of

4,6-DMDBT with H_2O_2 as oxidant. The performance in this reaction was investigated with respect to the addition of organic solvents (e.g. acetonitrile) the thermal stability of the enzyme and the influence of the different supports. In addition, different supports were explored such as SBA-15, SBA-16, MCM-41, and Al-MCM-41. It was found that the activity is reduced by only 20% in the presence of 60 vol.% acetonitrile compared to the homogenously catalyzed reaction in a buffer solution containing 20 vol.% acetonitrile. Surprisingly, CPO immobilized on Al-MCM-41, which shows the highest activity at room temperature in a reaction mixtures containing 20 vol.% acetonitrile, is no longer active in the presence of higher concentrations of acetonitrile. Increase of the temperature from 24 to 35°C results in a 2.5-fold higher reaction rate for the immobilized CPO, while the rate of the native enzyme decreased by 20%. In summary, this study indicates that the immobilization of CPO on mesoporous materials might be a promising approach for this specific case in petroleum industry. However, major hurdles to overcome still are the cost of CPO and its low stability.

The oxidation of indole to 2-oxindole catalyzed by immobilized CPO was studied by Jung *et al*. (234) under flow conditions in a fixed-bed reactor. The nonenzymatic synthesis of 2-oxindole requires harsh conditions or complex inorganic catalysts to be successful, since oxidation of the electron-rich 3-position is typically favored. Preliminary studies on CPO immobilized SBA-15 by physical adsorption were carried out by *Hartmann et al*. (213). External H_2O_2 addition to the batch reactor results in deactivation of the immobilized CPO due to high local H_2O_2 concentrations. Deactivation was circumvented by *in situ* hydrogen peroxide generation. H_2O_2 was produced by oxidation of glucose with glucose oxidase (GOx) from *Aspergillus niger* immobilized on SBA-15. By the use of this tandem reaction, CPO deactivation was largely suppressed due to the "sensitive" hydrogen peroxide generation. The maximum indole conversion of 91% is observed at a pH of 5.5, which is also the pH where the highest average H_2O_2 formation rate was observed. Moreover, the tandem catalyst can be recycled several times without significant loss of activity (234).

Besides deactivation, leaching of the enzymes is a frequently encountered problem. In order to avoid leaching from the mesoporous support, CPO and GOx were covalently anchored to the carrier surface via chemical bonding. Jung *et al*. (169) have observed that under continuous operation in a fixed-bed reactor leaching of the covalently anchored enzymes is significantly reduced as compared to catalysts containing physically adsorbed enzymes (Fig. 52.16). By using immobilized CPO and GOx as catalysts in this tandem reaction, the final 2-oxindole yield amounts to 8.3% after 50 h time-on-stream which is more than twice the amount found for the physisorbed CPO and GOx at similar catalyst loadings.

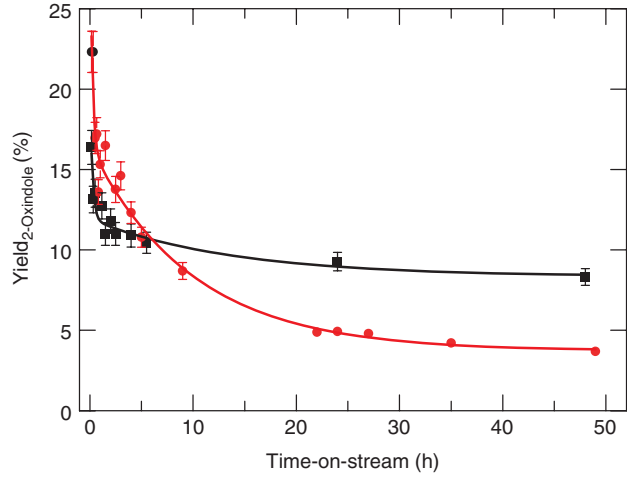

Figure 52.16. Oxidation of indole over 150 U CPO-GA-ATS-SBA-15 and 7 U GOx-GA-ATS-SBA-15 (•) and 150 U CPO-SBA-15 and 7 U GOx-SBA-15 (■) (after Jung *et al*. (169)). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Together with CPO, HRP belongs to the group of oxidoreductases. HRP is used as a reagent for organic synthesis, biotransformation and in coupled enzyme assays. Some applications of HRP are small-scale organic syntheses including N- and O-dealkylation, oxidative coupling, selective hydroxylation, and oxygen-transfer reactions. However, van de Velde *et al*. (254) raised the general point that scale-up of peroxidase-catalyzed enantioselective oxidations to industrial level will require a substantial reduction in the price of enzyme per unit of product. Solutions to this problem may include better process management of hydrogen peroxide to avoid enzyme inactivation (see paragraph on CPO) and use of engineered enzymes with improved stability and catalytic efficiency.

For evaluation of the catalytic activity and efficiency of HRP immobilized on mesoporous silica, the oxidation of 1,2-diaminobenzene in toluene was selected by Takahashi *et al*. (193) as test reaction. The experiments were performed in the absence of water; *tert*-butylhydroperoxide was used as the oxidant and HRP was immobilized on FSM-16, SBA-15, and MCM-41 materials with different pore diameters. The conversion over HRP immobilized on FSM-16 (d_p = 5.1 nm) and on MCM-41 (d_p = 5.0 nm) amounts to 75% and 63%, respectively, after 7 h. When HRP was immobilized on supports possessing pores smaller or larger pores than 5 nm, the conversion was lower. Thus, the authors concluded that the average mesopore sizes have to match the molecular dimensions of the enzymes in order to achieve immobilized enzymes exhibiting good stability and high activity.

The most abundant polymer on earth besides cellulose is lignin. About 65–75% of the dry mass of wood consists of lignin. It is extracted by the Kraft process, but for

further applications, for example, in the paper industry it has to be bleached. In an attempt to use manganese peroxidase (MnP) for chlorine-free pulp bioleaching, MnP from *Phanerochaete chrysosporium* has been immobilized on FSM-16 with a pore diameter of 7.0 nm (215). This support has nearly the same pore diameter than the size of the enzyme and the immobilized MnP exhibits high thermal stability and tolerance to H_2O_2. MnP immobilized on FSM-16 retained more than 80% of its initial activity even after 10 days of reaction. Moreover, a two-stage reactor system is proposed, in which the Mn^{3+} generation step and the pulp-bleaching step were separated. In the first step, the substrate solution comprising Mn^{2+}, H_2O_2, and malonic acid (as a chelating agent) was introduced in a column packed with FSM-16 supported MnP. In the next stage, the Mn^{3+} malonate complex generated by the immobilized MnP was transferred into the bleaching vessel containing unbleached treated kraft pulp. By using a two-stage reactor system, the conditions for the oxidation of Mn^{2+} to Mn^{3+} by MnP and the subsequent oxidation of lignin in pulp by Mn^{3+} can be optimized independently (215). The best results were obtained when the MnP reaction and the pulp-bleaching reaction were performed at 39 and 70°C, respectively, MnP activity was maintained throughout the reaction and the brightness of the pulp after 9 h had increased from 61% to 70%.

A further improvement of this process was achieved by combination of the bleaching process with a subsequent alkaline extraction. The enzyme-treated pulp was washed with deionized water and then suspended in a 2.5% NaOH solution. The enzyme treatment (55 min) and alkaline extraction (5 min) were repeated alternately for seven cycles. Seven hours after completion of the last treatment the brightness of the pulp has increased to about 88%.

Galarneau *et al*. (131) described the immobilization of alcohol dehydrogenase (ADH), which is known to be a fragile enzyme. ADH has been immobilized either alone or coimmobilized with its cofactor nicotinamide adenine dinucleotide (NAD^+) in SMS. The self-assembly of mixed-micelles of lecithin and dodecylamine in an alcoholic aqueous media allows to template the formation of SMS. The activity of this biocatalyst was tested in the oxidation of ethanol to acetaldehyde and compared to the activity of a similar catalyst prepared by coadsorption of ADH and NAD^+ on MCM-41 (Fig. 52.17). The authors concluded that this biocompatible method of SMS formation enhances enzymatic activity which allows the encapsulation of even very fragile enzymes for use in catalytic processes.

Penicillins are the most widely used β-lactam antibiotics, which hold a 19% share of the estimated worldwide antibiotic market. However, excessive use of these antibacterial drugs has led to the development of resistant pathogens. Currently, the only method of overcoming

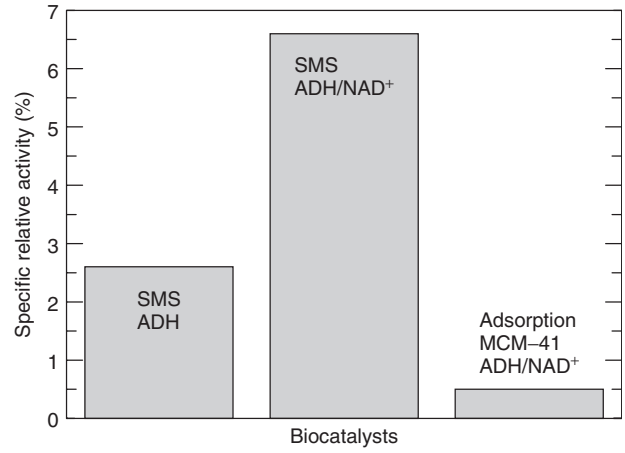

Figure 52.17. Relative specific activity of ADH encapsulated in SMS with and without its cofactor NAD^+. For comparison, relative activity of ADH immobilized with its cofactor NAD^+ by adsorption in a large-pore MCM-41-type material is given (after A. Galarneau *et al*. (131)).

the resistance problem is the use of newer semisynthetic antibiotics. 6-Aminopenicillanic acid (6-APA) is a key raw material for the production of semisynthetic penicillins and, thus, of increasing interest in pharmaceutical industries. 6-APA can be produced via hydrolysis of penicillin G by penicillin acylase (PA) (Fig. 52.18). Efforts to use PA have been hampered by its high cost, instability, and the difficulty in recovering the active enzyme for reuse. By immobilizing PA on a mesoporous support, it is hoped that the catalyst can be used in a continuous process and may also be readily separated from the reaction mixture and reused. Furthermore, the properties of PA may be enhanced or its lifetime may be increased, because immobilized PA is less susceptible to degradation, aggregation, or denaturation. He *et al*. (191) reported the immobilization of PA onto MCM-41 and Al-MCM-41 and its catalytic evaluation in penicillin G hydrolysis. The authors pointed out that PA can be immobilized on MCM-41 and Al-MCM-41 with different Si/Al ratios (Table 52.9) through either direct immobilization or covalent coupling with glutardialdehyde. Direct immobilization resulted in higher activities compared to covalent coupling.

7-Aminocephalosporanic acid (7-ACA) is an important starting material for the synthesis of semisynthetic cephalosporins (Fig. 52.19). The cephalosporins are a class of β-lactam antibiotics, which belong to a subgroup called *cephems*. The enzymatic transformation of cephalosporin C (CPC) into 7-ACA can be performed by a two-step process including the oxidative deamination of CPC to glutaryl-7-aminocephalosporanic acid (GL-7-ACA) catalyzed by a D-amino acid oxidase and the subsequent hydrolysis catalyzed by GL-7-ACA acylase (255). In this context, Park *et al*. (256,257) studied the immobilization of

Si/Al = 50	491
Si/Al = 25	511

GL-7-ACA acylase on a conventional silica gel modified with APTES followed by glutaraldehyde coupling and studied the resulting catalyst in the production of 7-ACA.

The Michaelis–Menten kinetic parameters, K_m and V_{max}, for free and the immobilized GL-7-ACA acylase on siclica gel were determined to be 9.9 mM and 171.36 μg/min and 15.4 mM and 114.94 μg/min, respectively. The pH values for optimum activity of the free and immobilized GL-7-ACA acylase were almost identical. However, the pH-dependent activity profile for the immobilized GL-7-ACA acylase is considerably expanded. A similar finding has been reported, for example, for CPO immobilized on mesoporous silica (213). In order to investigate the thermal stability of the immobilized GL-7-ACA acylase, experiments were carried out at various temperatures (20–60°C).

The thermal inactivation rate constant (k_i) values of the immobilized GL-7-ACA acylase at all temperatures studied were lower than those of the free GL-7-ACA acylase, and the half-lives for inactivation of the immobilized GL-7-ACA acylase were higher than those of the free GL-7-ACA acylase (Table 52.10). Consequently, the thermal stability of the immobilized GL-7-ACA acylase was increased significantly compared to that of the free GL-7-ACA acylase. Therefore, the authors conclude, that the immobilization strategy used in their study should be applicable to the production of 7-ACA in large scales. Moreover, the use of a suitable mesoporous silica support might also be interesting.

The last example in this chapter is devoted to a multistep synthesis in microfluidic devices which involves enzymes immobilized on (meso)porous silica. Luckarift *et al*. (258) reported the combinatorial synthesis of 2-aminophenoxazin-3-one (APO) in a microfluidic device (Fig. 52.20). Microfluidic channels (40 mm long × 1.5 mm wide × 0.1 mm deep; 6 mL volume) were fabricated in

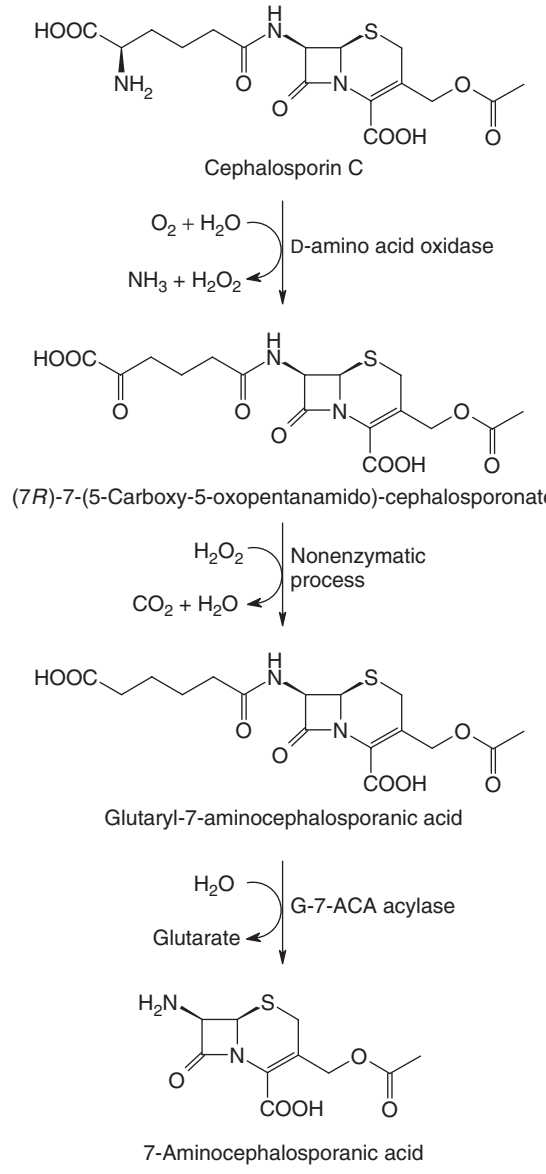

Figure 52.19. Synthesis route of 7-aminocephalosporanic acid for the production of semisynthetic cephalosporins with cephalosporin C as starting material.

polydimethylsiloxane. The resulting chip is fabricated with three 50 mm channels to form an exit network to retain the immobilized catalysts. The biocatalyst immobilized on silica was loaded into the channel by applying a vacuum to the product reservoir. Individual microfluidic chips containing

metallic zinc, silica-immobilized hydroxylaminobenzene mutase (HAB-mutase) and silica-immobilized soybean peroxidase (SBP) are connected in series to create a chemoenzymatic system for the synthesis. Zinc catalyzes the initial reduction of nitrobenzene to hydroxylaminobenzene (HAB), which undergoes a biocatalytic conversion to 2-aminophenol, followed by enzymatic polymerization to APO. The immobilization of the enzymes onto silica allows stabilization and a minimal preparation of the biocatalyst into the microfluidic device. The system proved suitable for synthesis of a complex natural product (APO) from a simple substrate (nitrobenzene) under continuous flow conditions.

This work is a fine example for a chemoenzymatic microfluidic device allowing synthesis of a natural product from nitrobenzene. The facile immobilization of the employed enzymes on silica provided stable heterogeneous catalysts, which can be easily incorporated into microfluidic chips. The invented flow-through system could, in principle, be applied to the transformation of a wide variety of nitroarene substrates into their corresponding phenoxazinone products, and provides an attractive alternative to conventional chemical synthesis. This example shall trigger more work in this area including the use of mesoporous silicas as support for immobilization of the enzyme. However, it is at present not clear whether an increase in performance will justify a potentially higher price of the device.

52.3 CONCLUSIONS AND OUTLOOK

Although quite young, the field of mesoporous silicas and carbons doped with biologically interesting molecules has already exhibited its diversity and potential applications at many frontiers of modern material science including biocatalysis, biosensing, drug release, and separation of biological molecules. It has been shown that ordered mesoporous materials are useful for stable entrapment of biofunctions and the stabilization of biological interesting molecules such as proteins and enzymes under severe conditions. For example, enzymes immobilized on ordered mesoporous supports often show higher stability as compared to the free enzyme. However, the activity of immobilized enzymes is often found to be lower than that of the free enzyme. Moreover, the access of a substrate to the enzyme confined in a mesoporous host might be orientation selective resulting in a unique selectivity of a reaction. While the activity of the immobilized enzymes is often assessed by a suitable assay, evaluation of the novel biocatalysts in reactions which are potentially interesting for an industrial application are rare. Moreover, tandem reactions which employ two or more enzymes in a one-pot reaction, which is one of the huge advantages of enzymatic biocatalysis, are seldom used. One of the major problems to be solved is the stability of mesoporous silicas upon prolonged exposure to aqueous solutions. Moreover, a possible reuse of these (at present cost-intensive) adsorbent/catalyst has to be investigated. For industrial applications, particle size and morphology of the mesoporous support are important issues with respect to reactor configuration, crystallization of reaction products, and intraparticle diffusions. Moreover, several critical points such as mechanical stability and shaping of (macroscopic) particles with well-defined properties have to be addressed in future work. Commercial issues such as cost of the support and scale-up of the preparation of a biocatalyst by immobilization of an enzyme have to be assessed in competition with existing materials. A major issue in biocatalysis is the low space–time yield in comparison to conventional "chemical routes." However, the high selectivity to the (enantiopure) target molecule might overcompensate this drawback. Although a number of ordered mesoporous materials

including PMOs and mesoporous carbons have been prepared, mesoporous silicas are still predominantly used. In particular PMOs offer the possibility of tailor-made functionalization of walls with suitable anchoring groups and tuning of the hydrophobicity of the support. In conclusion, the use of ordered mesoporous materials in biocatalysis, bioadsorption and biosensing is a young and growing but still challenging field with still high demand of new and improved materials and processes.

53.1 INTRODUCTION

Cell immobilization can be defined as entrapment or localization of living cells to a certain region of space with preservation of their metabolic and/or catabolic activity. Cell immobilization improves the efficiency of the cultures by mimicking cell natural environment. Numerous biotechnological processes are advantaged by the immobilization technology. There are numerous publications on immobilization of various cell types, emphasizing many advantages for biomass and metabolite productions compared with free cell systems, such as: high cell density, reuse of biocatalysts, improved resistance to contamination and other exterior influences, stimulation of production and secretion of secondary metabolites and physical and chemical protection of the cells. In addition, immobilized cell systems can be operated in continuous mode at higher dilution rates without the risk of cell washout. Especially attractive are the options for co-immobilization of different cell types for the simultaneous implementation of consecutive reactions. Another reason for co-immobilization is to promote growth of one species by co-immobilization with another type of microorganism. Moreover, the local oxygen environment can be manipulated by incorporating photosynthetic organisms for *in situ* generation, or conversely to provide a gradient, by binding aerobes externally to anaerobes to generate internal oxygen limitation. Except numerous benefits of immobilization, possible disadvantages like costs of immobilization, lowered specific activity of the biocatalyst, diffusion problems, or bad mechanical stability of the biocatalyst have to be considered and met by choosing the right immobilization technology.

So far, various types of living cells such as bacteria, yeast, plant, or mammalian cells have been successfully immobilized for applications in industry, medicine, and agriculture. The possible uses are numerous, ranging from ethanol and beverage production, food production, production of phytochemicals and biopharmaceuticals, treatment of waste water, soil and groundwater, construction of electronic devices to measure toxicity, such as biosensors, to disease treatment, tissue (pancreas, skin, liver, cartilage, heart, bone) engineering, and production of artificial seeds. Another attractive area of application of immobilized systems is the production of noncontaminant energy (such as H_2), intended to be explored in the next years. Issues of safety, simplicity, applicability, and price of immobilization technology may differ depending on the field of its application and purpose. The criteria for industrial acceptance of immobilization technology may be different from that for biomedical applications. The concept of immobilization is applied in both products and processes. Product examples include the bioactives in drug delivery. Encapsulation technology is widely used for stabilizing sensitive microorganisms (providing their metabolic activity after storage and intake by a new host), controlling the oxidative reactions, sustained or controlled release of active ingredients or to provide barriers between the sensitive bioactive materials and the environment. Process examples include the immobilization of biologically based catalysts, such as enzymes, cells,

and biologically active components promoting tissue formation.

53.2 CELL IMMOBILIZATION: CARRIERS AND TECHNIQUES

The key elements of an immobilized cell system are: cell type, immobilization material and method, and bioreactor design. Immobilization methods can be classified into four major categories (Fig. 53.1) based on the mechanism of cell localization employed and the nature of support material: (i) attachment or adsorption on solid carrier surfaces, (ii) entrapment within a porous matrix, (iii) self-aggregation by natural flocculation or with cross-linking agents, and (iv) cell containment behind barriers (1). The purpose of this review is to describe recent developments in immobilized cell technology.

53.2.1 Immobilization on Solid Carrier Surfaces

Many microorganisms have a natural tendency to adsorb spontaneously and grow on a wide variety of organic and inorganic supports. For example, algal cells (2) and fungi (3) spontaneously attach to loofa sponges. This is a process of passive immobilization, easily reversible and contamination of an effluent with unstuck cells is unavoidable. Active cell immobilization on solid carriers is based on physical or chemical adsorption to a surface induced by van der Waals forces, ionic bonds, hydrogen bridges, or covalent interactions between the cell membrane and the carrier. Chemical attachment of sensitive living cells may cause damage in cellular surfaces and drastically reduce viability of cells. Principally, ion attraction is not harmful to living organisms, but effectiveness of the immobilization process depends of pH and ionic strength of the surrounding media. Microbial cells exhibit a dipolar character and behave as cations or anions depending on the cell type and environmental conditions such as pH of the solution. The thickness of cell layer ranges from one layer up to few millimeters. The immobilization procedure is usually cheap and simple and therefore, a very popular method and convenient for industrial large-scale applications. The interaction forces between cells and supports are weak, hence the detachment of cells to the surrounding medium is likely to be possible. Eventually, the equilibrium between immobilized and free cells is established during processes in bioreactor systems. Various solid carriers have been used as supports, such as cellulosic materials (DEAE-cellulose, wood, sawdust, delignified sawdust), clays, inorganic materials (porous glass, porcelain) etc.

Natural supports, when they are safe and of food-grade purity, seem to have great potential in food production. For example, fruit pieces are of food-grade purity, cheap, abundant, and could be easily accepted by consumers. Therefore, apple (4), quince (5), and pear pieces (6) were proposed as immobilization supports for wine making due to ease in the immobilization technique. They gave the distinctive aromatic potential and improved sensory characteristics of the produced wines. One promising technology is the combination of immobilization and freeze drying techniques for

the preparation of biocatalysts. It may solve the problem of supplying industrial units with preserved and marketable ready-to-use immobilized cells due to possibility of storage of freeze-dried immobilized biocatalysts for long time intervals without any loss of cell viability and fermentation activity. Lyophilized gluten (a cheap and abundant material as the main substance of cereals) in the form of pellets has already been successfully applied in glucose (7), beer (8), and wine fermentations (9–11). Also, delignified cellulosic material showed commercial potential in lyophylized form (12,13).

53.2.2 Entrapment within Porous Matrix

In this type of immobilization, cells penetrate into the pores and throughout the channels inside the immobilization matrix. A rigid network keeps the cells inside the carrier and allows diffusion of nutrients toward the cells and metabolic products from cells to the outside medium, thereby making possible the growth and maintenance of active cells. This is the most frequently used immobilization method, where polysaccharides gels like alginate, pectate, carrageenan, chitosan, agar, polygalacturonic acid, and polymers like gelatin, collagen, polyvinyl alcohol (PVA), polyacrylamide are the most often employed. These can be gelled into hydrophilic matrices under mild conditions, thus allowing cell entrapment with minimal loss of viability. Very high biomass loadings can be achieved, since the cells are well protected. In order to provide even better protection from cell release, an external layer can be formed around the internal gel core. This is the so-called microencapsulation technique, which is well-established and the most often-used immobilization technology. It will be discussed in more detail in one of the following sections. The main disadvantage of gels is a limited mechanical stability under conditions of a rapid cell growth, severe shear stresses, and prolonged exposure to some chemical compounds (for example, phosphates disturb the alginate structure during the process of wort fermentation to beer). Several methods have been proposed for reinforcement of gel structures. For example, alginate gel can be strengthened by reaction with polyethyleneimine, gluteraldehyde cross-linking, addition of silica, genepin, and polyvinylalcohol or by partial drying of the gel. Another drawback of gel systems is mass transfer limitations. Understanding mass transfer phenomena within entrapment matrices may allow one to simultaneously provide different conditions at the carrier surface and in the interior. In this way, the gel bead can be made more stable and less permeable. In addition, the gels with heterogeneous cores could be attractive for co-immobilization of different cell types performing consecutive processes.

Unlike gels, porous preformed supports can be inoculated directly from the bulk medium. In these systems, cells are not completely separated from the effluent, similar to the adsorption method. Cell immobilization occurs by attachment to the internal surfaces, self-aggregation and retention in dead-end pockets within the material. Ideally, the colonized porous particles should retain some void spaces for flow so that mass transport of substrates and products could be achieved by both molecular diffusion and convection. Consequently, mass transport limitations are less stringent under optimal conditions as compared to gel entrapment method. However, fluid flow within the support can be realized only if cell adhesion is not very strong so that excessive biomass could be washed out from the matrix. When high cell densities are obtained, convection is no longer possible and the particles behave as dense cell agglomerates with high diffusion limitations. Yet the cell densities represented per unit of support volume are lower than those achievable by gel entrapment since the porous matrix material takes up significant volume fraction. As compared to gel particles, preformed carriers provide better mechanical properties and higher resistances to compression and disintegration. Numerous inorganic and organic materials have been used as preformed carriers: reticulated polyurethane (PU) and polyvinyl formal foam, other polymers, plastics, stainless steel, ceramic, glass, synthetic ion exchange resins, activated charcoal, aluminum oxide, diatomaceous earth, sand, cellulose, lignocellulose, cellulose acetate, and others. In addition, a variety of mixtures of different materials are commercially available for immobilization purposes, such as cytopore (cellulose with *N*,*N*-diethylaminoethyl groups), cytoline (polyethylene and silica), Bio-Sep beads (25% aramid polymer and 75% powdered activated carbon) etc. The porosity of the carriers varies across a rather wide range to suit immobilization of various bacterial, yeast, fungal, plant, and animal cells and tissues. Depending on the cell and the carrier type, immobilization then takes place in a combination of filtration, adsorption, growth, and colonization processes. Surface-associated growth of microorganisms in nature usually leads to a formation of highly structured biofilms, which are in fact naturally immobilized cells (14). The type of forces involved with cell immobilization surface interactions can involve Lewis acid/base (hydrophobic), Lifshitz–van der Waals (electrodynamic) and Coulombic (electrostatic). Carrier surfaces can be modified in order to affect cell immobilization. The surface of most inorganic supports is mainly composed of oxide and hydroxyl groups (e.g. in glass are silanol groups), which provide a mildly reactive surface for activation and binding of cell-surface proteins. Pretreatments of carriers can be accomplished by an inorganic and/or a cross-linked organic coating. Microorganisms interact with surfaces through many specialized structures on their walls (e.g. piles and pilus-associated

adhesions), exopolymers (glycocalyx in the case of bacteria), and complex ligand interactions involving signaling molecules (15). They have quorum-sensing mechanisms, as well. Therefore sensing either a biotic or an abiotic surface triggers genetic switches that can change cells' metabolism, phenotype, and morphology (16,17). Immobilization of plant and animal cells in the preformed carriers requires pretreatment of a carrier surface. A carrier can be modified to mimic biological extracellular matrix (ECM) proteins such as fibronectin, collagen, vitronection, elastin, laminin, and growth factors. A surface morphology (smoothness, roughness, micropatterning) can also be modified by etching, using lasers and photolithography (18).

53.2.3 Cell Flocculation

Cell flocculation is an aggregation process of cells that forms large clusters and represents biomass which sediments under gravitation. The ability to aggregate is seen in just a few types of cells, such as fungi, yeast, and some plant cells. This is the simplest and the least expensive immobilization method. In naturally nonflocculating cultures, sometimes, chemical agents or cross-linkers can help to induce the cell aggregation process. Interactions between cells keeping them together are very sensitive to conditions in a reactor, and are not easily controllable. Yeast flocculation is a property of major importance for the brewing industry as it affects fermentation productivity throughout yeast removal and recovery (19). Packed-bed, fluidized-bed, and continuous stirred-tank reactors are the most suitable fermenter types to employ flocculation immobilization method. In 2005, ethanol fermentation with self-flocculating yeast was commercialized, and a fuel ethanol plant with an annual production capacity of 200,000 tones was established at BBCA, one of the three ethanol producers in China.

53.2.4 Cell Containment behind Barriers

Mechanical containment of cells behind the barriers implies localization of cells either behind the membrane filters or inside a material (solid or fluid) surrounded by a semipermeable membrane. In process industry, micro- and ultrafilters are integrated inside the membrane reactors. This technology is relatively expensive and has found some applications in cell recycling and continuous processes (20,21).

53.3 MICROENCAPSULATION OF CELLS

Microencapsulation consists of entrapping a biologically active substance or cells in an appropriate material, to improve its performance, enhance its shelf life, or develop customized, high margin products. In strict terms, microcapsules are spherical beads coated with a membrane, that is capsules with a diameter of about 100–1000 μm. Besides traditional capsules consisting of a core and well-defined shell, plain microbeads without a distinct membrane have also been successfully used for encapsulation of cells. The capsules or beads should be semipermeable to allow diffusion of oxygen and nutrients into the cell inside the beads and metabolic products out of beads. The membrane insures the protection of the internal, bioactive substance, or cells. Despite its nonphysiological nature, the permselective capsule environment has been shown to support cellular metabolism, proliferation, differentiation, and cellular morphogenesis.

The application of capsules imposes demands on specific properties of capsules. Many different materials, approaches, and techniques for microencapsulation have been studied and some of them are summarized in recent reports (e.g. 22). Microcapsules are most frequently produced from water-soluble polymers. The hydrophilic nature of the immobilization material provides low interfacial tension with surrounding media or tissues and minimizes the protein adsorption and cell adhesion. Furthermore, gel materials enable the permeation of low molecular nutrients and metabolites. Water-insoluble immobilization materials require usage of organic solvents, which in most cases are harmful for living cells. Polyanions and polycations may form a gel by covalent or ionic cross-linking. Combination of covalent and ionic cross-linking may also be used. However, covalent cross-linking involves reactive chemicals and their applications are mainly limited to enzymes, fast-growing cells, or dead cells. Among water-soluble polymers, natural polysaccharides have been most frequently used for encapsulation of living cells, such as alginate, agarose, κ-carrageenan, chitosan, pectin, pectates, gellan. Alginate, pectate, and chitosan form gels by ionic cross-linking, whereas gelation of agarose, κ-carrageenan, and pectin is based on thermal procedure. A combination of thermal gelation and ionic cross-linking is used to produce gellan gels.

There are few different approaches to create semipermeable membrane for cell encapsulation, such as phase inversion, polyelectrolyte coacervation, interfacial precipitation, to mention some of them. Phase separation occurs from initially homogeneous solution, either by temperature change or exposing of a polymer solution to a nonsolvent component. The second procedure can be performed in a bath (wet process) or a saturated atmosphere (dry process). The coacervation process consists of decreasing the solubility of the encapsulating polymer by addition of a third component to the polymer solution in an organic solution. This procedure enables the separation of an aqueous polymeric solution into two miscible liquid phases: a dense polymer containing coacervate phase

and a dilute, supernatant equilibrium phase depleted in polymer. The active compound (cells) dispersed/dissolved in polymer solution is coated by the coacervate. Complex coacervation can result spontaneously on mixing oppositely charged polyelectrolytes in aqueous media. The charges must be sufficiently large to induce interaction, but not large enough to cause precipitation. The formulation of the process is very complex and variables (such as pH, ionic strength, temperature, molecular weight, and concentration) significantly affect the kinetics of the entire process and ultimately characteristics of the final microspheres (23). The obtained membrane porosity varies in a rather wide range from 0.1 to 50 μm, depending on several factors, such as polymer–nonsolvent compatibility, polymer precipitation time, diluent concentration. Various cell types have been encapsulated in semipermeable capsules of polyacrylate. In series of investigations, different combinations of polyionic species have been studied, such as alginate with either protamine or spermine (24), cellulose sulphate with poly(diallyldimethyl ammonium chloride), carboximethyl cellulose with chitosan, or diehylaminoethil dextran (25). The porosity of the network can be easily controlled by adjusting the osmotic condition and the molecular weight distribution of the polyionic species. There is also a possibility to improve biocompatibility and reinforce the network by one or multiplied coating process. More complex structures contain multicomponent polyelectrolyte mixtures of both polyanionic and polycationic species. Gelatin is often used as one of the polyelectrolites in combination with gum arabic, polyphosphate, heparin, carrageenan, and chitosan (26).

Alginate systems are based on interfacial precipitation in calcium chloride solution. The gelation of alginate–cell suspension in calcium chloride bath creates matrix suitable for immobilization of living cells. The network formation is usually further followed by the coating step with poly-L-lysine (PLL). The described procedure gives a capsule with solid core of calcium alginate coated with a one-layer membrane. In order to liquefy the core of capsules, Ca-alginate gel is subsequently dissolved with sodium citrate. The obtained capsules can be further fortified by coating procedure with alginate or another polyanion (27,28). Formation of double and multilayer membrane capsules have been suggested in the literature (29,30). Furthermore, PLL can be modified or exchanged with other polycations (31,32). Properties of capsules depend on composition and molecular weight of core and coating material, as well as on a way of exposure to gelation and coating solution (duration of this processes and concentration of solutions).

Beside the composition, the size of capsules is another very important feature. Smaller capsules show better mass transfer properties of nutrients and metabolic products. Moreover, reduction in capsule size lowers the shear forces and may increase their long-time stability. For implantation purposes, smaller capsules are by themselves shown to be more biocompatible than bigger capsules (33) and can be more easily implanted since they occupy less space. However, small beads have larger surface-to-volume ratio compared to big particles and therefore can be more easily damaged by swelling or by exposure to oppositely charged ions (34). In addition, smaller spheres are more fragile to internal stresses caused by cell proliferation and expansion of cell colonies. The choice of capsule size depends on specific application and the cell type is going to be entrapped in. Numerous techniques for bead production have been developed up to now and are available to achieve the desired size of capsules.

Capsules can release their contents upon applying specific treatments or conditions (heating, salvation, diffusion, and pressure). Sealed capsules are coated with semipermeable, spherical, thin, strong membrane around the solid or liquid core. A coating can be designed to open in the specific areas of the body and microcapsules can then gradually release active ingredients. The choice of core and coating materials and capsule design should be established according to the requirements of their application. To give an example, for engineering probiotic contained capsules, a coating which can withstand acidic conditions in the stomach acids after consumption by gastrointestinal fluids is usually employed. In this way, the protection of the biological integrity of probiotic products is achieved during gastro-duodenal transit, which is prerequisite for delivery of a high concentration of viable cells to the jejunum and the ileum. Since capsules should provide protection to sensitive microorganisms, against harsh conditions in the gut environment, the produced microspheres should be tested on swelling, erosion, disintegration in simulated gastric/intestinal fluids prior to industrial and real-life applications.

The capsules may be designed in wet or dry forms. Encapsulation in the hydrocolloid beads entraps the cell within the matrix; this provides good protection against environmental effects. Encapsulation of cells in gel–particle systems has been investigated for improving their viability in various products and the intestinal tract (35), then for delivering of active compounds, as well as to restore, maintain or improve tissue function. The mechanical or tissue irritation to surrounding tissue is reduced by the soft and pliable features of the gel. As a consequence of the hydrophilic properties of the material, there is virtually no interfacial tension with surrounding fluids and tissues which minimizes the protein adsorption or cell adhesion. Hydrogels have also been mainly utilized for fermentation processes, such as fermentation of whey (36), yoghurt manufacture (37), beer (38), wine (39) and cider (40). Hydrogels provide a high degree of

permeability for low-molecular-mass (Mr) nutrients and metabolites.

Drying techniques are often applied to give microorganisms more stability and flexibility. The dry product, after milling and screening are powder particles of freeze-dried or spray-dried microorganisms and additives. Capsule fillings, sachets, and tablets are also very popular among consumers and inexpensive to produce, thus manufactured in the pharmaceutical area.

There are more problematic issues when considering microencapsulation of cells in contrast to encapsulation of other active compounds. One of them is their size (at least several microns in diameter) which immediately restricts the application of nanotechnologies. Furthermore, encapsulation techniques involving harsh conditions usually are not acceptable for encapsulation of sensitive cells. However, relatively mild conditions (e.g. process carried out in aqueous conditions without the use of reactive species) generally yield a less durable microcapsule. Harsher encapsulation conditions might compromise cell viability but the resultant capsule may be more resilient and cell capable of proliferation may be suitable for such conditions. Fragile cells can also be subjected to harsher conditions provided that the cells are compartmentalized from toxic chemical or conditions. Then, it is necessary to provide hygienic conditions during cell processing. This makes encapsulation process and equipment difficult to handle.

A number of aspects of encapsulated cells are critical for the success of the technology: the capsule permeability, mechanical properties, immune protection in case of tissue transplantation, and biocompatibility. There are numerous publications on penetration rate of particular elements. Effective oxygen penetration (the most important element for cell growth), for example, has been estimated to be 0.1–0.15 mm in alginate beads (41) and 0.08–0.1 mm (42) in carrageenan beads. The metabolic requirements of various cell types are different and, hence, optimal membrane permeability is expected to be dependent on the choice of cells. Although the role of permeability for particular elements essential for cell survival has been explored [e.g. oxygen (43)], no systematic approach has been taken to determine permeability requirements of particular cell types. An empirical approach has been typically taken to tailor capsule permeability for cell survival. The upper limit of capsule permeability, that is molecular weight cut-off (MWCO), will be application dependent. Besides permeability, the next important consideration is the availability of an ECM to encapsulated cells (44). The ECM not only allows the cells to express their differentiation function, but also helps to organize the cell mass within the capsules for optimal viability. Capsule biocompatibility is critical when encapsulated cells are intended for transplantation since it is the compatibility of a biomaterial with the host that ultimately determines the nature of host response and graft survival. The physicochemical nature of a biomaterial and exploration of different materials for this purpose have out of necessity, developed different encapsulation procedures to accommodate the varying physicochemical properties.

53.4 REQUIREMENTS FOR CELL IMMOBILIZATION

In order to achieve successful process by implementing a cell immobilization, certain prerequisites should be fulfilled. In general, those requirements depend on a specific purpose of cell immobilization and can be different from one field of application to another. However, there are few characteristics considered as favorable for carriers in general. It is better if a support has a high surface area-to-volume ratio and if it is renewable. In industrial processes, the immobilized biocatalyst has to keep operational stability for longer times. The biological or catalytic activity must not be adversely affected by immobilization. The carrier should retain good mechanical, chemical, and biological stability and not be easily degraded by enzymes, solvents, pressure changes, or shearing forces (19). For food applications, the carrier material should be of food-grade purity and readily accepted by consumers, while in case of biomedical applications, biodegradable supports have advantages over nonbiodegradable. A carrier design may also differ from one application to another. For example, for the replacement of a biochemical function, nanoporous, immunoisolatory polymer membranes are convenient. Their pores should be large enough to allow diffusion of nutrients, waste, and bioactive factors, but not large enough as to allow immune cells to attack the cells within. Another case is when it is necessary to promote the formation of a new tissue that is structurally and functionally integrated with the surrounding tissue; then, micro- or macro-porous polymer scaffolds are more suitable.

53.5 BIOMATERIALS FOR CELL IMMOBILIZATION

In order to provide the varying requirements for each specific application, a variety of naturally derived and synthetic biomaterials are used for cell encapsulation. These materials can be processed into many different physical forms and geometries. Natural polymers are attractive for cell immobilization due to their abundance and apparent biocompatibility. These polymers can provide a wide range of physical properties that offer unique characteristics for cell encapsulation technologies. In addition, biopolymers are easily subjected to biodegradation. On the other hand, instead of being inert, they can act as media compounds

for potentially contaminating organisms (mostly molds) and thus are cleaved and metabolized. This can lead to more or less deterioration of the complete immobilized biocatalyst when operating under nonsterile conditions. In contrast, some synthetic polymers are hardly biodegradable which lowers demands on the process' sterility. Moreover, synthetic polymers are attractive due to the resultant properties able to be created by controlling the formation and structure of these materials. One of the main challenges in development of materials for cell immobilization is the creation of materials with predefined pore structures and appropriate degradation and mechanical properties. This chapter briefly describes the most frequently used natural and synthetic materials in cell immobilization technology.

53.5.1 Alginate

Alginate is the most widely used material for encapsulation/immobilization of various types of cells. Alginate is used in a form of a salt of alginic acid. Alginates are naturally derived linear copolymers of 1,4-linked β-D-mannuronic acid (M) and α-L-guluronic acid (G) residues (45). The ratio and sequential distribution of uronic acid residues, along the length of the alginate chain vary in alginates of different origins (brown seaweeds, certain bacteria) (46). There is no regular repeat unit in alginate polymers, and the chains can be described as a varying sequence of regions which usually denotes as M blocks, G blocks, and MG blocks. Dissolving alginate in water gives a viscous solution of which the viscosity will increase with the length of alginate molecules, that is number of monomers. Water solutions of polysaccharides form hydrogels in the presence of divalent Ca^{2+} ions via ionic interactions between the acid groups on G blocks and the gelating ions. As a result, calcium alginate gels are physically cross-linked polymers with mechanical and hosting properties dependant on the alginate composition. Monovalent cations and Mg^{2+} ions do not induce gelation, while ions like Ba^{2+} and Sr^{2+} will produce stronger alginate gels than Ca^{2+}. Alginate can be also covalently cross-linked using bifunctional molecules such as adipic dihydrazide, methyl ester L-lysine, and poly(ethylene glycol) (PEG). A potential limitation to the use of alginate is its often uncontrollable and unpredictable dissolution, which occurs by a process involving the loss of divalent ions into surrounding fluids (47).

However, since alginates are heterogeneous group of polymers, with a wide range of functional properties, the success will rely on an appropriate choice of materials and methodology for each application. This must be based on knowledge of their chemical composition, the correlation between structural and functional properties, and a sufficient understanding of the behavior of polysaccharide formulations on a macroscopic as well as molecular level

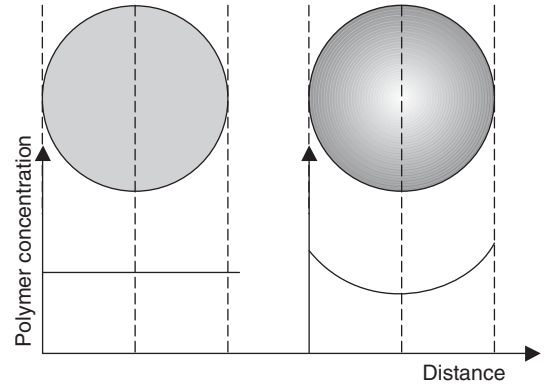

Figure 53.2. Polymer gradients in homogeneous and heterogeneous alginate gel beads [from (18)]. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

(47). The mechanical properties of an alginate gel will to a large extent vary with the alginate composition. Thus, gels made of alginates with a high G-block content will be stronger and more stable as compared to low G-block content alginate gels. The physical properties of alginate gels can be improved by formation of an heterogeneous structure (Fig. 53.2). Gels with varying degrees of anisotropy with respect to polymer concentration can be formed by controlling the kinetics of the gel formation. This heterogeneity is governed by the relative rate of diffusion of calcium ions and the rate of diffusion of the sodium alginate molecules toward and inward moving gelling zone. Simply by adjusting the concentration of alginate and the cross-linking ions, the distribution of the polymer in the gel can be controlled, and alginate beads with a capsular structure (with a polymer concentration of about 10% on the surface and less than 0.2% in the core) have been made without adding polycations or any other nongelling polymer (48). Also, the composition of alginate influences the bead homogeneity: G high degree alginates form more homogeneous gels than high M alginates (22).

Both techniques (extrusion and emulsion) can be applied to generate alginate microspheres. When a droplet of alginate falls into a bath containing divalent cations like Ca^{2+}, the gelling process will start immediately at the contact zone between the alginate droplet and the aqueous gelling ions generating a gel bead. The gel formation process may be controlled and gels with different properties may be formed. In particular, bead homogeneity is dependent upon the way in which the gelling ions are added. The distribution of the gel within the bead may thus to a large extent be controlled and beads even with a capsular structure can be made (48). In order to produce more heterogeneous beads while retaining physiologic conditions, sodium may be replaced by noncharged molecules like mannitol to prevent osmotic

stress to the cells (28). In the emulsion technique the addition of an oil-soluble acid, such as acetic acid, reduces the alginate pH from 7.5 to approximately 6.5, enabling initiation of gelation with Ca^{2+} (49). The gelling speed is roughly around 100 μm/min in 50 m*M* $CaCl_2$, which means that a 500 μm bead is gelled in approximately 2.5 minutes. This is near the rate of freely diffusing calcium ions (45).

The survivability of cell cultures in alginate beads in general depends on many factors such as concentration of alginate and gelation solution ($CaCl_2$), the duration of gelation, and cell concentration. The type of alginate and the initial cellular concentration seem to be very important in maximum cellular density that can be reached in immobilized cultures. Coated alginate microcapsules prove to have better protective characteristics compared to uncoated. PLL is of great interest as the coating material due to its better biocompatibility and potential applications in biomedicine and food industry. Champagne and coworkers (50) suggested coating of alginate beads with double layer of PLL, claiming reducing the cell release by a factor of 50. PLL-cross-linked alginate microparticles loaded with bifidobacteria successfully protected cells against low pH media and in addition, showed to provide improved stability during storage in a refrigerator compared to free cultures (51). But the high cost of poly-lysine may limit the large-scale use of alginate-poly-lysine microcapsule in microorganism immobilization. Therefore, except conventional polymers, polysaccharides (fructo-oligosaccharides, isomalto-oligosaccharides) and peptides may also been used as an outer coating layer (52). To give an example, alginate–chitosan–alginate has attracted much attention for its good biocompatibility and the low cost of chitosan, which is about 2500 times lower than that of poly-lysine.

53.5.2 κ-Carrageenan

Carrageenan is a natural polysaccharides isolated from marine macroalgae, commonly used as food additive and immobilization matrix. Carrageenan dissolves at high temperatures (60–80°C) in concentrations 2 to 5% (53). Dispersion of the carrageenan gel into small droplets has to be carried out at elevated temperatures (40–45°C) and gelation occurs during cooling procedure down to room temperatures. After the beads are formed *K* ions in the form of KCl are used to stabilize the gel, prevent swelling or to induce gelation (54). Audet and coauthors (36) reported inhibitory effect of KCl on some bacteria strains such as *Streptococcus thermophilus* and *L. bulgaricus*. The presence of monovalent ions such as Rb^+, Cs^+, NH_4^+ makes stronger gels (55). Locus bean gum in ratio to carrageenan of 1:2 significantly increases the strength of the gel through specific interaction of its galactomannan chains with carrageenan. Carrageenan–locus bean gum mixture has been frequently tested for microbial encapsulation, e.g. (56,57). The treatment with $Al(NO_3)_3$ has also been used to increase mechanical stability of carrageenan-based matrices (58).

53.5.3 Chitosan

Chitosan is a positively charged linear polysaccharide formed by deaceylation of chitin. It is widely found in crustacean shells, fungi, insects, and mollusks. Chitosan is water soluble below pH 6, forms hydrogels by ionic or chemical cross-linking with glutaraldehyde and degrades via enzymatic hydrolysis. The terms chitin and chitosan refer not to specific compounds, but to two types of copolymers containing the two monomer residues anhydro-*N*-acetyl-D-glucosamine and amino-D-glucosamine, respectively. Chitin is a polymer of β-(1,4)-2-acetamido-2-deoxy-D-glucopyranose and one of the most abundant organic materials. Chitosan, a polycation with amine groups, can be cross-linked by anions and polyanions, such as polyphosphates (59), $[Fe(CN)_6]^{4-}$ and $[Fe(CN_6)]^{3-}$ (60), polyaldehydrocarbonic acid (53), and sodium alginate (61). It is important biomaterial in food and pharmaceutical applications due to its favorable properties, such as good biocompatibility, biodegradability, and nontoxicity. Chitosan is often combined with other materials (like calcium phosphate and collagen) to achieve more desirable mechanical properties. It has been mainly utilized for wound dressings, drug delivery systems, space-filling implants, micro- and macro-porous scaffolds.

However, chitosan exhibits inhibitory effects on different types of sensitive lactic acid bacteria (62). Thus, chitosan is mainly used as a coating for conventional alginate gel beads [e.g. (54)]. Alginate–chitosan microcapsules can be made by one- or two-step processes, based on the presence or absence of Ca^{2+} in the receiving chitosan solution (63). The beads can be prepared in a way to differ in a level of homogeneity of the alginate concentration gradient through the cross-section of the bead, by addition of sodium chloride to the calcium chloride solution. The capsule's mechanical strength and permeability strongly depend on the process of capsule preparation (64). In the one-stage process (in the absence of Ca^{2+} in chitosan solution), chitosan is located only at the interface, as a thin-alginate-chitosan membrane with a weak mechanical resistance. The capsules were much stronger when the two-stage protocol was used. This difference between the two protocols of capsule formation is due to the ability of chitosan to penetrate through the membrane (63). The kinetics of membrane formation and the capsule parameters (thickness, permeability, and mechanical strength) depend on the concentration of components, molar masses of both alginate and chitosan reaction times, pH, and ionic strength. Sprayed particles coated with chitosan are recommended as impressively effective vehicles in delivering viable bacterial cells.

53.5.4 Hyaluronic Acid

Hyaluronic acid gels can be formed by covalently cross-linking with various hydrazide derivatives and these gels are enzymatically degraded by hyaluronidase. Hyaluronic acid can be readily isolated from natural sources; however, it requires purification for impurities and endotoxins to be removed prior to usage. Hyaluronic acid has been widely applied in micro- and macro-porous cell encapsulation.

53.5.5 Proteins

Industrial (bulk) proteins are biopolymers derived from plants and animals. Proteins are composed of amino acids linked via amide bonds giving chain lengths ranging from about 50 up to more than 100,000 amino acids. Amino acids are amphoteric due to the presence of basic (NH_2) and acidic groups (COOH). The degree of hydrophobicity and hydrophilicity of the amino acids is one of the major determinants of the three-dimensional structure of proteins. Protein denaturation occurs at elevated temperatures (above 75°C in water medium) or in the presence of certain chemical compounds, denaturants (e.g. urea, guadinium). Relevant protein properties for encapsulation purposes include surface active properties, biodegrability, good film forming and mechanical properties, high gas barrier properties, and high resistance to organic solvents and oils/fats, natural emulsifying, dispersing and gelling properties, processability (in melt, aqueous solutions and dispersions), variety in source, composition and number of functional groups, and ease of modification (26,65). In principle, any protein capable of forming a film is suitable for microencapsulation. Film formation is based on separation of proteins from the solvent phase due to changes in solvent conditions, thermal treatment, or drying. It is possible to alter some of protein properties (e.g. to improve water resistance, to increase water solubility, or mechanical strength to increase lipophilicity) by physical, chemical, or enzymatic means. Examples of proteins produced on large scales and suitable for immobilization purposes are collagen, gelatin, whey protein, casein, keratin, and plant proteins like wheat gluten, soy protein, pea, and potato protein.

53.5.6 Collagen and Gelatin

Collagen is the major component of mammalian connective tissues such as tendon, skin, bone, cartilage, and ligament. Due to the natural ability to bind cells and its abundance in nature, biocompatibility and biodegradability, and high tensile strength, collagen has been widely used in cell immobilization. It may be gelled utilizing changes in pH value. Collagen has been processed into porous sponges, films, micro- and macro-porous scaffolds, mainly to engineer a variety of tissues (66). Gelatins are derived by particle hydrolysis of collagen and have subsequently a quite similar amino acid composition as collagen. Gelatin dissolves in warm water and upon cooling, a gel is formed. Gelatin is a potentially useful biomaterial mainly because of its advantageous gelating properties, melting temperature of 37°C, low price, easy availability, and biodegrability.

53.5.7 Starches

Starch consists of two types of molecules, amylose and amylopectin. Chemically modified starches and starch hydrolysates are used as microencapsulation matrices. Blending of syrups and/or sugars with modified or hydrolyzed starches has been claimed to lead to optimal encapsulating materials. The increased interest to use bioactive compounds as functional ingredients in formulations of novel foods is a challenging field to apply microencapsulation technologies. Starch occurs naturally as discrete particles, called granules. The size of the granules depends on the starch origin ranging from 1–100 μm (67). The granular structure is lost upon heating above 80°C and the starch creates polymer solution. Commercial starch hydrolysates called dextrins are manufactured by prolonged heating under dry conditions with or without the addition of an acid. Starches have been mainly used in food area to encapsulate flavors. A recent study showed that starches can be successfully applied for immobilization of living cells such as bifidobacteria strains [e.g. (68)].

53.5.8 Polyvinyl Alcohol

PVA is a hydrophilic polymer which can be gelled in an aqueous solution during prolonged storage period. The network is formed by hydrogen bounds between hydroxyl groups of neighboring polymer chains and therefore is not stable at temperatures above 0°C. During the freezing process, phase separation occurs resulting in the formation of stronger hydrogel, so called cryogel. PVA cryogel is mechanically very stable, hardly biodegradable, and not soluble at temperatures below 60°C. Parameters influencing the gel strength are the degree of deacetylation of the used PVA, the chain length of the polymer, its concentration in the solution, and the rate of thawing (69). The process of gel formation by freezing–thawing procedure may lead to a loss of a microbial activity when living cells are to be immobilized, due to temperature stresses involved in the process. To counteract this loss of biological activity the method of room-temperature gelation was developed by Vorlop and Jekel (70) and the resulting particles were named LentiKats®. LentiKats particles have specific lenticular shape (Fig. 53.3) due to which they combine the advantages of small (good diffusion properties) and large

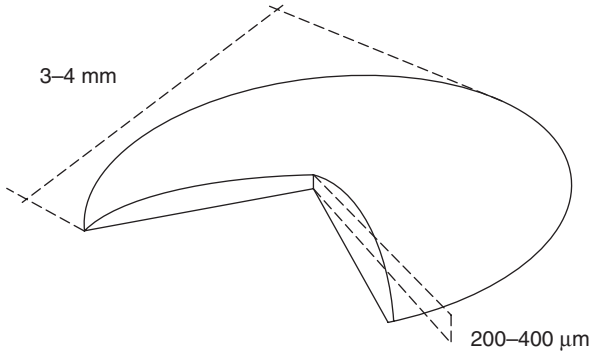

Figure 53.3. LentiKats® hydrogel particle based on PVA.

beads (easy retention and removal). Detailed information on preparation of LentiKats can be found in the literature (69) and on the Internet (71). Production of LentiKats particles is based on the usage of the specially designed LentiKats Printer on lab and industrial scales. Bacteria (72), fungi (73), yeast (74) and enzymes (75) have been successfully encapsulated in LentiKats particles up to now.

53.5.9 Poly(glycolide) and Poly(lactide)

The most widely used synthetic degradable polymer are poly(glycolide) (PGA), poly(lactide) (PLA), and their copolymer poly(lactide-co-glycolide) (PLGA). The degradation occurs via nonspecific hydrolysis of the ester linkage when lactic and glycolic acids are formed, which are naturally metabolized and easily cleared by the body (76). Poly(hydroxy esters) are mainly processed as scaffolds, where limited mechanical stability is the main problem.

53.5.10 Poly(ethylene oxide) and Poly(ethylene glycol)

Poly(ethylene oxide) (PEO) and PEG are synthesized by anionic or cationic polymerization of ethylene oxide. The surface of these polymers prevents the adsorption of nonspecific proteins, which makes them suitable for scaffold design. This attribute can also be useful when trying to pattern the biomaterial surface with specific signals that promote cellular attachment. PEG can be copolymerized with PLA to form a degradable, hydrophilic polymer that can be used as a hydrogel for cell immobilization.

53.5.11 Polyurethane Foam

PUs are formed by condensation of polycyanates (R-CNO) and polyols (R-OH) when carbon dioxide escapes from the matrix leaving pore spaces. Except for their open pore structure, they are convenient because of their inertness and mechanical strength. The pore size of PU foam matrices is usually expressed as the number of pores per linear inch (ppi).

53.6 TECHNIQUES FOR CELL IMMOBILIZATION

53.6.1 Gel–Particle Techniques

Extrusion or emulsification techniques may be applied to produce spherical polymer beads ranging from 0.3 to 3 mm in diameter. The first step in both gel–particle technologies (extrusion and emulsion) is mixing of cell culture with a polymer solution to create cell–polymer suspension (Fig. 53.4), which is then extruded through a needle to produce droplets collected in a bath where gelation occurs (ionotropic or thermal), or dispersed in a continuous phase applying mixing to create stable w/o emulsion.

Extrusion is the oldest and the most common approach to making capsules with hydrocolloids. It is based on forcing down a polymer-cell suspension through a nozzle to generate small droplets (Fig. 53.5). Extrusion bead production techniques (coaxial air flow, electrostatic, vibration, Jet Cutter, atomization) are based on applying the additional force to generate smaller spheres compare to those produce by simple dropping method. The polymer-cell droplets should fall directly into a continuously stirred gelling agent solution. The stirring can be maintained by a magnetic stirrer, or alternatively, a vessel containing the gelling agent solution is rotated by means of a motor. In case of the coaxial air flow, additional air flow through an outer concentric nozzle is applied to enhance dropping (Fig. 53.5a). The electrostatic extrusion is based on applying an electrostatic force to generate microdroplets (Fig. 53.5b). Even high electric fields (few thousand volts) do not adversely affect cell viability (77). A droplet generation by the vibration technology is achieved by adding a vibration on a laminar fluid jet which breaks apart definitely if the right wavelength has been applied (Fig. 53.5c). Jet Cutter technology is based on a mechanical cut of a liquid jet by rotating cutting wires installed in a cutting tool. The Jet Cutter may be operated in two different modes called the normal mode (Fig. 53.5di) or the soft-landing mode (Fig. 53.5dii). In the normal mode, the trajectory of the microspheres is top down in a rather direct way, whereas in the soft-landing mode it is diagonal bottom-up. In the soft-landing mode the velocity of the microspheres is dramatically reduced near the zenith of the trajectory where they are collected. Hence, the speed at which the microspheres enter a liquid collection bath is rather low so that the risk of microsphere deformation is reduced. The atomization technique applies a disk rotating at high velocity to atomize a liquid jet into fine microspheres (Fig. 53.5e).

The size of the particles can be adjusted by choosing the needle diameter and manipulating the distance between the outlet and the coagulation solution and other parameters of a technique. Extrusion technology is the most popular due to its simplicity, convinience of handling with the equipment, low cost, and gentle formulation conditions ensuring

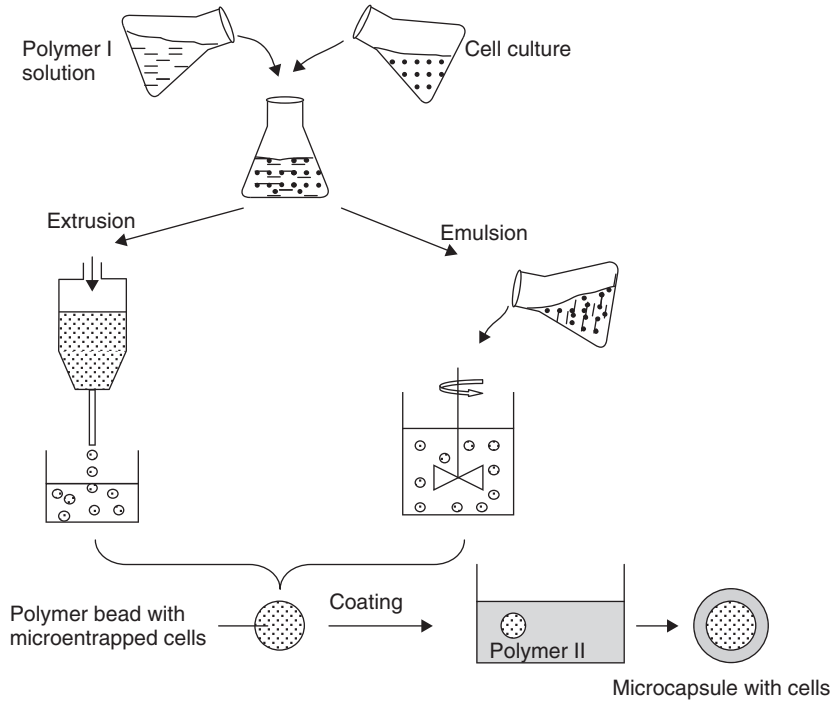

Figure 53.4. Gel–particle technologies for the microencapsulation of cells [from (44)].

high retention of cell viability. The lab devices are designed to work either with a single or a concentric nozzle. With the single nozzle, homogeneous beads with equally distributed cells over the whole cross-section could be obtained; for example, there are cells in the center and at the surface of the bead. With the concentric nozzle, it is possible to produce capsules with a defined core region having the cells and a shell region with pure polymer. In general, it is possible to process polymer solutions of wide range of viscosities (20–10,000 mPas) and to generate microspheres of the desired size with very narrow size distribution. For industrial-scale applications, multinozzle plants with multiplied productivity rates are more suitable than single-nozzle devices. In a recent report (78), several extrusion techniques were analyzed from the aspect of their advantages, limitations, and disadvantages and compared regarding the roundness and uniformity of obtained microspheres and with respect to the productivity and transferability of each technique.

In the emulsion technique, a small volume of cell–polymer suspension (discontinuous phase) is added to a large volume of an oil (continuous phase). The mixture is homogenized to form a water-in-oil (w/o) emulsion. In some cases emulsifiers are added to form more stable emulsions, since these agents lower the surface tension of droplets leading to smaller spheres. The most common emulsifier used is Tween 80 at low concentrations. Once the emulsion is formed, solidification occurs after the addition of an adequate solidifying agent to the emulsion. In the emulsion procedure, adjustment of agitation speed and phase ratio enables production of the targeted bead size. The size of the beads can vary between 25 μm and 2 mm. The double emulsion technique (water-in-oil-in-water, w/o/w), a modification of the basic technique in which an emulsion is made of an aqueous solution in a hydrophobic wall polymer can also be appropriate for incorporation of cells. The relative viability of the encapsulated cells depends on operating parameters, such as inner phase volume ratio and the median diameter of the oil droplets.

The obtained polymer beads with entrapped cells can be further introduced into the second polymer solution to create a coating layer which provides an extra protection to the cells and/or gives sensorial properties to the product (Fig. 53.3). Another way to perform coating is to use coextrusion devices, where beads formation and wrapping occur simultaneously. Coating can be performed with cationic (polyethilenimine, polypropileneimine, glutaraldehyde or combination of those) or other polymers. Formation of the membrane around the beads results in stronger microcapsules and minimized cell release.

53.6.2 Spray Coating

In spray coating, the core material needs to be in solid form and is kept in motion in a specially designed chamber,

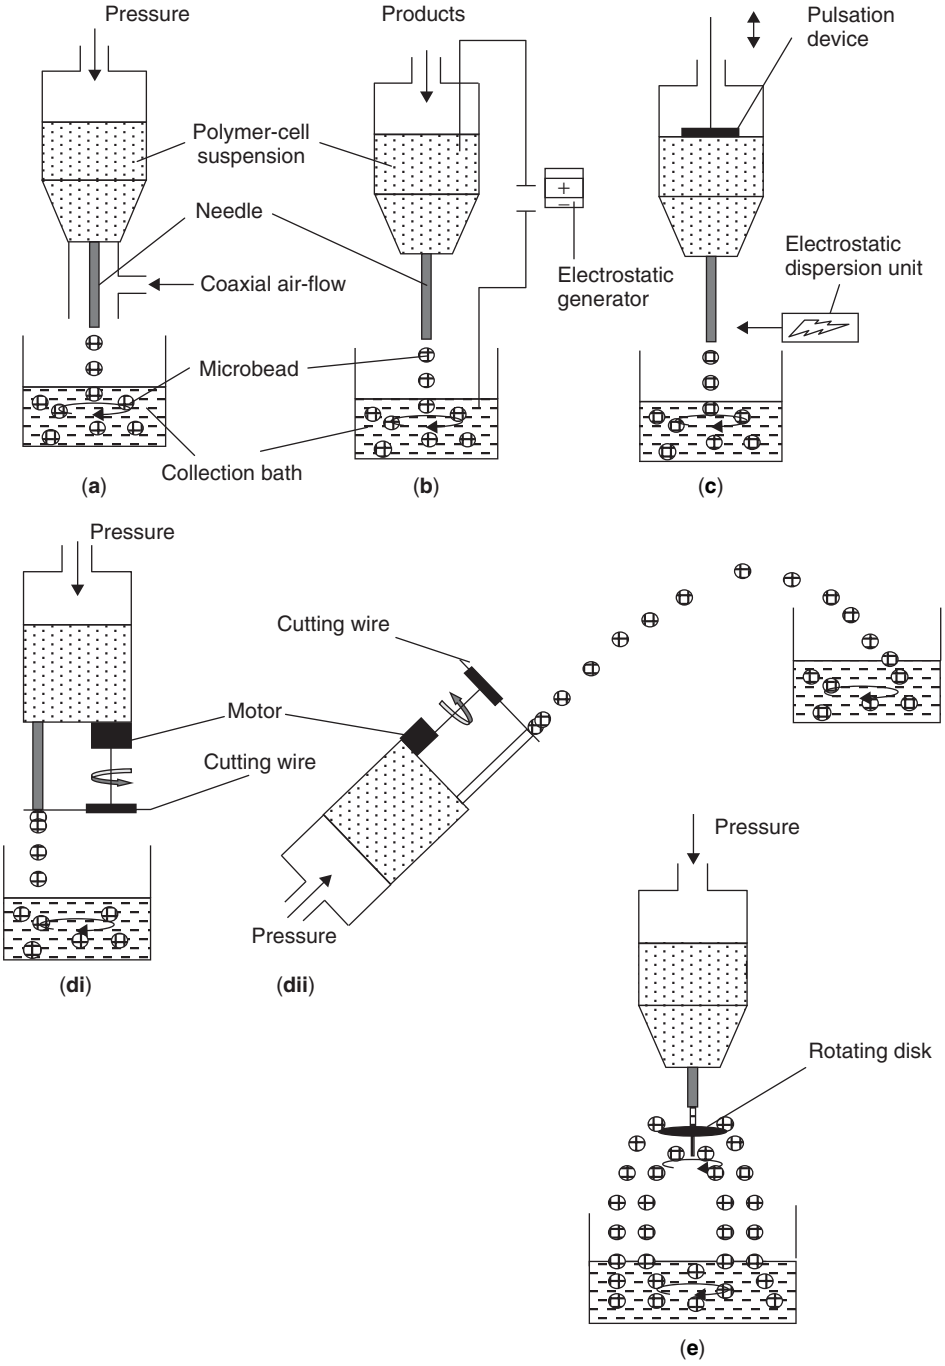

Figure 53.5. Extrusion techniques: (a) Coaxial air flow; (b) electrostatic extrusion; (c) vibration technique; (d) Jet Cutter with (i) normal mode, (ii) soft-landing mode; (e) atomization technique [from (68)].

either by injection of air at the bottom or by rotary action. A liquid coating material is sprayed through a nozzle over the core material, in a hot environment. The film formation begins, followed by successive wetting and drying stages which result in a solid, homogeneous layer on the surface of a core. The small droplets of the sprayed liquid contact the particle surface, spread on the surface and coalesce. The spray liquid, also referred to as shell, wall or coat material can be a solution, a suspension, an emulsion, or a melt. Any edible material, with a stable molten phase can be sprayed, allowing coatings with a thickness of 100 μm up to 10 mm, at high deposition rates. The coating

material can be injected from many angles and this influences the properties of the coating. In Fig. 53.6, the three spray coating technologies are presented; they principally differ in the type of air fluidization employed and the site in the vessel where the coating material is sprayed: the top spray, the bottom spray, and the tangential spray coating. The cells are presented in fine powder particles prepared by traditional methods (fermentation, concentration, freeze drying, and granulation). The coating material is introduced into the vessel under the compressed air. In food applications the coating is mostly lipid based (e.g. waxes, fatty acids, and specialty oils), but proteins (e.g. gluten and casein), or carbohydrates (cellulose derivatives, carrageenan, and alginate) can also be used (79).

Spray coating technique is suitable for particles with a diameter from 50 μm to 5 mm. Product quality characteristics depend on numerous variables, which affect different steps of the process. The film characteristics, through the evaporation rate are function of fluidization air velocity, temperature, and humidity (80). The coating homogeneity and success are influenced by the stickiness of the coating material, the wettability of particles by the coating liquid, and the operating conditions. The thickness of the final film coat is determined by the number of coating cycles (passages of the particles in the coating zone). An adequate choice of the coating material (with respect to viscosity and hydroscopicity), and control of the operating conditions, such as the particle velocity and bed moisture content, prevent collision between particles and agglomeration. During spraying process bubbles might form, due to shear, and be trapped in the coating film, which affects porosity, permeability, and mechanical properties of the shell layer.

In the top spray coating mode, the spray liquid and the air are in the counter current (Fig. 53.6a). Therefore, pulverization occurs at the top of the fluidized bed, involving a high risk of the droplets drying. Particles should travel fast to prevent agglomeration and the droplets should be small enough to sediment on the core and create dense coating film. In practical applications, the motions of fluidized core particles are random, resulting in a nonuniform coating. In the bottom spray coating, the spray liquid is introduced in the vessel through spray nozzles placed at the bottom, thus in the concurrent direction with the air (Fig. 53.6b). In 1950, Dr D. Wurster (81) improved the device by adding a cylindrical partition centrally placed and an air distribution plate. This improved device enables dense and homogeneous coating. Collision between droplets and particles is increased, resulting in higher coating efficiency, lower droplets drying, and minimal risk of agglomeration. In addition, the production capacity of the Wurster coating device is increased compared to a conventional top spray coating system. The tangential spray coating device is also called rotary-spray coating system (Fig. 53.6c). A rotary disk, placed at the bottom of the chamber maintains a complex fluidization pattern and the particles movement is influenced by centrifugal force, air stream, and gravity (80). The coating liquid is brought in tangentially, while air streams pass through the gap between the rotor disk and inside chamber wall, maintaining fluidization of the core particles. As with bottom spray device, the achieved coating is homogeneous. The main disadvantage of the technique is the high shear stress applied to the particles, thus it is limited to sturdy and resistant materials.

The spray coating is among all, the most applicable technique in industrial productions, since it is possible to achieve large batch volumes and high throughputs. Spray coating is widely used in industrial applications, mainly for microbial products. However, most of devices are proprietary and the information about how to control the process is very limited. Therefore, it is not easy for public scientists to design coated cultures and investigate their health effects in functional foods (79).

53.6.3 Spray and Freeze Drying

The first step of spray drying procedure involves the dispersion of the core (usually in oil) in a concentrated aqueous solution of the wall polymer, which is usually a water-soluble compound (such as gum arabic), to form an emulsion with droplets of few microns. The emulsion is then fed as droplets to the heated chamber of the spray drier where they are dehydrated to form solid capsules. The size of a spray-dried bead depends on both, physical and operating parameters, such as solution viscosity, density, surface tension, atomization pressure, nozzle type. The temperature of the sprayed emulsion must be optimized in order to avoid solidification prior to atomization on one side, and late solidification, resulting in odd-shaped sticky particles, on the other side (80).

Microencapsulation by spray drying is well-established technique suitable for large-scale industrial applications. However, the conventional procedure requires exposing of cells to severe temperature and osmotic stresses which results in relatively high cell mortality and/or viability and activity losses.

Freeze drying is preformed at low temperatures and under vacuum, avoiding water phase transition and oxidation. The obtained dried mixture must be grounded and the final particles are of wide size distribution and with low surface area. The freeze drying technology is very expensive and thus less frequently used compared to other encapsulation techniques.

One approach to improve cell survival during drying process is to use protectants added to media prior to drying. Hence, the addition of cryoprotectants helps to retain lacobacilis activity during freeze drying and stabilize them during storage.

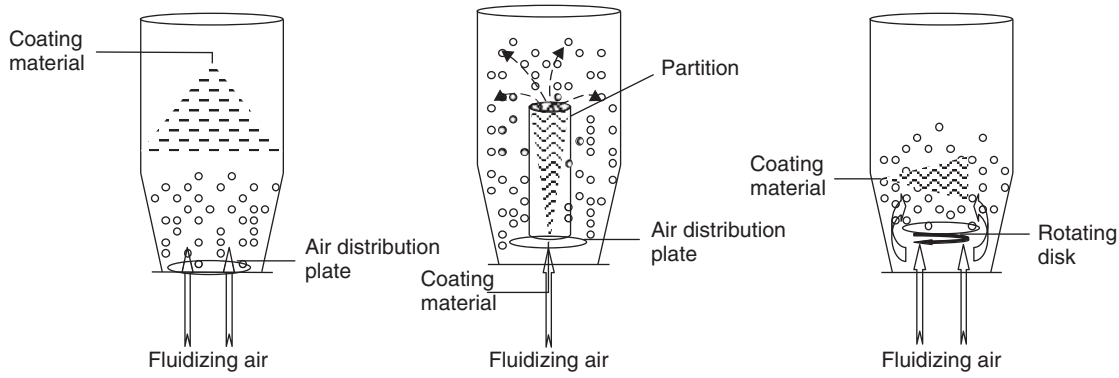

Figure 53.6. Spray coating methods for the microencapsulation of cells: (a) fluid-bed top spray coating, (b) fluid-bed bottom spray coating with the Wurster device, (c) fluid-bed tangential spray coating [from (69,70)].

Spray drying or freeze drying methods, followed by milling and other physical preparation steps are frequently used to produce technical powders of microorganisms aimed for commercial distribution. These powders have a large surface, are very hygroscopic and stable under adequate conditions.

53.6.4 Compression Coating

Recently, the compressing coating has been developed as a promising technique which permits the stabilization of lyophilized bacteria cells during storage (82). This technique involves compressing the lyophilized cell powder into a core tablet or a pallet and then compressing coating material around the core to form the final compact. The compressed cell pallet should be positioned on the center of the die before the rest of the coating material is poured on the top of it and the punch applied, as shown on Fig. 53.7. In this way, two coatings may be formed: the enteric and the outer coating layers. Sodium alginate or pectin can be used as coating material with the addition of a binder compound (such as hydroxypropyl cellulose) to make a more rigid compact. The viability of microbial culture after the compression to form a pallet gradually decreases with the pressure applied during compression procedure (upper punch pressure). Since the compression pressure could have harmful effects on the cells during compaction, careful selection of a pressure which will be employed is needed.

53.6.5 Spray Chilling

In spray chilling, a molten matrix with low melting point (32–42°C) containing the bioactive compound is atomized through a pneumatic nozzle into a vessel. This process is similar to spray drying with respect to the production of fine droplets. However, it is based on the injection of cold

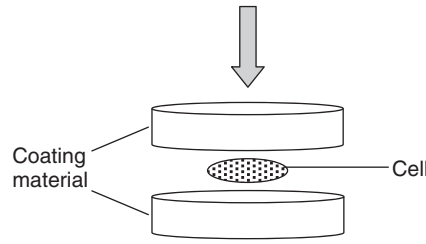

Figure 53.7. Compression coating of cells [from (72)].

air into the vessel to enable solidification of the gel particle, rather than on hot air which dries the droplet into a fine powder particle. The liquid droplet solidifies and entraps the bioactive product. Spray chilling is considered to be the least expensive encapsulation technology and offer few advantages over other encapsulation techniques. It may expand the range of matrices used. Further, it is possible to produce very small particles. However, so far it has been used rarely for cells (rather more suitable for encapsulation of active compounds, like water-soluble vitamins, fatty acids, antioxidants, fatty acids, yeasts, enzymes), since other technologies are easer to establish in laboratories.

53.6.6 Phase Separation (Coacervation)

Coacervates contain the core material suspended in the wall polymer. They are made by liquid–liquid phase separation induced by complex or salt coacervation. The only constraint is that the core material must be compatible with the polymer coating solution and insoluble or weakly soluble in the coacervation medium. There are several versions of the technique such as simple coacervation, salt coacervation, and complex coacervation. In the case of simple coacervation, only one polymer is involved and a phase separation is induced by an addition of an inducer such as ethanol or other water immiscible nonsolvent. In the case

of salt coacervation, phase separation is induced by an electrolyte such as sodium sulphate. The polymer absorbs on the surface of the hydrophobic oil droplets to form the capsule wall. The capsules have the tendency to aggregate. Thus, stabilization step must be provided which is usually based on the addition of cross-linking agents or variation of temperature and/or pH. Complex coacervation occurs through the interaction of two oppositely charged colloids in an aqueous solution, such as cationic gelatin and anionic gum arabic. Several factors determine the size and polydispersity of capsules, such as core material/wall polymer ratio, concentration of stabilizer, agitation speed, viscosity, temperature, and contact time.

53.7 EFFECTS OF IMMOBILIZATION ON CELLS

The study of immobilized cells requires specific experimental techniques. Many biophysical techniques have been used to study immobilized cells *in situ*. Only a few of theses techniques are noninvasive. Some involve the removal of the cells from the immobilization matrix and/or destruction of the sample. The biophysical methods for the direct examination of immobilized cells are overviewed by Willaert and coauthors in a recent report (83).

There are numerous reports on cell physiology, growth, morphology, metabolic activity that may be changed upon immobilization. The reasons for the altered metabolic behavior of cells may be various depending on the type of cells and immobilization method, as well as immobilization parameters. In case of microencapsulation technology, parameters such as microcapsules core status, initial cell density, microcapsule diameter, and membrane formation time influence on the growth, metabolism, and product secretion of microencapsulted microorganisms. Diverse effects on cells upon immobilization have been reported for a variety of type of cells. For example, in case of immobilization of yeast, mass transfer limitations by diffusion (84), disturbance in the growth pattern (85), surface pressure and osmotic pressure changes (86), reduced water activity (87), contacts between cells in limited space (88), changed membrane permeability (89) and availability of nutrients (90) have been attributed to be responsible for changes in cells properties. In specific, the immobilized *Saccharomyces cerevisiae* showed to have increased ethanol production and glucose consumption, higher ploidy and RNA content (85), lower internal pH value (91) and altered glucose catabolic pathways compared to free cells in suspensions, resulted in increased enzyme activity and therefore productivity (92). *Candida tropicalis* cells had higher intracellular levels of Na^+ and K^+ than suspended cells. Moreover, the intracellular environment was more viscous in immobilized cells (93). The immobilization reflected on metabolism of many other microbia cell types like *Propionibacterium acidi-propionici* (94), *Saccharomyces bayanus* (95), *Pichia stipitis* (93), *Escherichia coli* (96), *Pichia farinosa* (97), etc.

Physiology of mammalian cells is even more affected by immobilization than other cell types. However, no detailed investigation has been reported on the effect of both the immobilization matrix and its geometrical configuration on the medium-term viability and physiology of mammalian cells. In a recent study, it has been demonstrated that the shape of the calcium alginate immobilization matrix has considerably different effect on viability and physiology of neuroblastoma cells, whether the gel has a spherical or membrane form (98). Herein, a considerable decrease in the biosynthesis of reduced glutathione and RNA was observed in cell immobilized in thin membrane layers.

It has been demonstrated that cell immobilization has certain additional advantageous physiological effects. Herein, the immobilization reflects on plant cell differentiation and the production of secondary metabolites. In a recent study (99), an increased production of hydrogen peroxide and phenylalanine lyase was revealed in *Vitis vinifera* cells immobilized in pectin/chitosan coacervate capsules, while the immobilization process enhanced hydrogen peroxide and antraquinone synthesis by *Cruciata glabra* up to five times. Since cell growth was reduced in immobilized cultures, substrate consumption and flux of energy consumption were directed to the desired secondary metabolite pathway and improved product yield of the process. In general, the effect of stress factor caused by immobilization and elicitors (the matrix material works as an elicitor, a signal triggering the formation of secondary metabolites) is dependent on cell culture and metabolite pathway. This strategy may be used to improve the production efficiency of different kinds of secondary metabolites, extracellular enzymes, and recombinant proteins in plant cell cultures.

53.8 REACTOR DESIGN

The reactor design is another key factor of immobilized cell technology. It governs the overall fluid dynamic, mass, and heat transfer conditions at the biocatalyst surface. Reactor configuration is related to the choice of cell carrier and various modifications and combinations of stirred-tank, packed-bed, fluidized-bed, gas-lift, and membrane reactors have been proposed for different biotechnological processes. These types of bioreactors operating in a continuous operation mode are shown on Fig. 53.8.

The main issue when considering external mass transfer in immobilized cell systems is the choice between a packed-bed reactor and a fluidized or agitated reactor (100). Most of studies have been made in packed-bed bioreactor.

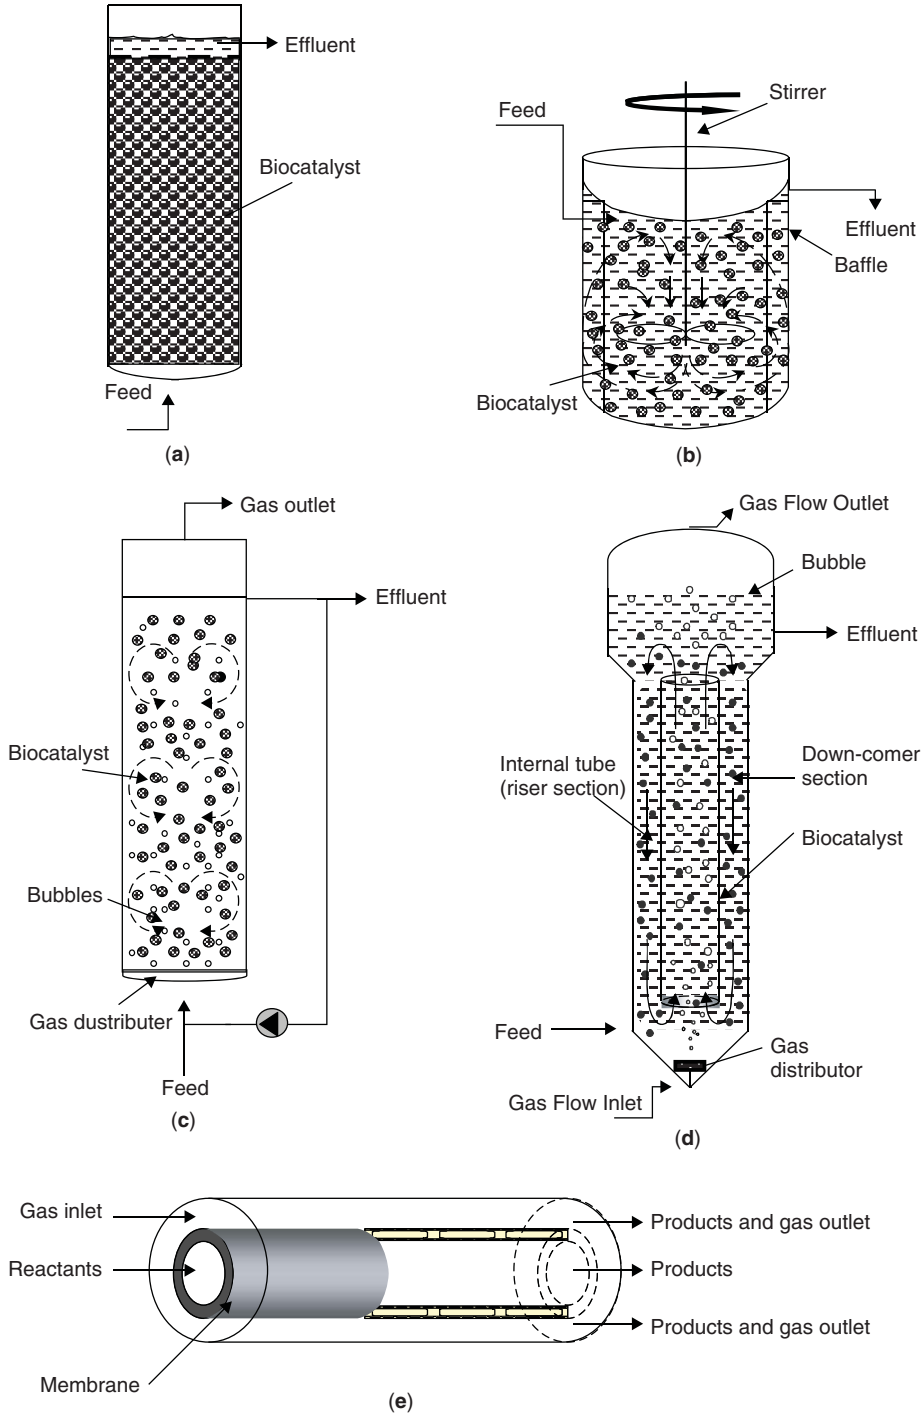

Figure 53.8. Bioreactor designs: (a) packed-bed reactor, (b) stirred-tank reactor, (c) fluidized-bed configuration: straight-bed configuration, (d) gas-lift reactors: internal-loop configuration. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

This type of reactor is traditionally used in industrial-scale productions and fermentation processes. Packed-bed bioreactors are characterized by a simple design, consisting of a column, which is packed with biocatalyst (Fig. 53.8a). Optionally, the column packing can be perfused by the liquid phase or with liquid circulation. The liquid flow is close to plug regime causing low shear rates. This enables usage of various, even fragile materials for cell immobilization.

However, the use of mechanically week materials such as hydrogels can be limited to lower bed heights and liquid flow rates due to possible compression of beads. Therefore, few modifications of packed-bed reactors have been designed and nowadays a variety of packed-bed reactor typologies are available. In one of these, new configurations layers of alginate beads are separated by screens (101). In another one, biocatalysts bed is divided in several chambers. This bioreactor is called multistage fixed bed tower bioreactor (MFBT). The MFBT has been successfully tested both in laboratory and pilot scale in beverage production applications and it seemed to have a great potential (11,102,103). Industrial packed-bed bioreactors put up with several engineering problems linked to mass transfer limitations, the accumulation of evolved gas, (which can be in high concentrations mortal to living cells and reduces the useful volume), the formation of preferential paths or channeling (causing concentration and temperature gradients), excessive pressure drop, as well as short circuiting and clogging. Some of these problems have been reduced by applying the perturbation in the form of pulsation into the fixed bed reactor which generates the slow movements of the bed. These movements regenerate the interfacial area, improve the distribution of the substrate and help to eliminate gaseous metabolites that cause the dead zones. The strategy of bed pulsation has been tried on alcoholic fermentation (104) and the process of phenol biodegradation (105) where layers of immobilized glass beads are separated by perforating plates exposed to pulsation movements. In packed-bed type of reactor, both internal and external mass transfer limitations should be taken into consideration. Some pilot and industrial-scale applications of packed-bed reactors include denitrification of water using sand immobilized heterotropic bacteria (106), sulphate removal using bacteria immobilized on PU foam (107), H_2S removal using bacteria immobilized on Rasching rings (108), beer maturation and low alcohol beer production (109).

The stirred-tank bioreactor was one of the first reactor types used in biotechnology. It consists of a vessel with one or more stirrers (Fig. 53.8b). A stirrer can have a variety of designs to satisfy specific operation conditions. For immobilized cell systems, stirrers providing more gentle mixing (such as helical ribbon, screw or anchor, modified and centrifugal impellers) are preferred instead of turbines and propellers. A vessel is usually equipped with baffles, which facilitate mixing and prevent undesirable bulk rotation since it causes high mechanical stresses in the stirrer shaft, bearings and seal (101). The fluid flow is generally turbulent maintaining an almost ideal mixing of the fluid phase. The shear is highest near the stirrer and gradually decreases toward the walls. Intensive shear rates may cause cell death, therefore, low power inputs are required for shear-sensitive cells. Mechanically weak hydrogel materials can not withstand abrasion during long-term operations.

In the fluidized-bed bioreactors, particles with immobilized cells are fluidized in the liquid up-flow, while gas can be optionally supplied (Fig. 53.8c). It is difficult to maintain low density particles in fluidization and prevent their washout. There is a specific geometry of this type of reactor with the enlargement of the reactor diameter in the upper zone. This geometry provides higher liquid velocities only in the tapered zone (instead of high liquid rates along the whole bed height), therefore the risk of particle washout is decreased. In order to assure particle retention within the reactor, a settling zone is usually installed at the top of the reactor. In the inverse fluidized-bed configuration, biocatalyst particles are fluidized in liquid down-flow. An alternative is a pseudofluidized bed type, where biocatalyst particles are fluidized by gas up-flow. As a consequence of particle fluidization, moderate local mixing is established providing better mass and heat distribution with more uniform liquid flow throughout the reactor volume, as compared to packed-bed reactors. Particle movements and collisions in the fluidized state result in moderate shear stresses and abrasion, creating a need for relatively mechanically stable supports. The scaling up of fluidized-bed bioreactors meets problems due to the difficulties in controlling the bed expansion or biofilm thickness and may encounter hydrodynamic problems; enlargement of distribution devices and/or oxygen saturation systems is also demanding task. Some industrial-scale applications of fluidized-bed reactors include biofilm and sludge blanket reactors for the treatment of wastes (110,111).

Gas-lift bioreactors are very attractive for various applications in biotechnology, because they feature effective mixing, with respect to the liquid and solid phases, pneumatic agitation with no mechanical devices, effective tuning of liquid recirculation, moderate shear stress and good interphase mass transfer. The pressure difference between the gassed and nongassed sections of the reactor provides liquid and solid circulation and efficient mixing. Gas-lift reactors contain base, riser, down-comer and a top section (Fig. 53.8d). They can be constructed as internal-loop or external-loop configuration. Air is commonly used as a gas in aerobic applications, while in anaerobic processes the circulation is induced by an inert gas, alternatively by a gas produced in the reaction. Gas-lift reactors can operate at different flow regimes, and hydrodynamic characteristics under different operating conditions have to be closely examined to achieve optimal external mass transfer. In general, the flow in the riser and down-comer section can be described as plug flow with axial dispersion. Efficient mixing and low shear rates make gas-lift reactors as suitable for all types of immobilization materials. At a lab scale, gas-lift reactors have been utilized for different applications [e.g. for beverage fermentations (112,113), phenol bioconversion (114)], while at an industrial scale, aerobic wastewater

treatments have been preformed in them (110,111). Another commercial application is the production of single cell protein (115).

As compared to conventional reactor types, the design of membrane reactors is relatively more complex and more expensive, mainly due to the high cost of the membrane material. Membrane reactors provide simultaneous bioconversion and product separation. Their usage is payable for production of high value biological molecules. Membrane reactors can be designed as flat sheet or hollow fiber configurations. A simple hollow fiber module is shown on Fig. 53.8e. Polymeric (nylon, polysulfone, teflon, polypropylene) microfiltration or ultrafiltration membranes have been usually used, although other types of membranes have been also investigated, such as ceramic, silicone, or ion exchange membranes. Mass transfer through the membrane is dependent on the pore size and structure as well as on the hydrophobicity/hydrophilicity and surface charge. Cell immobilization can occur on the membrane (as a biofilm), within the membrane or in a cell compartment separated by the membrane.

53.9 CONCLUSIONS

Various types of living cells such as bacteria, yeast, plant, or mammalian cells have been so far successfully immobilized for different applications in industry, medicine, and agriculture. Advantages of immobilized cell technology are numerous, where higher productivities, reuse of biocatalysts, and cell protection are the most important benefits.

There are different approaches how to place cells in a discrete location of a carrier and herein we categorized and described immobilization methods and techniques. Numerous organic and inorganic materials have been used so far as carriers to immobilize cells, while we gave an overview on chemical structure and properties of the most important polymers and proteins used in immobilized cell technology. Microcapsules have specific shell-core design and are mainly used in biomedical application. The manufacture of microcapsules is usually long-term and complex process, and the choice of core and coating materials determines capsule properties (permeability, mechanical properties, biocompatibility).

Reactor configuration is related to the choice of cell carrier. It governs the overall fluid dynamic, mass and heat transfer conditions at the biocatalyst surface. Packed-bed reactors are still the first choice in the industrial sector, mainly due to the simplicity of the design. Other bioreactor types provide better mixing, but high mechanical stresses and shear rates, large power inputs, investment cost, and difficulties in scale up are still the main issues constraining their wider application.

The selection of the suitable carrier and bioreactor system is a challenge and many issues should be taken into account, such as product quality, safety and stability, processing, investment and operating costs, as well as matters of legality. The assessment of the industrial feasibility of the immobilized technology is mandatory for providing cost-effective, large-scale applications. Further application of immobilized cell technology will depend on research results upon preservation of immobilized cells, as well as development of processes that can be readily scaled-up. Thus, research should be oriented toward the evolvement of reliable preservation and storage techniques that could be easily adopted by the industrial sector. Incomplete knowledge of the effects of immobilization on the physiology of cells led to incomplete and partially empirical use of immobilized cell technology. Ongoing basic research is continuing to identify and characterize changes in cell physiology and metabolism upon immobilization. Further research will explore new materials as potential carriers for microbial cells, and develop new or modify existing encapsulation processes.

IMMOBILIZED ENZYMES

Jose M. Guisan, Lorena Betancor, and Gloria Fernandez-Lorente
Instituto de Catalisis, CSIC, Madrid, Spain

54.1 INTRODUCTION

54.1.1 Enzymes as Industrial Catalysts

Because of their excellent functional properties (activity, selectivity, and specificity), the enzymes are able to catalyze the most complex chemical processes under the most benign experimental and environmental conditions. In fact, enzymes are able to catalyze very fast modifications of a unique functional group among several similar groups from a single molecule (substrate) in the presence of other very similar molecules, under very mild conditions. Therefore, enzymes could be excellent industrial catalysts in a number of areas of the chemical industry: biofuels, fine chemistry, food chemistry, analysis, and so on (1,2). For example, enzymes could be used to (i) transform lignocellulosic wastes (e.g. by mild hydrolysis of cellulose) into simple and valuable organic compounds, (ii) produce biodiesel via transesterification of fats and oils with aliphatic alcohols, (iii) asymmetric synthesis from prochiral ketones or prochiral diesteres, (iv) perform selective oxidations, (v) transform protein wastes into bioactive peptides, and so on.

However, enzymes have been modified throughout the long process of biological evolution, in order to optimize their behavior in the framework of complex catalytic chains inside living beings under stress and regulation. Obviously, enzymes have not been optimized to work inside industrial reactors. Thus, in addition to their excellent catalytic properties, enzymes have also some characteristics that are not very suitable for their industrial application: they are soluble catalysts, they are usually very unstable, they may be strongly inhibited by substrates and products, they work very properly only on natural substrates and under physiological conditions, and so on.

In most cases, enzymes have to be greatly improved before being industrially applied. The engineering of enzymes, from the natural environment inside living beings to the final chemical reactors, is one of the most exciting, complex and interdisciplinary goals of biotechnology. The massive implementation of enzymes as industrial catalysts requires a multidisciplinary utilization of very different techniques (Fig. 54.1): (i) screening of the biodiversity for enzymes with improved properties, (ii) improvement of enzyme properties via techniques of molecular biology, (iii) improvement of enzyme properties via immobilization and postimmobilization techniques, (iv) improvement of enzyme properties via reaction and reactor engineering, and so on. The successful improvement of enzyme properties constitutes one of the key solutions for the development of a much more sustainable chemical industry able to synthesize very complex and useful compounds under very mild and cost-effective conditions.

54.2 IMMOBILIZED ENZYMES AS CATALYSTS OF INDUSTRIAL CHEMICAL PROCESSES

For technical and economical reasons the majority of chemical processes catalyzed by enzymes may be greatly improved by the reuse or the continuous use of the biocatalyst for a very long time (3–6) (Fig. 54.2). Immobilization of enzymes may be defined as any technique able to allow the reuse or continuous use of the biocatalysts. On one hand, from that industrial point of view, simplicity and

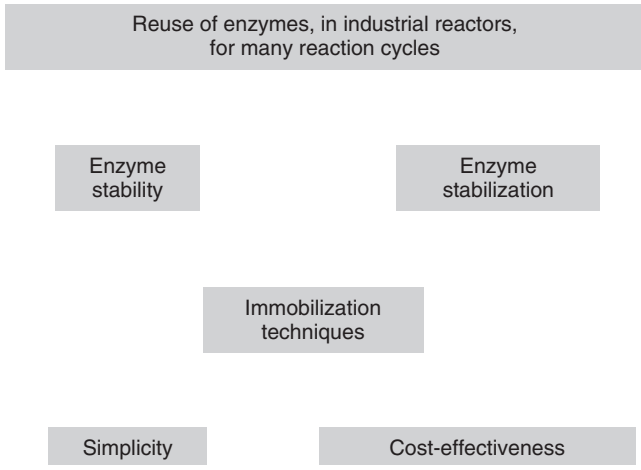

Figure 54.2. Some requisites for preparation of immobilized enzyme derivatives for industrial application.

cost effectiveness are key properties of immobilization techniques. On the other hand, a long-term industrial reuse of immobilized enzymes also requires the preparation of very stable derivatives with additional suitable functional properties for a given reaction (activity, selectivity, etc.) (7–10). At first glance, the practical development of protocols for immobilization of enzymes is intimately related to simplicity, cost-effectiveness, and stability and stabilization of enzymes (Fig. 54.3).

There are excellent revisions on immobilized enzymes and on a number of different protocols for enzyme immobilization. In this chapter, we focus our discussion mainly toward those protocols primarily related with industrial application. We will comment both on very simple protocols for enzyme immobilization and on the current and future protocols, which are able to greatly improve enzyme properties via immobilization techniques.

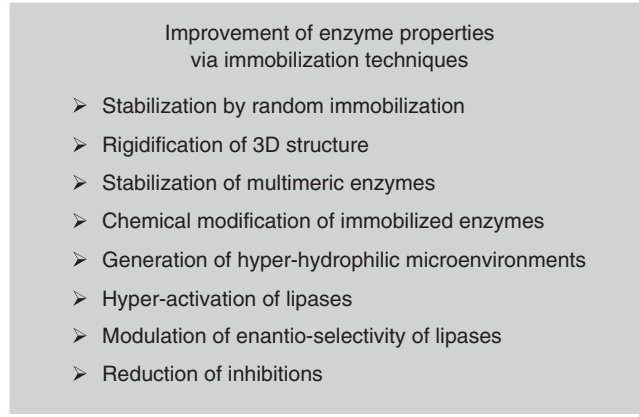

Figure 54.3. A summary of possible improvements of enzyme properties via immobilization techniques.

54.3 CURRENT INDUSTRIAL APPLICATIONS OF IMMOBILIZED ENZYMES

More than a hundred of different industrial biotransformations are catalyzed by immobilized enzymes used mostly for the production of pharmaceutical and agrochemical precursors (11). Some of the most relevant enzymes and products are summarized in Table 54.1 and Table 54.2. In the following sections we summarize the main processes that involve the use of immobilized enzymes.

54.3.1 Enantioselective Hydrolysis

The racemic resolution of *N*-acetyl amino acids via the enantioselective hydrolysis by amino acid acylase is perhaps one of the first industrial processes using isolated immobilized enzymes (11). Currently, immobilized lipases are being used for a number of enantioselective hydrolysis as well as the synthesis of racemic mixtures of chiral esters (containing chiral acyl donors or chiral alcohols). For example, methyl-*p*-methoxyphenyl glycidate is stereospecifically hydrolyzed by means of a lipase. Recently, a process to obtain (*S*)-1-phenylethylamine from the corresponding racemate was commercialized by BASF-Germany (12).

54.3.2 Chemioselective Hydrolysis

Another critical step in the industrial implementation of immobilized enzymes at large industrial scale is the production of 6-amino penicillanic acid from penicillin G using Penicillin G acylase (13). The enzymatic approach allowed the replacement of a complex and poorly sustainable chemical process. The production of acrylamide from acrylic acid using nitrile hydratase also benefited from the use of the immobilized enzyme (14). Immobilized commercial lipases (Novozymes, Amano,

TABLE 54.1. Some Relevant Products Industrially Synthesized with Immobilized Enzymes

Immobilized Enzyme	Product
Glucose isomerase	High fructose corn syrup
Amino acid acylase	Optically pure L-amino acids
Penicillin G acylase	Semi-synthetic penicillins
Nitrile hydrolase	Acrylamide
β-galactosidase	Hydrolyzed lactose
D-amino acid oxidase + glutaryl acylase	Semisynthetic cephalosporins
Thermolysin	Aspartame
Lipases	Lipids with improved properties
Lipases	Optically pure alcohols
Dehydrogenases	Optically pure secondary alcohols

TABLE 54.2. Some Examples of Immobilized Enzymes Commonly Used in Organic Synthesis at Laboratory Scale

Enzymes	Reactions
Esterase, lipases	Ester hydrolysis, synthesis
Amidases	Amide hydrolysis, formation
Dehydrogenases	Oxidoreduction of alcohols and ketones
Oxidases (mono- and dioxygenases)	Oxidation
Peroxidases	Oxidation, epoxidation,
Kinases	Phosphorylation
Aldolases, transketolases	Synthesis of (C–C bond)
Glycosidases, glycosyltransferases	Glycosidic bond formation
Sulphotransferases	Formation of sulphate esters
Transaminases	Synthesis (C–N bond)
Hydrolases	Hydrolysis
Isomerases	Isomerization

etc.) are also used for many processes of interesterification of fats and esterification of fatty acids (15).

54.3.3 Red-ox Processes

An isolated D-amino acid oxidase is used in the transformation of cephalosporin *C* to *R*-keto-adipyl-7-aminocephalosporinic acid, which is an intermediate in the acylase-catalyzed synthesis of 7-aminocephalosporanic acid (ACA) (16). Again, this transformation has successfully replaced a very complex and a poorly sustainable alternative chemical process.

Twenty years ago a process for the continuous regeneration of red-ox cofactors using isolated enzymes was developed (17). The reductive amination of trimethylpyruvate to L-*tert*-leucine was achieved using a combination of leucine dehydrogenase and formate dehydrogenase. This process has now reached ton-scale (18). A similar combination of a principal and an auxiliary dehydrogenase can be used for asymmetric reduction of prochiral ketones (e.g. alfa-keto acids) to optically pure secondary alcohols (e.g. the corresponding *R*-hydroxy acids). In this way, (*R*)-2-hydroxy-4-phenylbutyric acid (an important precursor for acetyl choline esterase inhibitors) can be obtained (19).

54.3.4 Transfer Processes

Glucose-6-phosphate is synthesized by means of a glucokinase starting from glucose in combination with an acetate kinase (20). This process is carried out in multikilogram scale by the Japanese company, Unitika.

54.3.5 Isomerization

The production of high fructose corn syrups by immobilized glucose isomerase is another classical industrial process catalyzed by an immobilized enzyme (21). In this case the enzymatic process comprises a breakthrough as the chemical alternatives are extremely complicated.

In some of the above examples, annual productions are higher than 1000 tons (acrylamide). In most cases the protocols for enzyme immobilization are very simple: adsorption on commercial resins, mild covalent attachement on glutaraldehyde and epoxy activated supports, and so on. In general, these simple immobilization protocols do not greatly improve the enzyme properties. These successful industrial applications are partially due to the good functional properties intrinsic to the enzyme. However, this is not the general case of thousands of very interesting biotransformations reported in the scientific literature (Fig. 54.2). In general, enzymes have to be greatly improved before their industrial implementation. For this reason, as we will propose in the second part of this chapter, the improvement of enzyme properties via immobilization methods could significantly improve the implementation of immobilized enzymes at industrial scale toward a much more sustainable chemistry.

54.4 IMMOBILIZATION PROTOCOLS

54.4.1 Very Simple Protocols for Enzyme Immobilization

Every day, new native enzymes showing good selectivity and stability properties become available (22,23). Under such circumstances, it will be possible to carry out many enzyme catalyzed reaction cycles without the need to improve the enzyme properties using immobilization and postimmobilization techniques. Therefore, it should be very interesting to develop very easy methods to prepare enzyme derivatives to be used at the industry scale.

Some desirable characteristics to develop very simple immobilization protocols can be summarized as follows:

1. Supports (even the whole reactors) should be reusable when the enzyme is inactivated. The inactive enzyme could also be desorbed from the support. Once the clean support has been recovered, fresh enzyme could be added and the whole biocatalysts should be used again. The chance for support reutilization has three important advantages: First, the industrial process becomes much cheaper. Second, high value supports (magnetic particles, macroporous supports with extremely good mechanical properties, etc.) could be used for extremely long periods of time (independent of enzyme stability). Finally, enzymes with a moderate stability (able to resist 20–30 reaction cycles) would become of high industrial interest if the support, and the whole reactor, can be easily recovered and reused.
2. Supports having very good mechanical properties will allow us to develop simple continuous reactors (e.g. high volumes of biodiesel can be produced by using continuous reactors with immobilized lipases). Another attractive industrial application could be the modification of solid substrates with enzymes (e.g. enzymes attached to magnetic particles could be applied to obtain glucose from cellulosic compounds).
3. Supports should be very stable (e.g. chemically inert supports used for physical adsorptions). Very inert/stable supports can be prepared and easily stored long before their use facilitating their transport between companies. This means that the whole enzymatic reactor could be prepared step-by-step in different companies even if they are far away from each other.
4. Immobilization processes should be fast and carried out under mild chemical and physical conditions (neutral pH, low temperature, etc.). Most enzymes are very stable in these conditions and very easy to handle.

The following sections highlight examples of very simple immobilization protocols.

54.5 ADSORPTION OF INDUSTRIAL ENZYMES ON IONIC EXCHANGERS

This is perhaps the simplest protocol for immobilization of enzymes on preexisting supports (24). The majority of the proteins become adsorbed (even at pH 7.0 and 4°C) either on anionic or cationic exchangers. Most of them (with a low isoelectric point) are mainly adsorbed on anionic exchangers. There are a number of organic and inorganic exchangers commercially available and able to strongly adsorb enzymes (e.g. agarose beads, Duolite, Levattit, Amberilite, porous glass, acrylic resins, etc.) (25). These supports containing high densities of quaternary ammonium salts or of sulfopropyl groups are the most suitable for a very intense anionic or cationic enzyme adsorption. Enzyme loadings on some macroporous commercial exchargers reach up to 100 mg of enzyme per gram of support. Commercial ion exchangers span a variety of mechanical properties: (i) some of them are very useful to be used in stirred tanks (e.g. agarose beads) and (ii) others are very useful to be used in packed beds (e.g. acrylic resins). The very high stability of ionic groups allows a full covering of the support surface with enzyme molecules and hence the preparation of very active immobilized biocatalysts.

At first glance, ionic adsorption does not improve the rigidity of immobilized enzyme molecules. However, enzyme molecules fully dispersed in the inner part of a porous structure are protected from some inactivation phenomena: aggregation, proteolysis, interaction with hydrophobic interfaces, and so on. Therefore, in many cases these immobilized derivatives are much more stable than the soluble enzymes.

These types of immobilized derivatives are very suitable for the immobilization of thermostable enzymes acting in anhydrous media or in aqueous media with very low salt concentration. In the presence of high concentrations of buffers or ionized substrates/products the enzyme may become desorbed from the support, for example, 90% of proteins of a crude extract from *Escherichia coli* are desorbed away from commercial DEAE-Sepaharose at 250 m*M* of NaCl (26).

Coating of the surface of a support with a deep and dense layer of ionic polymers [polyethylenimine (PEI), dextran-sulfate, etc.] constitutes an interesting alternative to get a much more intense ionic adsorption of enzymes. These supports, mimicking "ionic flexible and deep beds," have a much higher concentration of ionic groups than conventional supports and their flexible structure allows a better adaptability of the ionic layer to the immobilized enzyme (26–41) (Fig. 54.4). For example, a thermostable beta-galactosidase from *Thermus* sp. remains fully adsorbed of PEI agarose even at 400 m*M* of NaCl (28).

In addition, the very high hydrophilicity of these ionic polymers may also promote the stabilization of the immobilized enzyme against the deleterious effect of organic solvents since it is partially buried inside the hyper-hydrophilic bed (34). Moreover, the flexible structure of the ionic layer may also favor multisubunit adsorption of multimeric enzymes with their subsequent stabilization against dissociation (33).

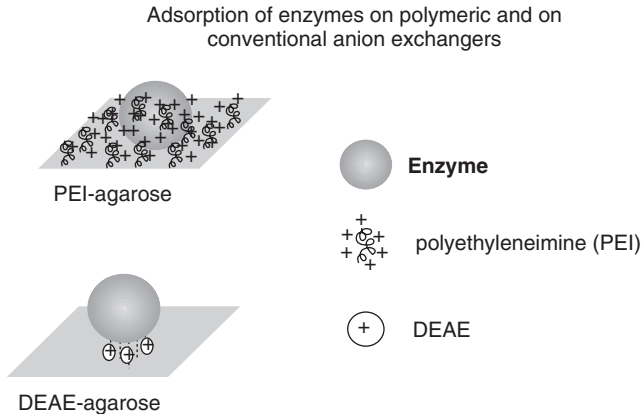

Figure 54.4. Schematic representation of the differences between anionic exchange on new polymeric layers and on conventional supports.

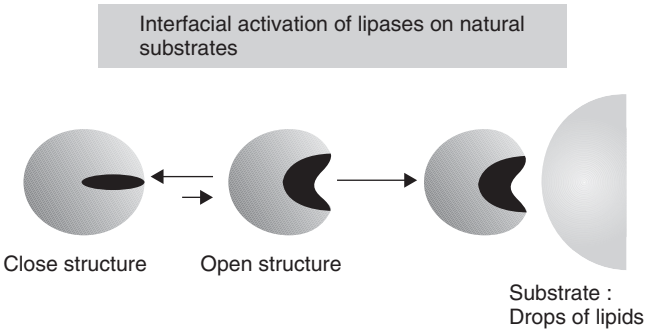

Figure 54.5. Interaction of soluble lipases on drops of lipids.

54.6 SELECTIVE ADSORPTION OF LIPASES ON HYDROPHOBIC SUPPORTS

Lipases interact with any hydrophobic surface like they do on fat surfaces: the enzyme adsorbs on the support surface with the active center lid wide open (35–38) (Fig. 54.5). In addition, this interaction is quite specific, lipases adsorb on hydrophobic surfaces at very low ionic strength and under these conditions most of the proteins are unable to adsorb on hydrophobic surfaces. Thus, purification and immobilization can be achieved in only one step (Fig. 54.6).

Additionally, the lipase-hydrophobic surface complex is fully stable and exhibits hyperactivation when acting on small esters in 100% aqueous media (Fig. 54.7). An important increase in catalytic activity of different lipases adsorbed on octyl-agarose was found by using p-nitrphenyl propionate as substrate (an hyperactivation ranged from 150% for a *Pseudomonas* lipase to 2000% for the *Thermomyces lanuginose* lipase) (37).

Lipases adsorbed on hydrophobic supports can be used both in aqueous and anhydrous media. However, lipases desorb away from the support when using water-cosolvent mixtures with a moderate or high concentration of organic

solvents. Other proteins (to be also used in anhydrous media) can also be dispersed on hydrophobic supports with no release of enzyme during such biotransformations (42).

54.7 BIOAFFINITY IMMOBILIZATION

The rationale behind this protocol is the selective adsorption of industrial enzymes on immobilized proteins or ligands. An excellent revision about this immobilization protocol has been recently published by Gupta *et al*. (43,44). The utility of this methodology is based on a number of advantages that are summarized as follows:

1. The purification and immobilization of a target enzyme may be achieved in unison, provided that the specificity of the biorecognition is high; for example, an enzyme adsorbed on its corresponding

immobilized antibody, adsorption of recombinant enzymes tagged with poly-His tails on immobilized metal chelates, and so on.

2. Biorecognition is generally performed under benign experimental conditions (e.g. pH 7.0 y 4°C), which allows for high recoveries of immobilized enzyme activies and the support can be fully loaded with immobilized enzyme.
3. In some cases, the stability of the immobilized enzyme may be enhanced [e.g. the interaction of concanavalin A (Con A) with some glycoproteins] (45).
4. Bioaffinity immobilization is reversible and the immobilized ligand could be reused after a partial inactivation of the immobilized enzyme. The immobilized inactivated enzyme could be then washed away from the support and the immobilized ligand used again to immobilize a new fresh enzyme solution.
5. A correct selection of the immobilized ligand (a lectin, a monoclonal antibody, etc.) may promote the adsorption of the enzyme through regions located far from the enzyme active center. In addition to that, the immobilized ligand may act as a spacer arm. Both effects could contribute to a better accessibility of the immobilized enzyme to macromolecular substrates and even insoluble substrates; for example, cellulases immobilized on nonporous magnetic nanoparticles acting on cellulose.

Some relevant examples of bioaffinity immobilization are as follows:

54.7.1 Adsorption of Enzymes on Immobilized Anti-enzyme Antibodies

Glucose oxidase and horseradish peroxidase have been adsorbed on their corresponding immobilized antibodies. These derivatives were very useful to design "flow injection analysis" of glucose and hydrogen peroxide. In both cases, immobilized enzymes were much more stable than their corresponding soluble counterparts allowing for their reuse in a number of analytical cycles (46). The production of monoclonal antibodies that strongly adsorb a target enzyme through regions far from the active center should allow the simultaneous purification, immobilization, correct orientation, and stabilization of industrial enzymes (47).

54.7.2 Adsorption of Glycosylated Enzymes on Immobilized Lectins

In 1991, Saleemuddin and Husain published an excellent review on the utilization of immobilized Con A for the adsorption of glycosylated molecules (48,49). Immobilized Con A presents itself as a very interesting alternative to tackle the difficult task of immobilizing glycosylated enzymes on preexisting supports. Immobilization on Con A is reversible and a partially inactivated enzyme may be removed by incubation of the derivative in the presence of high concentration of sugars. Very different glycoproteins have been successfully immobilized via this protocol (invertase (49), cellobiose (49), glucose, oxidase (49), etc.). In general, these derivatives are fully active and well-oriented because glycosidic chains are usually not involved in the active center of the enzyme. In some cases highly stable derivatives have also been prepared (49).

Bioaffinity layering (50) recently emerged as a new bioaffinity immobilization methodology. It was developed by immobilizing several superimposed layers of Con A-enzyme on the same support, which provided a significant increase in enzyme loading capacity and thereby highly active derivatives. Dalal and Gupta have applied this methodology for the preparation of very active derivatives of horseradish peroxidase able to be used for the treatment of phenolic wastewater.

54.7.3 Immobilization of Chimeras of Recombinant Proteins on Simple Immobilized Affinity Ligands

Recombinant proteins having a poly-His tail in either the amino or carboxyl terminus may be selectively adsorbed on tailor-made immobilized chelates (51,52). Again, this very selective adsorption may allow the purification and immobilization of industrial enzymes and the preparation of very active derivatives with a fully loaded support (under very mild condition) with pure enzyme (even using a highly impure crude protein extract as the source of the enzyme). The adsorption is very stable at neutral pH and it can be reversed after partial inactivation of enzyme by addition of imidazol (competing with His residues for the support) or by addition of chelating agents such as ethylenediaminetetraacetic acid (EDTA). Although significant stabilization factors should not be expected, a full multisubunit immobilization of dimeric or trimeric enzymes could be achieved if the different poly-His tails (one per subunit) are correctly oriented. As a result, immobilization of multimeric enzymes becomes much more intense and the dissociation of subunits now becomes impossible.

Other interesting chimeras may be constructed by using other tags. For example, a chimera of one industrial enzyme and a cellulose-binding domain can be directly and selectively adsorbed on cellulose supports (53).

54.8 COVALENT IMMOBILIZATION

54.8.1 Introduction

Covalent attachment of enzymes on preexisting supports containing reactive groups is perhaps the most popular protocol for enzyme immobilization. As commented before,

different macroporous supports able to immobilize up to 100 mg of enzyme per gram of support are commercially available. These commercial supports have different and excellent properties to be used in a variety of reactor configurations (stirred tank, packed beds, etc.) and in different reaction media.

A very stable covalent attachment of enzymes on these supports also allows the use of the biocatalysts in any reaction media without desorption of the enzyme: aqueous media at high ionic strength, aqueous media in the presence of high concentrations of cosolvents, organic media, ionic liquids, supercritical fluids, and so on.

The covalent one-point or multipoint immobilization of an enzyme promotes a full dispersion of isolated enzyme molecules on the inner surface of a porous support. This distribution avoids a number of effects that could potentially inactivate the enzyme: proteolysis, aggregation (by cosolvents, at the isoelectric point, etc.), interaction with hydrophobic interfaces (e.g. air bubbles in stirred tanks), and so on. It is for this reason that many authors often correlate immobilization with stabilization of enzymes. However, a real stabilization of the three-dimensional structure of enzymes requires a very careful design of the activated support and the immobilization protocol. In fact, only an intense multipoint covalent attachment of each enzyme molecule to the activated support accomplishes the dramatic stabilization required for the industrial application of immobilized enzymes.

Supports with covalently immobilized enzymes cannot be reused after enzyme inactivation. However, reactivation of the immobilized derivative after partial inactivation of the enzyme (e.g. by unfolding-refolding with urea or guanidine) could allow for reuse of the whole biocatalyst for many reaction cycles.

54.8.2 Immobilization Through the Amino Groups on the Protein Surface

Enzymes can be immobilized through different residues placed on their surface (e.g. Tyr react with diazonium salts, Cys react with reactive disulfide bridges, Asp and Glu (activated with carbodiimide) react with low pK amino groups, etc.). These and other immobilization protocols have been previously described in excellent reviews (54). However, in our opinion, the ideal functional groups for enzyme immobilization are the amino groups (amino terminal plus Lys). Nonionized amino groups are excellent nucleophiles without needing any kind of activation. In general, amino groups are also hydrophilic and abundant in the surface of industrial enzymes (Fig. 54.8).

We can consider two clases of amino groups on the protein surface:

1. Low-pKa amino groups (pK_a around 7.0–7.5). These groups are very reactive for enzyme immobilization (at neutral pH and even at 4°C) in the intermolecular process of reacting soluble enzymes with solid supports containing a high concentration of highly reactive groups. At first glance, only the terminal amino group has such a low pK. However, some Lys residues fairly exposed to the medium but surrounded by some special microenvironments could also exhibit a modified low pK and hence a good reactivity for immobilization.
2. High pK_a amino groups (pK_a around 10.5). Most of the Lys residues are very exposed to the medium and their ε-amino group has a very high pK_a. These Lys groups are poorly reactive for intermolecular immobilization at neutral pH even on highly reactive supports. However, these groups are usually abundant on the enzyme surfaces and they become very useful for further intramolecular multipoint attachment with stable groups on the support after the first process of enzyme immobilization.

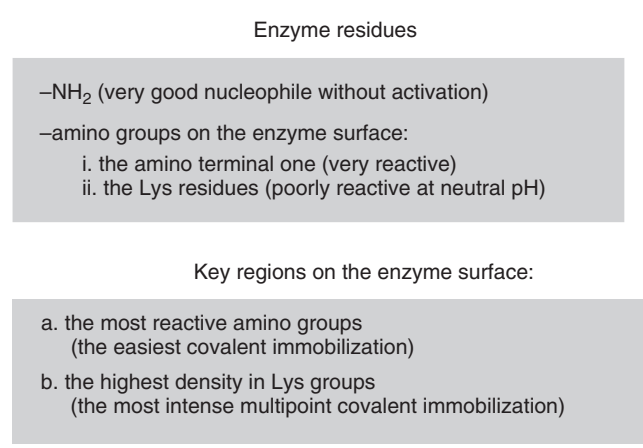

Figure 54.8. Main enzyme residues suitable for intermolecular and intramolecular covalent immobilization of industrial enzymes.

54.8.3 Activated Supports to React with Amino Groups of the Enzyme Surface

The different reactive groups able to react with amino groups of enzymes are shown in Table 54.3. At first glance, all these reactive groups could be useful for the immobilization of enzymes.

The most reactive groups allow the immobilization of a certain concentration of enzymes under very mild conditions. However, the most reactive groups are also very unstable in water and they are unable to allow a full loading of the support with immobilized enzyme molecules. In addition to that, the lack of stability of these highly reactive groups prevents an intense multipoint covalent immobilization with Lys residues (mainly under alkaline conditions where Lys are much more reactive).

TABLE 54.3. Covalent Immobilization Through Their Amino Groups on Differently Activated Supports

Reactive Group on the Support	Stabillity of Reactive Groups	Immobilization Rate at Neutral pH
Tresyl chloride	Very low	Very fast
Cyanogen bromide	Very low	Very fast
Epoxyde	Very high	Very slow
Glutaraldehyde	High	Fast
Glyoxyl	Very high	Very slow—very unstable bonds
N-hydroxy-succinimidyl	Low	Fast

On the other hand, the groups with a low intermolecular reactivity (epoxy, glyoxyl, etc.) are not very useful for simple enzyme immobilization. However, as discussed in subsequent sections, they are the most useful for obtaining very intense multipoint covalent immobilization and highly loaded derivatives.

54.8.4 Enzyme Immobilization on Agarose Beads Activated with Cyanogen Bromide

Agarose beads activated with cyanogen bromide are commercially available (CNBr-Sepharose™ from GE Healthcare). Its active groups are very reactive but also very unstable. In fact, they have to be stored after freeze-drying in the presence of dextran. As commented before this type of very reactive and unstable activated groups are not very suitable for the preparation of industrial biocatalysts. However, the utility of these supports lays in the determination of the industrial potential of a given enzyme (55). By using a diluted crude extract (without purification) a small amount of enzyme is immobilized via a single attachment or a very poor intense multipoint attachment (at pH 7.0, 4°C for 15 minutes and additional blocking with ethanolamine) Thus, fully dispersed immobilized enzyme molecules (without any interaction with interfaces, with proteases or with other proteins) will exhibit the exact functional properties (activity, selectivity, and stability) of the native enzyme. In fact, these derivatives should be used as the suitable control to compare the potential of novel immobilization protocols. On the contrary, the comparison of new immobilized derivatives with concentrated and impure preparations of the soluble enzyme may be influenced by a number of artifacts.

54.8.5 Enzyme Immobilization on Aminated Supports by Using Glutaraldehyde

1. *Aminated Supports Previously Activated With Glutaraldehyde.* Enzyme immobilization on amino-activated supports activated with glutaraldehyde is a straightforward process (56–58). Preactivated supports (amino-supports) are chemically very stable and can be stored, at 4°C, for very long time periods. Additionally, glutaraldehyde activation of these supports is simple and its Generally Recognized As Safe (GRAS) status allows for its utilization in food industry. Glutaraldehyde is attached to secondary amino moieties and hence these supports (at low or moderate ionic strength) have a high capacity to ionically adsorb proteins via anion exchange. In most cases, the first step of this immobilization, at low ionic strength, is a very fast ionic adsorption of the enzyme (pH 7.0, 4°C) on the amino-glutaraldehyde support. The region of the protein surface having a high density of negative charges becomes adsorbed on the secondary amino groups on the support. After the first adsorption, some amino group of the enzyme protein surface (having a low or high pK_a) can quickly react (via intramolecular reaction) with a high concentration of glutaraldehyde groups on the support. This immobilization method allows to immobilize enzymes (through the richest area in negative charges of the protein surface) that otherwise would be hardly adsorbed onto positive ionic supports. The second intramolecular- binding event is so fast that it shifts the adsorption equilibrium toward the full adsorption and reaction of the enzyme onto the aminated support. In fact, only 70% of the proteins from an *E. coli* extract adsorbs onto amine supports at pH 7.0, whereas, 100% of the protein from the same extract absorbs when the aminated support is activated with glutaraldehyde. It is noteworthing that this protocol is not very useful for a very intense multipoint covalent attachment, because of the instability of the glutaraldehyde groups under alkaline conditions necessary for the involvement of many Lys residues in the covalent attachment with the support (57). However, the first very rapid step of ionic adsorption allows the preparation of very highly loaded derivatives.
2. *Physical Adsorption of Enzymes on Inert Ionized Aminated Supports With Further Cross-Linking With Glutaraldehyde.* This protocol, although quite similar to the above mentioned one shows some additional advantages: (i) the enzymes can be adsorbed onto very stable amino-supports without any activation, (ii) enzymes may also be adsorbed on PEI of several sizes and having tertiary, secondary and primary amine groups, (iii) the further addition of soluble glutaraldehyde promotes a more intense multipoint covalent union between the amino groups of the protein surface and the amine groups of the support (58).

However, it must be borne in mind that the addition of soluble glutaraldehyde promotes the modification of all amino groups of the enzyme surface and this overall chemical modification may, in some case, have negative effects on enzyme activity and/or stability.

In general, derivatives obtained by using this second glutaraldehyde protocol are more stable than those obtained when using the first—more conventional—glutaraldehyde protocol (58).

54.8.6 Enzyme Immobilization on Commercial Supports Containing a High Concentration of Epoxy Groups

There are two commercial acrylic resins containing a high concentration of poorly reactive but very stable epoxy groups (Eupergit® C from Rohm Darmstadt and Sepabeads® from Residion-Mitsubishi Chem. Corp.) (6–59). Immobilization of enzymes on these supports is usually performed at very high ionic strength (e.g. 1 *M* phosphate buffer). The resins are moderately hydrophobic and hence enzymes are firstly adsorbed on the supports via hydrophobic adsorption (Fig. 54.9). After the first adsorption, any amino group of the enzyme surface placed in the vicinity of the hydrophobic pockets may become covalently attached (an intramolecular process) to the very dense layer of epoxy groups. The high stability of epoxy groups allows for a further incubation of the immobilized derivatives under alkaline conditions that increases the reactivity of all Lys residues existing in the vicinity of the hydrophobic pockets involved in the first adsorption of the enzyme. Finally, epoxy groups may be blocked with mercaptoethanol or glycine (59). The stability of epoxy supports also allows long time storages and transportation from the manufacturing company to the end-user company. Obviously these very stable supports permit a high loading of immobilized enzyme yielding very active biocatalyst with good prospects for industrial implementation. Again, as commented for glutaraldehyde, poorly reactive epoxy groups only act after a first adsorption of the enzyme, on the support in a second intramolecular event, leading to the covalent attachment of the already immobilized enzyme.

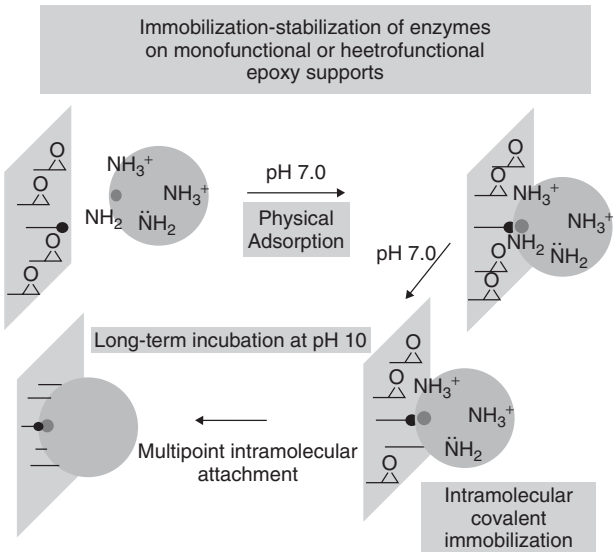

Figure 54.9. Schematic representation of a 2–3 steps process for a single or multipoint covalent immobilization of enzymes on epoxy supports. The Scheme is valid either for hydrophobic commercial supports or for heterofunctional supports reviewed below.

54.9 IMMOBILIZED ENZYMES WITHOUT SUPPORTS

Unsupported immobilized derivatives capitalize on their ease of preparation, their very high volumetric activities and their cost effectiveness. Many of them have industrial potential and in the following section we will summarize some examples of this type of immobilization.

54.9.1 Cross-linking of Soluble Enzymes With Glutaraldehyde (CLEs)

It is probably one of the first developed immobilization protocols that emerged around 1970 (60,61). They are easily prepared by cross-linking of an enzymatic solution with a high concentration of an inexpensive cross-linking agent (e.g. glutaraldehyde). The industrial application of cross-linked enzymes(CLEs) however may be restricted by their final gelatinous structure; for example, for their use in packed bed reactors or filtration steps. The reader is refered to a number of interesting reports on this immobilization protocol (60).

54.9.2 Freeze-Dried Enzymes

In 1980s, Klibanov promoted the use of enzymes in organic media (62). The idea was highly successful and in some cases very practical. The rationale was that because of their lack of solubility in organic media, freeze-dried enzymes (FDEs) or commercial enzyme powders could be used as heterogeneous biocatalyst without being immobilized. These extremely simple enzyme derivatives were very useful to work at laboratory scale, discovering exciting possibilities of industrial enzymes in organic media (63). However, FDEs also may exhibit a number of industrial limitations. For example, enzyme particles have poor mechanical properties, and catalytic activities per gram of solid biocatalyst are usually low (63).

54.9.3 Cross-Linked Enzyme Crystals (CLECs)

The cross-linking of crystallized enzymes with glutaraldehyde was firstly proposed by Quiocho and Richards in 1964 (64) with academic purposes. However, they discovered that these crystals preserved a good percentage of the initial catalytic activity. More than 25 years later, a company called Vertex used the same strategy to develop a method for the preparation of immobilized enzyme catalysts (65,66). These promising derivatives were further commercialized by Altus Biologics (65,66). The advantages of cross-linked enzyme crystals (CLECs) include mechanical robustness and high volumetric activities since almost 100% of their mass is composed by pure enzyme. In addition to that, CLECs usually are very stable, much more stable than soluble enzymes or one-point covalently immobilized derivatives. This stability may be due to the close contact among crystallized enzyme molecules and it is observed against any denaturing agent. On the other hand, CLECs are quite expensive because large amounts of pure and crystallized enzyme are required. Moreover, some enzymes are difficult to be crystallized and additionally the production of large crystal particles (e.g. 100 μm of diameter) is not easy limiting the industrial use of these immobilized derivatives. These extremely active catalyst may be very useful, however, both in aqueous or organic media as an alternative for enzymes exhibiting low intrinsic activity toward interesting nonnatural substrates.

54.9.4 Cross-Linked Enzyme Aggregates

Stable cross-linked enzyme aggregates (CLEAs) can be easily prepared in a two-step protocol (Fig. 54.10). Firstly, aggregation of soluble enzymes is performed in the presence of salts, organic solvents, polymers, and so on, under very mild experimental conditions (pH 7.0, 4°C), in order to be sure that every enzyme molecule remains fairly active. After a rapid aggregation, a strong stirring is promoted in order to get small particles of enzyme aggregates. Finally, enzyme aggregates are stabilized by using different cross-linking agents (i.e. glutaraldehyde). This method produces insoluble CLEAs once the aggregating agents are rinsed out. This methodology was first developed in Prof Sheldon′s laboratory and has allowed the easy preparation of a number of very active derivatives of industrial enzymes (67–71). The technique may also allow some interesting improvements of enzyme properties: (i) different enzymes can be coimmobilized if they must work close together, (ii) enzymes and highly hydrophilic polymers can be coimmobilized in order to improve the stability of enzymes against oxygen or organic solvents, (iii) enzymes and polymers containing a number of primary amino groups (i.e. PEI) can also be coimmobilized to enhance the intensity of chemical cross-linking (e.g. when using enzymes which are relatively poor in lysine residues), (iv) very complex quaternary structures of multimeric enzymes can be highly stabilized—avoiding subunit dissociation—as cross-linking agents keep the structure tightly joined.

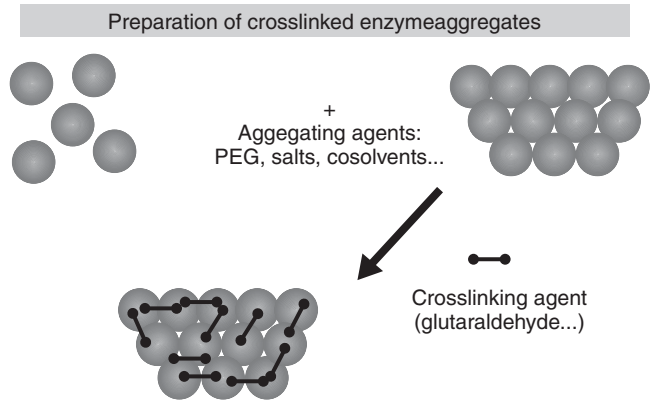

Figure 54.10. Schematic representation of the very simple preparation of cross-linked enzyme aggregates.

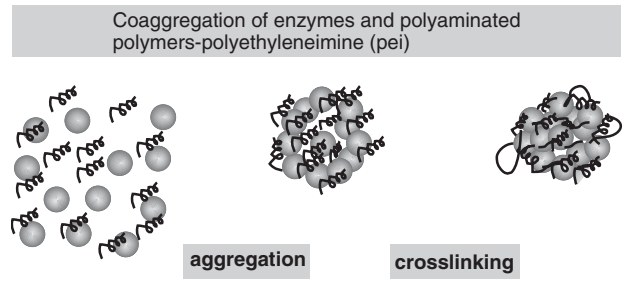

Figure 54.11. Coaggregation of enzymes and polyethylenimine.

This method can be applied to any enzyme and absolute purity is not necessary. Obviously, this method becomes much easier to use with enzymes from thermophilic microorganisms; these enzymes are more resistant toward aggregation processes and toward chemical modifications.

A scheme of the two main protocols for the preparation of CLEAs is shown in Fig. 54.10 and Fig. 54.11.

The CLE as a methodology is now reported by several research groups. The additional advantages of CLEAs are now more deeply commented:

1. *Stabilization of Multimeric Enzymes.* When multimeric enzymes are chemically cross-linked every enzyme subunit also becomes cross-linked avoiding dissociation. This advantage can be achieved even for complex multimeric enzymes (hexameric, heteromultimeric, etc.) that are difficult to stabilize

by immobilization on preexisting supports. Figure shows the stabilization of bovine liver catalase. Cross-linked derivatives are much more stable than their soluble counterparts. In addition to that, inactivation of cross-linked aggregates does not depend on dilution. When using nonstabilized derivatives a more diluted suspension inactivates much more rapidly because dissociation of subunits is favored. Similar stabilizations could be obtained via the CLEC methodology.

2. *Enzyme Stabilization Against Organic Solvents.* Coaggregation of enzymes and highly hydrophilic polymers (i.e. PEI) may produce a hydrophilic environment around the surface of every aggregated enzyme molecule. Thus, when the derivative is used in the presence of high concentrations of organic cosolvents there might be a partition effect of the cosolvent between the bulk solution and the enzyme environment. Owing to this partition effect the enzyme is in contact with a much lower concentration of organic cosolvent. In this way, the deleterious effect of the cosolvent becomes highly diminished (69) (Fig. 54.12). Obviously, cocrystallization of enzymes and polymers is not possible.
   In the best case, coaggregation of complex multimeric enzymes from thermophilic organisms and highly hydrophilic ionic polymers (with primary amines) will produce easy to prepare derivatives with high activity and stablity against dissociation and organic solvents.
3. *CoAggregation of Two Enzymes Acting in Tandem.* In some cases (e.g. oxidases plus catalases) two enzymes may act consecutively and the intermediate product (e.g. hydrogen peroxide) may be deleterious for the stability of both enzymes. In these cases, an instant removal of the product by the second enzyme is strictly necessary. Coaggregation may facilitate this instant removal of the toxic intermediate product. In other cases, the intermediate product may be very unstable hence its immediate modification may be strictly necessary. These "combi-CLEAs" may be an important practical alternative which again is not possible via cocrystalization of two very different enzymes (67).

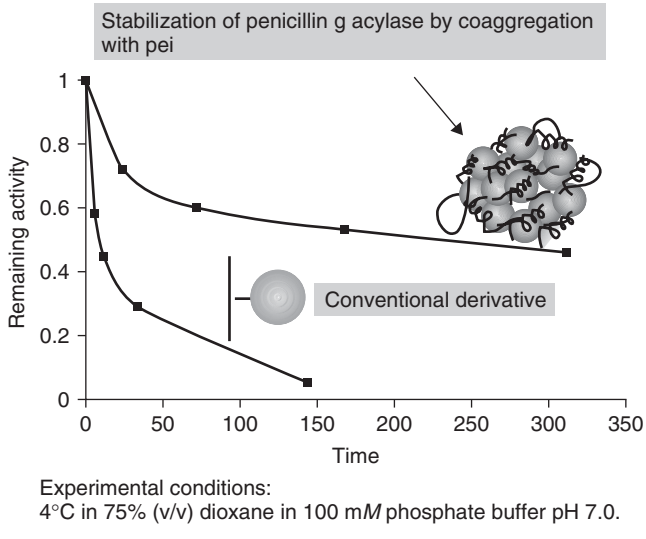

Figure 54.12. Time-course of inactivation by cosolvents of penicillin G acylase coaggregated with polyethyleneimine.

54.10 IMPROVEMENT OF ENZYME PROPERTIES BY IMMOBILIZATION TECHNIQUES

The majority of the enzymes of industrial interest are not very stable for reuse for long periods of time. In addition, enzymes may be poorly active and selective when acting on nonnatural substrates. For these reasons, as mentioned in the section titled Introduction, the additional improvement of enzyme properties through the necessary immobilization techniques became quite an exciting technological approach (72). Random immobilization of unstable or poorly active industrial enzymes is not very relevant from an industrial point of view. On the contrary, some interesting protocols to improve enzyme properties, with special emphasis in stabilization, will now be described:

54.10.1 Stabilization of Enzymes by Multipoint Covalent Immobilization: Glyoxyl-Agarose

The establishment of a number of attachments between every immobilized enzyme molecule and the support should exert very interesting stabilizing effects. When spacer arms (between the enzyme and the support) are very short and the support is very rigid, we can assume that all the relative positions among the enzyme residues involved in multipoint immobilization have to remain unmodified during any conformational change induced by any distorting agent (heat, organic cosolvents, etc.). Thus, the intensity of these conformational changes should be strongly diminished (Fig. 54.13). This very interesting hypothesis has been already established from the beginning of enzyme technology (around 1977) (73,74). However, currently, 40 years later, there are only very few immobilization protocols useful to promote very intense enzyme-support multipoint covalent immobilizations (75).

The internal morphology of agarose gels is composed of large highly hydrophilic fibers with a high geometrical congruence with proteins surfaces (76). At first glance, these gels when activated with glyoxyl groups (small

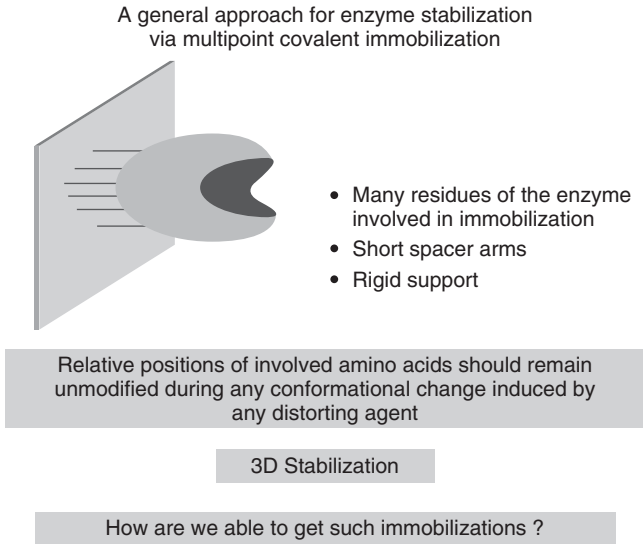

Figure 54.13. Rational explanation of the stabilizing effect promoted by multipoint covalent immobilization.

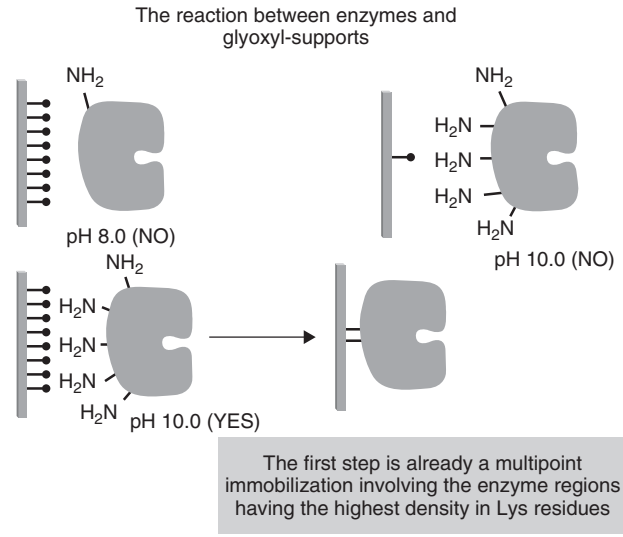

Figure 54.14. Some special features of immobilization of enzymes on glyoxyl activated supports.

aliphatic aldehydes) are very unsuitable for "enzyme immobilization." However, under "tailor-made" conditions, they seem to be the most adequate to get dramatic immobilization-stabilization of industrial enzymes. These activated gels are very easy to prepare and very stable (76) and they are commercially available from Biotica S.A. (76).

The binding between a unique glyoxyl group and a unique unionized amino group yields a very unstable Schiff's base, which tends to total dissociation. In fact, very highly activated glyoxyl-agarose (e.g. 100 μmols per mL of support) is not able to immobilize an enzyme at pH 7.0 (Fig. 54.14). Under these conditions, in most of the cases, enzymes have only one unionized amino group on their surface (perhaps the amino terminal one) since the pK of fairly exposed surface Lys groups is too high (higher than 10). On the other hand, poorly activated glyoxyl-agarose (e.g. 1 μmol per mL of support) is also not able to immobilize an enzyme at pH 10.0 (containing a number of reactive amino groups). However, the combination of very highly activated supports (100 μmols/mL) and very highly reactive enzymes (at pH 10.0) promotes a very rapid and irreversible immobilization of all enzymes (at least more than 50 different enzymes tested in our laboratory) (76–89). This result (and other experimental evidences already reported) seem to indicate that even the first immobilization process has to be a multipoint covalent attachment (77,78). Obviously, such type of immobilization should mainly occur through the region of enzyme surface having the highest density in Lys groups. That is, the best region to get a very intense multipoint covalent attachment after a long incubation (at

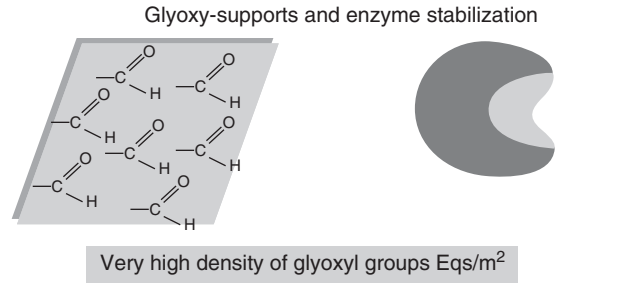

Figure 54.15. Overall advantages of glyoxyl supports to promote very intense and stabilizing multipoint covalent immobilizations.

pH 10 and 25°C) between the immobilized enzyme and the highly activated support containing very stable active groups. In fact, immobilized trypsin has formed seven linkages with the support per enzyme molecule having only 15 Lys residues on their surface (77).

In addition to that, the transformation of primary amino groups into secondary amino ones promotes a very small physicochemical modification of the enzyme surface, in

spite of a very intense multipoint attachment. For this reason, many enzymes have been dramatically stabilized with very small decrease of catalytic activity.

The overall characteristic of glyoxyl-agarose (Fig. 54.15) for multipoint covalent immobilization of enzymes cannot be found for more conventional immobilization protocols [cyanogen bromide (BrCN) supports, glutaraldehyde supports, National Health Service (NHS)-supports, etc.].

In fact very interesting stabilizations have been observed for different monomeric enzymes, which are associated with very small decrease of catalytic activities. Inactivation experiments made by comparison of stabilities of multipoint immobilized derivatives and stability of one-point immobilized ones (prepared by using very lowly activated supports). In this way, the stabilization factors reported in the Fig. 54.16 really represent the 3D rigidification of enzyme structures. Interesting stabilizing factors that are intrinsic to random immobilizations (no aggregation, no interaction with interfaces, etc.) are identical for the two types of derivatives. Similar stabilization factor for 3D structures of industrial enzymes are hardly reported in scientific literature.

Moreover, rigidification of enzymes by a very intense multipoint covalent immobilization should promote stabilization against any distorting agent (heat, organic cosolvents, saturating concentrations of organic solvents, pH, etc.) (89). Agarose beads are excellent supports for this type of stabilization. They are initially and finally very hydrophilic, they have a very high density of modifiable hydroxyl groups, they are very resistant to stirring and hence, very suitable to be used in stirred tank, and so on. However, this protocol for enzyme stabilization is not exclusive of agarose beads. Similar dense layers of glyoxyl groups can be also synthesized on the surface of very different solid supports (porous glass, polyacrylamides, cellulose, magnetic particles, etc.).

Some enzymes highly stabilized by multipoint covalent attchment on glyoxyl-agarose

Enzyme	Activity(%)	Stabilization
Trypsin	75%	10.000
Chymotrypsin	70%	60.000
Penicillin G acylase from *E. Coli*	70%	8.000
Penicillin G acylase from *K. citrophila*	70%	7.000
Ferredoxin NADP reductase from Anabaena	60%	1.000
Lipase from *C. rugosa*	50%	150
Glutamate racemase	70%	1.000
Esterase from *B. stearothermofilus*	70%	1.000
Thermolysin from *B. thermoproteolyticus*	100%	100

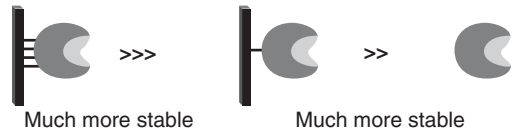

Figure 54.16. Some example of enzymes highly rigidified by multipoint covalent immobilization.

54.10.2 Stabilization of Enzymes by Multipoint Covalent Immobilization: Heterofunctional-Epoxy Supports

Immobilization on glyoxyl-agarose is, very likely, the most precise protocol to get very intense enzyme-support multipoint covalent attachments: the enzyme becomes immobilized through its surface region having the highest density of Lys (amino) groups. However, it is also probable that many enzymes may have different surface regions with different sensitivity against inactivation by different distorting agents. For example, a very flexible region close to the active center may be much more relevant to inactivation than a very robust one far from the catalytic site. On the other hand, sometimes multipoint attachment has to be promoted on the opposite side of the active center even with a less intense stabilization (e.g. enzymes acting on macromolecular substrates). Thus, the promotion of intense multipoint attachment on different regions of the enzyme surface may be quite interesting. As commented before, epoxy groups are very poorly reactive for immobilization (an intermolecular process) at neutral pH. The enzyme has to be adsorbed on the support before a covalent attachment between amino groups of the enzyme surface and a dense layer of epoxide groups on the support takes place. For this reason, in addition to monofunctional commercial epoxy supports (the enzyme is firstly adsorbed via hydrophobic adsorption), a number of hetero-functional epoxy supports can also be prepared, in order to promote different first adsorptions of the enzyme through different regions of the enzyme surface: (i) Immobilized Metal Affinity Chromatography (IMAC)-epoxy support promotes a first adsorption through the region containing the highest density of histidine groups, (ii) carboxy-epoxy support promotes a first adsorption through the region with the highest density of positively ionized groups, (iii) ionized amino–epoxy supports promote a first adsorption through the region with the highest density of negative charges, and so on. The amino-epoxy support is commercially available from Resindion-Mitsubishi Chem. Corp. and will be used as an example of this immobilization protocol.

We will now discuss the rigidification of enzymes, through the surface region with the highest density of negative charges (e.g. Asp + Glu), by using a highly activated commercial amino-epoxy supports (90–94).

The ideal amino groups on the support should have a pK around 9–10 in order to be easily modified with epoxy reagents and, after modification, to become ionized (as secondary amino groups) at pH 7.0 and 4°C. In this way, a very simple first adsorption of enzymes by anionic exchange may be achieved.

A three-step immobilization protocol on hetero-functional epoxy supports is represented in Figure 9.

This mechanism of immobilization is similar (the first two steps) to the one commented for glutaraldehyde activated supports. However, the stability under alkaline conditions of epoxy groups allows a third step of alkaline incubation that may now promote an intense multipoint covalent attachment, and much more intense enzyme stabilization. In general enzymes stabilized on amino-epoxy supports are much more stable than those immobilized via glutaraldehyde.

54.10.3 Stabilization of Multimeric Enzymes

Many enzymes of industrial interest have a quaternary structure and are composed of several subunits whose dissociation leads to the total loss of the catalytic activity (95). Prevention of subunit dissociation constitutes a key point to accomplish enzyme stabilization. A two-step protocol has been proposed to get such stabilization (Fig. 54.17): (i) first, an immobilization of the enzyme on highly activated supports involving the highest possible number of enzyme subunits and (ii) an additional cross-linking of all subunits (mainly those not immobilized on the support) by using polyfunctional flexible polymers (i.e. aldehyde-dextrane polymers of several sizes able to react with lysines located in different subunits of the enzyme). All the multimeric proteins from a crude extract from *E.coli* have been stabilized by this strategy. In addition, several successful stabilizations of relevant multimeric enzymes have also been reported (96,97).

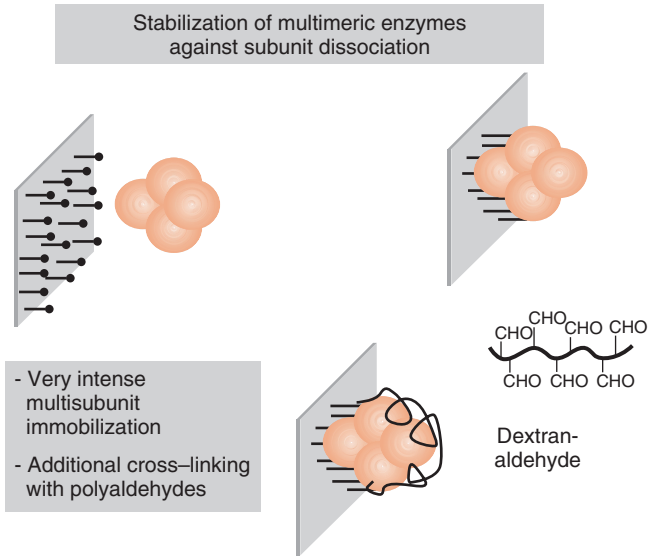

Figure 54.17. Schematic representation of a general strategy for stabilization of multimeric enzymes. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Glyoxyl supports have been used in the past to obtain a multisubunit immobilization of several enzymes with the additional advantage of a simultaneous rigidification of each immobilized subunit (97). This interesting complementary approach of multisubunit and multipoint immobilization requires the use of very highly activated support.

54.11 MODULATION OF SELECTIVITY OF LIPASES BY USING DIFFERENT IMMOBILIZATION METHODS

Lipases undergo important conformational changes during their catalytic action even in fully hydrophilic environments: an equilibrium is established between the close inactive form and the open active counterpart (98). Lipase open and close structures exhibit very different conformations even in regions quite far from the active center. Thus, the immobilization of the same lipase using different methods (e.g. via rigidification of different regions, etc.) would determine the degree of exposure of the active center. Therefore, by using different immobilization protocols it may be possible to involve different lipase regions, altering the mechanism of opening of the lipase as well as the exact conformation of the open active center. In fact, it has been observed that by using very different lipases, different immobilized derivatives of the same lipase may display very different enantio-selectivity, (from 1 to 100 *R* or 100 *S*) when hydrolyzing racemic mixtures of different chiral ester substrates (98–103).

54.11.1 Reactivation of Immobilized Enzymes

Reactivation of partially inactivated enzyme derivatives permits a much longer reuse of an immobilized enzyme catalyst. The most sustainable enzyme processes are developed under relatively mild conditions (moderate temperatures, moderate pH values, presence of inert solvents or cosolvents, etc.). Under these conditions, the primary structure of the immobilized enzyme should remain fully inalterated (104). Slight distortions of the 3D structure of the immobilized enzyme should be the only cause of its inactivation. A simple reincubation of the partially inactivated derivative under very mild conditions (pH 7.0, 25°C) for long incubations (24 hours) may in some cases promote the near full recovery of the initial activity (105). Each immobilized biocatalyst could then be reactivated several times and its operational stability would be strongly increased. In other cases, reactivation may be more complex and activity recovery may be low. It is possible that responding to the conformational changes promoted by a distorting agent the enzyme structure iterates until it encounters a fairly stable incorrect configuration. It has been described that complete disruption of

incorrect enzyme structures can be achieved via incubation of inactivated enzyme derivatives in the presence of urea or guanidine. Then, the further reincubation of the random-coiled immobilized enzyme molecule may promote a rapid and correct refolding up to the fully active structure.

The above-mentioned reactivation strategies are better developed using covalently immobilized enzymes on hydrophilic and inert support surfaces. In that case, unfolded enzymes do not desorb away from the support, interactions between several unfolded enzyme structures are impossible and new interactions between the distorted enzyme and the support are avoided. In addition to its stabilizing effect multipoint covalent immobilization also favors the correct refolding of inactivated enzymes (105).

54.12 FUTURE PROSPECTS: IMMOBILIZATION OF ENZYMES ACTING ON INSOLUBLE SUBSTRATES

Hydrolysis of cellulose, starch, solid proteins and other insoluble substrates are very relevant topics in Enzyme Biotechnology. Currently, the use of lignocellulosic wastes for the production of clean and renewable energy sources is of increasing interest (106). The possibility of reusing hydrolytic enzymes for many reaction cycles would greatly improve the practical potential of these processes. Considering that enzymes immobilized on porous supports are unable to hydrolyze these insoluble substrates new alternatives are required:

54.12.1 Immobilization of Enzymes on Nonporous Magnetic Nanoparticles

These supports (30–100 nm of bead diameter) have a similar loading capacity than conventional porous supports (40–100 mg of enzyme per gram of catalyst). A range of magnetic nanoparticles coated with different structures (polystyrene, polyvinyl alcohol, etc.) are currently available and can be activated for ionic, covalent or affinity immobilization of industrial enzymes. Magnetic particles should be resistant to abrasion and they are easily handled by using a magnet. They can be used as a support for all the immobilization techniques commented herein. However, in addition to a profitable stabilization (e.g. by multipoint covalent attachment of enzymes on the nanoparticles), a correct orientation of the active center of the enzyme accessible to insoluble substrates is in this case strictly necessary. Hetero-funcional epoxy or glyoxyl supports could be therefore an interesting alternative to get rigidification of a given enzyme with different orientation on magnetic nanoparticles (107).

54.12.2 Use of DNA Hybridization as a Thermo-Reversible Immobilization Protocol

Conjugation of an enzyme with a DNA probe and immobilization of the complementary probe on one support may allow the recovery of the soluble enzyme at high temperatures (e.g. required for cellulose hydrolysis). At the end of the process temperature is lowered and the enzyme becomes immobilized on the support via DNA–DNA hybridization (108).

54.12.3 Immobilization of Enzymes on Smart Polymers

Smart polymers are soluble molecules that can be precipitated by an appropriate stimulus such as changes in pH, temperature, and so on. The immobilization of enzymes on smart polymers has been excellently reviewed by Roy and Gupta (109). There are natural and synthetic smart polymers (alginates, Eudragit, etc.). Perhaps the synthetic polymers are more suitable for practical use. Then, during a reaction the polymer could be kept in solution while the enzyme (e.g. xylanase) is acting on the insoluble substrate (e.g. xylan). At the end of the reaction, the enzyme is precipitated, the reaction mixture is filtrated, and the enzyme could be then reused for new reaction cycles in a soluble manner (110–112).

54.13 CONCLUDING REMARKS

In this chapter, different protocols for enzyme immobilization have been commented. Rather than an exhaustive description of every immobilization protocol, we have selected those that, in our opinion, are the more suitable for industrial implementation. In general, the main advantages and possibilities of each protocol have been remarked. In some cases, we have also proposed some protocols that may now be quite complex and expensive: the utilization of magnetic nanoparticles as supports for immobilization, the use of monoclonal antibodies as immobilized affinity ligands, and so on. However, on the basis of the recent great advances in nanotechnology and immunology it could be assumed that these protocols will become economic and technologically suitable within the next few years. The existence of several interesting immobilization methods allows us to select the most suitable support and the most suitable immobilization protocol for each application. Different immobilization protocols should be selected depending on: (i) the added value of the corresponding reaction product, (ii) the stability and selectivity of the soluble enzyme, (iii) the reaction conditions (e.g. to use very high substrate concentrations), (iv) the environmental requirements, and so on.

In recent years, advances in a number of sciences such as microbiology, molecular boilogy and metagenomics have contributed to the availability of improved soluble enzymes. We anticipate that with such readily available better enzymes, very simple immobilization protocols will be used. For example, a very simple commercial derivative of one lipase (from *Rhizomucor miehi*e) can be used for 2 years catalyzing the esterification of fatty acids. In this and similar cases, the cost of the immobilized biocatalyst is minimized and the further improvement of enzyme properties (stabilization, reactivation, reuse of the support, etc.) may not be necessary. The mechanical properties of the support may then become a more critical parameter than the enzyme stability. However, in many instances the improvement of enzyme properties during and after immobilization will be strictly necessary: more inexpensive, more intensive or more selective processes will be necessary: biodiesel synthesis, hydrolysis of cellulose, bioactive ingredients, chemically improved foods, and so on. In these cases the availability of stable enzymes, the development of strategies for immobilization–stabilization (e.g. multipoint covalent immobilization), the design of strategies for reactivation of partially inactivated immobilized enzymes, and so on, will be strictly necessary for a much more massive implementation of enzyme processes at an industrial level.

IMPELLER SELECTION, ANIMAL CELL CULTURE

Alvin W. Nienow
University of Birmingham, School of Chemical Engineering, Birmingham, United Kingdom

55.1 INTRODUCTION

As in all stirred bioreactors, the impeller(s) used in bioreactors for animal (mammalian or insect) cell culture have to be able to achieve a number of different tasks. These tasks are essentially describable in physical terms, all of which are related to the fluid motion imparted by the impeller(s). The tasks are listed in Table 55.1 and in order to obtain sufficient understanding of the link between impeller type and each task, they can initially be studied without the complexity of actually growing an organism. Such studies are very important if the impeller choice is to be made rationally. The type of information needed is listed in Table 55.2 and it is important to know how changes of scale affect these physical parameters too. Finally, it is also necessary to have as much information as possible on the characteristics of the biological species of interest. These biological aspects are listed in Table 55.3 and many of them can be evaluated at smaller scales, including shake and spinner flasks and microwell plates, especially if they are well instrumented. Others require work in stirred bioreactors, albeit at the bench or pilot scale. Given the right combination of small- and large-scale data in relation to the parameters listed in Tables 55.2 and 55.3, it then becomes possible to choose the appropriate impeller(s) and design the whole bioreactor. Impeller selection will now be considered on the basis of the special needs of animal cell culture. The selection applies equally well to both mammalian and insect cells.

55.2 THE MOST IMPORTANT ASPECTS IMPACTING IMPELLER SELECTION

For all microorganisms, the feature of greatest importance in determining the overall agitation conditions is the level of oxygen demand (OD). To meet this demand, oxygen has to be continuously supplied because of its limited solubility in the media. In the case of animal cells, the specific oxygen demand (SOD) is low (typical values of about $\sim 1 \times 10^{-17}$ to 1×10^{-16} mol/s/cell (2,3) and though the cell density, X, has steadily increased over the years to about 10^7 cells/mL, relative to many other organisms, the overall $\mathrm{OD} = (\mathrm{SOD} \cdot X)$ is also low. This low OD means that the oxygen transfer rate is low and therefore because it is linked to the specific power input from the agitator when aerated, $P_g/\rho V$, and the sparge rate, these two operating parameters are low too, typical values being $< \sim 0.05$ W/kg and $< 5 \times 10^{-3}$ vvm (2,3) to give $k_L a$ values $< 15 \mathrm{h}^{-1}$ (2,3). A corollary to meeting the OD is adequate stripping of CO_2, which must also be achieved by the same agitation and sparging conditions. This aspect is particularly important for cell culture and is discussed in more detail later.

The other critical and special feature of animal cell culture that has had an impact on agitator selection, and agitation and aeration intensity, is the perception that the cells are very "shear sensitive." This perception arises from the fact that these cells do not have a cell wall and that as a result they can be easily damaged. In the early days of commercial scale animal cell culture, it was believed that

B. Suitable temperature, pH, dO_2, pCO_2, and osmolality ranges.
C. Any product inhibition or sensitivity to high nutrient concentrations
D. Sensitivity to temporal and spatial variations in temperature, pH, dO_2, CO_2, osmolality, or nutrients.
E. Sensitivity to stresses due to turbulence and bubble rupture
F. Changes in D and E with changes in scale.

the cells would be most susceptible to stresses associated with agitation so that airlift and bubble columns were proposed as a replacement for stirred bioreactors because of the reduced level of "shear" (4). More recent work has shown that the stresses associated with bursting bubbles at the upper surface of the media are much greater than those associated with the fluid motion induced by the impeller. As animal cells tend to attach to the bubbles, these stresses are lethal to cells (2,5). However, with the addition of the polyol surfactant, Pluronic F68 (2,6,7), cells do not attach and damage is thus prevented. Hence, because of their enhanced flexibility compared to bubble-driven configurations, stirred bioreactors are now the preferred choice and a number of reactors with volumes up to 25 m^3 have been reported to have been built.

Taken together, the concern for cell damage and the need to only provide low oxygen transfer rates leads to the decision to use low agitation intensity and aeration rates in animal cell culture and this decision along with the search for a "low shear" agitator has essentially defined the agitator types used. In the remainder of this chapter, aspects of these special features of animal cell culture will be developed in more detail and their impact on the other physical and biological aspects listed in Tables 55.2 and 55.3 will be outlined in relation to impeller selection.

55.3 OXYGEN TRANSFER CONSIDERATIONS

For stable operation, the oxygen transfer rate needs to meet the OD or oxygen uptake rate (OUR) (1). Thus,

$$\mathrm{OD} = \mathrm{OUR} = \mathrm{OTR} = k_L a.\Delta C \qquad (55.1)$$

In Equation 55.1, ΔC is the driving force and represents the difference in oxygen concentration in the liquid phase (media) in equilibrium with the partial pressure of oxygen in the air bubble (allowing for back pressure or the use of oxygen-enriched air or even pure oxygen) and that in the bulk of the media. The latter oxygen concentration must be controlled to ensure that it lies within the range of concentrations at which the cells grow satisfactorily. This range (along with the SOD for the particular cell line) can be determined at very small scale with proper instrumentation.

The constant of proportionality, $k_L a$, is often called the *mass transfer coefficient*, though strictly k_L is the mass transfer coefficient and a is the specific surface area of bubbles in the media. However, these separate parameters are intimately connected, both being heavily dependent on the interfacial properties of the media and their impact on bubble breakup and coalescence. With the current state of knowledge, this dependence makes both the separate parameters and the combination impossible to predict. Hence, the combination, $k_L a$ [with units of $(\mathrm{time})^{-1}$], are usually measured. In practice, $k_L a$ is surprisingly difficult to determine experimentally and the reasons for this are set out in detail elsewhere (1). As a result, it has proved impossible to measure $k_L a$ sufficiently accurately to distinguish the efficacy of one impeller type compared with another with respect to oxygen transfer (1). Thus, starting with the work of Van't Riet (8), correlations of the form

$$k_L a = A(\overline{\varepsilon}_T)_g^{\alpha} v_s^{\beta} \qquad (55.2)$$

have become accepted and Hoeks *et al*. (9) showed the applicability of Equation 55.2 across the scales in 12, 500, and 20,000 L bioreactors using animal cell culture media. Here, $(\overline{\varepsilon}_T)_g$ (watts per kilogram) is the total mean specific energy dissipation rate imposed on the system, and v_s (meters per second) is the superficial air velocity which is equal to (vvm/60)(volume of broth)/(cross-sectional area of the bioreactor). $(\overline{\varepsilon}_T)_g$ is made up of that (i) from air sparging, $(\overline{\varepsilon}_T)_S \approx v_s g$, where g is the acceleration due to gravity (9.81 m^2/s) and which can often be neglected and (ii) from the impeller under sparged conditions, $(\overline{\varepsilon}_T)_{Ig}$, where

$$(\overline{\varepsilon}_T)_{Ig} = P_g/\rho V = Po_g N^3 D^5/V \tag{55.3}$$

and Po_g is the power number of the impeller under aerated conditions, N (per second) and D (meters), the impeller speed and diameter, respectively, and V (cubic meters), the volume of media in the bioreactor. The exponents in Equation 55.2 are typically about 0.5 ± 0.1 independent of the system of interest. On the other hand, A is extremely sensitive to composition and the addition of antifoam or Pluronic F68 both of which lower k_La or salts which increase it, may lead to a 20-fold difference in k_La for the same values of $(\overline{\varepsilon}_T)_g$ and v_s (1). A recent attempt to mimic a media (which included sodium chloride, sodium bicarbonate, and 1 g/L Pluronic F68) used in industry for Chinese hamster ovary (CHO) cell culture at 3000–4400 L volume with a pipe sparger (3) led to the following correlation for k_La

$$k_La = 0.075(P_g/V)^{0.47} v_s^{0.80} \tag{55.4}$$

where the mean specific energy input is used, P_g/V (watts per cubic meter) and

$$P_g = Po_g \rho N^3 D^5 \tag{55.5}$$

Since Equation 55.4 was obtained under conditions that closely mimic those used under realistic large-scale culture, it may be a good one to use if information is not available for the precise cell culture under consideration.

Overall, $(\overline{\varepsilon}_T)_g$ (or the equivalent in watts per cubic meter) and v_s must together be sufficient to produce the necessary k_La to meet the OD of the cells while maintaining the dO_2 concentration in the media in the desired range. However, Equations 55.3 and 55.4 both suggest that the choice of impeller is largely confined to ensuring that whichever is chosen, it is of sufficient size and aerated power number and is run at a speed that will enable the power input to be generated to achieve the required k_La.

55.4 "SHEAR SENSITIVITY" TO IMPELLER-GENERATED FLUID DYNAMIC STRESSES

55.4.1 Reynolds Number, Power Number, and Flow Patterns

As in all fluid flow situations, both laminar and turbulent flow can exist in a bioreactor. In turbulent flow, inertial forces dominate and in laminar flow, viscous ones. Conceptually the ratio of these two forces is the Reynolds number (Re). For a bioreactor with a media of viscosity, μ, (or kinematic viscosity, $\nu(=\mu/\rho)$), the Reynolds number is defined as

$$Re = \rho N D^2/\mu = N D^2/\nu \tag{55.6}$$

If $Re > \sim 2 \times 10^4$, the flow is turbulent and even with the relatively gentle agitation found in cell culture bioreactors, it is in all sizes from the bench scale to the industrial scale. Under unbaffled conditions, the main flow will be totally dominated by horizontal rotational flows (swirling flow) with a central vortex (Fig 55.1). Under the gentle conditions found in cell culture bioreactors, the vortex depth will be small. In addition, the presence of inserts such as dO_2 probes will tend to damp out the swirl and reduce the vortex but the flow will still approximate that shown in Fig 55.1 whichever impeller is chosen. Under these conditions, there is poor vertical mixing so that homogenization of the media takes a relatively long time, the power input is limited, and solids such as microcarriers are more difficult to suspend.

Introducing baffles overcomes these problems. Also, once baffles have been introduced, the flow pattern is dependent on the agitator type. The impellers (Fig 55.2) are usually described as axial, producing a mainly vertically downward flow approximately parallel to the agitator shaft (Fig. 55.2a) as with the Chemineer HE3 (Chemineer Inc., Dayton, Ohio) (Fig. 55.3a) or radial, giving horizontal flow and a figure-of-8 flow pattern (Fig. 55.2b) as with the Rushton turbine (Fig. 55.3b). Some impellers produce a flow somewhere between the two (Fig. 55.2c) and are called *axial flow* or *pitched blade turbines* (Fig. 55.3c). The power drawn by the impeller and imparted into the media, P (watts), can be determined from the power number, Po:

$$Po = P/\rho N^3 D^5 \tag{55.7}$$

It is of critical importance for the mechanical design of shafts, gear boxes, seals, and so on, and for sizing drive motors, which must be $> P$ to allow for friction

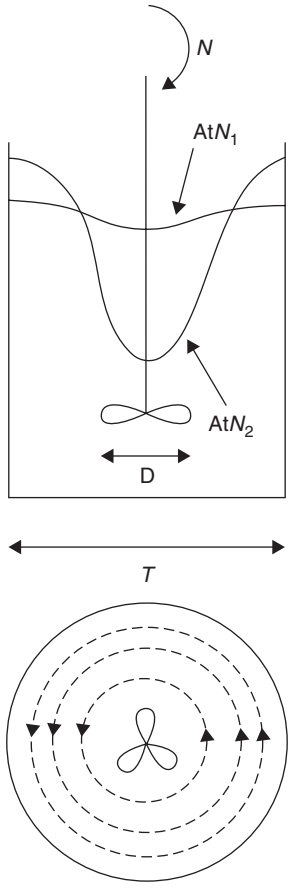

Figure 55.1. Flow patterns in an unbaffled cylindrical bioreactor, diameter T. ($N_1 < N_2$).

and energy losses in the motor, gear box, bearings, seal, and so on. Specific power based on the volume of media in the bioreactor, that is *P/V* (kilowatts per cubic meter) or *P/M* (watts per kilogram) is also used extensively to compare impeller performance. The latter is equivalent to the mean specific energy dissipation rate, $\overline{\varepsilon}_T$ (watts per kilogram or square meter per cubic second) in theoretical analysis of many phenomena in bioreactors and in scale-up considerations. *Po* is dependent on the impeller type and on its relative size, *D/T*, position in the tank, *C/T*, and so on, and impeller material thickness but in the turbulent region ($Re > \sim 10^4$), Po = constant, independent of *Re*. Most importantly, for geometrically similar systems (all length dimensions changed proportionally), it is essentially independent of scale.

55.4.2 High/Low "Shear" Impellers and Impeller Tip Speed

Another dimensionless group that can be used to characterize impellers is the flow number, $\mathrm{Fl} = Q/ND^3$, where Q is the volumetric flow rate of fluid generated by the impeller (10). Publications starting around the 1960s introduced the concept of considering impellers as having high "shear" or high flow characteristics based on the ratio of *Po/Fl*. Since flow numbers do not change very much, typically being between about 0.4 and 0.9 while *Po* values vary for agitators commonly found in bioreactors by a factor of about 20 (Table 55.4), it is essentially only *Po* that determines whether *Po/Fl* is high or low. Impellers with relatively high values of *Po* are often called *high shear impellers* while those with low values are considered *low shear ones*, especially by mixer manufacturers. The impeller most commonly called high "shear" whether in relation to cell culture or other purposes, for example the manufacture of oil in water dispersions with small oil drops, is the Rushton turbine, $Po = \sim 5$. Because of the perceived "shear" sensitivity of animal cells, therefore, the Rushton turbine has generally not been used for cell culture. Yet, that impeller was used successfully from the late 1960s to the mid-1980s in a bioreactor of 8 m^3 for the production of interferon from CHO cells at Wellcome Foundation (11). It also gave identical results to those obtained with a propeller agitator ($Po = \sim 0.3$) when used for growing a range of cell types

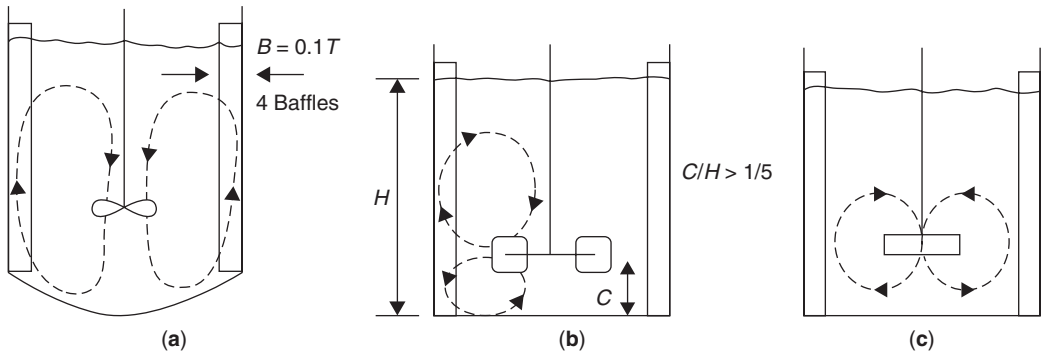

Figure 55.2. Flow patterns produced in an unaerated cylindrical baffled bioreactor by (a) down-pumping axial flow propellers or hydrofoils; (b) radial flow Rushton turbines; and (c) pitched blade or axial flow turbines.

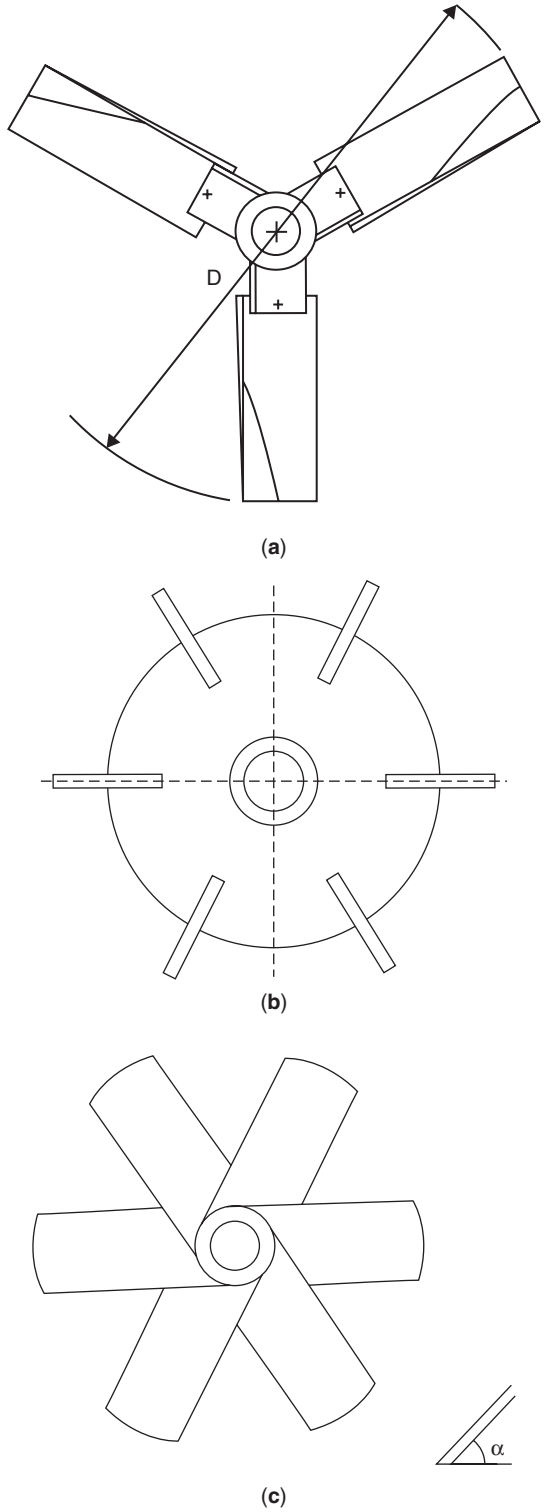

Figure 55.3. Different impeller types: (a) Chemineer HE3 (axial; "low shear"; $Po = \sim 0.3$); (b) Rushton turbine (radial; "high shear"; $Po = \sim 5.0$); (c) pitched blade turbine ($Po = \sim 1.7$, $\alpha = 45^\circ$).

TABLE 55.4. Power Numbers and Flow Numbers for Some Impellers in the Turbulent Regime in Baffled Bioreactors

Impeller Type	Shear Designation	Power Number	Flow Number
Rushton turbine	High shear	~5.0	~0.74
Chemineer HE3 hydrofoil	Low shear	~0.3	~0.41
6-blade, 45°-pitch turbine	Intermediate	~1.7	~0.73
Lightnin' A315 hydrofoil	Low shear	~0.84	~0.73
Applikon "Elephant ears"	Low shear	~1.7	~0.87

at the University of Birmingham (2) and also recently at Schering-Plough (12) for growing CHO cells to produce antibodies. It is also interesting to note that so-called low "shear" impellers cause greater disruption to mycelia than high "shear" Rushton turbines (13) and also produce smaller drops (14).

Another traditional way of considering the possibility of "shear" damage is to relate it to impeller tip speed which is equal to πND. For example, it has been stated (4) that "above 1.5 m/s, cell damage may begin." However, this statement was made without any referenced work to support it and from a fluid dynamic perspective, the dimensions of tip speed are not correct in relation to damage, and there is little or no evidence to support it (2). In addition, and somewhat strangely, the concept also suggests that the potential for "shear" damage increases with the use of low "shear" impellers if $(\overline{\varepsilon}_T)_I$ is held constant to maintain k_La! For similar reasons, it leads to the concept that "shear" damage increases with scale because tip speed increases with scale ($\propto$ (scale)$^{1/3}$) (10). Thus, maintaining tip speed $<$1.5 m/s is a major constraint on scale-up with severe implications for homogeneity (see below) as well as mass transfer. Indeed, in only one case has mechanical damage been clearly shown to occur under "normal" operating conditions of agitation intensity with any microorganism and that is in mycelial fermentations. Here, at equal $\overline{\varepsilon}_T$, that damage went down on scale-up in spite of the increase in tip speed (13). On balance, both tip speed and the low/high "shear" impeller concepts appear less than useful.

55.4.3 Kolmogoroff Eddy Size Concepts

Kolmogoroff's theory of homogeneous isotropic turbulence has been used extensively to predict the interaction between the turbulent structure of a flow in any type of equipment and its impact on dispersed entities. The equipment covered includes in-line static mixers, pipe flow as well as stirred vessels and the topics include the breakup of immiscible drops, bubbles, and flocs as well as damage to cells. More details can be found elsewhere (2,10). A critical feature of the theory is the Kolmogoroff or microscale of turbulence, λ_K, where

$$\lambda_K = ((\varepsilon_T)/\nu^3)^{-1/4} \tag{55.8}$$

where ε_T is the local specific energy dissipation rate in the flow and ν is the kinematic viscosity ($\approx 10^{-6}\text{m}^2/\text{s}$ for the cells suspended in media since the latter is water like). The mechanism of breakup depends on whether the dispersed entity is greater than or lesser than λ_K. Similarly, it is considered that if the cell of interest, in this case the animal cell, is $< \lambda_K$, damage due to flow associated stresses will not occur.

For all agitators, the maximum local specific energy dissipation rate, $(\varepsilon_T)_{\text{Imax}}$, is close to the impeller and is very high relative to the average $(\overline{\varepsilon}_T)_{\text{I}}$. However, most importantly, in relation to impeller selection, it also depends on the agitator type and probably its relative size, *D/T*. A typical example of the distribution of $(\varepsilon_T)_{\text{I}}/(\overline{\varepsilon}_T)_{\text{I}}$ where $(\varepsilon_T)_{\text{I}}$ is the local specific energy dissipation rate is shown in Fig 55.4, measured by laser Doppler anemometry (LDA). As can be seen, $(\varepsilon_T)_{\text{I}}/(\overline{\varepsilon}_T)_{\text{I}}$ varies enormously throughout the vessel (15). It is interesting to note that baffles were often excluded from animal cell culture bioreactors, again because of the perception that they would give rise to a region of high "shear." However, as can be seen in Fig 55.4, there is no indication that $(\varepsilon_T)_{\text{I}}/(\overline{\varepsilon}_T)_{\text{I}}$ increases in the region of the baffles. Their use is now not uncommon.

Table 55.5 shows some values of $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$ for some other impellers covering both a "high" and a "low" shear impeller and a pitched blade turbine. As can be seen, the values are a strong function of *D/T* with all types, those of the low shear Chemineer HE3 being quite similar to those of the Rushton turbine while those with the pitched blade turbine are somewhat lower. It should be recognized that to obtain $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$ requires certain assumptions to be made and considerable numerical manipulation of the raw LDA data and hence the absolute numbers should not be considered to be exact. In fact, values of $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$ from about 20 to about 100 have been reported just for 1/3 *D/T* Rushton turbines (10). However, Table 55.5 certainly does not suggest that the "low shear" Chemineer HE3, even though it has the lowest *Po*, is superior to the Rushton impeller. On the other hand, there is a strong indication that a larger *D/T* ratio minimizes $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$.

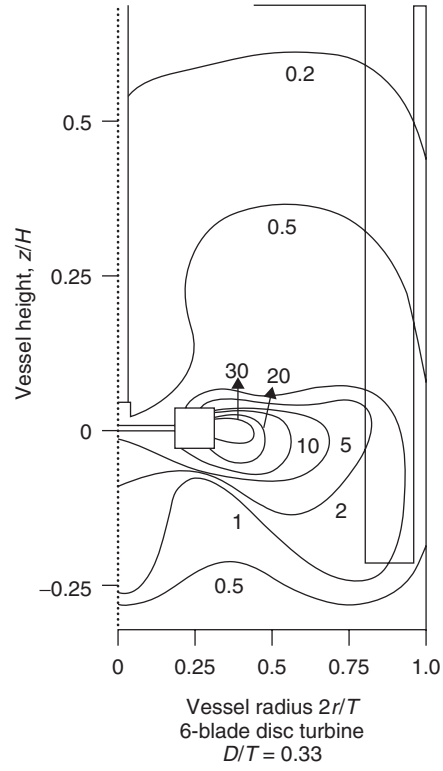

Figure 55.4. Contours of $(\varepsilon_T)_{\text{I}}/(\overline{\varepsilon}_T)_{\text{I}}$ in a vessel agitated by a Rushton turbine (15).

Since the value of $(\overline{\varepsilon}_T)_{\text{I}}$ must be set to give sufficient oxygen transfer whatever the agitator type following Equation 55.2, then the greater $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$, the greater will be the $(\varepsilon_T)_{\text{Imax}}$ value experienced by the cells. If a typical value for $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$ from Table 55.5 of 50 is taken for the commonly used *D/T* ratio of 1/3 along with the typical $(\overline{\varepsilon}_T)_{\text{I}}$ of 0.05 W/kg, then $(\varepsilon_T)_{\text{Imax}} = 2.5\text{W/kg}$ and from Equation 55.8, $\lambda_K = 25\ \mu\text{m}$. Since most animal cells are of the order of $14 - 18\ \mu\text{m}$ which is $< \lambda_K$, the lack of "shear damage" fits in with the Kolmogoroff eddy size concept. However, of course, it does not prove it.

Unfortunately, $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$ has not been measured for many impellers. In that case, it has been estimated

TABLE 55.5. Values of $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$ for Various Impellers as a Function of *D/T* (16)

Impeller Type	Shear Designation	*D/T*	$(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}}$
Rushton turbine	High shear	1/4	~147
		1/3	~48
		1/2	~23
Chemineer HE3 hydrofoil	Low shear	1/4	~135
		1/3	~99
		1/2	~14
6-blade, 45°-pitch turbine	Intermediate	1/4	~66
		1/3	~37
		1/2	~16

$(\overline{\varepsilon}_T)_{\text{I}} = P/\rho V = PoN^3D^5/V$

successfully when applying Kolmogoroff's theory to the breakage of immiscible drops by assuming that the power input was dissipated in the impeller swept volume, V_{swept}, that is $(\varepsilon_T)_{\text{Imax}}/(\overline{\varepsilon}_T)_{\text{I}} = P/\rho V_{\text{swept}}$ (10). This approach also suggests that the selection of a large D/T impeller would be beneficial in that it would lead to lower values of $(\varepsilon_T)_{\text{Imax}}$ for a given $(\overline{\varepsilon}_T)_{\text{I}}$. Another approach is to compare the impellers on the basis of turbulent kinetic energy which is easier to measure and is closely related to specific energy dissipation rate. This comparison has recently been done using particle image velocimetry (PIV). The impellers studied were an "elephant ears" impeller (Fig. 55.5a), which is currently being extensively used in industrial cell culture (17) because it is claimed to be a particularly low "shear" one, an up-pumping Hayward-Tyler B2 (Fig. 55.5b) (which is also designated a low "shear" impeller) and a pitched blade turbine. The work showed that essentially their turbulent kinetic energy characteristics (which mirrors ε_T) were all the same (18).

55.4.4 Energy Dissipation Rates and Cell Culture Performance with Different Impeller Types

There have also been some actual studies where the impact of specific energy dissipation rate on cell growth and other bioperformance parameters was measured. Work at Birmingham, first published in 1989 and recently summarized (2), showed that even at $(\overline{\varepsilon}_T)_{\text{I}}$ values up to 0.25 W/kg, a range of mammalian (TB/C3 mouse hybridomas, HPV cells producing antibodies, and CHO cells producing γ-interferon) and insect cell (Sf9 insect cells producing viruses) lines grew quite satisfactorily (same number of viable cells per ml and productivity) compared with culture at a typical industrial value of 0.01 W/kg both under unsparged and sparged conditions, the latter provided Pluronic F68 was present. These findings were obtained in bench-scale bioreactors up to ~5 L whether "low shear" propeller or "high shear" Rushton turbines were used. Another interesting experiment during these studies involved the removal of baffles. Removal reduced $(\overline{\varepsilon}_T)_{\text{I}}$ fivefold compared with the baffled case where satisfactory growth occurred without sparging. At the highest speed employed of 400 rpm, severe vortexing occurred, which led to air entrainment followed by bubbles bursting as it disengaged. The bursting bubbles caused cell damage, though it could be eliminated by the addition of Pluronic F68, as with normal sparging.

Meier (19) reported that at Genentech, Rushton turbines, Lightnin' A320s (Lightnin', Rochester, New York) and ABEC "Elephant ear" impellers (ABEC Inc., Bethlehem, Pennsylvania) had all been used successfully at $(\overline{\varepsilon}_T)_{\text{I}}$ values up to 0.1 W/kg at the industrial scale. Sandadi *et al*. (12) had equal success producing antibodies from CHO cells at Schering-Plough with a Rushton turbine and a propeller at 0.018 W/kg at the 30-L scale.

55.4.5 Studies in Other Configurations and a Comparison with Cell Strength

It is worth just briefly summarizing work characterizing cell strength and other studies as they impact on the question of impeller selection. The mechanical properties have been measured extensively by Thomas and Zhang using micromanipulation (20) and on the basis of these measurements, they have successfully predicted when lethal damage should occur under turbulent flow conditions (21). With

TB/C3 hybridoma and NS1 myeloma cells in turbulent flow through capillary tubes, ($\overline{\varepsilon}_T$) values as high as $10^5 - 10^6$ W/kg were predicted and shown to be required to totally disrupt the cells.

For some time, Chalmers and coworkers have been passing cells under laminar flow conditions through an extensional flow chamber particularly looking for nonlethal effects associated with mechanically generated stresses on protein product quality, especially with respect to glycosolation. In their most recent study, CHO cells were grown in a 2-L fed-batch process (22). During the 14-day run, a suspension of cells was continuously removed from the bioreactor and pumped through the device at ($\overline{\varepsilon}_T$) values from 60 to 6000 W/kg. They compared the results with those found with circulation but without the flow device. For all these ($\overline{\varepsilon}_T$) conditions, they monitored viability, cell size, necrosis, and apoptosis (using flow cytometry), LDH, glucose metabolism, molecular weight distribution, methionine oxidation, charge distribution, and glycosolation. For all the parameters measured except glycosolation and at all ($\overline{\varepsilon}_T$) values except the highest of 6000 W/kg, the control and the flow chamber gave the same results. In the case of glycosolation, a pattern shift was observed, though somewhat strangely, it was the same at all ($\overline{\varepsilon}_T$) values. A similar study with NSO cells did not show any effects at ($\overline{\varepsilon}_T$) = 300 W/kg. As can be seen, all the ($\overline{\varepsilon}_T$) values used in this study are orders of magnitude greater than those currently being used or likely to be used in the foreseeable future for animal cell culture even with increasing cell density. These results essentially fitted in with all the previous papers from Chalmers group that used the flow device.

55.4.6 Conclusions

Overall, these studies strongly suggest an excessive concern for agitator-generated stresses in animal cell culture processes; and that they should not be of importance for agitator selection. It is also worth noting that though $(\overline{\varepsilon}_T)_{\mathrm{Imax}}/(\overline{\varepsilon}_T)_{\mathrm{I}}$ is dependent on agitator type and size as shown in Table 55.5, it is independent of scale. Therefore, the possibility of stress sensitivity of a cell line at the large scale can be assessed by using geometrically similar impellers at appropriate $(\overline{\varepsilon}_T)_{\mathrm{I}}$ values at the bench scale.

55.5 OTHER PARAMETERS DEPENDENT ON AGITATION AND BIOREACTOR CONFIGURATION: IMPLICATIONS FOR IMPELLER SELECTION

55.5.1 Homogeneity

Under turbulent flow conditions, the time required to homogenize the contents of a bioreactor, the mixing time, θ_m (s), is related to agitation parameters by (10):

$$\theta_{\mathrm{m}} = 5.9(\overline{\varepsilon}_T)_{\mathrm{g}}^{-1/3}(D/T)^{-1/3}T^{2/3} \qquad (55.9)$$

for bioreactors for $H = T$. For bioreactors with an aspect ratio (2,10) AR($= H/T$) > 1, then

$$\theta_{\mathrm{m}} \propto (H/D)^{2.43} \qquad (55.10)$$

The applicability of Equations 55.9 and 55.10 has been demonstrated in an 8 m^3 animal cell culture bioreactor of different ARs from 0.3 up to 1.3 with a single impeller working in the draw and fill mode (2). The work covered a "high shear, low flow" Rushton turbine and a low "shear, high flow" Lightnin' A310 hydrofoil ($Po = \sim 0.30$) (Fig. 55.6a), each of $D/T = \sim 0.23$. As predicted from Equation 55.9, equal mixing times were obtained. Thus, both "high/low shear" and "high/low flow" concepts in relation to impeller selection are generally misleading. However, to demonstrate the validity of Equation 55.9 under simulated culture conditions, it was shown that, though not reported to have been used for cell culture, a larger *D/T* Intermig impeller ($D/T = \sim 0.4$, $Po = \sim 0.35$) (Fig. 55.6b) gave a slightly shorter mixing time (2). [in passing, it should be noted that the Intermig impeller is not appropriate in high oxygen demanding fermentations, especially viscous ones, because they often give rise to severe equipment vibrations when aerated under high agitation and aeration rates (10)].

Equation 55.9 clearly shows that if $(\overline{\varepsilon}_T)_{\mathrm{I}}$ is held constant under conditions of geometric similarity across the scales, the mixing time increases significantly with $T^{2/3}$(or (linear scale)$^{2/3}$) and Equation (55.10) shows its great sensitivity if fill height is increased. Large increases in AR with scale are common with fermentations involving other microorganisms, and for such cases multiple impellers are used, typically dual wide-blade, high solidity ratio (plan area of impeller blades/area of circle swept out by blades as they rotate), axial flow impellers. Examples of such impellers are the Lightnin A315 (Fig. 55.6c) or Hayward-Tyler B2 (Hayward-Tyler plc, East Kilbride, Scotland) and they are preferred because they reduce mixing times by a factor of ~ 2 compared with radial flow impellers.

Often, the absolute value of the mixing time, *per se*, is not so important. It is the trend for θ_{m} to get longer with scale and height, which means cells will experience greater temporal or spatial differences on scale-up of the parameters listed in Table 55.3, line D such as dO_2 (3) compared with the bench scale. The variations in dO_2 are also dependent on the OUR of the culture and the k_La and can be analyzed via regime analysis (2). With batch systems, pH problems are enhanced with the tendency on the larger scale to use more concentrated chemicals to reduce the quantities to be sterilized and by the tendency to add them to the top surface

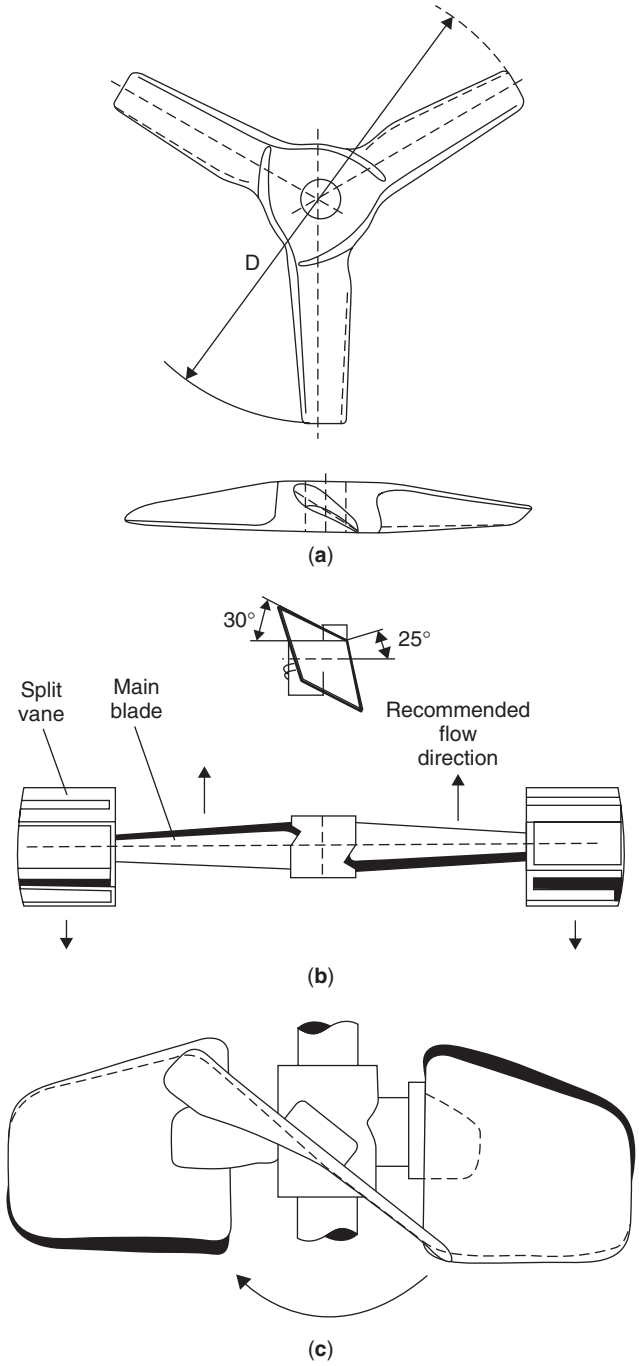

Figure 55.6. Some other impellers: (a) a Lightnin A310 impeller; (b) an Ekato Intermig impeller (Ekato, Schopfheim, Germany); (c) a Lightnin' A315 impeller.

of the media. With fed-batch operation, the need to add both pH control chemicals and nutrients to a surface, which may be a long way above the agitator as the bioreactor fills, only increases the problem (3). So far only the damage due to large spatial and temporal pH excursions from the mean has been clearly shown to exist and produce a reduction in performance in animal cell culture bioreactors. These points are discussed in detail elsewhere (2).

With respect to agitator selection and an operation strategy to help this inevitable loss of spatial and temporal homogeneity, it is suggested that dual axial flow impellers should be used. In addition, *H/T* should be ~1. Subsurface feeding of pH chemicals and nutrients during fed-batch operation is also recommended. Since that mode of operation is often objected to because of concerns for sterility, it has been shown that directing the feed at the surface where the discharge from an up-pumping impeller impacts is helpful in maximizing the rate of incorporation of the additive (23).

55.5.2 Aerated, P_g, and Unaerated, P, Power Input from the Agitator

These two aspects have already been discussed in some detail. However, the connection between them has not. In bioreactors with most other organisms (bacteria, yeast, mycelia) typical aeration rates are of the order of 1–2 vvm with power inputs between about 1 and ~5 W/kg from the impeller. These conditions are required to meet the much greater OD. In such cases, if the agitator speed is not fast enough the air is not dispersed and the system is flooded. It is important to avoid this condition and ensure that the system is loaded, that is the flow pattern is controlled by the agitator (Fig 55.7), if efficient mass transfer is to be achieved. Also, with most agitators, P_g/P is <1, often <0.5 and the relationship between the two is a complex function of impeller speed and aeration rate and depends on the agitator type. Because of their importance to these high oxygen demanding fermentations, aerated power draw and flooding–loading relationship is a critical consideration in impeller selection.

For insect and mammalian cell culture, such considerations are essentially unimportant. At the agitator speeds employed to give the desired power input to achieve adequate mass transfer, most of the dispersion is provided by the sparger and the impeller provides little or no additional effect. As a result, gas cavities do not form behind impeller blades (2) and the air passes through the impeller without significantly affecting the flow pattern close to the agitator; and $P_g \approx P$ and $Po_g \approx Po$ (2). Therefore, at present, this factor is unimportant for impeller selection for cell culture.

55.5.3 Heat Transfer

The OUR is very low compared to fermentations with other organisms. As a result, since the metabolic heat release Q_H (W/m^3) is proportional to the OUR (mol $O_2/m^3/s$) (24), that is,

$$Q_H = \sim 4.6 \times 10^5 \text{ OUR} \qquad (55.11)$$

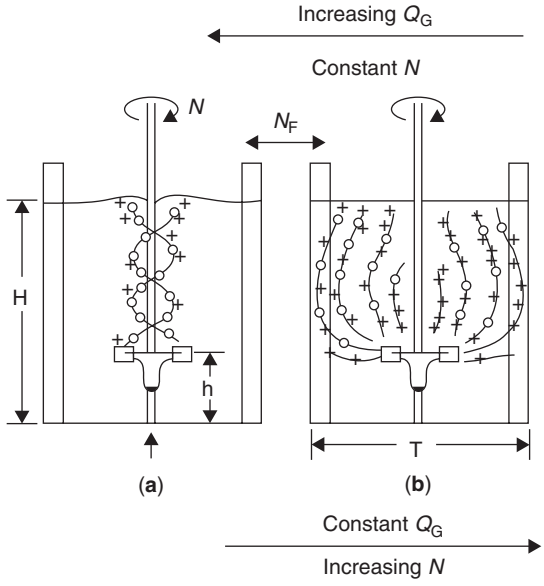

Figure 55.7. The flooding–loading transition with a radial flow impeller.

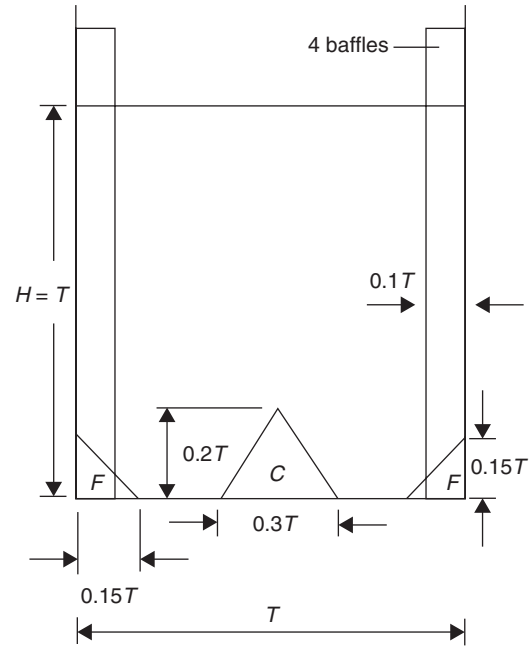

Figure 55.8. Modifications by the addition of a corner fillet (F) and a central cone (C) to a flat-based bioreactor to enable solids to be suspended at lower $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$ (the inverted cone can be used alone in a dished base). With this configuration, $C/T = 0.25$.

Thus, Q_{H} for animal cell culture is also relatively low. With other organisms, this cooling load at the commercial scale is often a problem as Q_{H} scales with the volume of the reactor, that is T^3, while cooling surface area scales with T^2. Hence, for such systems, cooling coils are often required. However, with animal cell culture bioreactors, simple cooling jackets are sufficient for good temperature control. In addition, agitation has little impact on overall heat transfer, though larger D/T ratios give a higher velocity at the inner surface of the bioreactor for a given $(\overline{\varepsilon}_T)_{\mathrm{I}}$ and hence they maximize the inner film heat transfer coefficient.

55.5.4 Microcarrier Culture

For adherent animal cells to be grown in large quantities in bioreactors, microcarriers are used. These are usually of the order of $150 - 200$ μm, either solid or macroporous, to give a large surface area for cell growth to enable a high cell density to be achieved. The most common ones commercially are Cytodex microcarriers with a density just greater than water (for Cytodex 3, it is 1040 kg/m^3). For the microcarriers to work efficiently, they must be fully suspended so that all of their surface area is available for cell growth. However, few of the papers on microcarrier culture have used impeller/vessel configurations that achieve suspension at low values of $(\overline{\varepsilon}_T)_{\mathrm{I}}$. In addition, all of the concerns discussed above with respect to oxygen transfer, homogenization and "shear" sensitivity also have to be considered once again.

The minimum agitator speed that keep the microcarriers suspended, N_{js}, and associated mean specific energy dissipation rate, $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$, are very sensitive to agitator type and precise vessel configurations. The use of a bioreactor with a hemispherical base has been recommended but in fact such a shape is not at all suitable if microcarriers are to be suspended at low values of $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$ in order to minimize the potential for damage to the cells growing on them. The presence of baffles is also important to avoid the swirling motion shown in Fig 55.1 and aid suspension (an off-center or angled impeller mounting without baffles might achieve the same effect on the small scale but it is mechanically not advisable at the industrial scale). A very efficient combination is to use an impeller such as the Chemineer HE3 (Fig. 55.6a) with a contoured base as shown in Fig 55.8. With this combination using D/T ratios from 0.44 to 0.35 at $C/T = 0.25$, it was possible to suspend Cytodex 3 microcarriers at $(\overline{\varepsilon}_T)_{\mathrm{Ijs}} <\sim 0.0005$ W/kg, though it took some time for full suspension to be reached. Even without the fillets and the flat base, $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$ was only a little higher (25). Thus, just placing a cone at the center of the dished base found in cell culture reactors would be expected to significantly lower $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$.

The reason for the desire to achieve such low values of $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$ is because it has been reported that cells on microcarriers are more sensitive to mechanical stress than when they are in free suspension (26,27). Thus, it has been suggested (26) that $(\overline{\varepsilon}_T)_{\mathrm{I}} < 0.001$ W/kg to avoid damage. This greater sensitivity is not unreasonable for two reasons. First, even at this $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$, λ_K is still only $\sim$180 μm and therefore less

than the size of many microcarriers so that cells on their surface might be damaged by turbulent eddies. Secondly, because of their size and density compared to free cells, microcarriers which are typically present at concentrations of about 5–15% of total culture volume may impact with each other or with the impeller. Such a problem is found with secondary nucleation with crystals in stirred reactors (28). Such impacts may damage cells directly or by dislodging them from the microcarrier surface. It has also been suggested that air bubbles may also dislodge cells from them.

The precise sensitivity of cells to damage on microcarriers is not well established. To reduce the possibility of damage by turbulent eddies or impacts, macroporous carriers where the cells may grow in the pores have been developed. In addition, reducing microcarrier size helps significantly to reduce damage by any mechanism. However, once a microcarrier is selected, if small-scale tests with the geometry suggested here (or with a similar down-pumping hydrofoil such as a Lightnin' A310 or even possibly an A315) show that cells can be grown successfully, since $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$ falls with increasing scale, then damage due to agitation should become less likely on scale-up.

Of course, it is quite possible that such low levels of $(\overline{\varepsilon}_T)_{\mathrm{I}}$ will cause oxygen transfer and homogenization concerns, though it can be easily increased by raising the agitator speed, and feeding into the impeller zone can enhance homogenization. However, these issues do not appear to have been addressed in the open literature. Therefore, choosing a geometry such as that recommended here that minimizes $(\overline{\varepsilon}_T)_{\mathrm{Ijs}}$ while ensuring higher speeds and $(\overline{\varepsilon}_T)_{\mathrm{I}}$ values can be obtained probably offers the best approach to culture on microcarriers at the present time.

55.6 IMPORTANT PARAMETERS NOT RELATED TO IMPELLER SELECTION

These are some very important issues in animal cell culture that are not associated with impeller selection but are worthy of a brief mention. They are discussed in more detail elsewhere (2).

55.6.1 Bubble Burst Phenomena

Bursting bubbles produce local specific energy dissipation rates up to $\sim 10^4$ to $\sim 10^5$ W/kg, with bubbles of 2 and 1 mm diameter, respectively. As stated earlier, Pluronic F68, as a result of preventing cell attachment is able to prevent damage in spite of these huge values. Nevertheless, since the impellers in animal cell culture bioreactors do not increase significantly bubble dispersion above that achieved by the sparger and the OD is relatively low, there is little need to produce such small bubbles anyway. However, it has been shown that if cell damage does occur, increasing the AR of a bioreactor reduces the proportion of the media in which it takes place (2). If a higher AR is chosen, the use of a second agitator becomes increasingly important at the commercial scale to minimize the increase in inhomogeneities.

55.6.2 pH, pCO_2, and Osmolality

pH, pCO_2 and osmolality are very important issues in animal cell culture. Under normal sparging conditions, impeller selection has no impact on CO_2 stripping rates since essentially the appropriate version of Equations 55.2 and 55.4 should apply and the k_La for O_2 transfer in and CO_2 out are approximately equal. However, largely because of the perception of shear sensitivity and bubble damage at the high superficial gas velocities implied by constant vvm scale-up, the OD at the large scale has often been met by increasing either a (and hence k_La) by producing small bubbles by sintered spargers or by enhancing ΔC by using oxygen-enriched air or a pure oxygen bleed. All these actions often lead to sparge rates that are unable to strip out the CO_2 produced at a respiratory quotient $\approx$1. As a result, pCO_2 may build up to levels $>\sim$150 mmHg, especially at the current largest scale being used ($\sim$20 m^3) at the cell densities ($\sim 10^7$ cells/mL) being achieved. As a result, pH falls, alkali must be added and osmolality increases. The low sparge rate and higher CO_2 level at the 5000 L scale has recently been considered to be one of the main reasons for the lower cell density achieved compared with those at the 5 and 20 L scale (3).

It is hoped that this discussion on the overreaction to the sensitivity of freely suspended animal cells to mechanical stresses associated with agitation and sparging will help reduce these approaches to scale up to meet the OD of the cells as they produce more problems than they solve.

55.7 SELECTION OF IMPELLER/GEOMETRY, SCALE-UP, AND OPERATIONAL STRATEGY

55.7.1 Free Suspension Culture

From the above analysis of the tasks required to be fulfilled by impeller(s) when undertaking animal cell culture and the special features involved in undertaking it, it can be concluded that many different impeller types could be used successfully. Indeed, many different types have been reported to have done so even at the commercial scale; Rushton turbines (2,12,19,29), Lightnin' A320s(19), propellers (3,12), and "elephant ear" impellers (19). This success is hardly surprising since it has been shown that both with respect to lethal (2,20) and sublethal (2,22) effects, animal cells

are much more robust (21) than their initial designation of "shear-sensitive" implied. It has also been shown here that the concept of "low" and "high shear" impellers is misleading. However, it is still possible to indicate which impeller(s) and associated geometry are likely to prove the most suitable. It is also important to point out that for ease of scale-up, the use of geometrically similar configurations at the different scales is recommended, especially if basic data like specific OUR for the particular cell line are not known. The relationships for the physical parameters that define the "mixing" conditions are much easier to match or determine across the scales if geometric similarity is followed.

Overall, based on the earlier analysis, the following general guidelines for the selection of impeller(s) and geometrically similar vessel geometry across the scales are recommended:

1. One of the major problems of scale-up in all bioprocessing is the decreasing homogeneity associated with increasing scale (Eq. 55.9) and vessel AR (Eq. 55.10). Because of the very low $(\overline{\varepsilon}_T)_{\mathrm{Ig}}$ value required to provide the k_La to meet the OD (Eq. 55.2), this issue is particularly significant in animal cell culture. Therefore, it is important to keep the vessel AR to a value $<\sim 1.3$.
2. Also for the best homogeneity for a given $(\overline{\varepsilon}_T)_{\mathrm{Ig}}$, use baffles (preferably four but three or even two are much better than none!). The use of baffles also ensures that if Po for the chosen impeller is known (and since at the low sparge rates used, Po_g can realistically assumed to be equal to Po), the speed to give $(\overline{\varepsilon}_T)_{\mathrm{Ig}}$ required for mass transfer can be calculated (Eq. 55.3).
3. Use subsurface feeding of pH control chemicals and nutrients if fed-batch operation is involved (2,29) to minimize spatial and temporal concentration variations. If concentration variations remain a problem, consider use of more dilute feeds (30).
4. Use dual, up-pumping, wide-blade axial flow hydrofoil or "elephant ear" impellers diameter of 0.4–0.5 of the vessel diameter with clearance between them of 0.33 to 0.5 T depending on the AR and the level changes (which may lead to splashing) associated with fed-batch operation if it is used. The lower impeller maximizes the level of air dispersion and though not important at present, as higher sparge rates will need to be utilized as cell densities increase further, they should continue to remain effective (31). The upper impeller improves homogeneity near the upper surface, especially if nutrients and pH control chemicals are added to the top surface (23,31). It also has been shown to reduce the amount of foaming compared with other impellers (31,32). The large D/T ratios also maximize the inner film heat transfer coefficient.
5. Estimate power requirements of the motor from the OD requirements of the organism (3). If the OD is not known, but small-scale operation in a bench-scale bioreactor has been achieved, use equivalent $(\overline{\varepsilon}_T)_{\mathrm{Ig}}$ on scale-up. Then select a variable speed motor capable of giving higher $(\overline{\varepsilon}_T)_{\mathrm{Ig}}$ values but with a large turn-down ratio. During the early stages of the culture when OD is low, this flexibility should allow less power to be used while maintaining dO_2 control. It also allows for the possibility of increased cell density and associated OD with improvements in animal cell culture technology elsewhere and if estimates of current operating requirements are under estimated.
6. Air/nitrogen should be introduced through a pipe (2,3,33) or ring sparger (2,34) [though exit velocities through the holes >30 m/s at the large scale should be avoided (34)] placed below the lower impeller. The total flow rate should approximate constant vvm across the scales and be balanced to give both the required k_La and dO_2 and the required CO_2 ventilation rate and pCO_2. If needed, oxygen can be introduced through a separate sparge pipe. This sparge strategy should also minimize foaming (2).
7. To minimize cell damage due to bubble bursts from aeration, use Pluronic F68 at concentrations ≥ 0.5 g/L.
8. Use antifoam to control foaming as appropriate. For a more detailed analysis of the use of antifoams and the optimum addition strategy, the papers of Denkov and Marinova are recommended (35).

55.7.2 Microcarrier Culture

All of the issues above apply to agitator choice for microcarrier culture. However, the issue of "shear damage" is almost certainly much more critical due to the size and to a lesser extent density of the microcarriers, increasing the chances of direct damage to the cells or to their removal from the microcarrier by bubbles, particle impacts or turbulence. The use of smaller microcarriers may help reduce this tendency. To minimize the possibility of damage due to agitation, a down-pumping hydrofoil is preferred with a contoured vessel base as shown in Fig 55.8. With the lack of literature available which report both successful microcarrier culture and details of the agitation system utilized on the commercial scale, it is therefore recommended that the considerations set out above be used generally to guide impeller and geometry selection. The major change would be to the lower impeller. It should be a down-pumping impeller, even possibly a thin blade hydrofoil such as the Chemineer HE3 which together with a shallow dished or

contoured base has been shown (25) to suspend microcarriers at very low values of $(\overline{\varepsilon}_T)_{Ijs}$, lower than those that have been reported elsewhere to prevent successful microcarrier growth (26,27). However, it must be recognized that if cell "damage" occurs as easily as has been suggested in the literature, problems due to other issues such as poor homogeneity, poor pCO_2 stripping and pH control, and osmolality buildup may well occur. In that case, whatever impeller is selected, there must be serious doubts about the viability of large-scale microcarrier cell culture.

The author's experience suggests that "shear sensitivity" has been frequently (and damagingly) overemphasized in the past and perhaps it has been again for microcarrier culture. Certainly, more work needs to be directed toward such systems; especially it is currently becoming an important issue for the scale-up of stem cell cultivation for regenerative medicine and for producing cells as an alternative to live animal testing. Such cells require the use of microcarriers as, at present, they cannot be grown in free suspension.

NOMENCLATURE

a	specific area of bubbles
A	dimensional constant
AR	aspect ratio, H/T
B	baffle width
C	clearance above vessel base
D	agitator diameter
Fl	flow number
g	gravitational constant
H	bioreactor fill level
k_L	mass transfer coefficient
k_La	specific mass transfer coefficient
M	mass of media
N	agitator speed
OD	oxygen demand
OTR	oxygen transfer rate
OUR	oxygen uptake rate
P	power
Po	power number
Q	liquid flow rate pumped by the impeller
Q_H	heat evolution rate
Re	Reynolds number
SOD	specific oxygen demand
T	bioreactor diameter
v_s	superficial gas velocity
vvm	specific volumetric flow rate
V	volume of media
X	cell density

Greek letters

α, β	exponents
α°	blade angle
ΔC	driving force
ε_T	local specific energy dissipation rate
$\overline{\varepsilon}_T$	mean specific energy dissipation rate
λ_K	Kolmogoroff turbulence scale
μ	viscosity
ν	kinematic viscosity
ρ	liquid density
θ_m	mixing time

Subscripts

g	when air is sparged
I	Impeller
js	just suspended
max	maximum
s	sparged
swept	impeller swept volume

56.1 INTRODUCTION

The year 2012 marked the 25th anniversary of the introduction of the first recombinant mammalian cell culture produced therapeutic protein, tissue plasminogen activator (Activase®) by Genentech. The first Chinese hamster ovary (CHO) cell produced protein drug was followed by the introduction of erythropoietin (EPO) (by Amgen in 1989). In the past decade, a rapid expansion of recombinant antibody-based therapeutics has pushed the annual production amount of therapeutic protein to tens of thousands of kilograms and over 20 billion US dollars in revenue per annum (Tables 56.1 and 56.2). Before the advent of recombinant DNA technology, industrial mammalian cell culture was used primarily for the production of biologics using isolated transformed cells and viral vaccines using primary cells and normal diploid cell strains. The arrival of rDNA technology and the expression of heterologous proteins in mammalian cells completely transformed cell culture technology. Except for the production of attenuated or inactivated viral vaccines, virtually all mammalian cell culture processes now employ continuous cell lines, most of which have been adapted to grow in suspension, without a surface support. The adoption of the growth of suspension cells as the typical vehicle for the production of complex molecules requiring extensive posttranslational modification also transformed the concept of bioreactor selection.

Most research and many commercial efforts on developing bioreactors for mammalian cell culture occurred in the 1980s and early 1990s. The anticipation was that the potentially detrimental effect of the air sparging on mammalian cells would require a newly designed bioreactor to accommodate the manufacturing needs of the new mammalian cell-derived products. What was unanticipated to researchers and altered the landscape of bioprocessing technology was the extraordinary capability of cells to adapt to suspension growth, serum-free, even protein-free, and other culture conditions at very large scale (over 20,000 L). Over time the bioreactors used for industrial cell culture converge on a few basic configurations. This chapter focuses only on the main types used currently for industrial cell culture. It should be noted that many of the bioreactors developed in the 1980s, although not commonly used, might find specialized applications in other areas, such as tissue engineering, gene therapy, and cellular therapy.

TABLE 56.2. Licensed Therapeutic Monoclonal Antibodies and Antibody Fusion Proteins in the United States (as of 2007)

Protein (Trade Name)	Cell Line Used	Therapeutic Use (Year Approved)
Anti-CD3 (Orthoclone OKT3)	Hybridoma	Allograft rejection (1986)
Anti-GPIIb/IIIa Fab fragment (ReoPro),	Sp2/0	Blood clots in angioplasty (1994)
Anti-IL 2 receptor a chain (CD25) (Zenapax)	NS0	Renal transplantation (1997)
Anti-CD20 (Rituxan)	CHO	Non-Hodgkin's lymphoma (1997)
Anti-IL 2 receptor a chain (CD25) (Simulect)	Sp2/0	Renal transplantation (1998)
Anti-respiratory syncytial virus (Synagis)	NS0	Respiratory syncytial virus (1998)
Anti-tumor necrosis factor a (Remicade)	Sp2/0	Crohn's disease (1998)
Anti-HER2 (Herceptin)	CHO	Metastatic breast cancer (1998)
Anti-tumor necrosis factor Fc fusion (Enbrel)	CHO	Rheumatoid arthritis (1998)
Anti-CD33 (Mylotarg)	NS0	Acute myeloid leukemia (2000)
Anti-CD52 (Campath)	CHO	B cell chronic lymphocytic leukemia (2001)
Anti-CD20 (Zevalin)	CHO	Non-Hodgkin's lymphoma (2002)
Anti-tumor necrosis factor a (Humira)	CHO	Rheumatoid arthritis (2002)
Anti-IgE (Xolair)	CHO	Asthma (2003)
Anti-CD20 (Bexxar)	Hybridoma	Non-Hodgkin's lymphoma (2003)
Anti-leukocyte function antigen-1 (Raptiva)	CHO	Psoriasis (2003)
Anti-leukocyte function antigen-3 (CD2) Fc fusion (Amevive)	CHO	Psoriasis (2003)
Anti-epidermal growth factor receptor (Erbitux)	Sp2/0	Colorectal cancer (2004)
Anti-vascular endothelial growth factor (Avastin)	CHO	Colorectal cancer (2004)
Anti-alpha4-subunit of alpha4beta1 and alpha4beta7 integrins (Tysabri)	NS0	Multiple sclerosis (2004)
Anti-CD80 and CD86 (Orencia), Fc fusion	CHO	Rheumatoid arthritis (2005)
Anti-epidermal growth factor receptor (Vectibix)	CHO	Metastatic colorectal cancer (2006)
Anti-C5 (the complement protein) (Soliris)	NS0	Paroxysmal nocturnal hemoglobinuria (PNH) (2007)

56.2 BASIC REACTOR OPERATION AND KINETICS

56.2.1 Basic Types of Reactors

Mammalian cell bioreactors can be generally categorized similarly to chemical reactors according to their mixing characteristics. It is instructive to review two ideal reactors: well-mixed stirred-tank- and plug-flow (tubular) reactor. In an ideal well-mixed bioreactor, the mixing is assumed to be intense enough that the fluid is homogeneous through the reactor. The mathematical description of ideal continuous flow stirred-tank reactor is described by the following first-order differential equation.

$$\frac{\mathrm{d}(VC_\mathrm{A})}{\mathrm{d}t} = F_\mathrm{i}C_\mathrm{Ai} - F_\mathrm{o}C_\mathrm{Ao} + r_\mathrm{A}^V \qquad (56.1)$$

V is the culture volume in the bioreactor, C_A the concentration of nutrient or product A, t is time, F is the flow rate, and r_A is the volumetric consumption rate of nutrient or production rate of product A.

In an ideal continuous stirred-tank reactor, there is no flow bypass and no shunt of substrate from inlet to outlet, no dead zones or clumps of undissolved solid substrate floating around. Any substrate added through feeding is instantaneously distributed throughout the entire reactor,

and when gas sparging is employed, the agitator provides an intimately mixed gas–liquid.

The basic model for the tubular reactor (such as hollow fiber and many other membrane bioreactor systems that are described later in this chapter) is that liquid phase moves as a plug-flow, meaning that there is neither variation of axial velocity over the cross section nor backmixing in the longitudinal direction. The mass balance for component A in a volume element $S\,\partial z$ that described an ideal plug-flow reactor is as follows:

$$\frac{\partial C_{\mathrm{A}}}{\partial t} = -\mathrm{v}_Z S \frac{\partial C_{\mathrm{A}}}{\partial z} + r_{\mathrm{A}} \tag{56.2}$$

where v_z is the linear velocity in the z direction and S is the cross-sectional area.

Given the initial condition in Equation 56.1, or both initial and boundary condition in Equation 56.2, one can obtain the concentration profiles over time; or for tubular reactors, the profile can be obtained over time and spatial position. At steady state (i.e. cell concentration and cellular activities are not changing with time), the equation for tubular reaction becomes

$$\frac{\partial C_{\mathrm{A}}}{\partial z} = \frac{r_{\mathrm{A}} \cdot S}{F} \tag{56.3}$$

which describes changes of concentration of A along the direction of fluid flow. It is clear that the nutrient concentration will decrease from inlet to the distal end of the reactor, while metabolite or product concentration increases. The length of the reactor is limited because eventually nutrient depletion or metabolite accumulation inhibits growth and metabolism.

These ideal cases of well-mixed tanks or plug-flow tubular reactors are situations that can be approximated in small-scale laboratory conditions. The conditions in larger scale reactors deviate significantly from these ideal conditions.

In a well-mixed bioreactor, there are no concentration gradients in either the gas or the liquid phase. In other words, none of the chemical species or cells is segregated in the reactor. The other extreme of mixing is total segregation where there is no interaction between different volume elements in the bioreactor. An ideal plug-flow reactor is assumed to be under conditions of total segregation. Most bioreactor systems have a mixing pattern between the two extremes and are under partially segregated conditions.

In general, laboratory and small pilot plant bioreactors are used for process development, optimization, and characterization. The fluid mixing characteristics are rather sensitive to the scale of the reactor. Furthermore, plug-flow bioreactors are intrinsically more difficult to scale up than mixing vessels, as the concentration gradient of essential nutrients, oxygen in particular, will inevitably become limiting in the downstream region of the reactor. In considering the selection of bioreactors for mammalian cell cultures, the mixing characteristics and their relationship to scale-up have to be kept in mind.

56.2.2 Batch/Fed-batch Versus Continuous/Perfusion Operations

Mammalian cell cultures can be operated in batch, fed-batch, and continuous modes. In a batch culture all nutrients are added at the beginning of a production cycle, except that oxygen is supplied continuously by diffusion through the interface with an oxygen carrying stream, which is part of the recirculating medium or air flowing through the culture. Using a conventional medium, the typical concentrations achieved in a batch culture are rather low, around $2-4\times10^6$ cells/mL. In many cases, batch operation tends to be run as extended batch processes that are sometimes referred to as *repeated batch cultures* with intermittent harvest. In this operation mode, spent medium with or without cells may be harvested periodically and replaced by an equal quantity of fresh medium. It allows a production process to be extended to a few weeks with an increased productivity for the reactor. With this technique it is possible to prevent the inhibitory products from accumulating to an exceedingly high level and to provide nutrients for cell growth and production.

To prolong the culture period, fed-batch operation is practised. The culture is started at less than full volume; after a short period of growth, concentrated nutrient stream containing amino acids, glucose, and some other nutrients is added continuously or intermittently until reaching maximum volume. The total amount of nutrients added to the reactor is typically substantially (a few fold) higher than if the reactor was filled with fresh basal medium at the beginning. Such fed-batch processes reach higher cell concentrations and prolong the product formation period. The final product concentration is substantially higher than that in a batch culture.

Continuous chemostat is a very useful research tool. Once a steady state is reached, the spent medium withdrawn is balanced by equal supply rate of fresh medium, and the amount of cells being continuously discharged from the bioreactor is balanced by growth. A drawback of a simple continuous culture is the low cell concentration, and the corresponding low product throughput of the system. To increase the cell concentration and the reactor throughput, a perfusion culture is more frequently used in industrial continuous operations. In a perfusion culture, a high medium flow rate (one much higher than the cell growth rate, which would wash out cells in a simple continuous culture) is used, but a cell retention device is used to prevent most of the cells from leaving the reactor. The cell concentration

in the reactor is many times higher than that for a simple continuous culture.

A cell retention device may be physically positioned inside or outside of the bioreactor vessel (1,2). The devices that have been used include settling tanks (3), external centrifuges (4) (5), external membrane filtration (6), internal microfiltration (7), rotating wire cage (spin filters) (8), and acoustic settling device (9). All these, or similar devices, have been shown to be effective at laboratory scale. On the industrial scale, bioreactors of up to hundreds of liters, centrifuges, settling devices, and spin filters appear to be the top choices. The employment of a centrifuge or a settling device necessitates a recirculation loop to return the concentrated cell stream back to the reactor, while discarding the purged cells along with the other stream. As the scale increases the holding time in the external recirculating loop also becomes longer and potential oxygen starvation must be avoided to minimize the risk of cell progression to apoptosis. Such concern may require the reduction of temperature in the external loop. Using an internal cell retention device minimizes such a concern. However, all cell retention devices may face occasional problems of cell clogging or mechanical failure. An external device is in general easier to be replaced or duplicated for alternating operation than an internal device. When a culture is operated in a continuous mode, it is desirable for the operation to last for months; a replaceable cell retention device can make the process more robust.

56.3 CELL SUPPORT FOR MIXING VESSELS

56.3.1 Microcarriers

The use of microcarriers for cell culture was first demonstrated four decades ago (10). The basic concept is to allow cells to attach to the surface of small suspended beads so that conventional stirred-tank bioreactors can be used for cell cultivation. The diameter and density of these cell-laden microcarriers are usually in the range of 100–300 μm and 1.02–1.05 g/cm^3 so that the settling velocity is in the order of centimeter per minute. This diameter range also gives a good growth surface area per reactor volume. Even at a moderate microcarrier concentration, in the range of 8–15% culture volume being occupied by microcarriers, a significantly larger surface area per reactor volume can be achieved in a microcarrier culture than in T-flasks, roller bottles, or other plastic reactors with flat surfaces.

Although even smaller microcarriers, less than 100 μm in diameter, can provide more surface area, they are not used often. Most adherent-dependent cells do not develop their normal morphology, and in many cases, do not multiply well on surfaces with an excessively high curvature. These cells do not grow well on small microcarriers. On the other hand, some cells, especially transformed cells, multiply well even though they are attached to small microcarriers and do not spread. These cells, after attaching to the small microcarriers, agglomerate to form aggregates and continue to grow to high density. The small microcarriers, usually with a diameter of about 50 μm, serve as nuclei for the initiation of aggregate formation (11).

The microcarriers can be made of many different materials, including dextran, gelatin (12), polystyrene (13,14), glass (15), and cellulose (16). Not all these are commercially available. In general, in addition to having a wettable surface, the backbone materials of microcarriers often need to be chemically modified to improve cell attachment. One of the most widely used microcarriers, the dextran based ones, are derivatized with charged molecules or collagen. Polystyrene microcarriers have also been coated with collagen or other adhesion molecules for better performance.

An advantage of microcarriers for the industrial-scale culture of anchorage-dependent cells is the ease of separating cells from culture medium. Many microcarrier cultures require medium exchanges during cultivation to remove accumulating lactate, ammonia, and other metabolites and to replenish nutrients. In many cases, the cell-laden microcarriers are simply allowed to settle and the spent medium is withdrawn and replenished. In large-scale operations, continuous or semicontinuous perfusion is more frequently used. This can be accomplished by withdrawing medium through a coarse screen that allows medium to pass through but retains microcarriers in the reactor. Many types of cells have been grown on microcarriers, including fibroblasts, kidney, epithelial, hepatocyte, neuroblastoma, and endothelial cells from various species. Overall, microcarrier culture is a convenient laboratory and research tool, and it has the advantage of being amenable to large-scale production if a large quantity of product is needed.

56.3.2 Macroporous Microcarriers

A variant of microcarriers is one with large pores of tens of micrometers in its interior. The void space inside allows cells to be cultivated not only on the external surface but also internally. Cells in the interior are less susceptible to mechanical damage caused by agitation and gas sparging. Of course, being in the interior of microcarriers, cells are more likely to be subject to oxygen limitation due to the long diffusional distance, especially since most macroporous microcarriers have a larger diameter (500 μm to a couple of millimeters). Macroporous microcarriers are made of different materials, including gelatin (17), collagen (18), and plastic (e.g. Cytoline®). Some macroporous microcarriers have apparent bulk density similar to that of conventional microcarriers. However, because of their larger particle size, the settling velocity is substantially higher. In some cases, the settling velocity is orders of

magnitude higher, in the order 100–1000 cm/min. These microcarriers are suitable for use in fluidized beds with a high fluid recirculation rate. Because of the high settling velocity even at high upward supervelocity, the carrier can be retained in the reactor. Similar to microcarriers many cell lines have been successfully grown on macroporous microcarriers including Vero, HepG2, CHO, and HEK293 cells. The final cell concentration achieved tends to be higher than that obtained with an equivalent volumetric concentration of conventional microcarriers. But, in some cases, the growth kinetics are a bit slower because the penetration of cells into the interior may be slowed or even retarded by restrictive opening of these pores.

Since the cells are protected inside the capsules, they are protected from hydrodynamic damage. The culture can be stirred at faster rates than conventional culture, which improves nutrient, metabolite, and gas exchange. Entrapped cells may be cultured in stirred-tank bioreactors, fixed-bed and fluidized-bed reactors. An airlift reactor could be used as well, provided that the beads are small and not significantly denser than the medium.

56.3.3 Aggregates

Some transformed cells that normally attach to or spread and grow on a surface can form aggregates when cultivated on less hydrophilic surfaces or in shaker flasks or stirred vessels (19). Different methods have been used to induce aggregate formation for cells. Aggregation can be promoted by manipulating the calcium concentration (20) in conjunction with the agitation rate. Aggregate cultures have advantages similar to microcarrier cultures. They can be cultivated in conventional stirred-tank reactors with environmental control. They can be allowed to settle relatively rapidly by stopping agitation. This permits medium replenishment readily.

For many cell types, one limitation for application of the aggregate culture is that the rate of aggregate formation is slow. One way to induce aggregate formation is to add microspheres, the small microcarriers with a diameter of about 50 μm, to cell suspension to allow for rapid agglomeration to the microspheres (11). If the aggregate diameters become too large, necrotic centers can be formed due to transport limitation. The aggregate size may influence the viral infection kinetic and yield for vaccine formation (21). Many cell lines, including BHK, CHO, 293, and ST cells, have been cultivated as aggregates with sizes ranging between 90 and 400 μm, without the formation of necrotic centers (11,22).

56.3.4 Cell Entrapment

Another method of cell cultivation, which enables the use of a stirred-tank reactor, is cell entrapment. This technique entails entrapping cells in polymeric spheres. The spheres can then be coated with another polymeric film with controlled cross-linking of the polymer to modulate the permeability to molecule according to their size. This is commonly referred to as *microencapsulation*. In other applications, the spheres with entrapped cells are cultivated in the same way as the beads suspended in medium to allow for cell growth. One of the polymers frequently used for cell entrapment is calcium alginate. Cell entrapment in calcium alginate is accomplished by preparing a cell suspension in sodium alginate and adding it, in a drop-wise fashion, into a solution of calcium chloride. A high calcium concentration promotes cross-linking of alginate, instantaneously forming beads containing entrapped cells. The alginate beads may be coated with polylysine for increased mechanical characteristics and structural integrity, but such treatment decreases the molecular weight cutoff (MWCO) and prohibits large-molecular weight proteins in the medium from reaching the cells. To prepare hollow spheres, the alginate gel inside a bead coated with a polylysine is liquefied by treatment with a calcium chelator such as EDTA (ethylenediaminetetraacetic acid) or citrate.

The diameter of these beads is often in the order of millimeters. The mechanical strength of the gel which constitutes the beads is relatively weak even with polymeric coating. Large-scale application using such techniques is not easy. On the other hand, the microcapsule provides a means of immunoisolation of transplanted cells or tissues (sometimes referred to as *artificial cells*) and could be suitable for some tissue engineering applications. Cell entrapment has been applied to hybridomas (23) and small clusters of adherent cells (24). It has also found applications in the cultivation of differentiated cells, such as insulin-secreting cells. For tissue engineering applications using differentiated cells, the enclosing membrane around the cells and the hydrogel must be biocompatible (25).

56.4 CELL CULTURE BIOREACTORS

Cells respond to fluid flow by changing their morphology, metabolism, and, in some cases, their signaling pathways. Excessive fluid shear causes cell damage and ultimately death. How cells respond to fluid flow is dependent on cell types, as well as the way they are cultivated. For cells capable of growing either in suspension or attached, the sensitivity to fluid flow may differ when grown in suspension or on a surface. Adherent cells may respond differently on a flat surface and on a curved surface such as microcarriers. Even surface roughness or adhesiveness may affect how they respond to fluid flow field. During the reactor selection process, the most fundamental consideration is that the reactor provides sufficient mixing and mass transfer

while minimizing potential cell damage. Cell damage from the interaction between microcarriers and turbulent eddies may be severe. Thus, fluid shear is of paramount consideration in microcarrier culture. This is especially of concern when the Kolmogorov length scale for the smallest turbulent eddies becomes comparable to the diameter of the microcarriers (26). The microcarrier–microcarrier collisions are also expected to increase in frequency and severity in the presence of eddies of size equal to the average interparticle distance. Suspended cells are generally less prone to hydrodynamic damage than cells on microcarriers. Overall, stirred-tank bioreactors are most commonly used for cell cultivation. The use of disposable cell culture devices (also referred to as a *single-use device*) suitable for process scale (up to hundreds of liters) has become common place in the past few years, especially in cell propagation for inoculum preparation.

56.4.1 Stirred-Tank Bioreactor

Stirred tanks have been widely used for culturing suspension cells since the 1960s. The basic configuration of stirred-tank bioreactors for mammalian cell culture is rather similar to that of microbial fermentors (Fig. 56.1). The aspect ratio (the height-to-diameter ratio) of bioreactors used for mammalian cell culture is often smaller than that for microbial cultivation. However, in recent years that distinction has become less apparent as the scale of cell culture bioreactors approaches tens of cubic meters in volume. However, the bioreactors used for microcarrier cultures generally have a low aspect ratio to provide a higher surface-to-volume ratio. The power input per unit volume of bioreactor is substantially lower in mammalian cell culture bioreactors. While the Rushton type impeller is the norm in microbial fermentors, mammalian cell culture bioreactors mostly employ pitched blade or marine type impeller. Like in microbial fermentors, multiple impellers are used in larger scale bioreactors for mammalian cell culture. The use of pitched blade, as opposed to Rushton turbine, reflects the different purposes of agitation. In microbial fermentation, agitation is needed at a higher power input to disperse air bubbles and to increase oxygen transfer efficiency, whereas in mammalian cell culture, a much lower agitation rate is sufficient to keep cells or microcarriers suspended in medium relatively uniformly and to support the oxygen demand of the culture. In general, the acceptable mixing time in a mammalian cell culture bioreactor is substantially higher than that in a microbial fermentor. The oxygen transfer capacity in a cell culture bioreactor is substantially lower than that in a microbial fermentor, since the typical oxygen demand in a mammalian cell culture is also much lower (10–50 times) due to lower cell mass than that in microbial fermentation.

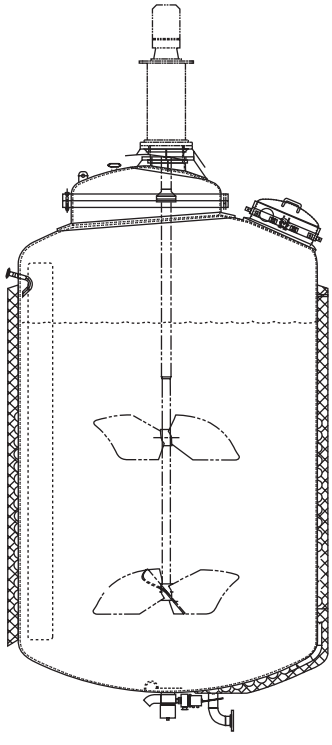

Figure 56.1. Schematic of a stirred-tank bioreactor. (Courtesy of Genentech, Inc.)

The most efficient way to supply oxygen, especially in large scale, is the direct sparging of air or oxygen-enriched air. Direct sparging, however, can potentially damage cells. Numerous studies have tried to clarify the mechanism of cell damage caused by direct gas sparging (27). The high energy released as the gas bubbles release from the liquid surface due to bubble ruptures appears to be responsible for its most damaging effects. These consequences can be partially alleviated by the addition of polyols in the culture medium to prevent cells from attaching to the bubble surface. It is, in fact, standard practice to include Pluronic F-68® in low protein or protein-free medium for suspension cultures. This effectively prevents cells from attaching to the bubble surface, thus minimizing cell damage or death due to bubble ruptures. Commonly used spargers include open pipe, ring sparger with multiple holes of a diameter of ~1/16 in., and microsparger made of sintered stainless steel. Microspargers create swarms of small bubbles and are efficient for oxygen transfer, as they create a larger interfacial area at a given air flow rate. With the use of microspargers, the gas flow rate required to supply oxygen to maintain certain dissolved oxygen levels tends to be smaller, leading to a lower CO_2 removal rate and a generally higher CO_2 concentration in culture. Furthermore, in larger vessels, bubble coalescence is unavoidable, thus offsetting the advantage of small bubbles. The open pipe or multiple-hole spargers are simple and are generally used in large reactors. In general, gas flow rates for sparging can

be scaled up by keeping the same superficial gas velocity. However, it is important to increase the number of holes for sparging linearly to the gas flow rates in order to keep the gas entrance velocity at the same levels as it has been reported recently that a high gas entrance velocity of more than 30 m/s may exert an adverse effect on NS0 cells (28).

56.4.2 Airlift Bioreactor

An airlift reactor is essentially a relatively high aspect ratio (tall and thin) tank with an internal concentric draft tube as a guide for fluid recirculation (Fig. 56.2). The internal liquid circulation is achieved by sparging at the bottom of the draft tube. The sparged section has a lower effective density than the bubble-free section, and the difference in hydrostatic pressure between the two sections induces the liquid circulation upward in the sparged section (riser) and downward in the bubble-free section (downcomer). The loop has the advantages of permitting high efficiency mass transfer and improving the flow and mixing properties in the vessel. A potential advantage of airlift reactors is the low capital costs because of their simple mechanical configuration. Although simple in construction, sound design is critical for optimal hydrodynamic behavior. Airlift reactors have been used successfully with suspension cultures of BHK 21, human lymphoblastoid, CHO, hybridomas, and insect cells. In the past decade, the cell concentration achieved in cell culture bioreactor increased substantially as fed-batch culture became the prevailing mode of operation. In a fed-batch mode, the culture is often initiated at about two thirds of the maximum volume. The other one third is gradually fed throughout the cultivation period. The initially low volume makes the use of airlift bioreactors impractical as the draft tube is not completely submerged in the medium. Furthermore, the increased oxygen consumption caused by the high cell concentration requires a faster mixing time provided by a stirred-tank reactor. As a result stirred-tank bioreactor has become the prevailing type used for cell culture.

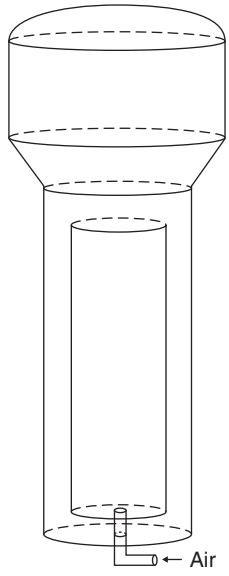

Figure 56.2. Schematic of an airlift bioreactor.

56.4.3 Disposable Single-Use Bioreactors

Many different types of disposable single-use plastic bioreactors including T-flasks, roller bottles, and multiple flat panels are commonly used for production of recombinant proteins and viral vaccines using both attachment-dependent and suspension cells. Their surface may be treated to facilitate attachment of adherent cell cultures. However, for suspension cells, it is usually more convenient to grow the cells in a stirred vessel, and disposable plastic bioreactors are used only at smaller scale when ease of operation is a more important consideration.

Roller bottles are cylindrical screw-capped bottles with a total volume ranging from 1 to 1.5 L suitable for a culture volume of 0.1–0.3 L. Stacks of bottles can be placed on a rack and can be rotated at 1–4 rpm. For small-scale operations, roller bottles provide many advantages for the cultivation of adherent cells. It is relatively inexpensive to set up. It allows for a rapid change of throughput in response to the need. Furthermore, replacing medium from cell growth medium to one designed for product formation is rather straightforward. It is particularly useful in the case that the serum-containing medium needs to be replaced by a serum-free or protein-free medium for the production of secreted proteins or viruses. The transparent glass or plastic wall allows visual or microscopic examination of the culture status. Microbial contaminated bottles can be readily spotted and discarded before being pooled together with others.

However, the drawbacks of roller bottles are numerous for large-scale production of biologics. On-line environmental monitoring and control is virtually impossible, or at least impractical. The aseptic bottle handling for inoculation—protease treatment for cell detachment and expansion, medium exchange, and product harvest—requires extensive well-trained labor to ensure a low failure rate. Each batch of manufacturing can easily involve hundreds or even thousands of bottles, and the large number of manual steps involved makes the risk of microbial contamination rather high. Despite these significant drawbacks, roller bottles are still widely used in the production of recombinant proteins and viral vaccines, often because the product involved has been approved by regulatory agencies and a process change would incur too high a cost and may result in product comparability issues. In some cases, roller bottles are selected because the process is easy to implement and the production capacity needed is manageable. Notable examples include

the production of EPO using recombinant CHO cells and the production of the live attenuated chickenpox (varicella) vaccine and herpes zoster (shingles) vaccine using adherent secondary human lung fibroblasts MRC-5 cells. Recent improvements include developing a fully automatic and continuous cell culture for a large number of roller bottles to make industrial-scale production by mammalian cell culture (29).

Nunc Cell Factories® (NCFs) are widely used in laboratories and in industrial production of viral vectors, vaccines, and recombinant proteins. They are ideal to support growth of adherent cells; however, they can also be used for suspension culture. A 40-tray NCF has a capacity of 25,280 cm^2 and ~8000 mL liquid volume. In one study adherent PER.C6® cells, grown on a single tray and transfected with adenovirus plasmid, produced 5×10^{10} of an adenovirus type 5 vector expressing HIV-1 gag gene (MRKAd5gag). Scale-up can be easily performed using multiple tray systems (30). For large-scale manufacturing using tray disposal device, a mechanical handling system can be used. One notable example is the production of a recently licensed multivalent Rotavirus vaccine using Vero cells, a continuous African green monkey kidney cell line. The vaccine is a live attenuated virus vaccine that contains five different human-bovine virus reassortants, each produced from a different process (31).

Another multiple plate system (CellCube Module) entails 9 $in.^2$ polystyrene plates stacked vertically at 1 mm spacing in an overmolding resin case. The space between stacks is completely filled with medium. Continuous medium circulation is used for oxygen and nutrient supply. It has been used in the cultivation of MRC-5 cells for the production of attenuated hepatitis A virus (HAV) and for the production of VA2TA, an inactivated HAV vaccine. These disposable bioreactors have also found some popularity for the production of cells and gene therapy vectors at intermediate scales of operation (32,33).

Disposable cell culture wares suitable for modest scale of suspension culture are increasingly being used for production of biopharmaceuticals. Most of them use disposable plastic bags as cell chambers. They are especially suitable for cell expansion before reaching the production scale. Wave™ mainly consists of a presterilized, disposable Cellbag and a special rocking platform. The rocking motion of this platform induces waves in the culture fluid. These waves provide mixing and oxygen/gas transfer to support over 20×10^6 cells/mL. With no cleaning or sterilization required, disposable bags simplify setup operations. Various systems at a culture volume from 0.1 to 500 L are available (http://www.wavebiotech.com/products/wave_bioreactor/index.html). pH, dissolved oxygen (DO), temperature sensors are designed for these single-use bioreactors. In manufacturing settings, validating the equipment for restart of the process contributes to a very significant part of overall operating cost. The use of disposable bag systems can significantly shorten the process development time, require much less capital investment than installing stirred-tank bioreactors, and reduce the cost associated with validation.

A more extreme case of single-use alternative to conventional fermentor is a retrofit product to mimic existing stainless steel bioreactor vessel. It consists of a reusable stainless steel outer support container and single-use BioProcess Container (BPC®) with a working volume of up to 1000 L, which can be integrated with the existing bioreactor control system. The integrated sparging system provides effective oxygen transfer (http://www.hyclone.com/bpc/new_prod/sub.php). Since all parts contacting the cell culture are single-use and tested, no cleaning or sterilization is needed.

56.4.4 Hollow Fiber Bioreactor

The use of hollow fiber reactors for cultivation of mammalian cells dates back to the early 1970s (34). A hollow fiber system can be used for anchorage-dependent and suspension cells. It consists of a bundle of capillary fibers sealed inside a cylindrical tube. The basic configuration is rather similar to the hollow fiber cartridge used in kidney dialysis. In fact, many hollow fiber bioreactors basically consist of a kidney dialysis hollow fiber unit connected to a medium recirculating reservoir. The hollow fiber, in most cases, consists of supporting polymeric porous materials for mechanical strength and a thin layer of membrane that provides selective passage of molecules depending on their size. The MWCO of the membrane differs according to applications, ranging from a few thousand to a hundred thousand daltons. In most cases, an ultrafiltration membrane is used (35). The ultrafiltration membrane prevents free diffusion of secreted product molecules from passing through the membrane and allows them to accumulate in the extracapillary space to a high concentration. The culture medium is pumped usually through the fiber lumen, and cells grow in the extracapillary space or the shell side. Supply of low molecular weight nutrients to the cells and the removal of waste products occur by diffusive transport across the membrane between the lumen and the shell spaces. Although the use of microfiltration hollow fiber membranes for cell culture is infrequent, it does find application in various research uses for studying metabolism and for the cultivation of anchorage-dependent or highly aggregated cells for which a convective flow of medium through the extracapillary space to bathe cells in medium is desired.

Most hollow fiber systems used for cell culture employ fibers of approximately 250–350 μm in outer diameter. The interfiber distance is at least as large. A factor limiting the potential of scaling-up of a hollow fiber system is mass transfer. In the radial direction, the nutrient (including

oxygen) diffuses through the hollow fiber wall and membrane to reach the site of cells for consumption by the cells. In the axial direction, the medium entrance region is exposed to fluid with higher oxygen, while the exit end inevitably sees a lower concentration of oxygen. Oxygen is of primary concern because it is usually the first nutrient to become growth limiting. To ensure ample oxygen supply, the recirculating medium is typically passed through an oxygenator (e.g. one used in surgery operations) before it enters the hollow fiber system. A typical setup of a hollow fiber system therefore includes not only a constant temperature incubator to house the hollow fiber bioreactors but also pH control, oxygenation and oxygen monitoring systems, and a medium reservoir for recirculating medium. In addition, frequently a small medium reservoir is used to supply high molecular weight nutrient supplements to the extracapillary space directly. A harvest reservoir is used to collect the product containing fluid from extracapillary space. In a hollow fiber bioreactor, a nonuniform growth of cell mass and product accumulation is often seen (36). This is usually caused by the small convective flow in the shell side, the difficulty to inoculate cells uniformly, and settling due to gravity.

Techniques to improve oxygen supply include the use of fiber or silicon tubing for oxygen supply into the shell side of the reactor. However, the use of mixed fibers in the bioreactor makes the bioreactor harder to manufacture. Another technique is to reverse the flow direction periodically to inverse the axial regions exposed to high and low oxygen concentration.

Despite its limitation in scaling-up, the hollow fiber system is a proven technology relatively easy to apply to processes requiring a modest amount of product. In some tissue engineering and cellular therapy applications, the product is often patient specific and the quantity of cells needed is relatively small. A hollow fiber system could be ideal for those applications.

56.4.5 Bioreactors for Scale-Down/High Throughput Operations

Cell culture has long been carried out in small scales, such as 96 well or even 384 well format, for various biological assays. Such small-scale systems are ideal for parallel cultures for testing medium components or other biologically active ingredients. They are also convenient for screening a large cell population to identify cell variants or clones that have certain desired characteristics. Although those small-scale systems are largely carried out as stationary cultures like T-flask, there are also deep well systems in such 96 or 384 well format for parallel culture of cells kept in suspension. The use of suspension system allows for larger quantities of cells be grown, which is important for some cases where the assay requires a larger sample volume. Such systems are also more amenable to optimization of culture conditions. The systems conform to the standard format of laboratory liquid handling robotic systems and are suitable for high throughput operations needed for drug screening, toxicity testing, or gene transfection studies. These high throughput formats are also employed in screening clones with high productivity as well as in media development and optimization.

In the past few years, smaller scale operations are increasingly being used in bioprocess industry as they enable reduction in labor and material costs and expand the number of variables that can be investigated as compared to conventional laboratory bioreactors with a culture volume varying from 0.5 to 10 L. Recent efforts on bioreactor miniaturization also aim to reproduce the conditions of process scale to render the studies at small scale more relevant to manufacturing conditions.

The key parameters of design and operation in those small-scale reactors are thus mixing, mass transfer, and other factors affecting environmental control (such as pH, dissolved oxygen, and nutrient levels). The most commonly used small-scale bioreactors that provide mixing is the shaker flask. Mixing is carried out simply by shaking the 'bioreactor' using various shaking diameters and angles. Although convenient for cultivating cells, conventional shaker flasks require large space for a given culture volume. The rotational speed that can be used is limited to avoid spillage. Furthermore, the rotary motion used in providing mixing does not provide a high oxygen transfer rate. In the past decade a number of culture tube small-scale systems became available commercially. The simple cylindrical shape and the relatively small volume of culture fluid allows a high shaking speed to be used. Oxygen transfer rate can possibly be improved by using square- versus round-shaped wells (37). A high $k_L a$ value has been reported in square-shaped shake tubes with gas permeable membrane for oxygen delivery (38). The volume of such tube-based culture system ranges from a couple to tens of milliliters. In some cases, mixing is provided by high frequency motion in a vertical direction, instead of the traditional rotary motion. Small tube cultures in 96 well format with mixing provide a mechanism amenable to robot-assisted high throughput operation. However, with a small culture volume and highly turbulent liquid mixing, evaporation can be seriously affecting the osmolality of culture. Evaporation in the plate formats is generally prevented by using low-evaporation lids.

From an operational standpoint of view, especially ease of sampling as well as lower risk of cross-contamination, 24 and 96 well plates are more commonly used for cell cultivation compared to plates with more densely packed wells (37,39). μ24 MBR (manufactured by Micro-Reactor Technologies, Inc., Mountain View, CA) and marketed by Applikon, Inc., Foster City, CA) is an example of

microbioreactor system made using special 24-well micro titer plate.

To mimic large-scale cultures, small bioreactors employing stirred agitation using impellers driven with a shaft or magnetic transmission are used. Stirred minibioreactors may be constructed using wide range of materials including glass and polymers, with a working volume in the order of 20–100 mL (40). Larger volume compared to miniature plates allows for ease of feeding, sampling, better instrumentation, and control. However, relatively higher cost of the stirred minibioreactors may limit their application for high throughput screening. The system needs to be better optimized to provide high quality instrumentation at a lower price.

Instead of employing ministirred bioreactors with tens of milliliters of culture volume, some have miniaturized mixing by employing lab-on-a-chip idea to allow for cultivation on polymer or glass plates (41,42). These reactors are typically very small with 5–150 μL working volume (47), and the capacity to measure critical process variables on-line and even perform chemostat cultivations (42,43). It is worthwhile to note that the small working volumes require analytical tools capable of analyzing correspondingly small samples. In the literature, microbioreactors and larger, liter-scale cultivations comparisons have reported equivalency for process parameters and optical density measurements (40,44).

To be better able to manipulate the environment to mimic large-scale operations, environmental monitoring and control is important. Because of the small culture volume and restriction on sample volume, on-line monitoring is highly desirable or even essential for high throughput operations. Typically on-line monitoring of bioreactors relies on *in situ* electrical probes that convert chemical state or reaction to an electric signal. Miniaturized pH and DO probes can be used with stirred minibioreactors (Frachon *et al*., 2006). Such wired, fix-position probes are cumbersome to use in high throughput systems employing culture tubes or shaker flasks and are too large for 96 well format based systems. For these microscale bioreactors, optical sensor technology that monitors pH and dissolved oxygen noninvasively and possibly transmits the signal remotely is preferred. Fluorescence measurement techniques for measuring dissolved oxygen and pH using dye in culture media and/or sensing patches are being developed (42,44–46). Biomass measurements can possibly be made by using simple transmission intensity measurement (42) or miniature capacitance probe. The availability of better on-line sensing will certainly facilitate the use of miniaturized cell culture systems.

56.4.6 Bioreactor Scale Translation and Intensification

As the mammalian cells become a major workhorse for the production of biopharmaceuticals, the focus of process research and development also shifted from the development of bioreactors to process optimization and intensification using existing bioreactors. In the past decade, we have witnessed a surge in the productivity, from 100s mg/L to 2–5 g/L, in the production of recombinant proteins from cell culture processes. This increased productivity has been the result of intensified optimization of fed-batch processes to increase cell concentration and to extend the high productivity stage of the culture. The advances have allowed a much higher demand of product be met without increasing physical manufacturing capacities and have saved large sums of capital investment. Such fed-batch cell culture processes are now commonly used for production of clinical and commercial supplies of antibody products at scales of up to 20,000 L. The continued advances are reliant on process productivity enhancement and scale-down efforts. Current protocol of generating a high producing cell line involves isolation and evaluation of cell clones derived from single cells after the introduction of transgene. Clonal variation renders their behavior difficult to predict under different culture environment. Rapid optimization of a high productivity process and successful bioreactor scale translation, especially predicting a particular producing cell line's behavior in manufacturing environment, is critical for the production of biopharmaceuticals. Cell line characterization and process optimization are invariably performed in small-scale- and pilot-scale bioreactors. A high confidence on the translatability of small- and pilot-scale results to manufacturing conditions will greatly fasten the timelines and reduce the drug development cost. In addition, a suitable scale-down model is needed to support process characterization, troubleshooting, and process validation.

A successful scale-up and scale-down depends on a good understanding of physical and chemical parameters affected by scale, their quantitative or qualitative relationship to scale, and the design of the scale-down model. It is the changes in the dynamics of these critical parameters in scale translation that eventually cause changes in cellular physiology and productivity. Mechanical agitation and shear, aeration, and oxygen (and carbon dioxide) transfer, which are the conventional subjects of scale-up studies, are apparently important parameters. Additionally, the parameter values for pH and gas flow control often scale nonlinearly causing subtle differences in chemical environment, such as dissolved carbon dioxide and osmolality. There have been few reports on scale-down models, which describe time profiles of scale-sensitive physical and chemical parameters. It is worth noting that key to scale-up studies is the comparison of the cellular physiology in both small and large scales. The profiles of cell growth, metabolism, and product formation have been the key parameters being compared in scale translation. However, in the past few years we have seen various omic tools, especially DNA microarrays, increasingly finding their applications in bioprocessing research.

Its potential in physiological comparative studies on scale translation is worth exploring.

56.5 CONCLUDING REMARKS

The reactors discussed above (see also Chapter 57 in this volume) are the ones commonly used in manufacturing of biopharmaceuticals. The selection of a reactor for a particular process is largely based on process needs, especially whether the cells employed are adherent or suspension cells. Large-scale bioreactors, whether they are used for fed-batch operations or perfusion cultures, are mostly stirred tanks. Their dominance is attributed to the robust performance gained through their wide use in various bioprocesses over the decades. However, many other considerations, especially low capital investment and ease in operations and validation, have rendered an increased usage of disposable devices in the past few years. Many processes of moderate scales and seed culture preparations of large-scale culture are increasingly being performed in disposable devices. Other types of reactors, many of which were innovated a couple of decades ago, although not commonly used in bioprocessing nowadays, are finding applications in tissue engineering. Furthermore, miniaturized bioreactors (see Chapter 32, volume 1) are increasingly being used in high throughput operations. In the near future, we may see that the experience gained in bioprocess technology begin to benefit high throughput technology.

MAMMALIAN CELL CULTURE REACTORS, SCALE-UP

J. Bryan Griffiths
Scientific Consultancy & Publishing, Salisbury, United Kingdom

57.1 INTRODUCTION

Although mammalian cells have been grown in vitro since before 1907 (1) the factor that gave impetus to their current widespread laboratory and industrial use was the discovery by Enders (2) that human pathogenic viruses could be grown in cell cultures. Following this demonstration by Enders in 1949 it took only 5 years for the first cell-based vaccine to be licensed for clinical use (Salk polio vaccine in primary monkey kidney cells in 1954). This opened up 20 years of continuous development of human and veterinary viral vaccines and created the need for industrial-scale cell culture processes. The most effective large-scale process developed during this period was for foot-and-mouth disease virus (FMDV) based on suspension culture of baby hamster kidney (BHK) cells (3). Developments in processes for human vaccines were less dramatic because of the need to use biologically safe cell lines. This meant that the use of human diploid cell lines, such as WI-38 (4) and MRC-5 (5), because of their normality (i.e., they behaved as cells in vivo without tumorgenic transformation), only grew attached to a substrate (anchorage dependent) and only reached low cell densities. The wide range of animal cell reactors available is partly due to the dual development of systems for anchorage-dependent cells (ADCs) and free-suspension cells (6,7). ADCs were grown in small culture vessels, and a production batch constituted hundreds or even thousands of replicate cultures (i.e., a multiple-batch process) (8). The need for a unit batch process (one large culture vessel), such as the fermentors used for suspension cells, saw the development of a wide range of novel culture reactors (6,7), but the significant breakthrough came with the microcarrier system (9). This procedure, developed in 1967 by van Wezel (9), allowed cells to grow attached to small (200 μm) spheres that were stirred in a large tank fermentor analogous to suspension cells. This was the first successful large-scale unit process for ADCs.

Vaccines were the dominant product until the 1970s, but changes in regulatory and licensing procedures then allowed cells from sources other than normal tissues to be used for human medicinal products. This came about during the development of an interferon process using a cancer cell line, Namalva, by Wellcome (10). This company's pioneering work established the safety criteria, and thus acceptance, for using nonnormal (heteroploid, transformed, or tumor-derived cell lines) and the feasibility of scaling up an industrial cell culture process to 8,000 L. Cell culture then entered a new, or modern, phase in which a wide variety of cell products (Table 57.1) is produced from a range of cell types (Table 57.2). Two of these products can be highlighted as being significant milestones. First, the production of monoclonal antibodies from hybridoma cells (the fusion of a normal antibody producing cell and a hemopoitic cancer cell) (12) has given rise to hundreds of new products. Second, the development of recombinant tissue plasminogen activator (tPA) by Genentech (14) gave rise to the first genetically engineered clinical product from cell cultures. Currently applications are widening to include the cell itself as a product in tissue engineering, organ replacement, and gene therapy (15).

In this chapter the description of cell culture reactors is given against this historical evolution of cultures from small-scale virus production through scale-up to the more

TABLE 57.1. Mammalian Cell Products

	Native products
Human vaccines	Polio (1954), measles (1963), rabies (1964), mumps (1969)
Veterinary vaccines	Foot-and-mouth disease vaccine, rabies, Marek's, pseudorabies, BVD, louping ill, bluetongue, avian influenza, canine distemper (examples)
Interferon	Refs 10 and 56
	Engineered products
Monoclonal antibodies	OKT3/Orthoclone (1987), Centoxin (1990), Reopro (1994), Myoscint (1989), Oncoscint (1990)
Tissue-type plasminogen activator	Activase/actilyse (1987)
Erythropoeitin (EPO)	Epogen/Procrit/Eprex (1989), Epogin/Recormon (1990)
Human growth hormone	Saizen (1989)
HBsAg	GenHevac B Pasteur (1989), HBGamma (1990)
Interferon	Roferon (1991)
Colony stimulating factor (G-CSF)	Granocyte (1991), Neupogen (1991)
Blood factor VIII	Recombinate (1992), Kogenate (1993)
Dnase I	Pulmozyme (1993)
Glucocerebrosiduse	Cerezyme (1994)
Follicle-stimulating hormone	Gonal-F (1995)
	rDNA products in development/clinical trial
HIV vaccines (gp120, pg160, CD4)	
Herpes simplex vaccines (gB, gD)	
Chimeric monoclonal antibodies (her2, CD4, TNFa, CD20, Cd18, TAC, leukointegrin, CF54, RSV)	
Others (TSH, TNF, M-CSF, IL-6, IL-1)	
In vitro diagnostic monoclonal antibodies (1–200)	
Tissue engineering and replacement (e.g., skin, artificial kidneys)	

than 10,000-L unit processes that now play a dominant role in the health biotechnology industry, with hundreds of products either already available in the clinic or going through phase I through III clinical trials. The emphasis is on scale-up because of the relatively low biomass productivity of animal cells compared with bacteria, the low product expression rates (one clinical dose is often equivalent to 0.1 to 100 L of culture supernatant), and the need to introduce more efficient and economical industrial processes.

TABLE 57.2. Typically Used Cells in Biotechnology

Cell line	Derivation	Application
CHO	Chinese hamster ovary	Good product glycosylation
CHO dhfr	Mutant for genetic amplification	Principal substrate for recombinant products
BHK21	Syrian hamster	Viruses/veterinary vaccines
Vero	African green monkey	Viral vaccines
HeLa	Human cervical adenocarcinoma	Polio vaccine
MRC-5/WI-38	Human fetal lung fibroblasts	Human vaccines
MDCK	Cocker spaniel kidney	Viral vaccines
Namalwa	Human B lymphoblastoid	Interferon
COS 1/COS 7	African green monkey kidney	Recombinant products
NS0/NS1 and Sp2/0-Ag14	Myeloma	Fusion partners for monoclonal antibody production immunoglobulin
J558L	Mouse Balb/C myeloma	Secretes immunoglobulin A
NIH/3T3	Swiss mouse embryo	Sarcoma virus
GH3	Rat pituitary tumor	Hormone studies
293	Adenovirus transformed HEK	Gene therapy
X CRE/Y CRIP	Mouse NIH3/Moloney leukemia	Retrovirus packaging
		Insect
Sf9	Spodoptera frugipeda	Baculoviruses
Schneider-2	Drosophila melangogaster	Recombinant products

57.2 BACKGROUND

57.2.1 Mammalian Cells

Major differences between single mammalian cells and microorganisms should be noted because they influence, and put constrictions on, the culture process. Cells do not have a cell wall but a thin cell membrane (a phospholipid bilayer) that mediates communication between the cell and the environment. They are thus very sensitive to environmental stimuli, such as pH, nutrients, oxygen, regulatory molecules, and hydrodynamic forces. Cell shape and morphology are controlled by cytoskeletal elements attached to the membrane and running through the viscous cytoplasmic gel. The degree of polymerization of the microtubular network regulates the shape, whether spherical or elongated, flattened or attached. Mammalian cells are on the order of 12–20 μm in diameter (i.e., 1,000-fold greater volume than microorganisms), which means diffusion into the cytoplasm is greatly reduced in the spherical state. When flattened, membrane folding and ruffling give a much greater surface area. Also, mammalian cells are far more fastidious in their nutrient requirements, with critical optimal chemical and physical environmental parameters. The consequence of these factors is that cells need more gentle stirring and aeration procedures than bacteria, which greatly reduces mass transfer and homogeneous mixing in the culture. This need for more moderate stirring and aeration procedures, together with greater sensitivity to nonoptimum or fluctuating culture conditions, slower growth rate (14–22 h average doubling time), and vulnerability to microorganism contamination, means that the culture system has to be extremely well controlled and contained. Some key issues in setting up successful cultures are as follows:

- Cells should be inoculated from the late logarithmic phase rather than stationary cultures.
- Cells should be prepared for inoculation as quickly as possible and the time they are exposed to trypsin, acidity, or low temperatures limited during harvesting.
- The new culture medium should be at the required temperature (37°C), pH (usually 7.1–7.3), and so forth before inoculating.
- The minimum inoculation density ($1–2 \times 10^5$/mL or 2×10^4/cm^2) should always be exceeded.

57.2.2 Scale-Up

57.2.2.1 Principles. Normally a culture process begins with an ampoule, stored at −196°C, of about 5 million cells put into 10 mL of medium, which can then be expanded up to a final volume of 10–20,000 L at 2 million cells per milliliter (i.e., a 1 to 2 million–fold scale-up). This expansion is achieved by a series of ever-increasing culture volumes (the seed train), each step bringing about a 5- to 10-fold volume increase and taking 4 to 5 days. Thus, before the final production culture is initiated, cells will have been passaged at least five times over 25 days. This investment in time and resources shows how important it is to keep sterility by strict attention to all aspects of the process (equipment, reagents, and handling procedures). The scale-up process involves many factors, including engineering (especially to maintain sterility and reliability), physiological (supply of oxygen and nutrients and critical maintenance of the correct environmental conditions), monitoring and control (biosensors, performance measurements, and computer control), logistics, and compliance with pharmaceutical licensing and health and safety regulations. The aim of such scale-up is to provide more cells and more cell product in as efficient and cost-effective a manner as possible while complying with all regulatory and health and safety criteria. This emphasizes the importance of moving from a multiple-unit (many replicate bottles, roller cultures, spinner flasks, etc.) to a high-volume-unit process. Such a shift allows economy in manpower (reduction in repetitive steps), space (expensive hot rooms), and time and an increased efficiency by being able to reproducibly control environmental factors, such as pH and oxygen, in a unit process. The wide range of alternative culture systems that are or have been available (6,7,16) is due (*1*) the need to find processes for both suspension and ADC cells and (*2*) various solutions to overcoming limiting factors in scale-up (17).

57.2.2.2 Limiting Factors in Scale-Up. The first problem in moving from a small, multiple unit process to a large unit process is usually oxygen limitation. To overcome this problem and supply oxygen without the damaging effects of air bubbles from sparging and the high stirring speeds needed to effect efficient mass transfer, bioreactors have been developed that oxygenate through a membrane. This bubble-free aeration has been achieved by means of long lengths of tubing in the bioreactor (18–20) or external medium loops through hollow fiber oxygenators. A related factor is mixing, and low-shear modifications to impellers and the airlift bioreactor concept (21) have been introduced. A problem for ADCs is the limitation on surface area during scale-up. A huge range of reactors have been developed (multiple plates, spirals, ceramic matrices, glass beads), but the most successful method has been the microcarrier (9,22). The large fermentor systems used for suspension cells thus became available for ADCs because the small microcarriers with cells attached behaved analogously to a suspension cell.

The next problem to be overcome is nutrient limitation and toxic metabolite buildup. Although media changes can be used (especially for attached cells), the most efficient

means of overcoming these problems is continuous medium perfusion. To perfuse suspension cells cells and waste medium have to be physically separated; this separation has been done by means of spin filters, external loops to filters or centrifuges, or gravitational settling devices (18). The use of perfusion resulted in the development of many immobilization procedures to prevent cell washout (e.g., encapsulation, hollow fiber devices, membrane reactors, gels, fibers, and porous microcarriers). Additional benefits to these developments were the provision of huge unit surface areas for cell attachment and the ability to grow cells at 50- to 100-fold higher densities than previously achieved in free suspension. Thus these developments mean that manufacturers have a choice in scale-up routes (6).

57.2.2.3 Scale-Up Strategies. Some scale-up strategies are as follows (22–24):

- High-volume (to 10–20,000 L) tank fermentor systems with conventional cell densities of $1–2 \times 10^6$/mL
- Low-volume (<1 L) but very-high-density ($1–2 \times 10^8$/mL) heterogeneous systems (e.g., hollow fiber bioreactors)
- Intermediate systems using spin filters to increase cell density to $1–2 \times 10^7$/mL but to a volumetric scale of only 500 L
- High-density (1×10^8/mL) scaleable systems (to 200 L) based on porous microcarriers

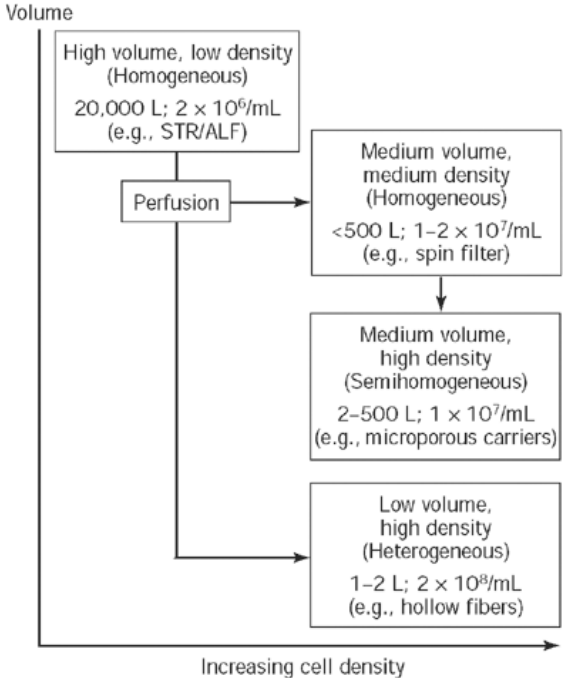

Figure 57.1. Scale-up strategies and the evolution of high cell density culture systems. STR, stirred-tank reactor; ALF, air-lift fermenter.

These systems are summarized conceptually in Figure 57.1. It should be emphasized at this stage that there is no ideal system, but the advantages of high-density systems, summarized in Table 57.3, show why a choice has to be made. Immobilized systems, such as porous microcarriers, also have the advantage of being equally suitable for suspension and anchorage-dependant cells (the Universal System?), protecting from shear, and having a three-dimensional structure that enhances productivity. Basically, the low-volume, high-density systems fill an important niche in manufacturing capability (e.g., gram amounts of monoclonal antibodies), whereas the high-volume systems are the most widely used scale-up route for pharmaceutical products.

57.2.3 Culture Modes

Suspension culture is the preferred method for scale-up because it is easier and cheaper to scale up, requires less space, can monitor cell growth, and can more easily control environmental parameters. However, many cell lines have higher specific productivity when attached to the substrate. In the urge to move to suspension systems the following advantages of anchorage-dependent systems should not be overlooked:

- They facilitate complete medium changes, which are often needed to wash out serum before adding serum-free production medium, for example.
- They are easier to perfuse and thus achieve higher cell densities and healthier cells.

TABLE 57.3. Comparison of High- and Low-Cell-Density Culture Systems

Advantages of high cell density
Smaller reactor volume and therefore reduced need for high-quality laboratory space
More concentrated product
Reduced requirement for expensive serum and growth factors
Long run lengths (50–100 days) and thus less downtime and seed preparation
Daily or continuous harvesting
Shorter residence time for products (and exposure to preteolytic degradation)
Cell debris washout
Disadvantages of high cell density
Volumetric scale-up more difficult and complex
Mass transfer problems leading to heterogeneity
Sterilization problems because some systems cannot be heat sterilized
Higher degree of process control needed (direct cell measurement impossible)
More validation and regulatory conditions for product licensing needed
Perceived as experimental and therefore not accepted as readily as traditional methods

- Media-to-cell ratios are more easily changed during an experiment, thus increasing product titre.

Microcarrier culture, especially porous microcarrier (25), has most of the advantages of both suspension and anchorage-dependent systems.

Different types of culture strategy can be employed; they are defined as follows:

Batch culture. Cells grow from seed to final density over a 4- to 7-day period and are then harvested (typical monoclonal antibody yield is 6 mg/L per batch run)

Fed-batch culture. Additional media or medium components are added to increase culture volume and density of cells as the culture progresses.

Semicontinuous batch culture. A batch culture is partially harvested (e.g., 70%), topped with fresh medium, allowed to grow up again, and reharvested. Typically three to four harvests can be made, although usually with diminishing returns at each harvest.

Continuous-flow (chemostat) culture. Because it is completely homogeneous for long periods of time while cells are in a steady state, this is an extremely useful tool for physiological studies but not very economical for production (by definition, cells are never at maximum density).

Continuous-perfusion culture. This type of culture differs from chemostat in that all nutrients are kept in excess and cells are retained within the bioreactor. This is the most productive culture system, with typical monoclonal antibody yields of 10 mg/L per day for 50–100 days.

There is no definitive answer as to the best system to use; the answer depends on the nature of the cell and product, the quantity of product, downstream processing capability, licensing regulations, and so forth. However, a rough guide to relative costs for producing monoclonal antibodies by perfusion, continuous-flow, and batch culture is 1:2:3.5 (26).

57.3 REACTORS FOR ADCS

57.3.1 Basic Culture Units

Tissue culture flasks and tubes giving surface areas of 5–200 cm^2 are the familiar stock items of any culture laboratory. The largest stationary flask routinely used is the Roux bottle (or disposable plastic equivalent), which gives a surface area of 175–200 cm^2 (depending on make and type), needs 100–150 mL medium, and utilizes 750–1,000 cm^3 of storage space. Such a vessel will yield 2×10^7 diploid, or 10^8 heteroploid cells; thus, to produce a modest 10^{10} cells, more than a hundred replicate cultures are needed (i.e., manipulations have to be repeated 100 times) and 100 L culture space is required. The need to move to larger units is obvious and is approached by increasing the surface-area-to-volume ratio. The first step in scale-up usually involves a change from stationary flasks to roller bottles (i.e., a dynamic system). Roller bottles can be up to 1,750 cm^2, use 350 mL medium, and have a volume of 2.5 L (i.e., a ninefold increase in surface area but only a threefold increase in medium and total volume). This is brought about by using the total internal surface area for cell growth and more efficient aeration as the cells move in and out of the culture fluid. However, this procedure has been used industrially for viral vaccines, veterinary vaccines in multiples of 28,000 (8), interferons, and EPO. It has a place in modern processes largely because it is automatable with robotic systems, such as the Cellmate (Automation Partnership, Royston, Herts, U.K.) and that described by Kunitake *et al*. (27). All the routine manipulations of cell seeding, media changing, bottle gassing, cell sheet rinsing, trypsinization, and cell collection by scraping can be carried out automatically, and reproducibly, with very precise volumes. Examples of products produced by this method are Varivax (Merck varicella vaccine) and Saizen (Serono recombinant human growth hormone).

Many modifications have been made to the roller bottle to increase the surface-area-to-volume ratio. Although some of the following adaptations are no longer commercially available, they are included to stimulate further innovation:

- *Disks*. A series of vertical disks placed along the horizontal axis of the roller bottle (28)
- *Spira-Cell Multi-Surface Roller Bottle (Bibby Sterlin Ltd.)*. A spiral polystyrene cartridge on which cells grow on both sides of the film, available in 2,000, 4,500, and 6,000 cm^2 sizes (29).
- *Glass tubes*. A roller bottle packed with a cluster of small glass tubes arranged in parallel and separated by silicone spacer rings, available in 1,000, 10,000, and 15,000 cm^2 sizes (Bellco-Corbeil Culture System) (30). The initial concept was developed by Chemap as the Gyrogen (31)
- *Extended surface area roller bottles (ESRB)*. A polystyrene roller bottle with a ribbed, or corrugated, surface that doubles the area of an 850-cm^2 bottle to 1,700 cm^2 (Bibby Sterlin Ltd.).
- *ImmobaSil*. Silicone rubber matrix–coated roller bottles that increase the surface area severalfold (Ashby Scientific Ltd., Coalville, U.K.).

Also, to increase cell productivity, roller bottle perfusion systems (32) with specially modified swivel caps (Bellco Autoharvester, New Brunswick Roller Apparatus) can be

used. The roller bottle is a well-established technique and is still widely used in both the research laboratory and the industrial plant. Some cell lines (particularly epithelial) may not be as successfully grown in roller bottles because of streaking, clumping, or inadequate spreading over the total surface (i.e., nonlocomotory cell lines) as in stationary bottles. An alternative scale-up route is to use multisurface plate stationary systems.

57.3.2 Multisurface Plate Units

There are two commercially available examples of multiple-layered polystyrene plates stacked within a polystyrene box. In the Cell Factory (A/S NUNC, Roskilde, Denmark), the trays are 335 × 205 mm (600 cm^2) and can be obtained in multiples of 1, 2, 10, and 40. The largest, therefore, has a surface area of 24,000 cm^2 and needs 8 L medium (i.e., it is equivalent to 14 large roller bottles but requires half the incubation space and no ancillary roller equipment). However, for convenience of handling, especially large numbers, the Cell Factory Manipulator is advantageous because it can be operated robotically.

Although the CellCube (Costar, Cambridge, Mass., USA) (33) also has parallel polystyrene trays, it is a modular closed-looped perfusion system, including an oxygenator, pumps, and a system controller (pH, O_2, level control). The unit is very compact, with the trays being only 1 mm apart; thus, the smallest unit of 21,250 cm^2 is less than 5 L total volume (1.25 L medium). Additional units of 42,500 cm^2 (2.5 L medium) and 85,000 cm^2 (5 L medium) are available, and four units can be run in parallel in the system, giving 340,000 cm^2 growth area.

57.3.3 High-Volume Units

High-volume units are true unit process systems, analogous in volume and performance to suspension cell fermentor vessel processes. Examples include (*1*) the multisurface propagator (34), with vertically stacked circular stainless steel plates on a central revolving shaft scaled up to 200 L (200,000 cm^2), and the titanium plate reactor (35); (*2*) the plate heat exchanger (36,37); (*3*) glass spheres (38–41); (*4*) microcarriers (9,42,43); (*5*) porous microcarriers (44–46); and (*6*) stainless steel wire coils (48).

57.3.3.1 Glass Bead Culture. Packed beds of 3- to 5-mm glass spheres through which medium is continuously perfused has a demonstrated scale-up to 100 L (49). Spheres of 3-mm diameter pack sufficiently tightly to prevent the bed from shifting but allow sufficient medium flow up the column so that fast flow rates, which would cause shear damage, are not needed. The physical properties of glass spheres are given in Table 57.4. Medium can be circulated by pump or by airlift (to give better oxygenation) (50). Although 3-mm beads are normally used to maximize the available surface area, the use of 5-mm spheres can actually give a higher total cell yield, despite the reduced surface area per unit volume, because of better physiochemical conditions (6,39). Scale-up has vertical limitations in that it is difficult to maintain a uniform plug flow without channeling. For inoculation, the use of a perforated tube placed centrally for the height of the bed allows even distribution of cells. Also, alternating the direction of medium flow on a daily basis increases homogeneity and thus scale-up potential. In conclusion, glass sphere packed beds constitute a simple system (that minimizes moving parts and the risk of mechanical failure) with an inexpensive and reusable substrate capable of considerable radial and reasonable vertical scale-up to operate beds of volumes more than 200 L using 5-mm spheres. The disadvantages are that it is a low-intensity system (spheres have the minimum surface area per unit volume) and is limited to secreted products because it is difficult to harvest cells from the bed (i.e., it is ideal for long-term continuous cultures rather than batch cultures, as demonstrated by Brown *et al*. (51)). Experimental protocols for using glass sphere technology have been published (52).

57.3.3.2 Microcarrier Culture. Microcarriers are small particles, usually spheres, 100 to 300 μm in size, that are suspended in stirred culture medium. The concept was initiated in 1967 (9); however, the chromatographic grade of dextran (Sephadex A-50) then used proved unsuitable for consistent and reliable growth. After considerable developmental work, Pharmacia produced a range of suitable microcarriers—the Cytodex series. The first industrial process based on microcarriers was for FMDV (43,53). Subsequently a wide range of microcarriers based on gelatin, collagen, polystyrene, glass, cellulose, polyacrylamide, and silica have been manufactured to meet all situations (23,54) (Table 57.5). The key criteria were to get the surface chemically and electrostatically correct for cell attachment, spreading, and growth. The power of the method is exemplified by the following data:

TABLE 57.4. Properties of Solid Glass Sphere Fixed-Bed Reactors

Glass sphere (diameter)	3 mm	5 mm
Weight, g	0.0375	
Surface area, cm^2/kg	7,546	4,570
Volume, mL/kg	990	625
Void fraction	0.46	0.40
Void volume, mL/kg	455	250
Channel size, mm^2	0.32	1.00
Vero cell yields		
$10^5/cm^2$	0.78	2.5/3.1[a]
10^8/kg	4.00	8.0/9.9
10^6/mL	1.6	3.2/4.0

[a] Yield in 1 kg/10 kg bed reactors.

TABLE 57.5. Microcarriers

Name	Manufacturer	Material	cm^2/g
	Solid microcarriers		
Bioglas	Solo Hill Engineering	Glass/latex	350
Bioplas	Solo Hill Engineering	Polystyrene	350
Biosilon	Nunc	Polystyrene	255
Cytodex 1, 2	Pharmacia	Dextran	6,000
Cytodex 3	Pharmacia	Collagen	4,600
Dormacell	Pfeifer & Langen	Dextran	7,000
Gelibead	Hazelton Laboratories	Gelatin	3,800
Micarcel G	Reactifs IBF	Polyacrylamide	5,000
Microdex	Dextran Products	Dextran	250
			Diameter (μg)
	Microporous microcarriers		
Cellsnow	Kirin Ltd	Cellulose	800–1,000
Cytocell	Pharmacia	Cellulose	180–210
Cultispher	Hyclone	Gelatin	170–270
Cytoline 1,2	Pharmacia	Polyethylene	1,200–1,500
ImmobaSil	Ashby Scientific	Silicone rubber	1,000
Siran	Schott Glaswerke	Glass	400–5,000

1 g Cytodex = 6,000 cm^2, which at 2 g/L = 12,000 cm^2/L (i.e., eight large roller bottles). Scale-up to 4,000 L (equivalent to 3,200 roller bottles) has been achieved in an environmentally controlled and optimized process. This method opened up industrial production opportunities (Table 57.6) and allowed research laboratories to easily produce substantial quantities of developmental products.

Experimental considerations and principles (54) are as follows:

- Because cells differ in their attachment requirements, a range of microcarriers should be assessed.
- Microcarriers vary in their density (1.01 to 1.06), mechanical robustness, hardness, and the concentration at which they can be used. These factors have implications for the choice of process (e.g., stirring system, need for rapid sedimentation due to frequent medium changes, and total unit surface area required: Cytodex 6,000 cm^2/g, glass or polystyrene 300 cm^2/g).
- Culture equipment is critical. Small-scale culture requires the use of specially designed spinner flasks rather than the conventional magnetic bar and siliconized glass to prevent microcarrier attachment.
- Culture initiation conditions are critical and should include a high-quality single-cell inoculum and a prewarmed and stabilized culture medium. Inoculation should not be undertaken below the minimum cell number per bead (usually five, optimally seven), and a nutritionally supplemented medium (e.g., with nonessential amino acids) might be necessary.
- Instead of counting by the trypan blue technique, after trypsinization the nuclei-counting method (57), should be used.
- Some microcarriers can be reused, and it may be possible to recolonize microcarriers in situ during scale-up (58).
- >Enzyme harvesting (e.g., trypsin) can be difficult or damaging, so consideration should be given to using a microcarrier that can be enzymically digested (e.g., by dextranase or collagenase), leaving the cells intact.

TABLE 57.6. Industrial Processes Using Microcarrier Technology (See also Chapter 32 in volume 1)

Product	Cell line	Scale (L)	Company	Reference
Foot-and-mouth disease vaccine	Pig kidney	235	Merrieux	50
Polio and rabies vaccines	PKMC	500	RIVM (Bilthoven)	55
Polio and rabies vaccines	Vero	1,000	Merrieux	43
Human IFN-β	HDC	50	Sclavo	11
Human IFN-β	HDC	4,000	Toray	
Human growth hormone	Vero	100	UNSW (Australia)	56
Tissue-type plasmingon activator	Bowes melanoma	40	RIVM (Bilthoven)	42

- Microcarriers, such as Cytodex, should be used between 1 and 3 g/L unless a perfusion system (e.g., using a spin filter) is employed, with which concentrations of 15 g/L are feasible (39).
- Inoculation in a reduced volume assists attachment and should be followed by topping up to the final working volume after 4–8 h.
- An advantage of microcarriers is the ease with which cell samples can be taken and analyzed.
- As the culture progresses, partial medium changes will have to be carried out and the stirring speed increased from 40–60 rpm to 75–90 rpm to prevent microcarrier aggregation.

In conclusion, microcarrier culture is the most versatile, reliable, and well-characterized procedure for unit volume scale-up of ADCs. It has had widespread use for industrial processes (Table 57.6), as well as many developmental uses (59), has been scaled up to 4,000 L, and has the potential for process intensification by perfusion with spin filters or by the use of microporous microcarriers.

57.4 REACTORS FOR SUSPENSION CELLS

57.4.1 Laboratory Scale

The basic culture unit for suspension cells is the spinner flask, so called because it has a magnetic bar operated by standing the unit on a magnetic stirrer. Initially a bar magnet was placed on the floor of the glass vessel, but spinner flasks now have the magnet suspended just above the bottom of the culture on a stirrer shaft fitted to the bottle top to prevent cells from being crushed. Side arms are usually fitted to allow gassing with CO_2/O_2 through a filter and for sampling. There are many variations in the design of spinner flasks, most affecting the size, number, and positioning of the stirrer bar (6,23). The spinner flask is usually glass, with a silicone- or Teflon-coated magnet and is available in sizes from 50 mL to 20 L, although 10 L should be considered the maximum practical size. The quality of the magnet stirrer (usually multibased to take at least four replicates) is extremely important because it must maintain a stable rpm between 30 and 300, an accurate tachometer, ability to restart after power interruptions at the set speed, a surface that does not become hot, and reliable operation for long periods in a 37°C environment. It is advisable to siliconize the culture vessel and add medium supplements, such as Pluronic F-68 (polyglycol) (BASF, Wyandot) at 0.1% to protect against mechanical damage, especially if low serum concentrations are used. Carboxymethyl cellulose (CMC, 15–20 cps) can also be used to protect cells (0.1%) and antifoam (6 ppm) if foaming is a problem (usually when serum is present at 5–10%). Stirring speeds for suspension cells are usually within the range of 100–250 rpm (depending on cell type and vessel geometry), and a culture will expand from $1–2 \times 10^5$/mL to $1–2 \times 10^6$/mL in 4 to 5 days before needing either harvesting or a medium change. Cell clumping is often a problem but can be reduced by using low Mg^{2+} and Ca^{2+} ion media. Conventional spinner flasks are available from a wide range of laboratory suppliers. The range includes ones with large-bladed paddles attached to the magnet. They are primarily designed for microcarrier culture to give better mixing at the lower speeds necessary. Modified spinner cultures include a radial stirring action (Techne) (60), a floating impeller (Techne BR-06 Bioreactor), the Superspinner (Braun Melsungen AG), CellSpin (Tecnomara AG, Switzerland), and a dual overhead drive system to allow perfusion (Bellco). Experimental details for using spinner flasks have been published (61).

57.4.2 Scale-Up

Suspension culture is the preferred method for scaling up cell cultures because it is easier to volumetrically increase the size of a single fermentor vessel than the specialized units used for ADCs. Although some cell lines will not grow in suspension (e.g., human diploid cell lines WI-38 and MRC-5), many lines can be adapted to grow in free suspension by recognized procedures (62).

Several physical factors must be satisfied for successful scale-up. Good mixing is essential for homogeneity and efficient mass transfer, but during scale-up the power needed to produce these conditions can cause problems. The energy generated at the tip of the stirrer blade is a limiting factor because it gives rise to damaging shear forces (created by fluctuating liquid velocities in turbulent areas); because mixing efficiency increases with turbulence, a compromise has to be reached to minimize cell damage. Thus cell cultures use large impellers running at relatively low speeds. Magnetic bars used in spinner flasks give only radial mixing, with no lift or turbulence, and scale-up means a move to marine (not turbine) impellers. Alternative systems developed to avoid stirring are as follows:

- *Airlift fermentor.* The airlift fermentor uses the bubble column principle to both agitate and aerate a culture (21,28,63,64). Air bubbles are introduced into the bottom of a culture vessel (aspect ratio 8–12:1) and rise up an inner draft tube. Aerated medium has a lower density than nonaerated medium so the medium rises through the draft tube and circulates down the outside of the vessel (upflow and downflow approximately equal volumes). The amount of energy needed is very low and shear forces are absent; thus it is an ideal method for fragile cells. Airflow rates of about 300 mL min^{-1} are used. Vessels are available from 2 L upward, with 2,000 L reactors used in industrial

manufacturing processes. However, scale-up is more or less linear, and a 90-L vessel requires 4 m headroom; special manufacturing suites are thus needed for large-scale operations.

- *Vibro-mixer.* The Vibro-mixer (65) is a nonrotating agitator that produces a stirring effect by a vertical reciprocating motion with a path of 0.1–3 mm at a frequency to 50 Hz. The mixing disk is fixed horizontally to the agitator shaft, and cone-shaped holes in the disk cause a pumping action as the shaft vibrates. This is a low energy system with reduced shear forces and foaming.
- *Celligen fermentor.* This fermentor (66,67) is available from New Brunswick Scientific and is designed so that the impeller acts as a fluid pump and aerator. Macrocirculation mixing is generated by the hollow central shaft filled with three rotating horizontal jet tubes in a low-shear bulk movement of cells and medium (cell-lift effect).

The other principal physical factor to be accommodated is aeration. Sparging can cause cellular damage unless carried out at very low rates. General guidelines are to use large bubbles (1–3 mm diameter) and low flow rates (5–10 cm^3/L/min), which means relatively inefficient mass transfer, especially at the low stirring rates used. Even though cell bioreactors have an aspect ratio of less than 2:1 to maximize surface diffusion, a means of increasing oxygen supply during scale-up is essential. Strategies for increasing the oxygen supply have included a surface aerator (68), multiple nozzle injection on the medium surface (69), caged aerator (70), spin exchange aerator (37), external and internal loop oxygenator (71), membrane tubing arranged in the vessel (19), and stirring system (20). The use of closed perfusion loops through external reservoirs is also an efficient means of oxygenation as long as the perfusion rate is fast enough (6), which requires a very efficient spin filter or other cell separation device in the culture.

Scale-up from laboratory spinner cultures to fermentors (1–10,000 L) has the following consequences:

- Change from glass to stainless steel vessels
- Change from mobile (autoclavable) to in situ system connected to steam, seed, medium holding and downstream harvesting vessels, and so forth
- Requirement for water jacket, or internal temperature control
- Greater sophistication in environmental control systems and engineering to preserve integrity

Animal cell bioreactors were adapted from the microbial fermentation tanks with only minor modifications:

- Suitable impeller (e.g., marine)
- No baffles and a curved base for better mixing at low speeds
- Water jacket rather than immersion heater type of temperature control (to avoid localized heating at low stirring speeds)
- Top-driven motor stirrer so that cells cannot become entangled between moving parts
- Mirror finish to internal surfaces to reduce mechanical damage and cell attachment

57.4.3 Large-Scale Bioreactors

Large-scale bioreactors described in the previous chapters are based on either the fermentor tank or the airlift principle. Stirred tanks have been operated at 8–10,000 L (14) for the production of interferon and tPA and airlift at 2,000 L principally for monoclonal antibodies. The preference is for the tank fermentor because this is a well-tried and familiar production method using conventional production plant facilities that have been refined over the past 30 years. However, most processes run at scales between 50 and 500 L. Airlift bioreactors are considered more flexible in that a greater range of cells (including extremely fastidious and fragile types) can be grown in them. However, scale-up is very dependent on tall buildings. A modification of the single-cell suspension system is to grow cells as aggregates or flocculants brought about by the addition of slightly positively charged polymers (e.g., poly-L-histidine) (72). Flocculants facilitate process operations such as filtration, centrifugation, perfusion, and sedimentation, and the microenvironment created within the cell aggregate can increase specific productivity (73).

Scale-up increases the complexity of equipment and the process and thus gives rise to greater risks of system failure, loss of integrity (sterility), and potential release of hazardous materials. Because the reason for scale-up is the production of therapeutic biological products, conditions have to comply with current good manufacturing practice (cGMP) standards acceptable to the relevant licensing authorities. Containment of the process to prevent ingress of contaminating factors and release of materials that may affect the process worker and environment are thus key factors in these processes. Microbiological containment of small-scale systems (below 20 L) in class III microbiological cabinets is possible (74), and larger-scale fermentation plants can be contained to P3 standards at least up to the 150-L scale (75).

The scale-up chain to the final production vessel is governed by the split ratio possible with the particular cell line at each subculture and is usually between 1:3 and 1:5. The chain starts with an ampoule of cells stored at $-196^{\circ}C$ (liquid nitrogen) in a master cell bank (MCB) that has been fully characterized for biological contaminants and cell line stability (76). All manipulations are carried out according

to standard operating procedures to obtain reproducibility between runs and to generate the necessary quality control data for acceptance of the final product.

The engineering complexity and considerable resource investment in money and time to build and operate a large-scale production process means that many new products are still brought to market using replicate small-scale systems. This provides for quicker market entry but requires complete reregistration of the product if the product is later moved to a large-scale production process. The experimental procedures for scaling up a stirred bioreactor process have been described (77).

57.5 HIGH-CELL-DENSITY BIOREACTORS

The alternative strategies for scale-up were outlined earlier. In this section the processes that support cells at significantly greater densities than the classical $2-3 \times 10^6$/mL level are described. In the human body cells in tissues are on the order of $2-3 \times 10^9$ cells/cm^3, and this has always been a target for in vitro systems. However, 2×10^8 cells/mL has so far been the practical limit of density scale-up; even so, this is a 100-fold increase over the conventional low-density methods described so far. The two critical factors needed to achieve higher unit cell density are (*1*) perfusion to supply nutrients and remove waste products (78) and (*2*) cell immobilization to perfuse media at a fast enough rate without damaging or washing the cells out of the culture. Many devices have been developed to meet these requirements (6,7,18,22) (Table 57.7), of which hollow fiber bioreactors, spin filter perfusion, and microporous microcarriers are the most successful in terms of acceptance and use.

57.5.1 Hollow Fiber Bioreactors

Use of hollow fiber bioreactors was pioneered by Knazek *et al*. (95) using ultrafiltration capillary fibers. They can be considered analogous to a blood vascular system because the fibers selectively (by molecular weight cutoff) allow passage of macromolecules through the spongy fiber wall (60 μm) as the medium flows continuously through the lumen (200 μm in diameter). Cells are kept in the extracapillary space. A unit consists of thousands of fibers potted at either end in a cylindrical housing and capable of supporting both ADCs and suspension cells at $1-2 \times 10^8$/mL. This concept has been widely developed, with many commercial units available, and has been used particularly for producing monoclonal antibodies. The principal limiting factor in its exploitation is the difficulty in scaling up beyond very small volumes (25 mL). The problem is due to transmembrane flux being directed back into the lumen for the latter half of the flow path (6,112). Methods of overcoming this gradient problem include the insertion of contraflow and aeration fibers (112), cyclical flushing of medium between the lumen and extracapillary compartment (113), use of flat-bed rather than cylindrical filtration cartridges (91), and use of a radial flow reactor (114). The concept of using pressure differentials to simulate in vivo arterial and venous flow is used in the Acusyst System (Cellex Biosciences, Inc.). This system is well documented (113), including experimental details (115), and is probably the most used and successful application of hollow fiber technology.

To allow ADCs to attach, special fibers can be used (e.g., Amicon 3S1000) to give a huge surface area (1-L cartridge has 1 m^2 surface area and supports 10^{10} suspension cells or 2×10^9 ADCs). Thus this method gives a very large surface-area-to-volume ratio, allows continuous removal of waste products and supply of nutrients, supports high cell densities with a tissuelike architecture, and allows a concentrated product to be harvested. The disadvantages are diffusional limitations that cause culture inhomogeneity and cell necrosis, process control complexity, and difficulty in sterilization.

TABLE 57.7. Devices Used for Immobilizing Animal Cells to Permit Medium Perfusion (see also Chapter 46 in this volume)

Device	Reference
Gravitational settling of cells in medium outflow	79–81
Spin filter	5,66,69,81–85
Centrifuge circulation loop	86,87
Filtration membrane

Hollow fibers	91–95
Membranes	96,97
Encapsulation	98–100
Entrapment	
Textured ceramics	101
Tubular flow reactor	102
Cellulose or polyurethane sponges	103,104
Fibers	105,106
Polyester (Fibra-cel)	107
Microporous microcarriers	46,47,108–111

57.5.2 Spin Filters

Because all static filters within a culture eventually become blocked, the development of a rotating filter that creates a boundary effect, thus delaying cell attachment and filter clogging, has been a successful step forward. The principle was introduced by Himmelfarb in 1969 (82) using a 3-μm stainless steel mesh rotated at 300 rpm. Subsequently there have been many variations (reviewed in Ref. 6): polymers (84), ceramics, microfibers, porcelain, immersed cages, baskets semiimmersed in the culture or attached to the stirrer shaft, separate rotating shaft (to increase rpm), filter within a draft tube and so forth. They provide a simple technical solution to scaling up process intensity within well-established stirred fermentors. They are limited in

that clogging eventually occurs and in the perfusion rate that can be maintained. However, they are particularly useful for microcarriers because a far larger mesh can be used, thus reducing the onset of filter clogging and permitting cell densities of 2×10^7/mL to be attained.

57.5.3 Microporous Microcarriers

Microcarrier culture has proven to be the most effective scale-up method for ADCs, despite its limitations (critical procedures, low surface-area-to-volume ratio of a sphere). Attempts were made to increase the surface area by surface indenting techniques but were not successful until the fabrication of porous particles. The initial particle was the Verax microsphere (47,108), which was 500 μm in diameter and manufactured from bovine collagen; the interconning channels of 20–40 μm diameter gave an internal open volume of 80% of the sphere. They were designed for fluidized-bed reactors, and thus their specific gravity was artificially increased to 1.7 with the addition of small metallic weights incorporated into the matrix. The spheres were fluidized at 75 cm/min upward flow, and cell densities in excess of 10^8 per milliliter intrasphere volume were achieved (equivalent to 4×10^7/mL in the bioreactor). The sphere matrix provided a huge surface area for attachment of ADCs but was equally suitable for suspension cells (which were entrapped in the pores). The system was scaled up to 24 L routinely and 200 L in the company's production unit and used for more than 85 different cell lines producing many cell products (including tPA, pro-urokinase [proUK], EPO, interferon, interleukin, factor VIII, and various immunoglobulins).

Verax was initially a closed product in that you had to invest in the complete system. Thus other microporous beads were quickly developed (Table 57.5). Alternative systems are also available such as the Pharmacia Cytopilot using Cytoline porous microcarriers (110). Microporous microcarriers that could be used in stirred rather than fluidized bioreactors are preferred and now available (Cellsnow and ImmobaSil). ImmobaSil (116) is of particular value because it is extremely permeable to oxygen, a robust, nonanimal product safe from bovine contaminants that can be used in all culture modes. Because the concentration of spheres is far less, the total cell mass is greatly reduced in stirred systems. However, it allows manufacturers to use conventional stirred equipment and increases cell density in the microcarrier system from 2×10^6/mL to in excess of 5×10^7/mL (using spin filter perfusion and aeration).

An alternative to using stirred or fluidized microporous carriers is use of a fixed bed of porous glass spheres (e.g., Siran) (46,109). Fixed-bed reactors of solid glass spheres have many advantages (111), and the disadvantage of low cell density can be overcome by using 5-mm Siran spheres. These spheres have surface areas of 75 m^2/L with interconning pores and channels of 60–300 μm and can be stacked in 5-L beds and perfused at 5 linear cm/min to provide a high feed rate without washing out or damaging the cells (protected from shear within the particles). The versatility and usefulness of this technique has been demonstrated for a range of suspension and anchorage-dependent cells, resulting in a 10-fold higher productivity over equivalent systems (18,117–119). A characteristic of all microporous carrier systems is that cell specific productivity is always higher (18,117), presumably due to the favorable environment of cells packed together in almost tissuelike density. Details on experimental methods have been published; fluidized-bed (120), fixed-bed (121), and commercial fixed-bed reactors are available (Meredos GmbH, Bovenden).

The advantages of porous carrier culture are summarized in Table 57.8. This technology is truly universal in being equally suitable for suspension cells and ADCs and flexible in the range of bioreactor systems it can be in. It is the only truly scaleable high-cell-density system available and provides a microenvironment that stimulates cell product expression. As the need for high-quantity biopharmaceutical manufacture increases, this technology will become increasingly widespread in application and use (Table 57.9).

TABLE 57.8. Advantages of Microporous Microcarriers

Unit cell density 50- to 100-fold higher than that of free suspension
Suitable for both attached and suspended cells
Can be used in fluidized- and fixed-bed reactors and stirred suspension
In situ 100- to 250-fold seed expansion eliminates seed chain steps
Diffusion into a sphere efficient (30% diameter penetration = 70% of volume)
Cells protected from shear
Specific cell productivity increased three- to five-fold
Three-dimensional structure easily derivitized for specialized cells
Capable of long-term (>100 days) culture with continuous harvesting
Scale-up potential by comparison with analogous systems (microcarrier to 4,000 L)

TABLE 57.9. Necessary Conditions for the Acceptance of Scaleable Immobilized Bioreactors

Insufficient quantities produced by other methods
Product only produced by immobilized or specialized cells that need three-dimensional culture
End product price only attainable with scale-up economies possible with these systems
Increased production plant capacity when expansion is no longer possible
New company or product beginning registration process
Sufficient data and experience accumulated to give manufacturing confidence

57.6 COMPARISONS, CONCLUSIONS, AND FUTURE DEVELOPMENTS

Given the range of culture strategies and options mentioned in this chapter, how does one choose the system best suited to the problem at hand? In Figure 57.2, a flow sheet of the options is given by which a product manager can reach such a decision based on the cell line, the product type, the time table, the available plant and resources, the manpower, and the annual product requirement. The question of whether to take the high-volume or high-density option is based on the considerations summarized in Tables 57.3 and 57.8 and the range of total cell densities that various bioreactors will support (Fig. 57.3). The system chosen will be the one that fulfills the defined need at the minimum commercial risk, because there is no one ideal system to meet all needs.

The future of animal cell biotechnology as a production vehicle for therapeutic products is as an essential component in a range of biological processes. Recombinant microorganisms will be the first method of choice for simple, nonglycosylated products without complex three-dimensional configurations necessary for bioactivity. Transgenic production may take over for products needed in 50 to 100-kg quantities. However, society may demand that these products be produced even at greater considerable cost in culture systems to reduce the exploitation of animals; this will be the driving factor for high-volume high-density systems based on microporous microcarriers. Finally, engineering solutions (122) to scale-up are not the only means of increasing unit productivity and economy of cell manufacturing processes. Considerable advances are being made in increasing cell-specific productivity from a modest 0.2 mg/10^6 cells/day to nearer in vivo levels of 7 mg/10^6 cells/day by cell engineering (recombinant control of metabolic processes). Advances are also being made in development of media and the environment to

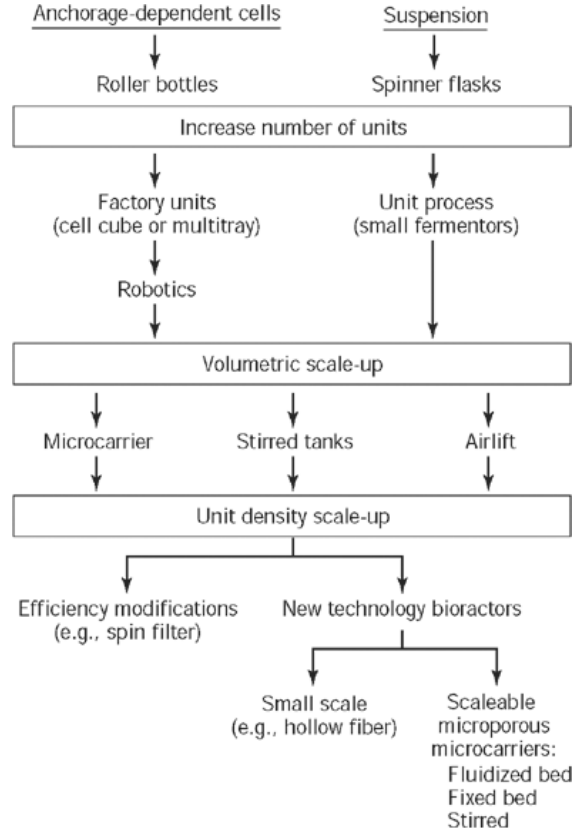

Figure 57.2. Scale-up: the decision process.

Scale (L)	System	Area (cm^2) (batch size)	Cells per batch (cells/L)
	Roller	1,750 (× 100)	2×10^{10} (2×10^{8})
	Multitray	24,000 (× 10)	3×10^{10} (3×10^{9})
	Cell cube	85,000 (× 4)	4×10^{10} (9×10^{9})
1	Hollow fiber	20,000	10^{10} (10^{11})
20	Microporous microcarrier	2.5×10^{6}	10^{12} (5×10^{10})
100	Glass sphere	10^{6}	10^{11} (10^{9})
200	Stacked plate	2×10^{5}	2×10^{10} (1×10^{8})
500	Microcarrier (with spin filter)	2×10^{10}	10^{13} (5×10^{10})
2,000	Airlift		4×10^{12} (2×10^{9})
4,000	Microcarrier	5×10^{6}	8×10^{12} (2×10^{9})
10,000	Stirred tank		2×10^{13} (2×10^{9})

Figure 57.3. Comparison of culture systems indicating volumetric size, unit, and system cell yields.

regulate cell growth, metabolism, and product expression in simpler (cheaper) media. There are also considerable improvements to be made in downstream scale and efficiency, where often only 20% of the product survives the purification process.

MASS TRANSFER

YUSUF CHISTI
Massey University, School of Engineering, Palmerston North, New Zealand

58.1 INTRODUCTION

Mass transfer phenomena impact upon all facets of bioprocessing. Transport effects often determine the productivity of bioreactors and the downstream recovery operations. Gas–liquid mass transfer problems arise during supply of oxygen from a gas phase to liquid culture, and during removal of metabolically generated carbon dioxide from a culture fluid to a gas phase. Similarly, gas–liquid mass transfer issues must be faced again during recovery operations such as distillation. Liquid–liquid mass transfer occurs when oxygen is supplied through liquid carriers such as perfluorocarbons during liquid–liquid extraction, and during degradation of water immiscible liquid substrates. Solid–liquid mass transfer problems are faced during recovery by adsorption, during chromatographic separations, and in operations such as crystallization. Performance of solid-phase biocatalysts such as immobilized cells and enzymes is often limited by solid–liquid mass transfer. Solid–liquid mass transfer effects influence the workings of membrane separations such as microfiltration and ultrafiltration. Transport within solid particles or intraparticle mass transfer becomes limiting in certain cases. Gas–solid transport is seen during some drying situations. Some of these transport issues are the focus of this chapter.

Ultimately the transport of a solute through any fluid or space is governed by the molecular diffusivity or the diffusion coefficient of the solute in the fluid or solution. How diffusivity is affected by factors such as temperature and viscosity, and the estimation of diffusivities in various situations are discussed below.

58.2 DIFFUSION COEFFICIENT OR DIFFUSIVITY

Diffusion coefficient is a measure of a solute's mobility in a solvent. Diffusion coefficient depends on temperature, the type of solvent and its viscosity, and the concentration of solute in solution. Diffusivities in liquids and gases generally increase with temperature. Liquid-phase diffusivities are little affected by pressure, but in gases diffusivities decline as pressure increases. Typically, liquid-phase diffusivities are much lower, only about a hundredth, compared to those in gases. Diffusion coefficients of common solute–solvent combinations are available in handbooks. Tables 58.1 and 58.2 provide some bioprocess-relevant data. Methods of measuring diffusion coefficients have been described by Geankoplis (1) and Pratt (2). When diffusion coefficients are not available, they can be estimated.

Diffusivities of small solutes diffusing in dilute liquids can be estimated using the Wilke and Chang (3) equation,

$$D_{\mathrm{L}} = 1.173 \times 10^{-16} \frac{(\xi M_{\mathrm{L}})^{0.5}\, T}{\mu_{\mathrm{L}} V_{\mathrm{M}}^{0.6}} \qquad (58.1)$$

where M_{L} and μ_{L} are the molecular weight and the viscosity of the solvent, respectively; T is the absolute temperature, V_{M} is the molar volume of the solute at its boiling point, and ξ is the association parameter—a measure of polar interactions among molecules—of the solvent. Association parameters of some common solvents are noted in Table 58.3. The molar volumes are given in handbooks,

Ethanol	1.5
Benzene	1.0
Ether	1.0
Heptane	1.0
Other unassociated solvents	1.0

Based on Ref. 3.

or, for organic solutes, they are easily calculated by the group contribution method (1,2). Equation 58.1 is suitable for small solutes with $V_M \leq 0.500$ m^3/kmol. When molar volumes are larger, as with globular proteins, the Stokes–Einstein equation may be used to estimate diffusivities; thus,

$$D_L = \frac{9.96 \times 10^{-16}\, T}{\mu_L V_M^{1/3}} \tag{58.2}$$

Larger molecules diffuse more slowly than smaller ones. For example, the diffusivities of globular proteins (Table 58.2) are much lower than those of smaller solutes listed in Table 58.1.

Small solutes such as sugar or oxygen diffusing in solutions of proteins, move more slowly than in water. Diffusion coefficient D_P of a small solute in a solution of globular protein can be approximated as (1)

$$D_P = D_L(1 - 1.81 \times 10^{-3} C) \tag{58.3}$$

where D_L is the diffusivity of the solute in water and C (kilograms per cubic meter) is the concentration of protein in solution. Equation 58.3 is suitable only when the diffusing solute does not associate with the protein molecule. When a solute associates with the protein, a part of the observed diffusivity of the solute is due to diffusion of the protein molecules, and a part is due to diffusion of unassociated solute.

Small molecules diffusing through gels such as agar, gelatin, and alginate, diffuse more slowly than in water. The diffusion coefficient declines with increasing concentration of the gelling agent; however, in typically formulated gels, diffusivities are only 20–50% lower than in water. Inorganic salts and electrolytes that dissociate in water actually diffuse as "molecules" in the absence of electric fields. Diffusivities of electrolytes may be estimated using methods discussed by Pratt (2) and Knudsen *et al*. (4).

58.3 GAS–LIQUID MASS TRANSFER

Many industrial fermentations require oxygen. Oxygen supply must at least equal the oxygen demand or the fermentation will be oxygen limited. Oxygen demand is especially difficult to meet in viscous fermentation broths and in broths containing a large concentration of the oxygen consuming cells. In large fermenters, oxygen transfer becomes difficult when demand exceeds 4–5 kg/m^3 h (5). Above a critical concentration of dissolved oxygen, the amount of oxygen does not influence the specific growth rate. The critical dissolved oxygen level depends on the microorganism, the culture temperature, and the substrate being oxidized. The higher the critical dissolved oxygen value, the greater the likelihood that oxygen transfer will become limiting (5). Under typically used culture conditions, fungi such as *Penicillium chrysogenum* and *Aspergillus oryzae* have a critical dissolved oxygen value of about 3.2×10^{-4} kg/m^3. For baker's yeast and *Escherichia coli*, the critical dissolved oxygen values are 6.4×10^{-5} and 12.8×10^{-5} kg/m^3, respectively (5). For comparison, the dissolved oxygen concentration in an air saturated sterile medium is typically around 7×10^{-3} kg/m^3; hence, in terms of percentage of

air saturation, the minimum acceptable dissolved oxygen level in a fungal fermentation is about 5%.

Oxygen uptake rate of mammalian cells is typically $(0.8–8.0) \times 10^{-15}$ kg O_2/cell h. In suspension culture of animal cells, cell concentrations typically reach $(1–1.2) \times 10^6$ cells/mL; concentrations up to 1.2×10^7 cells/mL are attained in perfusion culture and even higher values occur in immobilized cell bioreactors. The critical dissolved oxygen concentration for animal cells tends to be low, for example, 0.5% of air saturation, or 0.035 kg/m^3.

The transport route of a soluble gas from the gas to the liquid phase is schematically illustrated in Figure 58.1. The gas may be imagined as passing through stagnant gas and liquid films on either side of the gas–liquid interface. The resistance to transfer is localized within the stagnant films and the gas–liquid interface is itself assumed to offer no resistance to mass transfer. Mass transfer in the films occurs solely by diffusion; therefore, at steady sate, linear concentration profiles exist in the films (Figure 58.1). The transport flux (J) of the diffusing species is related to the concentration gradient (ΔC) in the film and to the film thickness (δ) as follows:

$$J = \frac{D}{\delta}\Delta C \tag{58.4}$$

In Equation 58.4, D is the diffusivity of the transferring component in the film. The ratio D/δ is known as *the mass transfer coefficient*, k.

In the steady state, the flux of the diffusing component—or the rate of transfer per unit cross-sectional area—is the same through the gas and the liquid films; thus, Equation 58.4 may be written for each of the two films:

$$J = k_G(C_G - C_{Gi}) \tag{58.5}$$

$$= k_L(C_{Li} - C_L) \tag{58.6}$$

where k_G and k_L are the gas and the liquid film mass transfer coefficients, respectively. The overall mass flux from the gas to the liquid phase may be written as follows:

$$J = K_L(C^* - C_L) \tag{58.7}$$

where C^* is the saturation concentration (i.e. the maximum possible value) of the diffusing component in the liquid in equilibrium with the gas phase and K_L is the overall mass transfer coefficient based on the liquid film. The saturation concentration C^* in the liquid is related to the gas-phase concentration (C_G) of the diffusing component by Henry's law:

$$C_G = HC^* \tag{58.8}$$

where H is the dimensionless Henry's constant (6). Using Equations 5–8 and the knowledge that $C_{Gi} = HC_{Li}$ (i.e. equilibrium exists at the interface because the interface offers no resistance to mass transfer), the various mass transfer coefficients can be shown to be related as follows (6):

$$\frac{1}{K_L} = \frac{1}{k_L} + \frac{1}{Hk_G} \tag{58.9}$$

For a sparingly soluble gas such as oxygen, H is much greater than unity ($H \approx 30$ for oxygen in water); furthermore, the coefficient k_G is typically larger than k_L because the gas-phase diffusivities are vastly greater than those in liquids (e.g. $D_{oxygen/air} = 10^4\ D_{oxygen/water}$ at 20°C). Consequently, the second term on the right-hand side of Equation 58.9 is negligible relative to the first, and the equation becomes

$$\frac{1}{K_L} \approx \frac{1}{k_L} \tag{58.10}$$

This implies that essentially all resistance to interfacial mass transfer of a sparingly soluble gas is localized in the liquid film at the interface, that is, the mass transfer is liquid film controlled (6).

Because the transport flux J equals the rate of transfer per unit gas–liquid interfacial area, Equation 58.7 may be expressed in terms of rate as follows:

$$\frac{dC_L}{dt} = K_L a_L(C^* - C_L) \tag{58.11}$$

where C_L is the dissolved gas concentration at time t and a_L is the gas–liquid interfacial area per unit volume of the liquid.

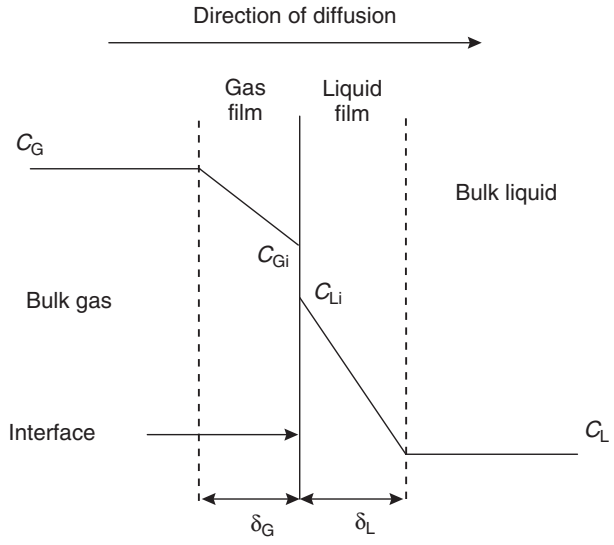

Figure 58.1. Steady state dissolved oxygen concentration profile in the vicinity of the gas–liquid interface.

58.3.1 Volumetric Gas–Liquid Oxygen Transfer Coefficient, $k_L a_L$

In view of approximation 10, the overall volumetric mass transfer coefficient $K_L a_L$ for gas–liquid mass transfer is often expressed as $k_L a_L$. The overall volumetric gas–liquid mass transfer coefficient $k_L a_L$ and the concentration driving force $(C^* - C_L)$ for mass transfer must be known if the rate of supply of oxygen or other soluble gases is to be quantified (6). The mass transfer driving force, which is easily determined, depends on temperature and pressure. The coefficient $k_L a_L$ depends on the properties of the fluid, the hydrodynamic regime, and the configuration of the bioreactor. The factors influencing $k_L a_L$ and mass transfer are summarized in Table 58.4. Prediction of $k_L a_L$ is an important part of bioreactor design. The individual terms in $k_L a_L$ are difficult to measure directly, but the product is relatively easily measured (6).

Usually the overall volumetric gas–liquid mass transfer coefficient is expressed in terms of the liquid volume in the fermenter; however, sometimes the basis of expression has been the gas–liquid dispersion volume (6). An identical basis is necessary for comparing mass transfer capabilities, and the coefficient expressed in one form may be converted to the other if the overall gas holdup (ε_G) is known.

$$k_L a_L = \frac{k_L a_D}{1 - \varepsilon_G} \tag{58.12}$$

Some typical $k_L a_L$ values seen in various types of bioprocesses are noted in Table 58.5.

As noted earlier, the rate of diffusive transport of a component through a unit area perpendicular to the direction of transport can be expressed as mass flux or molar flux, that is, kilogram or kilomole of component transferred per unit area per unit time. The flux J is proportional to a mass transfer driving force and a mass transfer coefficient K_L, or $J = K_L \times$ (driving force). Mass transfer is driven by differences in chemical potential. A species diffuses from regions of high potential to those of low potential until the difference has been eliminated. In practice, the driving force for mass transfer may be expressed as a concentration difference, partial pressure difference, or mole fraction difference. For example, when oxygen-free water is brought into contact with air, oxygen diffuses from air to water until the water becomes saturated. At this point the oxygen concentrations in the two phases are in dynamic equilibrium, but there is no net transfer. Note that the concentrations of oxygen in water and air are not equal, but the chemical potentials are. Depending on how the mass flux J and the driving force are expressed, the mass transfer coefficient may have different numerical values and different units as noted in Table 58.6 for a few cases. A coefficient expressed in one form may be easily converted to a different one.

TABLE 58.4. Factors Influencing Gas–Liquid Mass Transfer

Temperature	Concentration of solids

58.3.2 Measurement of $k_L a_L$

Several methods are available for measuring $k_L a_L$ values (1,6–8). Only a few of the more useful and common methods will be noted here.

TABLE 58.6. Possible Ways of Expressing Mass Flux and Mass Transfer Coefficient

Flux, J	Driving Force	Units of K_L
kg/s m^2	Concentration difference, kg/m^3	m/s
kg/s m^2	Mole fraction difference	kg/s m^2
kg/s m^2	Partial pressure difference	kg/s m^2
kmol/s m^2	Concentration difference, kg/m^3	m/s
kmol/s m^2	Mole fraction difference	kmol/s m^2
kmol/s m^2	Partial pressure difference	kmol/s m^2
m^3/m^2 s (for transfer of a gas)	Partial pressure difference	m/s

58.3.2.1 Sulfite Oxidation Method. The sulfite oxidation method has been extremely widely used, but it is suited to measurements only in physical systems (no live microorganisms) such as water or some polymer solutions. The method is subject to too many interferences (6,7) and, therefore, is not suitable for use in most culture media or in nonviable fermentation broths. Moreover, because of high ionic strength, the sulfite oxidation medium is strongly noncoalescing and rheologically quite different from fermentation systems. Consequently, the sulfite oxidation measurements are not readily translated to biologically relevant systems.

The sulfite oxidation method relies on oxidation of sulfite to sulfate using dissolved oxygen:

$$SO_3^{2-} + 1/2\ O_2 \xrightarrow{\text{catalyst}} SO_4^{2-}$$

The reaction is catalyzed by copper(II), cobalt(II), as well as other metal ions. The rate of sulfite oxidation is a measure of the rate of oxygen transfer to the liquid. The overall reaction generates H^+, and pH control is necessary because the reaction rate is pH-dependent. Also, the temperature needs to be controlled carefully to assure constant reaction kinetics. Impurities such as iron, manganese, and other transition metals in the parts per million range affect the reaction.

For k_La_L measurements, the reaction conditions should be such that the reaction occurs in the bulk liquid and not at the gas–liquid interface. Thus, Cu(II) catalysis is used with a sufficiently high sulfite concentration, such that the oxidation rate is independent of the sulfite level. The rate of sulfite consumption is given by

$$-\frac{d[SO_3^{2-}]}{dt} = k_La_L(C^* - C_L) \qquad (58.13)$$

where C^* and C_L are the saturation concentration of dissolved oxygen and the actual instantaneous concentration at time t, respectively. C_L is usually close to zero. The sulfite consumption rate, which should remain constant, is followed by quenching the samples taken at various times with excess iodine, and back titration of the residual iodine with thiosulfate (6).

Another oxygen consuming reaction is the oxidation of dithionite ($S_2O_4^{2-}$) in alkaline solutions; however, in view of uncertain kinetics and other factors, the usefulness of that reaction for k_La_L measurements remains questionable.

58.3.2.2 Chemical Absorption of Carbon Dioxide. This method is similar in principle to the sulfite oxidation procedure. Carbon dioxide is absorbed into a mildly alkaline or suitably buffered solution where it is converted to other species. Chemical absorption of carbon dioxide into Na_2CO_3–$NaHCO_3$ solution is sufficiently slow for use in k_La_L determinations when the ratio of carbonate to bicarbonate concentrations is between 3 and 5 (6). Other reaction conditions need to be controlled to ensure that the reaction rate does not enhance mass transfer. The method has limitations similar to those of the sulfite oxidation technique.

58.3.2.3 The Hydrazine Method. The hydrazine method makes use of the reaction

$$\underset{\text{hydrazine}}{N_2H_4} + O_2 \xrightarrow{\text{catalyst}} N_2 + H_2O$$

The reaction is best carried out at pH 11–12 using copper sulfate catalyst (6). A steady flow of hydrazine into an aerated reactor is used to maintain a constant concentration of dissolved oxygen. The amount of hydrazine consumed per unit time equals the oxygen absorption rate. The reaction does not produce any ionic species; hence, the ionic strength of solution can be kept lower than with the sulfite oxidation or the carbon dioxide absorption methods.

58.3.2.4 Oxygen Balance Method. This technique depends on measurement of mass flow rates of aeration gas into and out of the fermenter. The mass fraction of oxygen in the inlet and exhaust gas streams must also be determined (mass spectrometer, paramagnetic oxygen analyzer), in addition to the steady state dissolved oxygen concentration in the broth (dissolved oxygen electrode). The k_La_L value is obtained from the oxygen balance

$$F(x_i - x_o) = V_Lk_La_L(C^* - C_L) \qquad (58.14)$$

where F is the mass flow rate of gas, x_i and x_o are the mass fractions of oxygen in the gas (i = inlet, o = outlet), and V_L is the volume of the broth in the fermenter. Equation 58.14 assumes no evaporation and it does not correct for carbon dioxide production; however, the necessary corrections can be easily incorporated. For constant volume continuous culture, Equation 58.14 needs to be further modified to account for oxygen entering and leaving the fermenter via the liquid streams.

The oxygen balance method requires accurate measurements of gas flow rates and oxygen concentrations. The oxygen mass fraction in the inlet and outlet gas must differ measurably—that is, the oxygen consumption rate in the fermenter should be relatively large—for reliable k_La_L measurements. Under suitable conditions, the method is very reliable and it does not disturb the fermentation by interrupting the air supply (8).

58.3.2.5 Enzymatic Oxidation Method. Oxygen transfer may be followed by the formation of gluconic acid via oxidation with oxygen in presence of the enzyme glucose oxidase. The rate of absorption of oxygen is calculated from the rate of consumption of alkali that is needed to neutralize the acid. The liquid-phase oxygen concentration is determined with a dissolved oxygen electrode. The cost of the enzyme restricts the method to small-scale applications (6). Other similar methods have been described (9). Enzyme catalyzed oxidation can potentially be used only in the absence of microorganisms and under a restricted range of conditions.

58.3.2.6 The Dynamic Gassing-In Method. In a fermentation at steady state, the oxygen supply rate exactly matches the rate of consumption by the microorganisms and the concentration of dissolved oxygen does not change, that is,

$$\frac{dC_L}{dt} = \underbrace{k_L a_L (C^* - C_L)}_{\text{oxygen supply or mass transfer term}} - \underbrace{q_{O_2} X}_{\text{consumption term}} = 0 \qquad (58.15)$$

where q_{O_2} is the specific oxygen consumption rate and X is the concentration of viable biomass. If the oxygen supply is interrupted now, the mass transfer term in Equation 58.15 becomes zero and, as shown in Figure 58.2, the dissolved oxygen concentration declines linearly with time (8). The slope of C_L versus t line during the unaerated period provides $q_{O_2} X$. After a short period, before the oxygen concentration has dropped to the critical level, the oxygen supply must be resumed. Now, the dissolved oxygen level rises (Figure 58.2). During the rise period, the dissolved oxygen concentration as a function of time is given by

$$C_L = C^* - \frac{1}{k_L a_L}\left(q_{O_2} X + \frac{dC_L}{dt}\right) \qquad (58.16)$$

which is a rearranged form of Equation 58.15. Thus, $k_L a_L$ can be calculated from the slope of a plot of C_L versus $\left(q_{O_2} X + \frac{dC_L}{dt}\right)$. This procedure requires interrupting the oxygen flow to the fermenter and the dissolved oxygen electrode needs to be capable of a rapid response.

The gassing-in method is commonly applied also to physical systems (6). In such cases the dissolved oxygen in the liquid is first reduced to nearly zero by bubbling with nitrogen. The nitrogen flow is then stopped, the bubbles are allowed to leave the fluid, and the system is oxygenated by bubbling with air. The concentration of the dissolved oxygen in the liquid is followed as a function of time, and the $k_L a_L$ is calculated as the slope of the linear equation

$$\ln\left(\frac{C^* - C_{L0}}{C^* - C_L}\right) = k_L a_L t \qquad (58.17)$$

where C^* is the saturation concentration of dissolved oxygen, C_{L0} is the initial dissolved oxygen concentration at time t_0 when a hydrodynamic steady state has been reestablished upon commencement of aeration, and C_L is the dissolved oxygen concentration at any time t (5). Equation 58.17 is obtained by integration of Equation 58.15, assuming a well mixed liquid (i.e. uniform C_L), no change in gas-phase composition (i.e. a constant C^*), and an absence of oxygen consumption (i.e. $q_{O_2} = 0$) in the physical system.

Correct evaluation of $k_L a_L$ by this method requires attention to several factors including the response dynamics of the dissolved oxygen electrode and the nature of mixing in the gas and the liquid phases. In large intensely mixed fermenters, a well mixed liquid phase may still be assumed, but the gas-phase composition changes significantly from the inlet to exhaust. The gas is generally in plug flow and, thus, a log mean concentration driving force $(C^* - C_L)_{LM}$ should be used in Equation 58.15. The driving force is

$$(C^* - C_L)_{LM} = \frac{C^*_{in} - C^*_{out}}{\ln\left(\frac{C^*_{in} - C_L}{C^*_{out} - C_L}\right)} \qquad (58.18)$$

where C^*_{in} and C^*_{out} are the saturation concentrations in equilibrium with the gas-phase composition at the fermenter inlet and outlet, respectively.

Generally, the nature of mixing in the gas phase is inconsequential in $k_L a_L$ determinations so long as $1/k_L a_L$ is less than the residence time of the gas phase in the liquid.

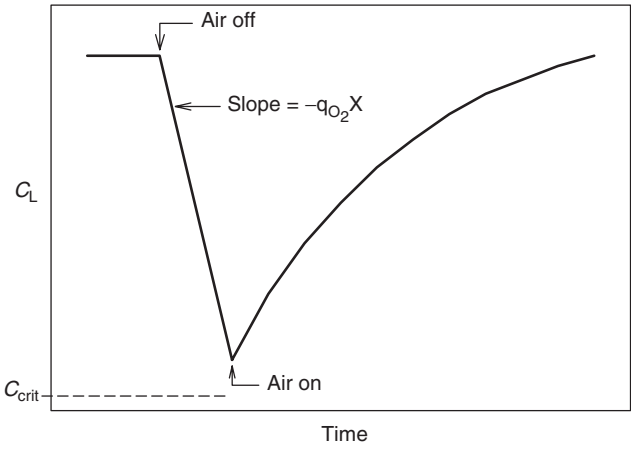

Figure 58.2. Dissolved oxygen concentration as a function of time during dynamic determination of the overall volumetric gas–liquid mass transfer coefficient in a fermentation.

The mean residence time t_R of the gas phase in bubble columns and stirred tanks can be estimated using (6)

$$t_R = \frac{h_L \varepsilon_G}{(1-\varepsilon_G)U_G} \tag{58.19}$$

where ε_G is the overall gas holdup. Equation 58.19 may also be applied to risers of airlift reactors when there is little or no gas in the downcomer. In the latter case, the U_G should be replaced with U_{Gr}—the superficial gas velocity based on the riser cross-section—and the gas holdup should be replaced with ε_{Gr}. When there is gas in the downcomer, Equation 58.19 may still be used because the downcomer gas holdup acts mostly as a dead volume.

The response characteristics of the dissolved oxygen electrode have little influence on the dynamic determination of $k_L a_L$ if the response time (63% of full response) is less than or equal to $1/k_L a_L$. Consult Chisti (6) for additional details. Other variations of the gassing-in technique exist. For example, methods have been developed to simultaneously determine $k_L a_L$ and the oxygen consumption rate without having to interrupt the flow of gas (10). Such schemes are especially useful for use in bubble columns and airlift bioreactors in which gas is the sole mechanism of achieving mixing.

58.3.3 Estimation of $k_L a_L$ for Gases Other Than Oxygen

Most of the available data and correlations for $k_L a_L$ were obtained for mass transfer of oxygen. The overall volumetric mass transfer coefficient for transfer of other gases can be estimated using the oxygen transfer data and the diffusion coefficients for oxygen and the other gases (6); thus,

$$(k_L a_L)_{gas} = \frac{D_{gas}}{D_{oxygen}} (k_L a_L)_{oxygen} \tag{58.20}$$

or

$$(k_L a_L)_{gas} = \sqrt{\frac{D_{gas}}{D_{oxygen}}} (k_L a_L)_{oxygen} \tag{58.21}$$

Equation 58.20 applies when the transfer can be ascribed to the film penetration mechanism of the two-film theory (6). Equation 58.21 is applicable when the surface renewal is the predominant mechanism of mass transfer (6). The difference between the two correction factors is small. The diffusivities used for the correction should be at the same temperature as the $k_L a_L$ data. The correction is satisfactory only for transfer in identical fluids at identical hydrodynamic conditions. Data on carbon dioxide mass transfer have been reviewed by Ho and Shanahan (11).

58.3.4 Solubility of Oxygen

Information on solubility of oxygen is needed for estimating the concentration difference driving force for mass transfer. Calculation of the saturation concentration C^* of dissolved oxygen (Eq. 58.8) requires a knowledge of the Henry's law constant, H. The dimensionless H for oxygen in pure water may be calculated as a function of temperature T (degrees Celsius) using the equation:

$$H = -9281.4 \times 10^{-3} + 4030.9 \times 10^{-3} T - 1403.5 \times 10^{-4} T^2 + 178.8 \times 10^{-5} T^3 \tag{58.22}$$

Equation 58.22 provides almost exact values of H over the range 20–30°C. Oxygen solubility in water at a pressure of 1 atm can be calculated with the equation,

$$C^* = 2178.549 \times 10^{-3} - 549.304 \times 10^{-4} T - 848.781 \times 10^{-6} T^2 - 483.785 \times 10^{-8} T^3 \tag{58.23}$$

where the temperature T is in degrees Celsius and C^* is in millimoles per liter. Equation 58.23 applies over 0–40°C. In addition to temperature, other factors influence oxygen solubility and the H value. Solubility declines with increasing ionic strength of solution. Solubility also depends on the types of ions in solution. For example, for the same molar concentrations of sodium chloride and hydrochloric acid in different samples of pure water, the oxygen solubility is lower in the salt solution. Solubility data for oxygen and other gases are available in handbooks. At 37°C, the saturation concentration of dissolved oxygen in a typical animal cell culture medium with serum is about 6.5×10^{-3} kg/m^3.

58.4 LIQUID–LIQUID MASS TRANSFER

Transfer of a solute from an immiscible liquid dispersed into another liquid (the continuous phase) can be analyzed using the two-film approach discussed for gas–liquid mass transfer. Now, the overall mass transfer coefficient K_L and the film coefficients for the dispersed (k_{Ld}) and the continuous (k_{Lc}) phases are related as follows:

$$\frac{1}{K_L} = \frac{1}{k_{Lc}} + \frac{K_p}{k_{Ld}} \tag{58.24}$$

In Equation 58.24, K_p is the partition coefficient of the solute between the two phases. The partition coefficient defines the equilibrium distribution of the solute between the phases; thus,

$$K_p = \frac{C_{Lc}}{C_{Ld}} \tag{58.25}$$

where C_{Lc} and C_{Ld} are the equilibrium concentrations of the solute in the continuous and the dispersed phases, respectively. Again, as for gas–liquid mass transfer, the interface between the phases is assumed to offer no resistance to mass transfer; hence, the equilibrium relationship determines the solute concentrations at the interface.

The overall volumetric mass transfer coefficient for liquid–liquid mass transfer is $K_L a_{Lc}$ where the specific interfacial area (a_{Lc}) is based on the volume (V_{Lc}) of the continuous phase. The rate of mass transfer from the dispersed to the continuous phase is given by

$$\frac{dC_{Lc}}{dt} = K_L a_{Lc}(C^* - C_{Lc}) \tag{58.26}$$

where C^* is the saturation concentration of the solute in the continuous phase in equilibrium with the dispersed phase.

58.5 SOLID–LIQUID MASS TRANSFER

Mass transfer to or from suspended solids is important in many bioprocess situations. Solid–liquid mass transfer may be rate limiting in immobilized enzyme and cell reactors, during dissolution of solids, adsorption, as well as in other cases. The rate of mass transfer to or from the suspended particle depends on the solid–liquid mass transfer coefficient (k_L), the total solid–liquid interfacial area (A_s), and the concentration driving force; thus,

$$V_L \frac{dC_L}{dt} = k_L A_s(C^* - C_L) \tag{58.27}$$

where C_L is the concentration of the transferring component in the liquid at time t, C^* is the saturation concentration (or solubility) of the transferring component, and V_L is the volume of the suspending liquid. Equation 58.27 is written for transfer from the solid to the liquid. By analogy with the film model of mass transfer, the coefficient k_L conceptually equals the diffusivity of the solute divided by the thickness of the stagnant liquid film at the solid–liquid interface; k_L is needed for quantifying the rate of mass transfer. Methods for estimating the solid–liquid or solid–gas (also gas–liquid if liquid is adsorbed as a very thin film on the surface of the solid) mass transfer coefficient k_L in various situations are discussed in a later section of this chapter.

58.6 MASS TRANSFER BEHAVIOR

58.6.1 General Aspects

Mass transport by diffusion and forced convection are influenced by the following variables: the mass transfer coefficient k_L, the molecular diffusivity of the transferring component D_L, the fluid density ρ_L and viscosity μ_L, a characteristic length d, and the velocity of flow U_L. Mass transfer by natural convection is also influenced by the gravitational acceleration g and the density difference $\Delta\rho$ between phases. These variables can be grouped into the following principal dimensionless groups or "numbers":

$$Re \text{ (Reynolds number)} = \frac{\text{inertial force}}{\text{viscous force}} = \frac{\rho_L U_L d}{\mu_L} \tag{58.28}$$

$$Sh \text{ (Sherwood number)} = \frac{\text{total mass transfer}}{\text{diffusive mass transfer}} = \frac{k_L d}{D_L} \tag{58.29}$$

$$Sc \text{ (Schmidt number)} = \frac{\text{momentum diffusivity}}{\text{mass diffusivity}} = \frac{\mu_L}{\rho_L D_L} \tag{58.30}$$

$$Gr \text{ (Grashof number)} = \frac{(\text{inertial force})(\text{bouyancy force})}{(\text{viscous force})^2} = \frac{d^3 \rho_L \Delta\rho g}{\mu_L^2} \tag{58.31}$$

$$Fr \text{ (Froude number)} = \frac{\text{inertial force}}{\text{gravitation force}} = \frac{U_L^2}{gd} \tag{58.32}$$

The above noted dimensionless numbers represent ratios of various factors that may play a role in a given situation. Grashof number is important in situations where density difference driven natural convection affects mass transfer. Reynolds number is employed in situations where forced convection is the predominant influence on transport processes. Froude number is useful in describing gravity-influenced flows. Schmidt number, or ratio of momentum diffusivity to mass diffusivity, is a measure of relative effectiveness of mass and momentum transfer. Some of those dimensionless numbers may be expressed in other forms depending on the situation. A few possible alternatives are noted in Table 58.7. In addition to the dimensionless groups discussed above, other groups relevant to mass transfer and related fluid mechanics are encountered in the literature. Some of the more common ones and their physical significance are noted in Table 58.8.

Grouping the many variables that affect mass transfer into a few dimensionless numbers greatly simplifies the process development experimentation and data correlation

TABLE 58.7. Alternative Methods of Expressing Dimensionless Groups

Group	Alternative Expressions
Reynolds number, *Re*	$\frac{\rho_L U_L d}{\mu_L}$ or $\frac{\rho_G U_G d}{\mu_G}$ (in pipes and channels)
	$\frac{\rho_L N d_i^2}{\mu_L}$ (stirred tanks)
	$\frac{\rho_L U_L L}{\mu_L}$ or $\frac{\rho_G U_G L}{\mu_G}$ (flow past a plate)
	$\frac{\rho_L U_L d_p}{(1-\phi)\mu_L}$ or $\frac{\rho_G U_G d_p}{(1-\phi)\mu_G}$ (flow past particles in packed beds)
Sherwood number, *Sh*	$\frac{k_L d}{D_L}$ or $\frac{k_G d}{D_G}$ (d may be diameter of a particle, flow channel, etc.)
Froude number, *Fr*	$\frac{U_L^2}{g h_L}$ or $\frac{U_G^2}{g h_L}$ (in bubble colums and airlift reactors)
	$\frac{N d_i^2}{g h_L}$ or $\frac{N^2 d_i}{g}$ (in stirred tanks)
Peclet number, *Pe*	$\frac{U_L h_L}{D_L}$ or $\frac{U_B d_B}{D_L}$ (in bubble colums and airlift reactors)
	$\frac{N d_i^2}{D_L}$ (in stirred tanks)

TABLE 58.8. Other Dimensionless Groups Relevant to Mass Transfer and Related Fluid Mechanics

Group	Definition	Physical Significance
Bond number, *Bo*	$\frac{g d_p^2 \Delta\rho}{\sigma_L}$	$\frac{\text{Gravity force}}{\text{Surface tension force}}$
Peclet number, *Pe*	$\frac{U_L L}{D_L}$	$\frac{\text{Bulk mass transport}}{\text{Diffusional mass transport}}$
Poiseuille number, *Ps*	$\frac{\mu_L U_p}{\rho_L g d_p^2 \Delta\rho}$	$\frac{\text{Viscous force}}{\text{Gravity force}}$
Power number, *Po*	$\frac{P}{\rho_L N^3 d_i^5}$	
Rayleigh number, *Ra*	*Gr Sc*	
Stanton number, *St*	$\frac{Sh}{ReSc}$	
Weber number, *We*	$\left(\frac{U_p^2 \rho_L d_p}{\sigma_L}\right)^{1/2}$	$\frac{\text{Inertial force}}{\text{Surface tension force}}$

for predicting the behavior of a system. For example, for fluids flowing in straight pipes the flow pattern changes from laminar to turbulent at a Reynolds number value of about 2300. This occurs irrespective of which specific fluid (e.g. air, water, milk, or thick glucose syrup) is being used so long as the combination of the fluid density, viscosity, flow velocity, and pipe diameter yields a Reynolds number value that exceeds 2300. Equations for correlating the mass transfer behavior of systems are often expressed in terms of dimensionless groups.

58.6.2 Behavior of Dispersions

A dispersion consists of one or more phases dispersed in a continuous phase. The continuous phase may be a gas or liquid. The dispersed phase may be liquid droplets, solid particles, or gas bubbles. The magnitude of the mass transfer coefficient inside and outside fluid particles depends on whether the particles behave as ridged spheres or are mobile. Small drops and bubbles behave as noncirculating ridged spheres. Larger bubbles and drops have internal fluid circulation and mobile interfaces because of relative motion between the particle and the surrounding fluid. Bubbles are immobile if the dimensionless diameter $d^* \leq 10$. The interface is nearly always mobile if d^* exceeds 50. Here, the dimensionless "diameter number" is

$$d^* = d_B \left(\frac{\mu_L^2}{\rho_L g(\rho_L - \rho_G)} \right)^{-1/3} \tag{58.33}$$

as defined by Wesselingh (6). Using this criterion, in air–water, bubbles smaller than 0.5 mm will always be ridged, whereas bubbles larger than about 2.5 mm will have mobile interfaces (6).

In certain cases, drops and bubbles may experience additional interfacial motions that are a consequence of mass transfer itself. Because the local mass transfer coefficient around a particle may be different at different locations, the local mass transfer rates may be different. In this situation, uneven transfer of a solute such as acetone or ethanol will generate solutions of different local concentrations and surface tensions. Adjacent films of different surface tensions lead to violent motions: regions of high surface tension contract and the film ruptures in regions of low surface tension. This effect is the well known Marangoni effect and it can significantly enhance mass transfer especially in liquid–liquid extraction processes.

For suspended solids, increasing agitation beyond that needed to achieve complete suspension has little impact on the mass transfer coefficient. The coefficient is influenced by relative velocity between the phases, which is determined by density differences. In gas–liquid dispersions too, the k_L is not substantially affected by increasing agitation, but the overall volumetric mass transfer coefficient ($k_L a_L$) increases because of the increase in gas–liquid interfacial area.

For freely suspended particles and bubbles, mass transfer to or from the bubble or particle obeys the general relationship

$$Sh = f(Gr, Sc) \tag{58.34}$$

For just suspended small particles ($d_p < 0.6$ mm) in stirred tanks, Calderbank and Moo-Young (12) recommended the equation

$$k_L = \frac{2D_L}{d_p} + 0.31 Sc^{-2/3} \left(\frac{\Delta\rho_L \mu_L g}{\rho_L^2} \right)^{1/3} \tag{58.35}$$

which is suitable for suspensions as well as gas–liquid dispersions of noncirculating bubbles ($d_p < 0.6$ mm). For larger circulating bubbles and liquid drops ($d_p > 2.5$ mm) in a just suspended state, the recommended equation is

$$k_L = 0.42 Sc^{-0.5} \left(\frac{\Delta\rho_L \mu_L g}{\rho_L^2} \right)^{1/3} \tag{58.36}$$

For bubbles in the 0.6–2.5-mm range, the k_L may be estimated as a linear function of bubble diameter.

Large spherical cap bubbles frequently occur in gas–liquid dispersions especially when the viscosity of liquid exceeds about 7×10^{-2} Pa s. Calderbank and Lochiel (13) correlated mass transfer from such bubbles using the equation

$$Sh = \frac{1.79(3R_b^2 + 4)^{2/3}}{R_b^2 + 4} (ReSc)^{1/2} \tag{58.37}$$

where R_b is the ratio of bubble width to bubble height. For spherical caps, R_b is about 3.5; hence, Equation 58.37 becomes

$$Sh = 1.31(ReSc)^{1/2} \tag{58.38}$$

Mass transfer to or from a particle suspended in a stagnant fluid occurs solely by diffusion. For a single spherical particle surrounded by a stagnant medium, the theoretical minimum value of the transfer coefficient is given by $Sh = 2$. For a single particle in the creeping flow regime ($Re < 0.1$), the specific relationship is

$$Sh = 0.39(GrSc)^{1/3} \tag{58.39}$$

Equation 58.39 applies to particles with ridged interfaces and this includes noncirculating small bubbles ($Re < 0.1$) in fermentation broths. Thus, compared to the case of a single noncirculating bubble (Eq. 58.39), the mass transfer coefficient in swarms of ridged bubbles (Eq. 58.35) is about 20% lower.

For power inputs greater than needed for just suspension, Calderbank and Moo-Young (12) have established the following equation in stirred tanks

$$k_L = 0.13 \left(\frac{\left(\frac{P_G}{V_L}\right) \mu_L}{\rho_L^2} \right)^{1/4} Sc^{-2/3} \tag{58.40}$$

where P_G / V_L is the power input per unit volume.

Transfer coefficient correlations generally require a knowledge of liquid properties such as viscosity and density. This is usually not a problem when dealing with Newtonian liquids, but difficulties arise with slurries and non-Newtonian media. Slurries of biomass solids may be usually treated as pseudohomogeneous fluids (6). Depending on the amount of suspended solids, slurries may behave as Newtonian or non-Newtonian power law fluids. For small amounts of spherical solid particles, Newtonian behavior is commonly observed, and in this case the viscosity of the slurry is independent of shear rate. The Newtonian viscosity may be estimated using equations of Einstein and Vand (8). Another suitable equation is that of Thomas:

$$\mu_{SL} = \mu_L(1 + 2.5\phi_S + 10.05\phi_S^2 + 0.00273e^{-16.6\phi_S}) \tag{58.41}$$

where ϕ_S is the volume fraction of suspended solids and μ_L is the viscosity of the suspending fluid.

When the slurry behaves as a non-Newtonian power law fluid, the apparent viscosity depends on shear rate; thus,

$$\mu_{ap} = K\gamma^{n-1} \tag{58.42}$$

where K is the consistency index or "thickness" of the fluid and n is its flow behavior index. The parameter γ is the shear rate. The shear rate is difficult to define in most realistic configurations of bioreactors under the usual operational conditions; nevertheless, the following expressions are commonly employed in estimating shear rates:

58.6.2.1 Bubble Columns and Airlift Devices

$$\gamma = \alpha U_G \tag{58.43}$$

where the constant α has been specified variously as 1000, 2800, 5000 m, and so on (14). Equation 58.43 has also been applied to airlift reactors, but that use is incorrect; for airlift reactors, the superficial gas velocity based on the cross-sectional area of the riser should be used in expressions such as Equation 58.43 as recommended by Chisti (6). Depending on the constant used, Equation 58.43 provides wildly different values of the supposed shear rate; hence, its use is not generally favored and it has been severely criticized (6,14,15). Another expression for shear rate in airlift reactors is

$$\gamma = 3.26 - 3.51 \times 10^2 U_{Gr} + 1.48 \times 10^4 U_{Gr}^2 \tag{58.44}$$

which was developed for $0.004 < U_{Gr}$ (meters per second) < 0.06 (16). Equation 58.44 also has significant problems as discussed elsewhere (15,17). Alternative approaches for estimating shear rates have been propounded by Molina Grima *et al*. (15). Methods of estimating shear rates in other process devices have been discussed exhaustively, elsewhere (18–20). An excessive shear rate can be damaging to some fragile biocatalysts and macromolecules (18–20).

58.6.2.2 Stirred Vessels.

The mean shear rate in impeller agitated tanks is usually given as

$$\gamma = k_i N \tag{58.45}$$

where k_i is an impeller-dependent constant (8). Some typical k_i values are: 11–13 for six–bladed turbines, 10–13 for paddles, ~10 for propellers, and ~30 for helical ribbon impellers. Again, as with pneumatically agitated bioreactors, much of the discrepancy among various predictive correlations that rely on a shear rate–dependent apparent viscosity has been associated with the use of equations such as Equation 58.45 (21). Equation 58.45, although empirically derived, has been shown to have a more fundamental basis (22).

The apparent viscosity of many fermentation fluids declines with increasing shear rate, that is, $n < 1$ (Eq. 58.42), and these fluids are known as *shear thinning* or *pseudoplastic*. Because shear rate is not easily defined in typical bioreactors (6,14,15,21), correlations employing solids holdup directly are preferred to those relying on a poorly established apparent viscosity of the slurry (6). As with viscosity, the density of a pseudohomogeneous slurry may be related to phase holdups as follows:

$$\rho_{SL} = \rho_L(1 - \phi_S) + \rho_S\phi_S \tag{58.46}$$

In some viscous fermentations, the principal resistance to oxygen transfer may be in the bulk fluid or at the cell–liquid interface and not at the gas–liquid interface. In such cases, dilution of the broth with water and increased agitation may slightly improve the transfer rate. In broths of filamentous fungi, promoting pelletlike growth as opposed to the usual pulplike morphology may substantially reduce the broth viscosity and improve mass transfer. Additional details on transport fundamentals of dispersions have been noted by Moo-Young and Blanch (23) and Knudsen *et al*. (4). Similar discussions with a focus on gas–liquid mass transfer in non-Newtonian media are due to Oolman and Blanch (24). Carbon dioxide mass transfer in bioreactors has been treated in depth by Ho and Shanahan (11). Mass transfer in gas–liquid dispersions and slurries can be substantially enhanced by the use of ultrasound, as reviewed by Chisti (25).

58.6.3 Gas–Liquid Mass Transfer

Either the bubble-free aeration of the liquid surface in a bioreactor may be used to provide the needed oxygen or the

aeration gas mixture may be bubbled or sparged through the body of the fluid. These schemes are discussed separately below.

58.6.4 Surface Aeration

Oxygen transfer through the surface of a fluid is useful in relatively small-scale devices, or in microaerophilic processes and certain wastewater treatment applications (26). Surface aeration is especially common in early stages of culture, for example, in shake flasks, tissue culture flasks, roller bottles, and spinner flasks. Understanding and characterization of surface aeration in small-scale devices is essential for process scale-up that minimally attempts to reproduce on larger scale the culture performance attained in the laboratory. Surface aeration is also employed in relatively small production bioreactors for growing cultures with extremely low oxygen requirements. Surface aeration in the principal types of laboratory and production culture devices is detailed in the following sections.

58.6.4.1 Laboratory Culture Devices

58.6.4.1.1 Shake Flasks. In 500-mL Erlenmeyer flasks placed on reciprocating and rotary shaker platforms, Yamada *et al*. (27) measured the volumetric rates of oxygen transfer in sulfite solutions and in *Acetobacter suboxydans* fermentations for converting sorbitol to sorbose. The rates were expressed in terms of the volumetric oxygen transfer coefficients through the flask closure (K_p) and across the gas–liquid interface (K_S):

$$\text{Volumetric rate of oxygen transfer} = (\text{mol } O_2/\text{mL h})\frac{1}{\left(\frac{1}{K_P}+\frac{1}{K_S}\right)}\frac{1}{V_L}(p_{atm}-p_L) \tag{58.47}$$

In Equation 58.47, V_L (milliliters) is the volume of liquid in the flask; p_{atm} (atmospheres) and p_L (atmospheres) are the partial pressures of oxygen in the atmosphere outside the flask and in the liquid in the flask, respectively. The units of K_p and K_S are moles of oxygen per atmosphere per hour. The mass transfer coefficient K_p through the closure declined with increasing weight (3–7 g) of cotton used to form the plug. The mean K_p value for cotton plugs was 2.87×10^{-2} mol O_2/atm h. Values for polyurethane foam and silicone foam plugs were a little lower. Compared to open flasks, cotton plugs restricted oxygen transfer. The K_S values in sulfite oxidation solutions agitated at 110–140 rpm ranged over $(2.04–4.63) \times 10^{-2}$ mol O_2/atm h. Under similar conditions in *A. suboxydans* fermentations, the K_S values were lower—only 50–60% of those obtained with sulfite oxidation. Various types of baffles and indentation in the flasks enhanced K_S by about 50% relative to the base case.

For mass transfer from liquid surface in unbaffled Erlenmeyer shake flasks, the following equation has been recommended (28)

$$k_L a_L\left(\frac{\mu_L}{\rho_L g^2}\right)^{1/3} = 0.5\left(\frac{\mu_L}{\rho_L D_L}\right)^{-1/2}\left(\frac{d_F}{V_L}\right)^{8/9}\left(\frac{\mu_L^2}{\rho_L^2 d_F^3 g}\right)^{8/27}\left(\frac{N^2\sqrt{\hat{e}d_F}}{g}\right)^{0.5} \tag{58.48}$$

where d_F is the maximum diameter of the flask, N is the speed of rotation, and $\hat{e}$ is the eccentricity of the shaker platform. Equation 58.48 applies to animal cell culture media when the liquid volume in the flask is 50–200 mL.

Open unbaffled shake flasks of 250 mL capacity filled to 100 mL with water at 37°C have been reported to have a $k_L a_L$ value of 30.8 ± 6.7/h when agitated at 250 rpm on an orbital shaker (29). For otherwise identical conditions, the measured $k_L a_L$ value in baffled flasks was 59.2 ± 7.4/h (29). Mass transfer data in shake flasks operated with various combinations of fill levels, agitation speed, and liquid viscosity have been published (30,31).

The type of closure used significantly affects oxygen absorption in Erlenmeyer flasks (32,33). Nikakhtari and Hill (34) correlated gas–liquid volumetric mass transfer coefficient in open Erlenmeyer flasks using the following equation:

$$k_L a_L = 2.584 T_L (V - V_L)^{2/3} \tag{58.49}$$

The variable T_L in Equation 58.49 is a liquid turbulence factor defined as follows:

$$T_L = \frac{V^{0.463}}{V_L} N \tag{58.50}$$

In Equations 58.49 and 58.50, $k_L a_L$ is in per hour, V is the volume of the flask in liters, V_L is the volume of the liquid in liters, and N (per second) is the shaking speed.

58.6.4.1.2 T-Flasks. Tissue culture flasks or T-flasks are commonly used in initial stages of animal cell culture. During typical culture conditions, the cells utilize the oxygen in the liquid layer, but the concentration of oxygen in the gas phase is little affected irrespective of whether the flask is fully closed or the cap is cracked open (35). Clearly, diffusion through the liquid layer controls mass transfer; thus, the shallower the liquid depth, the better. The oxygen transfer resistance of the deposited cell layer at the bottom of the flask is insignificant compared to the resistance

through the bulk liquid layer (35). The observed oxygen transfer rates through the liquid layer tend to be greater than if the transfer was purely by diffusion. This suggests that convection and micromixing (e.g. during sampling, opening or closing of incubator door) significantly contribute to transfer. In typical culture, the dissolved oxygen declines linearly with time until, by about 60 h, the dissolved oxygen level is reduced to below 10% of air saturation (35). Because T-flasks are typically inoculated and transferred every other day, the observed decline in oxygen may be of little real consequence; however, if the culture period is to exceed 60 h and dissolved oxygen levels of 10% or higher are wanted, then once or twice-daily gentle agitation of T-flasks is recommended.

58.6.4.1.3 Roller Bottles. Roller bottles are commonly used for initial stages of cell culture. Typically about 0.1 m in diameter and about 0.25 m tall, plastic roller bottles are filled to about a third of their height with culture fluid. The bottles are laid on their sides in a roller cabinet and rotated at 1–2 rpm. Roller bottles are used to culture both adherent cells as well as free suspension cells. The interfacial area for oxygen transfer is the surface of the culture fluid and the liquid film on walls that continuously enters and leaves the pool of liquid. Mechanized and automatic handling of a large number of roller bottles have extended this culture technique to commercial production scale in a few cases, but this kind of processing has a limited scope. The surface aeration capability of roller bottles, corrected for differences in surface-to-volume ratio, is somewhere between that of Erlenmeyer style shake flasks under typical conditions and the stationary T-flasks.

58.6.4.1.4 Spinner Flasks. Aunins *et al*. (36) reported k_La_L measurements (surface aeration) in 500-mL Corning spinner flasks (Figure 58.3) filled to a depth of 0.08 m with Dulbecco's Modified Eagle's Medium (DMEM), supplemented with 5% (vol/vol) fetal calf serum and 1 kg/m^3 ethylenediaminetetraacetic acid (EDTA). The data were obtained at 37°C and followed the equation

$$Sh = 1.08Re^{0.78} \tag{58.51}$$

where the Sherwood number is based on the vessel diameter and the Reynolds number is based on the impeller diameter. The measurements spanned the impeller speed range 25–150 rpm, impeller diameters of 0.0525 and 0.078 m, and impeller Reynolds number of 1500–20,000. Locating the impeller less than 0.01 m below the liquid surface dramatically enhanced the k_La_L value. At 50 rpm, with 0.078-m diameter paddle impeller placed at the liquid surface, the k_La_L value was about 9.72×10^{-4}/s. Moving the impeller to 0.01 m below the surface provided

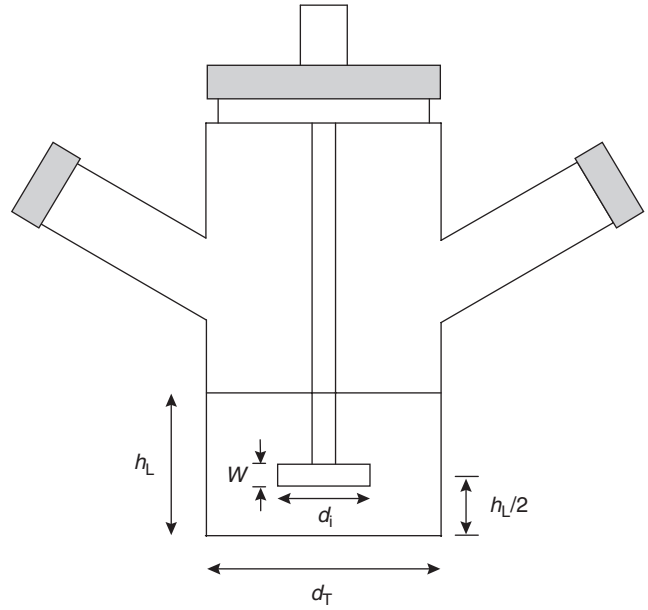

Figure 58.3. Geometry of 500-mL Corning spinner flasks: $h_L = 0.08$ m; $d_T = 0.096$ m; $d_i = 0.078$ m ($W = 0.025$ m), or $d_i = 0.053$ m ($W = 0.019$ m).

a k_La_L value of about 4.17×10^{-4}/s. Lowering the impeller further into the fluid did not affect the k_La_L value significantly.

58.6.4.1.5 Stirred Vessels. Lavery and Nienow (37) reported k_La_L measurements in water, RPMI 1640 basal cell culture medium, and the medium supplemented with 5% (vol/vol) fetal calf serum in a small, unbaffled, spherical cell culture vessel (1.5 L, static surface area of liquid $= 2.23 \times 10^{-2}$m^2) stirred with one or two, three-bladed propellers ($d_i = 0.060$ m, located 0.035 m apart). The lower impeller was positioned 0.003 m from the bottom of the vessel flask and the upper was 0.002 m below the surface of the liquid. The agitation speeds were 1.6–5.8/s (100–350 rpm). Air was sparged (100 mL/min) either in the liquid under the lower propeller or only through the headspace (i.e. surface aeration). The submerged aeration k_La_L values generally agreed with predictions of Van't Riet's correlation for nonionic solutions (i.e. Eq. 58.63). Relative to measurements in water, the serum and the basal medium had little effect on k_La_L values. The k_L for surface aeration was little affected by the number of impellers (whether 1 or 2). The k_La_L values for surface aeration were about 75% of those for submerged aeration in the reactor used. Addition of silicone antifoam (6 ppm) reduced the k_La_L values by about 50%. In the basal medium with the serum and the antifoam, the k_L values for surface aeration (no vortex) were $(1.18–3.54) \times 10^{-5}$ m/s. The k_La_L values for submerged aeration were $(2.8–8.5) \times 10^{-4}$/s.

58.6.4.1.6 Other Devices. For absorption of oxygen at the free surface of sodium sulfite solution in cylindrical containers placed on an orbital shaker platform, the volumetric mass transfer coefficient has been correlated (38) as follows:

$$k_L a_L = 6 \times 10^{-5} \left(\frac{P}{V_L}\right)^{0.4} d_T^{-0.25} h_L^{-0.6} \tag{58.52}$$

Equation 58.52 is independent of the gas flow rate in the headspace; it was determined for $20 \le P/V_L$ (watts per cubic meter) ≤ 500 and $0.5 \le h_L/d_T \le 1.5$ ($d_T = 0.12$ or 0.15 m). The agitation speed of the shaker platform varied over 1.2–3.3/s, and the moving vessel described a diameter of 0.01–0.04 m.

Sulfite oxidation method has been used to measure $k_L a_L$ in 48-well microtiter plates (39). The volumetric mass transfer coefficient depended on the fill volume, shaking frequency, and shaking diameter. Combinations of low fill volume and high shaking frequency generally produced high $k_L a_L$ values of up to 1600/h. Prediction of $k_L a_L$ values in microtiter plates is further discussed by Doig *et al*. (40). $k_L a_L$ values for various miniature bioreactors (0.15–500 mL) that are used typically in animal cell culture, have been provided by Betts and Baganz (41). Microliter bioreactors have been discussed by Fernandes and Cabral (42). Oxygen transfer in single-use disposable culture pouches is discussed by Kilani and Lebeaut (43).

58.6.4.2 Larger Systems

58.6.4.2.1 Stirred Tanks. Multibladed disc turbines located at the surface provide superior surface aeration relative to other types of impellers (44). To prevent entrainment of bubbles, the turbines must be operated such that (44)

$$N d_i \le 0.11 \left(\frac{d_i}{d_T}\right)^{-0.2} \tag{58.53}$$

As the tank diameter increases, the ability of a given impeller to agitate the entire liquid surface declines if the agitation speed is to remain below the bubble entrainment limit. The optimum impeller size for surface aeration is given by Henzler and Kauling (44)

$$\frac{d_i}{d_T} \approx 0.5 \tag{58.54}$$

Surface aeration is suited only to small reactors because $k_L a_L$ declines rapidly with increasing tank volume of surface aerated bioreactors. For subsurface impellers operated such that there is no entrainment of gas, the mass transfer coefficient k_L has been correlated with the impeller Reynolds number as follows (28):

$$Sh = 1.4 Re_i^{0.76} \tag{58.55}$$

which applies to waterlike media.

The contribution of the free surface to aeration in conventionally stirred, baffled tanks declines as the scale of operation increases. The liquid-phase mass transfer coefficient at the free surface (no vortex) in such tanks can be estimated using the correlations summarized in Table 58.9. A preferred correlation (45) is

$$k_L = 0.138 Sc^{-\frac{2}{3}} \left(\frac{4\mu_L Po N^3 d_i^5}{\pi d_T^2 h_L \rho_L}\right)^{\frac{1}{4}} \tag{58.56}$$

TABLE 58.9. Correlations for Liquid-Phase Mass Transfer Coefficient at Free Surface in Baffled Stirred Tanks (No Vortex)

$k_L = 5.11\times10^{-3}\left[\frac{11^{n-1}K}{\rho_L}\left(\frac{3n+1}{4n}\right)^n\right]^{-0.426} D_L^{0.5} d_i^{0.852} N^{1.352-0.426n}$	Perez and Sandall (46)
$k_L = 0.322 Sc^{-2/3} N^{0.7} d_i^{0.4} \left(\frac{\mu_L}{\rho_L}\right)^{0.3}$	Hikita and Ishikawa (45)
$k_L = 0.0256 Sc^{-1/2} \frac{Po^{1/3} N d_i^2}{\left(\frac{\pi d_T^2 h_L}{4}\right)^{1/3}}$	Farritor and Hughmark (47)
$k_L = \left\{0.432\left(\frac{d_i}{d_T}\right) - 0.13\right\}\left(\frac{E\rho_L}{\mu_L}\right)^{1/3} D_L^{1/2}$	Bin (48)
$\frac{k_L d_i}{D_L} = 0.04\left(\frac{N d_i^2 \rho_L}{\mu_L}\right)\left(\frac{N^2 d_i^3 \rho_L}{\sigma_L}\right)^{1/2}\left(\frac{\mu_L}{\rho_L D_L}\right)^{1/2}$	Kataoka and Miyauchi (45)

where Po is the power number ($Po = P/(\rho_L N^3 d_i^5)$), d_T and d_i are the diameters of the tank and the impeller, respectively, h_L is the height of liquid in the tank, N is the impeller rotational speed, and P is the power input. Equation 58.56 applies to Newtonian media without antifoams or surfactants. Added surfactants, fatty acids and proteins reduce k_L relative to values in clean liquids.

For a large (1.46 m^3) concentric draft-tube reactor with downward pumping five-bladed hydrofoil impellers located in the draft-tube, Chisti and Jauregui-Haza (49) correlated the $k_L a_L$ for surface aeration (air–water) with the impeller speed (N), as follows:

$$k_L a_L = 8.043 \times 10^{-6} e^{1.197N} \tag{58.57}$$

At the lowest aeration rate used (0.0156 m/s superficial aeration velocity in the annular zone) in the sparged mode of operation, the contribution of surface aeration to the total mass transfer varied from 1.5% to 11.6%, depending on the speed of the impeller (49).

58.6.4.2.2 Vortex Aeration. In unbaffled stirred tanks, agitation with a centrally located impeller creates a vortex that draws closer to the impeller as the rate of agitation increases (Figure 58.4). In a vortex aerated industrial fermenter (240 L) used in producing diphtheria vaccine, the following equation has been reported (26):

$$k_L a_L = 7.33 \times 10^{-4} + 1.36 \times 10^{-4} Q_G \tag{58.58}$$

where Q_G is the surface aeration rate (10–45 normal L/min). The equation was developed in aqueous sodium chloride (2.5 kg/m^3) and in the medium used in culturing the diphtheria bacterium. The tank was agitated with a six-bladed Rushton-type turbine (without disc) and the agitation rate was 300–800 rpm. The working aspect ratio was 0.74, which is substantially lower than values that are typically used in sparged microbial fermenters. Over the entire range of agitation rates used, the vortex was fully developed and reached the eye of the impeller (26). The conditions used in establishing Equation 58.58 were identical to those employed in commercial processes for producing the vaccine (26).

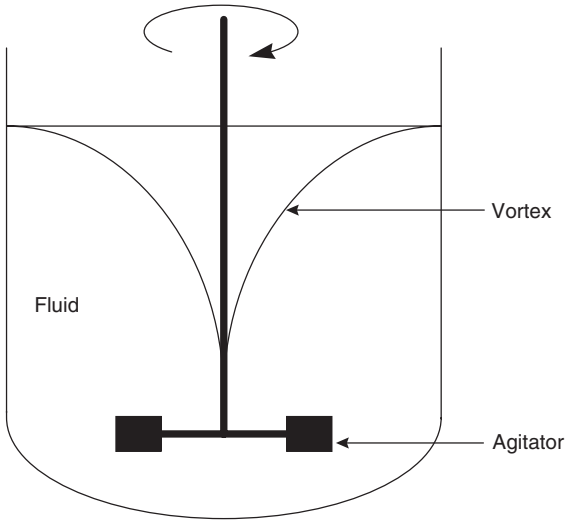

Figure 58.4. Vortex aeration in a stirred fermenter.

58.6.4.2.3 Wetted–Wall Columns. Mass transfer coefficient in liquid films in wetted-wall falling film columns can be estimate with the following equation (58.2)

$$k_L = 9.0 Re^{-0.40} Sc^{-0.67} U_L \tag{58.59}$$

where the Sc and Re are based on properties of the liquid. Depth of the film and the mean film velocity (U_L) are used to calculate the Reynolds number. Equation 58.59 is appropriate for $Re < 2000$ and $Sc < 100$. Another useful equation is

$$Sh = 0.023 Re^{0.8} Sc^{1/3} \tag{58.60}$$

The gas and liquid film coefficients in highly turbulent films ($Re > 4000$) in cocurrent wetted-wall columns can be estimated using the following equations (50):

$$Sh_L = 0.01613 Re_G^{0.664} Re_L^{0.426} Sc_L^{0.5} \tag{58.61}$$

$$Sh_G = 3.1 \times 10^{-4} Re_G^{1.05} Re_L^{0.207} Sc_G^{0.5} \tag{58.62}$$

These equations apply when $4000 \leq Re_L \leq 12{,}000$ and $7500 \leq Re_G \leq 18{,}300$. Other correlations for mass transfer in wetted-wall columns have been summarized by Spedding and Jones (51).

58.6.5 Submerged Aeration

Submerged aeration in which an oxygen containing gas is sparged or bubbled through the culture fluid is the norm in large-scale processes including animal cell culture. Typically, submerged cultivation is carried out in stirred tanks, bubble columns, and airlift bioreactors. Stirred vessels are relatively more common, but the number of airlift devices continues to increase. Bubble columns are employed less frequently (14). Typically, sparged aerated bubble columns and stirred tanks have aspect ratios between three and four. Airlift devices generally have higher aspect ratios, usually greater than six. Stirred vessels used in culturing animal cells are usually shorter with aspect ratios less than two. Microbial fermentations are aerated at high rates with superficial aeration velocities of up to 0.1 m/s in airlift vessels and somewhat lower maximum values in bubble columns. Aeration rates are substantially lower in stirred tanks to

prevent flooding of the impeller. A flooded impeller is a poor mixer and gas disperser.

Sparged aeration can potentially damage sensitive animal cells (15,52–55) and cells of certain cyanobacteria. Nevertheless, sparged aeration is successfully used quite widely in commercial culture of animal cells (56–58); however, the superficial aeration velocity in cell culture vessels is always low, usually well below 2.5×10^{-3} m/s. Supplementing the culture medium with serum, albumin, viscosity enhancers such as carboxymethyl cellulose, or surfactants such as Pluronic F68 is known to suppress the damaging effects of sparged aeration in cell culture (15,19,59).

As a rule, serum supplementation of basal animal cell culture media has little effect on mass transfer under conditions that are typically employed. Properties of serum supplemented media are usually quite similar to those of serum-free basal media. At 37°C, the surface tension of a typical cell culture medium with serum is about 0.060–0.064 N/m as compared to 0.071 N/m for water; and the viscosity is about 0.75×10^{-3} Pa s. This viscosity value is satisfactory for media containing 5–10% serum. In submerged aeration, serum-containing media tend to foam especially if a fine-pore sparger is employed for aeration (56); however, fine-pore aeration is not the norm.

58.6.5.1 Stirred Frmenters. The gas–liquid volumetric mass transfer coefficient in stirred vessels has generally shown good correlation with agitation power input and the superficial gas velocity; thus,

$$k_L a_L = \alpha \left(\frac{P_G}{V_L} \right)^{\beta} U_G^{\gamma} \tag{58.63}$$

where P_G/V_L (watts per cubic meter) is the gassed power input and U_G (meters per second) is the superficial aeration velocity; generally, $0.4 < \beta < 1$ and $0 < \gamma < 0.7$ (7). For pure water, α, β, and γ values are 2.6×10^{-2} ($s^{\beta+\gamma-1} m^{3\beta-\gamma} J^{-\beta}$), 0.4, and 0.5, respectively, when $500 < P_G/V_L$ (watts per cubic meter) $< 10,000$ (7). These values have been shown to apply over a wide scale: $0.002 \leq V_L$ (cubic meters) ≤ 2.6. In strongly ionic aqueous solutions, the α, β, and γ values become 2.0×10^{-3} ($s^{\beta+\gamma-1} m^{3\beta-\gamma} J^{-\beta}$), 0.7, and 0.2, respectively, when $500 < P_G/V_L$ (watts per cubic meter) $< 10,000$ and $0.002 \leq V_L$ (cubic meters) ≤ 4.4 (7). In pure water and ionic aqueous media, the volumetric mass transfer coefficient depends only on the specific power input irrespective of the type of stirrer—whether turbines, propellers, paddles, or self-sucking agitators—used for agitation. Neither does the number of impellers matter and nor does the location so long as it is within the usual ranges. Similarly, the height of liquid and the type of sparger have negligible influence under the usual operating conditions (7). The parameters values noted above assume an absence of flooding. Maximum aeration rates that still assure unflooded operation depend on the geometry of the impeller as discussed by Nienow (60).

For single impeller stirred air–water system, Bakker *et al*. (61) have recommended the following values of the constants in Equation 58.63: $\beta = \gamma = 0.6$, and $\alpha = 0.015 \pm 0.005$. The parameters noted apply only to the nonflooded state. At high gas flow rates, concave-bladed gas dispersion impellers (Figure 58.5) yield at least 20% higher $k_L a_L$ value than obtainable with Rushton turbines under the same conditions (61). The constants in Equation 58.63 can be strongly affected by fluid properties, presence of surfactants, and insoluble oils. For fluids other than water and for multi-impeller systems, Bakker *et al*. (61) recommended measuring α, β, and γ in a geometrically similar small-scale stirred fermenter. This data can be used in Equation 58.63 for scale-up.

For fermentations of *Endomyces* sp. in stirred fermenters, α, β, and γ values in Equation 58.63 have been reported to be 4.015×10^{-2} ($s^{\beta+\gamma-1} m^{3\beta-\gamma} J^{-\beta}$), 0.33, and 0.56, respectively, over a broad scale ($0.03 \leq V_L$ (cubic meters) ≤ 50). In a 5-L stirred fermenter operated with high density culture of a recombinant *E. coli*, Shin *et al*. (62) reported the following equation for $k_L a_L$

$$k_L a_L = 0.0195 \left(\frac{P_G}{V_L} \right)^{0.55} U_G^{0.64} (1 + 2.12X + 0.20X^2)^{-0.25} \tag{58.64}$$

where X (grams per liter) is the biomass concentration. The X values ranged over 0–75 g/L and the $k_L a_L$ values during culture varied over $(10–25) \times 10^{-3}$/s.

In stirred tank bioreactors for animal cell culture, the type of impeller used does not affect $k_L a_L$ so long as

$\frac{k_L a_L}{N} = 0.113\left(\frac{d_T^2 h_L}{W\ell(d_i - W)}\right)^{1.437}(Nt_m)^{-1.087}\left(\frac{d_i}{d_T}\right)^{1.021}$	
2. Yagi and Yoshida (65)	Viscous Newtonian and non-Newtonian liquids, including viscoelastic fluids
$\frac{k_L a_L d_i^2}{D_L} = 0.06\left(\frac{d_i^2 N\rho_L}{\mu_L}\right)^{1.5}\left(\frac{d_i N^2}{g}\right)^{0.19}\left(\frac{\mu_L}{\rho_L D_L}\right)^{0.5}\left(\frac{\mu_L U_G}{\sigma_L}\right)^{0.6} \times\left(\frac{N d_i}{U_G}\right)^{0.32}[1+2\sqrt{\lambda N}]^{-0.67}$	
For non-Newtonian fluids use apparent viscosity instead of μ_L. λ is the characteristic time or "relaxation time" of viscoelastic fluids; $\lambda = 0$ for nonviscoelastics	
3. Perez and Sandall (46)	Carbon dioxide absorption in water and non-Newtonian power law solutions
$\frac{k_L a_L d_i^2}{D_L} = 21.2\left(\frac{\rho_L N d_i^2}{\mu_{ap}}\right)^{1.11}\left(\frac{\mu_{ap}}{\rho_L D_L}\right)^{0.5}\left(\frac{U_G d_i}{\sigma_L}\right)^{0.447}\left(\frac{\mu_G}{\mu_{ap}}\right)^{0.694}$ $\mu_{ap} = K(11N)^{n-1}\left(\frac{3n+1}{4n}\right)^n$	
4. Kawase and Moo-Young (66)	Newtonian and non-Newtonian power law fluids
$k_L a_L = 0.675\sqrt{D_L}\frac{\rho_L^{3/5}E^{\frac{9+4n}{10(1+n)}}}{\left(\frac{K}{\rho_L}\right)^{\frac{1}{2(1+n)}}\sigma_L^{3/5}}\left(\frac{U_G}{U_B}\right)^{0.5}\left(\frac{\mu_{ap}}{\mu_w}\right)^{-0.25}$	
5. Niebelschütz (21)	Non-Newtonian power law fluids such as broths of *Aspergillus niger, Penicillium chrysogenum*, and xanthan fermentation.
$k_L a_L\left(\frac{V_L}{Q_G}\right)Sc^{0.3} = 0.103\left(\frac{P_G}{Q_G\rho_L\left(\frac{g\mu_L}{\rho_L}\right)^{2/3}}\right)^{0.53}$	$0.035 \le V_L\ (m^3) \le 0.070$, $0.02 \le \mu_L$ (Pa s) ≤ 3.1; μ_L was calculated at shear rate $= 10^4$/s
6. Reuss (21)	Newtonian broths of *Saccharomyces cerevisiae* and gluconic acid, glucose solutions, $\mu_L \le 12 \times 10^{-3}$ Pa s, $0.05 \le V_L\ (m^3) \le 1.9$
$\frac{k_L a_L}{U_G}\left(\frac{\mu_L^2}{g\rho_L^2}\right)^{1/3}Sc^{0.3} = 5.5\times10^{-4}\left(\frac{P_G}{V_L U_G\rho_L g}\right)^{0.7}$	
7. Chandrasekharan and Calderbank (67)	Air–water
$k_L a_L = \left(\frac{0.0248}{d_T^4}\right)\left(\frac{P_G}{V_L}\right)^{0.551}Q_G^{\frac{0.551}{\sqrt{d_T}}}$	

mixing is sufficient. For power inputs that are typical (< 25 W/m^3) better mixing is attained with relatively large ($d_i/d_T \sim 0.5$–0.6), slow moving, axial flow impellers. For typically used conditions, the $k_L a_L$ should be calculated as for bubble columns (Eq. 58.66) because for impeller power inputs less than about 40 W/m^3, the impeller has little effect on $k_L a_L$. Stirred tank design considerations for animal cell culture have been discussed by Chisti (56) and others (44).

Some of the main correlations for estimating gas–liquid volumetric mass transfer coefficient in stirred microbial fermenters are summarized in Table 58.10, which includes

equations suitable for relatively viscous power law broths. Methods for estimating the power input in mechanically agitated fermenters have been detailed by Chisti and Moo-Young (8) and Nienow (60) and Ascanio *et al*. (63).

58.6.5.2 Bubble Columns. For a given fluid in bubble columns the k_La_L is affected mainly by the superficial gas velocity, which also determines the specific power input (6). The specific power input can be calculated using the equation

$$\frac{P_G}{V_L} = \rho_L g U_G \tag{58.65}$$

where V_L is the volume of the liquid or slurry and ρ_L is its density. Properties of the fluid also affect k_La_L. In waterlike fluids, the aspect ratio of bubble columns does not affect k_La_L so long as the column diameter exceeds about 0.1 m (6). Similarly, liquid superficial velocities do not affect k_La_L provided $U_L \leq 0.1$ m/s.

For power inputs that are typically used in microbial culture, the k_La_L value in relatively coalescing media is little influenced by the design of the sparger because the turbulence in the fluid controls the bubble size. In strongly ionic low viscosity media, bubbles do not coalesce easily and the bubble size depends on the characteristics of the gas sparger. Porous plate spargers and those with smaller holes produce smaller bubbles and higher k_La_L values; however, small bubbles are rapidly exhausted of oxygen and have long residence times in the fluid. Small bubbles are produced also under highly turbulent conditions irrespective of the sparger hole size. Such bubbles are especially persistent in viscous media because the viscous drag prevents them from leaving the fluid. Persistent microbubbles are seen in broths of *Streptomyces*, mycelial fungi, and certain fermentations that produce extracellular polymers such as xanthan.

In coalescence inhibiting media typical of animal cell culture the k_La_L values in bubble columns at the very low superficial gas velocities that are normally used depends on the sparger hole diameter: the k_La_L value declines as the sparger hole diameter increases over the range 0.01–2 mm (44). Relative to values in clean fluids, surfactants and proteins reduce k_La_L value, but the reduction is greater in finer dispersions (i.e. in small, ridged bubbles) generated by small hole spargers than in dispersions of larger, circulating bubbles. For aeration rates relevant to cell culture, the k_La_L values for water may be calculated with the following equation (44):

$$\frac{k_La_L}{U_G}\left(\frac{\mu_L^2}{\rho_L^2 g}\right)^{\frac{1}{3}} = \alpha\left[\left(\frac{\mu_L g}{\rho_L}\right)^{-\frac{1}{3}} U_G\right]^{-\beta} \tag{58.66}$$

The values of α and β for use with various sparger hole sizes are noted in Table 58.11. The k_La_L values in culture media are only about 50% of those obtained with Equation 58.66 for water. Equation 58.66 was developed in bubble columns with aspect ratios $1 \leq (h_L/d_T) \leq 3$ when the specific power inputs were $3 \leq P_G/V_L$ (watts per cubic meter) ≤ 38.

Although the overall k_La_L in tall bioreactors may be little affected by the height, the overall mass transfer rates tend to be greater in taller systems because the mass transfer driving force increases with increasing hydrostatic pressure. Mass transfer in bubble columns is discussed further by Shah *et al*. (68), Chisti (6,17), and Deckwer (69), and Deckwer and Schumpe (70). The various correlations available for estimating k_La_L or k_L in bubble columns are summarized in Table 58.12. Those correlations apply to the relatively high gas flow rates that are typical of microbial fermentations. The correlation of Akita and Yoshida (71) is recommended for viscosities less than about 21×10^{-3} Pa s. The correlation of Kawase *et al*. (72) (Table 58.12) has also agreed well with independent measurements (73).

58.6.5.3 Airlift Bioreactors. Because of superior oxygen transfer performance airlift bioreactors have given excellent productivities with yeasts, bacteria, and filamentous fungi (6,17). Processes that produce highly viscous broths, including several biopolymer producing fermentations, have been successfully carried out in airlift devices (17). Similarly, many hybridoma cultures and plant cell suspensions have

13. Godbole *et al*. (81) $k_L a_D = 8.35 \times 10^{-4} U_G^{0.44} [K (5000 U_G)^{n-1}]^{-1.01}$	Non-Newtonian power law fluids

given good results. As a general rule, the volumetric productivity of airlift bioreactors equals or betters that of conventional stirred tanks (17). Typically, this level of performance is achieved at substantially lower power input than in stirred vessels. Furthermore, the probability of mechanical failure and likelihood of loss of sterility are lower with airlift bioreactors. Airlift devices outperform bubble columns in suspending solids. Relative to bubble columns, the airlift reactors have a better defined flow pattern; airlift systems are better than bubble columns in heat transfer capabilities (17). The operational range of airlift bioreactors tends to be generally broader than similar bubble columns. Unlike in bubble columns, the overall height h_L of liquid in airlift reactors affects $k_L a_L$ because the height strongly influences the liquid circulation velocity and, hence, the gas holdup (17).

Many equations have been developed to relate the apparent viscosity of non-Newtonian media to the $k_L a_L$ in airlift reactors. Most authors agree that $k_L a_L$ generally declines with increasing apparent viscosity; however, there is great discrepancy on the precise magnitude of the viscosity effect (6,17). The exponent on the apparent viscosity term has been given variously as -0.255 (82), -0.66, -0.89, and other values (see Ref. 6). Such discrepancies are associated in part with the questionable practice of defining shear rate as an arbitrary linear function of the gas velocity (6,14). The viscosity associated decline in $k_L a_L$ is especially pronounced for viscosities exceeding about 2.5×10^{-2} Pa s. In highly viscous non-Newtonian fermentations, the use of a supplementary axial flow impeller in the draft-tube of airlift reactors is known to enhance fermentation performance.

Table 58.13 lists the correlations available for estimating the gas–liquid mass transfer coefficient in airlift bioreactors. Other correlations have been reviewed by Petersen and Margaritis (83) and Kilonzo and Margaritis. (84). These correlations are suitable only for initial estimates because the hydrodynamic and transport behavior of airlift devices is quite sensitive to the type of fluid, the reactor geometry, the distribution of gas holdup in the various zones, and the induced liquid circulation rate. Because of the numerous influences, a superior approach to prediction of mass transport for a more reliable design and scale-up relies on data measured at small-scale. This method is discussed below.

58.6.5.3.1 A General Method of Predicting $k_L a_L$ for Scale-up. Although various correlations can be used to directly estimate $k_L a_L$, the reliability of such estimates is often quite poor. A more reliable prediction of $k_L a_L$ for process scale-up is based on methodology that combines fundamental principles with small-scale experimentation. This proven approach is especially suited to prediction of $k_L a_L$ in complex media. Thus, based on purely analytical

TABLE 58.13. Gas–Liquid Volumetric Mass Transfer Coefficient Correlations for Airlift Bioreactors

Configuration	Equation	Ranges
Concentric-tube internal-loop vessels (annulus sparged)	$\frac{k_L a_D \sigma_L}{D_L g \rho_L} = 2.25\left(\frac{\mu_L}{\rho_L D_L}\right)^{0.500}\left(\frac{\rho_L \sigma_L^3}{g\mu_L^4}\right)^{0.136}\left(\frac{d_H}{d_T}\right)^{-0.0905}\varepsilon_G^{1.26}$ Average estimation error was 12% for 175 measurements Koide *et al*. (85)	Newtonian media, $3.71 \times 10^2 \le \mu_L/\rho_L D_L \le 6.00 \times 10^4$, $1.18 \times 10^6 \le \rho_L\sigma_L^3/g\mu_L^4 \le 5.93 \times 10^{10}$, $0.471 \le d_i/d_T \le 0.743$, $7.14 \times 10^{-3} \le d_H/d_o \le 2.86 \times 10^{-2}$, $0.0302 \le \varepsilon_G \le 0.305$, $6 \le$ aspect ratio ≤ 15, $0.52 \le A_d/A_r \le 1.23$
Concentric-tube internal-loop vessels (draft-tube sparged)	$\frac{k_L a_D d_T^2}{D_L} = 2.66\left(\frac{\mu_L}{\rho_L D_L}\right)^{0.500}\left(\frac{g d_T^2 \rho_L}{\sigma_L}\right)^{0.715}\left(\frac{g d_T^3 \rho_L^2}{\mu_L^2}\right)^{0.251}\left(\frac{d_i}{d_T}\right)^{-0.429}\varepsilon_G^{1.34}$ Koide *et al*. (86)	Newtonian media, $\rho_L = 997$–$1182\,\text{kg/m}^3$, $\mu_L = (0.894\text{–}17.0) \times 10^{-3}$ Pa s, $\sigma_L = (51.7 - 73.0) \times 10^{-3}$ N/m, $D_L = (0.145\text{–}2.42) \times 10^{-9}$ m^2/s, $A_r/A_d = 0.3$–0.8, aspect ratio = 6–15
External-loop reactor	$\frac{k_L a_L L}{U_{Lr}} = 14.5\left(\frac{U_{Gr}}{U_{Lr}}\right)^{0.83} Pe^{-0.6}$ *Pe* value is for the entire loop Verlaan *et al*. (87)	Air–water in 0.165 m^3 reactor, aspect ratio = 16 (based on riser), $A_r/A_d = 4$, no gas in downcomer, $0.01 \le U_{Gr}$ (m/s) ≤ 0.14, $Pe = U_L L/E_L$, $Pe = 40$–60 (increased with gas flow rate)
A bubble column and a draft-tube sparged concentric-tube airlift vessel	$\frac{k_L a_L d_T^2}{D_L} = 0.018\left(\frac{K(2800U_G)^{n-1}}{\rho_L D_L}\right)^{0.5}\left(\frac{g d_T^2 \rho_L}{\sigma_L}\right)^{0.20}\left(\frac{U_G}{\sqrt{g d_T}}\right)^{0.51} \times \left(\frac{g d_T^3 \rho_L^2}{[K(2800U_G)^{n-1}]^2}\right)^{0.62}(1 + 0.12Wi)^{-1}$ Suh *et al*. (88)	Non-Newtonian xanthan fermentation broths of the obligate aerobic bacterium *Xanthomonas campestris*. Bubble column (0.05 m^3, aspect ratio $\approx$ 19); airlift bioreactor (1.2 m^3, $A_r/A_d = 1$, aspect ratio $\approx$ 12)
Concentric-tube internal-loop (draft-tube sparged)	$k_L a_L = 3.43 \times 10^{-2} U_{Gr}^{0.524} \mu_{ap}^{-0.255}$ μ_{ap} was calculated by assuming the shear rate to equal $5000U_{Gr}$ for $U_{Gr} \ge 0.04$ m/s, or $1000(U_{Gr})^{0.5}$ for $U_{Gr} < 0.04$ m/s Li *et al*. (82)	Aqueous carboxymethyl cellulose ($K = 0.286 - 11.5$ Pa s^n; $n = 0.441 - 0.617$, 0.055 m^3 vessel, $A_r/A_d = 0.618$, aspect ratio $\sim$ 26.0.020 $\le \mu_{ap}$ (Pa s) ≤ 0.85
Concentric-tube internal-loops (draft-tube sparged)	$\frac{k_L a_D d_T^2}{D_L} = 2.66\left(\frac{\mu_L}{\rho_L D_L}\right)^{0.500}\left(\frac{g d_T^2 \rho_L}{\sigma_L}\right)^{0.715}\left(\frac{g d_T^3 \rho_L^2}{\mu_L^2}\right)^{0.251}\left(\frac{d_i}{d_T}\right)^{-0.429} \varepsilon_G^{1.34} \times \left(1 + 0.099\left(\frac{C_S}{\rho_S}\right)^{0.069}\left(\frac{\rho_L \sigma_L^3}{g\mu_L^4}\right)^{0.023}\left(\frac{U_t}{U_G}\right)^{0.046}\right)^{-1}$ Average estimation error was within 17% for 383 measurements Koide *et al*. (86)	Suspensions of glass or bronze spheres, $3.71 \times 10^2 \le \mu_L/\rho_L D_L \le 9.92 \times 10^4$, $1.36 \times 10^3 \le g d_T^2 \rho_L/\sigma_L \le 1.22 \times 10^4$, $1.29 \times 10^8 \le g d_T^3 \rho_L^2/\mu_L^2 \le 1.26 \times 10^{11}$, $0.471 \le d_i/d_T \le 0.743$, $3.99 \times 10^{-2} \le \varepsilon_G \le 2.73 \times 10^{-1}$, $1.69 \times 10^{-11} \le g\mu_L^4/\rho_L\sigma_L^3 \le 2.55 \times 10^{-6}$, $0 \le C_S/\rho_S \le 8.00 \times 10^{-2}$, $1.17 \times 10^{-2} \le U_t/U_G \le 0.844$, $A_r/A_d = 0.3$–0.8, aspect ratio = 6–15
Concentric-tube internal-loop reactors (draft-tube sparged)	$\frac{k_L a_D d_T^2}{D_L} = \frac{4.04}{1 + 2\phi_S^{1.3}}\left(\frac{\mu_L}{\rho_L D_L}\right)^{0.5}\left(\frac{g d_T^2 \rho_L}{\sigma_L}\right)^{0.67}\left(\frac{g d_T^3 \rho_L^2}{\mu_L^2}\right)^{0.26}\left(\frac{d_i}{d_T}\right)^{-0.047}\varepsilon_G^{1.34}$ Average error of estimation was 14% for 260 data; U_G is based on the diameter d_T of the outer column The $k_L a_D$ values in water and salt solutions were similar. Koide *et al*. (89)	Suspensions of relatively low density calcium alginate beads in water, aqueous glycerol and aqueous salt solutions (0.10 or 0.27 kmol/m^3 barium chloride; 0.4 kmol/m^3 sodium sulfate), 0–20% vol/vol solids, 1.88–3.98-mm bead diameter, $A_r/A_d = 0.3$–1.2, aspect ratios = 6–16, $\mu_L = (0.894\text{–}12.5) \times 10^{-3}$ Pa s, D_L of oxygen $= (0.194\text{–}2.42) \times 10^{-9}$ m^2/s, $3.71 \times 10^2 \le \mu_L/D_L\rho_L \le 5.52 \times 10^4$, $2.66 \times 10^3 \le \rho_L d_T^2 g/\sigma_L \le 1.22 \times 10^4$, $2.35 \times 10^8 \le \rho_L^2 d_T^3 g/\mu_L^2 \le 3.29 \times 10^{11}$, $0.471 \le d_i/d_T \le 0.743$, $1.69 \times 10^{-11} \le Mo \le 6.67 \times 10^{-7}$, $3.79 \times 10^{-2} \le \varepsilon_G \le 2.24 \times 10^{-1}$, $0 \le \phi_S \le 0.2$; where the Morton number is $Mo = \frac{g(\rho_L - \rho_G)}{\sigma_L^3 \rho_L^2} K^4 \left(\frac{8U_{Lr}}{d_r}\right)^{4(n-1)}\left(\frac{3n+1}{4n}\right)^{4n}$

reasoning, the volumetric mass transfer coefficient (k_La_L), gas holdup (ε_G), the Sauter mean bubble diameter (d_B), and the true mass transfer coefficient (k_L), have been related as follows (6):

$$\frac{k_L}{d_B} = \frac{k_La_L(1-\varepsilon_G)}{6\varepsilon_G} \tag{58.67}$$

Calculations of the k_L/d_B ratio from the measured k_La_L and gas holdup have shown that in bubble columns and airlift devices this ratio is constant for a given fluid irrespective of the aeration rate (6,90). The value of k_L/d_B depends on the properties of the fluid. Thus, in slurries of mycelia-like cellulose fiber particles, k_L/d_B is affected by the concentration of solids (Figure 58.6). For aqueous salt solution (0.15 *M* sodium chloride) with or without suspended cellulose fiber, the k_L/d_B ratio has been expressed as (6)

$$\frac{k_L}{d_B} = 5.63 \times 10^{-5}\left(\frac{g\rho_L^2\sigma_L D_L}{\mu_L^3}\right)^{\frac{1}{2}} e^{-0.131C_S^2} \tag{58.68}$$

where C_S is the concentration of solids (% wt/vol). Equation 58.68 applies to airlifts as well as bubble columns. Chisti's (6) observations of constant k_L/d_B ratio in pneumatically agitated reactors have also been confirmed by others (17).

The observed constancy of k_L/d_B provides a reliable method for predicting k_La_L in large-scale bioreactors from data easily measured in a small-scale model unit (6). This proven technique consists of the following steps:

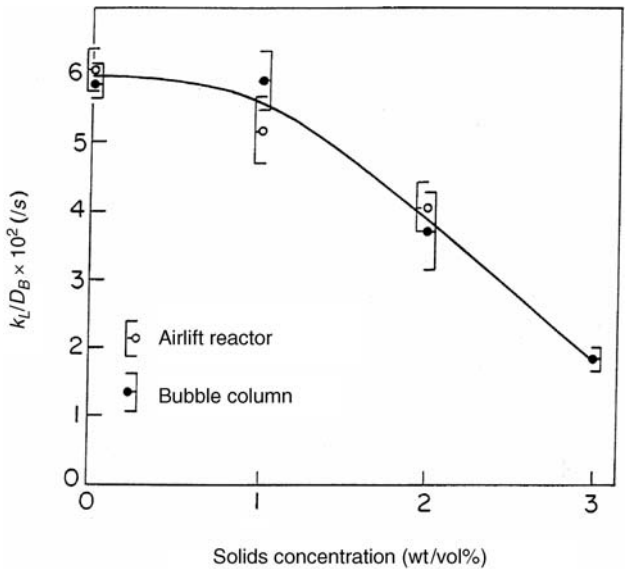

Figure 58.6. Effect of concentration of mycelia-like cellulose fiber particles on the k_L/d_B ratio in aqueous salt solution (0.15 M sodium chloride) (6).

1. Measure the gas holdup and the k_La_L in a small model reactor with the fluid of interest over the range of gas flow rates that are of interest.
2. Use the data from step 1 to calculate the constant k_L/d_B ratio (Eq. 58.67).
3. Measure or calculate the riser gas holdup (ε_{Gr}) in the full scale reactor. (See Refs 6,17)
4. Calculate the k_La_L value for the large reactor:

(a) for bubble columns

$$k_La_L = \frac{k_L}{d_B}\frac{\varepsilon_G}{(1-\varepsilon_G)} \tag{58.69}$$

(b) for airlift bioreactors

$$k_La_L = \frac{k_L}{d_B}\frac{\varepsilon_{Gr}}{(1-\varepsilon_{Gr})}\frac{A_r}{A_r + A_d} \tag{58.70}$$

In Equations 58.69 and 58.70 the gas holdup and the geometric parameters A_r and A_d are for the large reactor; the k_L/d_B value is from step 2. The rationale for Equations 58.69 and 58.70 has been discussed by Chisti (6).

Figure 58.7 compares the measured k_La_L values with prediction of the foregoing procedure for 11 reactors including bubble columns and external- and internal-loop airlift devices. The comparison spans waterlike media

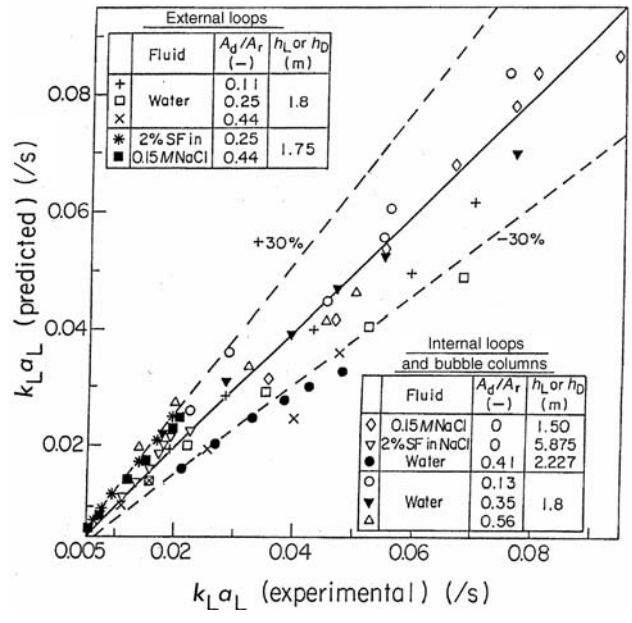

Figure 58.7. Predicted versus measured overall volumetric gas–liquid mass transfer coefficient in bubble columns, external-loop and internal-loop airlift devices in "Solka Floc" (SF) cellulose fiber slurries and solids–free media (6). The solid line represents exact prediction.

as well as pseudoplastic slurries of cellulose fiber. In all cases the predictions agree remarkably well with the measurements (Figure 58.7). Note that the "Solka Floc" cellulose fiber slurries in aqueous salt solutions used in Figures 58.6 and 58.7 were meant to simulate the fermentation broths of mycelial fungi and filamentous bacteria (6,90). Such broths are usually pseudoplastic. The non-Newtonian flow properties of cellulose fiber suspensions are quite close to those of the typical fungal fermentation broths (6).

For the low aeration rates typical of animal cell culture, the k_La_L in an internal-loop draft-tube airlift vessel is almost identical to that in an equivalent bubble column; hence, Equation 58.66 can be used for an estimation. Although the gas is sparged only in the draft-tube or in the annulus of an airlift bioreactor, for estimation of k_La_L with Equation 58.66 the superficial gas velocity should be calculated using the cross-sectional area of the outer column. For conditions typical of animal cell culture, whether the gas is sparged in the draft-tube or the annulus, does not affect k_La_L so long as the outer-to-inner tube diameter ratio is 1.6–2.1 and $2 \leq h_L/d_T \leq 5$. Large concentric draft-tube type of airlift bioreactors are used in commercial culture of animal cells (57,58). Various aspects of design of airlift bioreactors have been exhaustively treated in the literature (6,17). A few specifics are discussed in the following sections.

58.6.5.3.2 Axial Dissolved Oxygen Profiles. As clearly demonstrated (6,91,92), the steady state dissolved oxygen concentration varies axially in tall bubble columns and airlift reactors even in the absence of an oxygen consuming reaction. The exact nature of the concentration profile depends on the state of mixing in the reactor. During culture of baker's yeast in a draft-tube sparged concentric-tube internal-loop airlift reactor ($A_r/A_d = 0.8$; aspect ratio $\approx$ 10; 0.25 m^3), Russell *et al*. (93) observed that the steady state dissolved oxygen concentration in the riser and the downcomer increased with increasing aeration rate. The dissolved oxygen levels were always several fold higher in the downcomer than in the riser (93). In the riser, the dissolved oxygen levels tended to be $\leq$ 30% of air saturation. The oxygen concentration did not vary radially either in the riser or in the downcomer. Similarly, no significant variations were observed axially in the downcomer (93).

Using the annulus sparged mode of the same vessel as was employed by Russell *et al*. (93), Pollard *et al*. (94) found that the axial dissolved oxygen profiles in the riser showed a constant zero level of oxygen over a broad range of superficial gas velocities (0.036–0.136 m/s) during baker's yeast fermentations. Surprisingly, the dissolved oxygen concentration increased down the downcomer, peaking close the bottom of the draft-tube, and declining sharply to zero as the fluid moved into the riser. These anomalous results seemed to indicate better oxygen transfer in the downcomer relative to the riser (94). In view of the observed profile, the cells experienced extreme dissolved oxygen heterogeneity in the reactor; however, there seemed to be no effect on the culture performance. Installation and operation of a marine propeller (diameter = 0.16 m; 1000 rpm) near the bottom of the draft-tube, combined with a high level of aeration (0.358 m^3/ min), enhanced liquid circulation and oxygen transfer so much so that the dissolved oxygen level did not drop below 35% of saturation anywhere in the reactor.

58.6.5.3.3 Contributions of Various Zones to Overall k_La_L. Many airlift reactors consist of two hydrodynamically distinct zones—the riser and the downcomer—that contribute differently to the observed mass transfer (6). Sometimes a third zone—the gas–liquid separator (95)—may also exist with its own contribution toward mass transfer.

In airlift bioreactors that do not have gas–liquid separators, the measured k_La_L consists of contributions from the riser and the downcomer zones; thus,

$$(k_La_L)_{measured} = \frac{A_r(k_La_L)_r + A_d(k_La_L)_d}{A_r + A_d} \qquad (58.71)$$

Equation 58.71 is an analytical expression that relates the measured k_La_L to the separate, hypothetical, contributions of the riser and the downcomer (6). Equation 58.71 leads to the general conclusion that for any airlift device in which gas–liquid mass transfer is confined to the riser (i.e. no gas in the downcomer), the actual volumetric mass transfer coefficient in the riser would be larger than the apparent measured value; the difference being dependent on the A_r/A_d ratio. Equation 58.71 applies to reactors in which the riser and the downcomer have approximately equal heights. In cases in which a significant portion of the liquid resides in the head zone, Equation 58.71 should be modified to account for that volume (17); generally, $(k_La_L)_d < (k_La_L)_r$.

On the basis of data obtained in several concentric draft-tube airlift reactors that were sparged either in the draft-tube or the annulus (aspect ratios = 6–11; $U_G = 0.019$–0.12 m/s), Koide *et al*. (96) suggested that in air–water the contribution of the downcomer zone to gas–liquid mass transfer was "relatively large." Furthermore, in liquids such as aqueous salt solutions in which the bubbles are smaller, the riser and the downcomer were claimed to contribute to the total mass transfer in proportion to the fraction of the total volume occupied by those zones (96). These observations in relatively small reactors are not entirely consistent with other findings (6,17).

58.6.5.3.4 Mass Transfer Enhancement by Static Mixers. Installation of static mixer elements in airlift and bubble column bioreactors is known to enhance the gas–liquid mass transfer coefficient relative to mixer-free operation (17,97). The enhancement is mostly due to an increase in the gas–liquid interfacial area that is brought about by the bubble breaking action of the mixer elements. Improved productivity of cephalosporin C by *Cephalosporium acremonium* was observed (98) in an airlift reactor when static mixers were installed.

The mass transfer enhancing effect of static mixers is most pronounced in viscous fluids that give rise to large spherical cap bubbles (97); though less dramatic, large improvements are still observed with waterlike media. Generally, for a given fluid, the mass transfer coefficient and the gas velocity in the riser of a given airlift reactor may be correlated in the form

$$k_L a_L = \alpha U_{Gr}^{\beta} \tag{58.72}$$

For a given fluid, the exponent β in Equation 58.72 is not affected by the presence of static mixers in the reactor; however, the mixers significantly enhance the value of α (97). The improvement in α depends mainly on the consistency index (K) or the "thickness" of the fluid: generally, the thicker the fluid, the greater the effect of static mixers (97). The approximate relationship among α, α_M (the α value in presence of static mixers), and K has been established to be (97)

$$\frac{\alpha_M}{\alpha} = 4.43K^{0.12} \tag{58.73}$$

Equation 58.73 was determined for approximately 10^4-fold variation in K. The flow behavior index n (varied between 0.5 and 1.0) had no direct impact on enhancement of $k_L a_L$ by the mixers (97). Depending on the fluid, the static mixers were found to enhance $k_L a_L$ by 30–500% relative to mixer-free operation (97). The constants in Equation 58.73 are expected to depend on the type of static mixer used.

Installation of mixing elements in airlift bioreactors slows down the circulation of fluid; hence, fewest possible mixing elements should be used to satisfy the mass transfer needs while limiting the loss of liquid circulation. The optimal interval between elements depends on the type of fluid. The more coalescing the fluid, the closer the mixers must be positioned for maximum performance. There is an upper limit to the viscosity that may be used in airlift reactors with static mixers (97). In excessively viscous media, just a few mixing elements can slow down the liquid so much so that the reactor stagnates. Static mixers are further discussed by Thakur *et al*. (99).

58.6.5.4 Reciprocating Jet Fermenter. A reciprocating plate or reciprocating jet fermenter has been employed in a few laboratory studies. The device is similar to a pulsed extraction column. It consists of a cylindrical tank containing a central shaft that supports a frame of evenly spaced perforated plates or discs. The plates are mounted horizontally relative to the axis of the shaft. The plates or baffles remain clear of the fermenter walls; the interdisc space and the diameter of perforation varies. Typically, discs are placed 0.07–0.10 m apart and the perforations, 0.06–0.08 m in diameter, occupy a large proportion of the disc surface. The stack of discs oscillates up and down through the fluid. The liquid moves through the perforations as jets that change direction as the movement of stack reverses. The frequency of oscillation is usually a few cycles per second and the vertical movement is small. Brauer reported on these devices in the early 1980s and more gas–liquid mass transfer data have since appeared (100–102). The $k_L a_L$ in reciprocating jet reactors increases with increasing frequency and amplitude of oscillation of the baffles. The power input also increases. The $k_L a_L$ generally follows the equation

$$k_L a_L = \alpha \left(\frac{P}{V_L}\right)^{\beta} U_G^{\gamma} \tag{58.74}$$

where α, β, and γ depend on the bioreactor geometry, fluid properties, and the power input range. Some typical values for these variables are noted in Table 58.14. Commercial utility of reciprocating plate fermenters remains to be proven.

58.6.5.5 Tubular Loop Fermenters. Tubular loop fermenters employ cocurrent flow of gas and liquid in a pipe. The liquid is recirculated by a pump. This design is generally not practical except for low volume fermentations or unusual situations such as those seen in the tubular solar receivers of photobioreactors used in culturing microalgae (103–105). For a tubular loop (0.025 m tube diameter, 22 m length), Ziegler *et al*. (106) recommended the equation

$$k_L a_L = 5.321 \times 10^{-5} \left(\frac{P_G}{V_L}\right)^{0.9} U_G^{0.2} + 8.333 \times 10^{-3} \tag{58.75}$$

Equation 58.75 was obtained using the sulfite oxidation system. Gas–liquid mass transfer in loop reactors is further discussed by VandenHeuvel *et al*. (107).

58.6.5.6 Fluidized Beds. Gas–liquid–solid fluidized bed bioreactors are seen in immobilized cell culture and wastewater treatment processes. These reactors usually consist of a cylindrical vessel containing a suspension of

TABLE 58.14. The Parameters in Equation 58.74 for Pulsed Baffle Fermenters

Fluid	α ($s^{\beta+\gamma-1}m^{3\beta-\gamma}$ $J^{-\beta}$)	β	γ	Ranges
Water	4.86	0.364	1.55	$23 \le P/V_L$ (W/m^3) ≤ 3620 $0.0049 \le U_G$ (m/s) ≤ 0.0099 $h_L/d_T \approx 40$
Water	0.281	0.632	1.138	$35 \le P/V_L$ (W/m^3) ≤ 6600 $0.0005 \le U_G$ (m/s) ≤ 0.004 $h_L/d_T \approx 1.87$
Water–glycerol (1:1 by vol)	0.0039	0.735	0.668	$35 \le P/V_L$ (W/m^3) ≤ 6600 $0.0005 \le U_G$ (m/s) ≤ 0.004 $h_L/d_T \approx 1.87$
Aqueous yeast slurry	4.8	0.268	1.184	$d_T = 0.05$ m

immobilized biocatalyst. The solids are kept in suspension by continuous flow of a liquid and gas. A solid–liquid separator, usually a sedimentation device, located near the top of the reactor prevents washout of solids. Essential design features of gas–liquid–solid fluidized bed reactors are discussed by Muroyama and Fan (108). The gas–liquid mass transfer coefficients in three-phase fluidized beds may be estimated using the correlation:

$$\frac{k_L a_L d_p^2}{D_L} = \alpha \left(\frac{d_p U_t \rho_L}{\mu_L}\right)^{3.3} \left(\frac{\mu_L U_G}{\sigma_L}\right)^{0.7}$$
$$(\alpha = 2.33 \times 10^{-5} \text{ when } Re_t < 2000; \alpha = 3.946 \times 10^{-7} \text{ when } Re_t > 2000) \quad (58.76)$$

where U_t is the terminal settling velocity of the particle and Re_t is the Reynolds number based on the terminal settling velocity. Equation 58.76 was developed for carbon dioxide absorption in water containing porcelain beads, sand, lead shots, or iron shots. The terminal settling velocity of the solids ranged over 0.12–0.815 m/s. Other parameters were: $0 \le U_G$ (meters per second) ≤ 0.1; $0.05 \le U_L$ (meters per second) ≤ 0.172; $1.06 \le d_p$ (millimeters) ≤ 6.84; and $2400 \le \rho_S$ (kilograms per cubic meter) $\le 11{,}180$.

Another correlation for gas–liquid mass transfer in fluidized beds is due to Nguyen-Tien *et al*. (109):

$$k_L a_L = 0.394 \left(1 - \frac{\varepsilon_S}{0.58}\right) U_G^{0.67} \quad (58.77)$$

where ε_S is the volume fraction of solids. For three-phase circulating bed fermenters, Loh *et al*. (110) have recommended the following equation

$$k_L a_L = 1.4 \times 10^{-4} \left(\frac{P}{V_L}\right)^{0.91} \frac{(1 - 2.5\varepsilon_S)^{0.95}}{(1 - \varepsilon_S)^{4.3}} \quad (58.78)$$

Because $k_L a_L$ is generally not too sensitive to the liquid flow rate, the equations developed for slurry bubble columns may also be applied to fluidized beds. Consult Muroyama and Fan (108) for further details on gas–liquid mass transfer in fluidized beds.

58.6.5.7 Other Factors Affecting $k_L a_L$

58.6.5.7.1 Surfactants and Antifoam Agents. Relative to clean systems, addition of surfactants may reduce or enhance $k_L a_L$. The specific effect and its magnitude depend on the type of surfactant, its concentration, and the nature of the broth. The coalescence promotion effect of some surfactants reduces the specific interfacial area a_L and the $k_L a_L$. Addition of surface active agents such as ethanol to water generally increases a_L and $k_L a_L$. Surfactants such as sodium dodecyl sulfate (SDS) or sodium lauryl sulfate (SLS) accumulate at the gas–liquid interface and usually cause a reduction in k_L.

58.6.5.7.2 Temperature. The overall volumetric gas–liquid mass transfer coefficient $k_L a_L$, generally increases with increasing temperature. This is mainly because the diffusion coefficient increases with temperature. Also, the viscosity of the liquid declines with increasing temperature; hence, for a given energy input, the film thickness declines and the interfacial area may increase slightly. The $k_L a_L$ value at any temperature T (degree Celsius) may be calculated from the $k_L a_L$ at 20°C using the equation:

$$(k_L a_L)_T = (k_L a_L)_{20^\circ C} \theta^{(T-20)^\circ C} \quad (58.79)$$

where θ is 1.200–1.024.

58.6.5.7.3 Suspended Solids. How and how much suspended solids affect $k_L a_L$ depends on several factors including concentration of solids, the density difference between the solid and the suspending fluid, the particle diameter, the operating conditions of the reactor (i.e. the power input), and the hydrophobicity of the solids. Up to 15% (wt/wt) of particles smaller than about 50 μm have little effect on $k_L a_L$; however, much smaller amounts

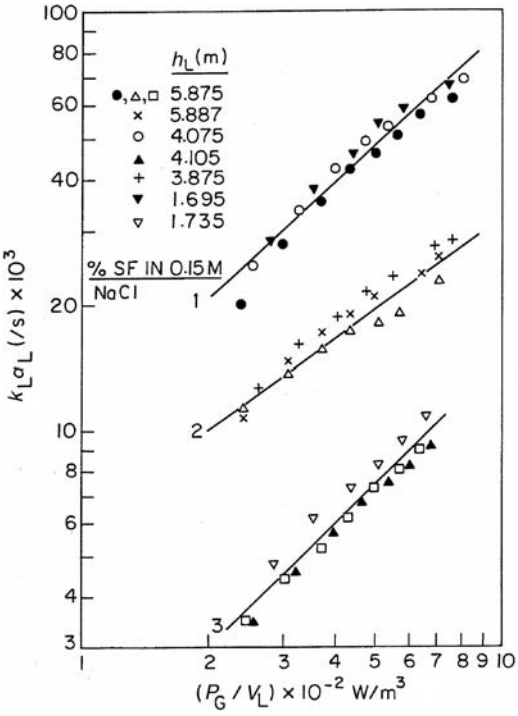

Figure 58.8. The effect of "Solka Floc" (SF) cellulose pulp fibers on gas–liquid mass transfer coefficient in bubble columns at various static slurry heights h_L. The fibers were suspended in 0.15 M sodium chloride in tap water (6). The $k_L a_L$ is shown as a function of the specific power input.

of larger particles can reduce $k_L a_L$ significantly. Very small concentrations of relatively high density solids may actually enhance $k_L a_L$ a little. Increasing amounts of low density filamentous or mycelial biomass rapidly increase the apparent viscosity of the slurry and the $k_L a_L$ may decline sharply (6). The effect of such solids on $k_L a_L$ is illustrated in Figure 58.8, which is for paper pulp fibers that simulate filamentous mycelial biomass.

In a draft-tube sparged concentric draft-tube airlift reactor for potential application to microbial desulfurization of coal, the mass transfer coefficient data in a simulated basal salt medium was reported by Smith and Skidmore (111). The medium contained a total 1.9 kg/m^3 of various salts in distilled water. Pulverized coal particles (74×10^{-6} m particle diameter; density = 1415 kg/m^3) were suspended in the fluid to a concentration of 0–40% wt (equivalent to 0–0.315 volume fraction of solids in gas-free medium). Over the temperature range 303–345 K, the $k_L a_L$ values were strongly enhanced by increasing temperature. Increasing concentration of solids over 0–5% wt (equivalent to ϕ_S of 0–0.035) increased the $k_L a_L$ values slightly, but further increase in solids loading strongly lowered the mass transfer coefficient (111). This phenomenon was explained as being due to penetration of fine solid particles in the stagnant liquid film around gas bubbles, thereby reducing the effective diffusion length (111). However, as the concentration of solids increased beyond 5% wt, the solids caused a blocking effect, which reduced the effective mass transfer area (6,111). In the region of enhanced mass transfer ($0 \leq \phi_S < 0.035$), the $k_L a_L$ was correlated with (111)

$$k_L a_L = (5.7 - 144.8\phi_S + 5048.3\phi_S^2) \times 10^4 U_{Gr}^{1.55} e^{-2990/T} \tag{58.80}$$

whereas in the "blocking" region ($0.035 \leq \phi_S \leq 0.315$), the following equation was obtained (111)

$$k_L a_L = (2.6 - 16.8\phi_S + 29.4\phi_S^2) \times 10^6 U_{Gr}^{1.45} e^{-4130/T} \tag{58.81}$$

Equations 58.80 and 58.81 agreed with the data to within about ±20%. These equations applied over the U_{Gr} range $(0.154–1.39) \times 10^{-1}$ m/s, when the A_r/A_d and the aspect ratios were 1.3 and about 5, respectively.

Mass transfer measurements in suspensions of agar-filled soft polyurethane foam particles ($d_p = 3$ mm; $\rho_p = 1030$ kg/m^3) in uninoculated penicillin culture medium ($\mu_L = 1.9 \times 10^{-1}$ Pa s) in draft-tube sparged concentric-tube airlift reactors have been reported (112). Increasing volume fraction of solids over the 0–0.1 range, enhanced the volumetric mass transfer coefficient by 15–20% over solids-free operation (112). Further increase in solids loading to 40% (vol/vol) caused a decline in $k_L a_L$ values. The mass transfer coefficient values in airlift reactors were up to threefold higher than in comparable fluidized beds.

In suspensions of relatively low density calcium alginate beads in water and other Newtonian fluids (0–20% vol/vol solids, 1.88–3.98 mm bead diameter) in draft-tube sparged concentric–tube airlift reactors, Koide *et al*. (89) noted that the mass transfer coefficient declined with increasing concentration of solids, but was not affected by the size of the particles.

58.6.6 Oxygen Transfer in Wastewater Treatment Processes

The typically used bioreactor in activated sludge treatment of wastewater consists of a relatively shallow (~4-m deep) rectangular basin aerated by sparging through perforated pipes or diffusers located at the bottom of the tank. The oxygen transfer capability of such systems is quite limited; hence, biodegradation is slow. Usually only about 0.5–2 kg O_2 can be transferred per kilowatt-hour of energy spent. The oxygen transfer capabilities of other conventional aeration systems have been detailed by Winkler (113).

Faster degradation of pollutants can be achieved with low volume high rate oxygen transfer systems. One such technology is the "deep shaft" reactor based on the airlift principle. This advanced activated sludge process relies on

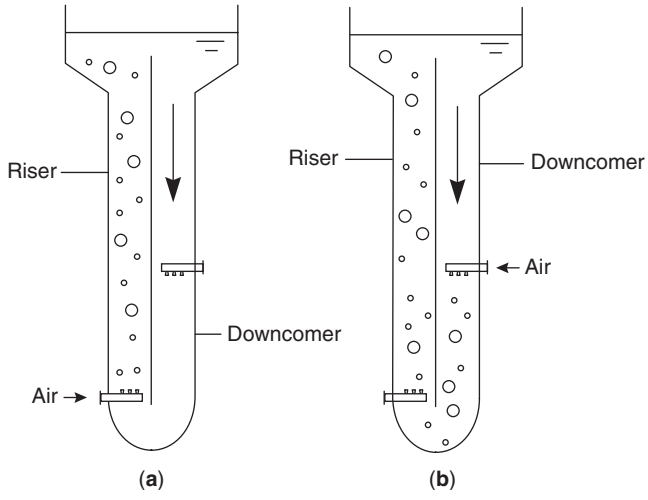

Figure 58.9. Deep shaft airlift reactor: (a) aeration in riser during start-up; (b) aeration in downcomer during normal operation. In case (b) no gas is being injected in the riser; all the gas bubbles in the riser are due to circulation from the downcomer.

high hydrostatic pressure in a deep airlift column to significantly enhance oxygen transfer. In comparison with conventional processes, oxygen transfer rates are up to 10-fold greater (113). The transfer rate at peak load is about 1 kg O_2/m^3 h (17). Several factors combine to yield this high level of performance, including long gas–liquid contact times and intense turbulence in the circulating fluid with Reynolds numbers of the order of 10^5 or higher (113). The shaft is 30–220 m deep (113), 0.5–10 m in diameter, and partitioned vertically into a riser and a downcomer. Air is injected into the downcomer, about 20–40 m below the surface (113), except during start-up when the riser is aerated (Figure 58.9). To ensure that air bubbles move down the downcomer, a superficial liquid velocity of 1–2 m/s must be generated in the downcomer zone. Because the gas is not recirculated, the downcomer region above the sparger is free of bubbles. Oxygen transfer efficiencies of 3–5.5 kg O_2/kWh can be attained (113). Up to 90% of the oxygen in the air is used up.

For deep shaft plants, Winkler (113) cites a biochemical oxygen demand (BOD) loading of 0.9 kg BOD/kg sludge solids per day. A retention time of about 1.5 h has been mentioned for 92% BOD removal (113). Volumetric BOD removal is of the order of 3.7–6.6 kg BOD/m^3 d, which is generally associated with high rate treatment processes. Sewage is treated without primary sedimentation; only preliminary de-gritting is needed (113). Sedimentation of grit at the bottom of the shaft is prevented by ensuring that the flow velocity at the bottom exceeds 1 m/s. See Chisti (17) for additional details.

In addition to the deep shaft, a "biotower" configuration is increasingly being used in wastewater treatment. The biotower units consist of a relatively shallow (18–20 m) above-ground pool of liquid with or without multiple draft-tubes (downcomers). The towers handle streams with 2–12 kg/m^3 chemical oxygen demand. The oxygen transfer efficiency ranges over 1.2–3.8 kg O_2/kWh (114). The biomass sludge produced rises to the top with the bubbles and is separated in an integral settling zone. Chisti (17) provides further details.

58.6.7 Liquid–Liquid Mass Transfer

Liquid–liquid dispersions are encountered in solvent extraction and in fermentations of hydrocarbons or other water immiscible liquid substrates. Liquid–liquid dispersions also occur in extractive fermentations where a product is continuously extracted into a water immiscible phase. Similarly, oxygen supply using water immiscible perfluorocarbons and other fluids utilizes liquid–liquid mass transfer. While in gas–liquid dispersions only the liquid film around the bubble is the principal resistance to mass transfer, in liquid–liquid dispersions the film inside the dispersed drops also affects the transport rate. Tables 58.15 and 58.16 list the correlations that are useful in calculating the mass transfer coefficients in the dispersed and continuous phases. Noncirculating small drops can be treated as ridged particles and solid–liquid mass transfer correlations (see later sections) developed for suspended spherical solids can be used. Presence of surfactants often renders drops nonmobile and solid-sphere correlations apply again. For larger, mobile, or oscillating droplets, both the continuous phase and the dispersed phase mass transfer coefficients are greater than for solid spheres.

58.6.8 Perfluorocarbons and Oxygen Vectors

Perfluorocarbons are water immiscible liquids that dissolve 10–20 times more oxygen than water. These fluids can be used for bubble-free oxygenation and removal of carbon dioxide in animal cell culture. Another potential application is stripping of inhibitory oxygen produced via photosynthesis in cultures of microalgae. Perfluorocarbons are biologically inert, and suitably selected ones are nontoxic to animal cells and microorganisms. Indeed, emulsified perfluorocarbons have been used to supplement blood to improve oxygen supply to human patients. In microbial culture, perfluorocarbon concentrations as low as 10% vol/vol have significantly enhanced culture performance.

One scheme for bubble-free oxygenation using perfluorocarbons is illustrated in Figure 58.10. A separate vessel is used to aerate the organic phase and strip the carbon dioxide. The oxygen enriched liquid is pumped to the fermenter and "sprayed" into the culture medium. As the droplets settle to the bottom in the relatively quiescent environment of animal cell bioreactors, the oxygen transfers to the aqueous phase. The oxygen depleted perfluorocarbon from the

TABLE 58.15. Mass Transfer Coefficient Inside Mobile or Oscillating Drops in Liquid–Liquid Dispersions

Correlation	Range
$Sh \approx 16.7$	$Re < 50$
$Sh = 0.320 Re^{0.68} \left(\frac{\sigma^3 \rho_C^2}{g \mu_C^4 \Delta\rho}\right)^{0.10} \left(\frac{4 D_D t_C}{d_D^2}\right)^{-0.14}$	$Re > 150$–200
$Sh = 0.32 Re^{0.63} Sc^{0.50} \left(1 + \frac{\mu_D}{\mu_C}\right)^{-0.5}$	$10 \le Re \le 1000$ Spherical drops
$Sh = 7.5 \times 10^{-5} Re_C^{2.0} Sc^{0.56} \left(1 + \frac{\mu_D}{\mu_C}\right)^{-0.5}$	$100 \le Re_C \le 1500$ Larger oblate drops

Re in these equations is based on drop diameter and relative velocity between phases; all other properties are for the drop phase unless otherwise noted. The density and viscosity in Re_C are for the continuous phase. The subscripts C and D refer to continuous and dispersed phases, respectively.

TABLE 58.16. Continuous Phase Mass Transfer Coefficient Correlations for Liquid–Liquid Dispersions

Small, noncirculating drops	$Sh = 2 + 0.79 Re^{0.5} Sc^{0.33}$ $Sh = 2 + 0.76 Re^{0.5} Sc^{0.33}$ $Sh = 0.562 Re^{0.5} Sc^{0.33}$
Larger, mobile drops	$Sh = \frac{2}{\sqrt{\pi}} \left[1 - Re^{-0.5} \left(2.89 + 2.15 \left(\frac{\mu_D}{\mu_C}\right)^{0.64}\right)\right]^{0.5} (ReSc)^{0.5}$ when $Re < 120$, $(\mu_D/\mu_C) \le 2$, and $0 \le (\rho_D/\rho_C) \le 4$ $Sh = -126 + 1.8 Re^{0.50} Sc^{0.33}$ when $8 \le Re \le 800$ $Sh = -178 + 3.62 Re^{0.50} Sc^{0.33}$

Re in these equations is based on drop diameter and relative velocity between phases; all other properties are for the continuous phase unless otherwise noted. The subscripts C and D refer to continuous and dispersed phases, respectively. Based on Pratt (2) and Schügerl (115).

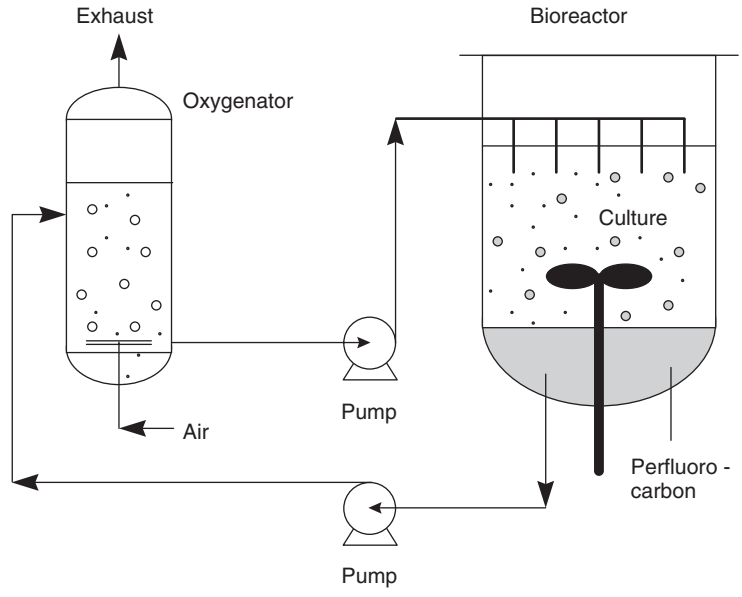

Figure 58.10. Bubble-free aeration with perfluorocarbon oxygen vector in a cell culture bioreactor.

bottom of the fermenter is recycled to the external aerator. Perfluorocarbons and other oxygen vectors enhance oxygen transfer performance, when added to an aerated reactor also. The oils extract more oxygen from the gas phase and effectively increase oxygen–culture contact time. In agitated continuous culture of *E. coli* operated at a dilution rate of 0.275/h and 35.5°C, an emulsified perfluorocarbon added to the feed at 50% volume fraction could provide 0.17 kg O_2/m^3 h when the biomass concentration was 0.74 kg/m^3 (116). The same system removed 0.23 kg/m^3 h of carbon dioxide.

With animal cells, clumping has been reported at the interface between the culture medium and the perfluorocarbon layer at the bottom of the fermenter, when the agitator is placed in the bottom layer. Cells generally do not adhere to perfluorocarbon droplets. Other oxygen carriers have been tested, including hemoglobin solutions and erythrocytes, hydrocarbons such as *n*-hexadecane and *n*-dodecane, silicone oil emulsions, and soybean oil. Relevant properties of two types of oxygen vectors are noted in Table 58.17. Gas–liquid mass transfer enhancement due to the presence of water immiscible oxygen vectors in aerated aqueous dispersions has been reviewed by Dumont and Delmas (117).

58.6.9 Aqueous Two-Phase Extractions

Aqueous two-phase extraction is used in bioprocessing to recover and purify bioactive proteins that are susceptible to denaturation during traditional solvent extraction that employs hydrophobic solvents. Save *et al*. (118) measured mass transfer coefficients of cytochrome-c, amyloglucosidase, and β-galactosidase in aqueous two-phase systems in a stirred cell with a flat interface between phases. In the poly(ethylene glycol) (PEG)–dextran system, the controlling resistance to mass transfer occurred in the heavy phase (the dextran-rich phase). This was correlated as

$$k_L = 3.9 \times 10^{17} D_L^{1.8} E^{0.42} \mu_L^{0.78} \tag{58.82}$$

For PEG–sodium sulfate systems, the controlling resistance lay in the light phase (PEG-rich phase) and the mass transfer coefficient was correlated as (118):

$$k_L = 0.17 D_L^{0.33} E^{0.38} \tag{58.83}$$

In Equations 58.82 and 58.83, μ_L is the viscosity of the phase and D_L is the estimated diffusivity of the protein in that phase. The agitation power input per unit phase mass is represented by E. The E values ranged over $\sim(2–32) \times 10^{-4}$ W/kg.

58.6.10 Solid–Liquid and Gas–Solid Mass Transfer

Dissolution or vaporization of a solid phase into a fluid, or crystallization from a liquid are problems of solid–fluid mass transfer. Other similar situations occur in adsorption/desorption of material and during reaction catalyzed by a solid-phase biocatalyst. Common examples of gas–solid mass transfer are seen in various kinds of drying operations. Mass transfer may occur to or from a fluid flowing past a stationary solid, or the solid may be suspended in the fluid. These cases are treated separately below.

58.6.11 Flow Past a Solid Surface

Material transport to or from a fluid moving past a stationary solid is encountered in packed beds of biocatalysts, chromatographic media, and solid adsorbents such as activated carbon. Other occurrences are in membrane processes, solid-state state fermentations (119–121), surfaces of biofilms, capillaries containing surface-immobilized enzymes, and biofilters for treating gaseous effluents. The rate of mass transfer in flow past a solid is controlled by the flow rate of the fluid, the geometry of the solid surface, the diffusivity of the solute, and the physical properties of the flowing fluid. Suitable correlations for estimating the mass transfer coefficient for flow past solids of various geometries (e.g. flat plate, sphere, pipe) are listed in Table 58.18. The correlations given are for smooth surfaces. Predictive equations such as those in Table 58.18 and others in this chapter are usually accurate to only about ±50% of the actual value. Some more important bioprocess-relevant cases of mass transfer in flow past stationary solids are discussed in greater depth in the following sections.

58.6.11.1 Packed Beds. External mass transfer to or from spherical solid particles in packed beds has been correlated

with the following equations:

$$Sh = \frac{0.4584}{\phi} Re^{0.5931} Sc^{\frac{1}{3}} \tag{58.84}$$

for gases when $10 \leq Re \leq 10{,}000$ (123);

$$Sh = \frac{1.09}{\phi} Re^{\frac{1}{3}} Sc^{\frac{1}{3}} \tag{58.85}$$

for liquids when $0.0016 \leq Re \leq 55$ and $165 \leq Sc \leq 70{,}600$ (1); and

$$Sh = \frac{0.250}{\phi} Re^{0.69} Sc^{\frac{1}{3}} \tag{58.86}$$

for liquids when $55 \leq Re \leq 15{,}000$ and $165 \leq Sc \leq 10{,}690$ (1). The Reynolds number in these equations is based on the particle diameter; the superficial fluid velocity is based on the total cross-section of the bed, and ϕ is the voidage of the packed bed. For nonspherical particles, these equations should be corrected: the Reynolds number should be calculated using the diameter of a sphere having the same surface area as the particle. Mass transfer in packed beds has been reviewed by Larachi *et al*. (124) and Wang *et al*. (125).

Chromatography columns are a form of packed bed. Mass transfer in chromatographic columns has been discussed by Li *et al*. (126). Mass transport aspects of high-performance liquid chromatography (HPLC) have been reviewed by Miyabe and Guiochon (127). Mass transfer of proteins in ion exchange media such as those used in many chromatographic separations, has been discussed by Carta *et al*. (128). During chromatography of macromolecules such as proteins, the combination of molecular diffusivities, particle size of the stationary phase, and elution velocity are such that separation is invariably controlled by mass transfer of the solute to the stationary phase.

58.6.11.2 Aeration Through Polymer Tubing. Bubble-free gas exchange through polymer tubing has been employed in animal cell culture and culture of microalgae. In the latter case, the gas inside the tube is carbon dioxide, which is used by photosynthetic cultures to generate carbohydrates and cell mass. For animal cell culture, the tube may be supplied with air, pure oxygen, or an atmosphere containing 5% (vol/vol) carbon dioxide for pH control.

Either microporous or nonporous tubing may be used for oxygenation of cultures having low oxygen demands. Microporous tubing is made of polytetrafluoroethylene or polypropylene, both of which are strongly hydrophobic. Micropores, 0.03–3.5 μm in diameter, occupy between 30% and 75% of the surface of the tube. The tubing is fairly ridged, with typical outer diameters of 2.5–4 mm and a wall thickness of about 0.5 mm. The pressure inside the tubing cannot exceed the bubble point pressure or else, the gas will issue through the pores as bubbles. The bubble point pressure tends to be low, of the order of 10 mbar. So long as the pores are gas-filled, they do not pose a significant resistance to mass transfer (28), which occurs only through the liquid film held outside the pores. Microporous tubing generally provides a better mass transfer performance than the nonporous silicone tubing, if the pores remain unwetted. Pore wetting can be a problem especially during prolonged use.

In homogeneous nonporous silicone tubing, also known as *solution-diffusion tubing*, the oxygen from inside the tube transfers to the outside by diffusion through the silicone tube wall; the transfer rate is quite slow compared to unwetted microporous tubing. The typical dimensions of silicone tubing are: inside diameter = 1.8 mm and outside diameter = 3.2 mm, or inside diameter = 3 mm and outside diameter = 4.6 mm. The silicone tubing may be internally pressurized. Because of stretching and internal gas pressure, the surface area of the installed tubing differs from that in the relaxed state. The entire surface of the tubing is effective in

mass transfer, except when the tubing has been reinforced. Solubilities and diffusivities of different gases are different in silicone; hence, transport is selective (28).

The mass transfer coefficient k_L outside the microporous tubing in agitated tanks has been correlated as (44)

$$Sh = (7.8 + 0.0021 Re^{1.2}) Sc^{\frac{1}{6}} \tag{58.87}$$

for $250 < Re < 6000$ and $200 < Sc < 500$. The Reynolds number in Equation 58.87 is based on the impeller tip speed and the outer diameter d_o of the tube; thus,

$$Re = \frac{\pi N \rho_L d_i d_o}{\mu_L} \tag{58.88}$$

The Sherwood number is based on d_o and oxygen diffusivity in the liquid. The d_i in Equation 58.88 is the impeller diameter. Equation 58.87 was developed in a cell culture vessel having the polymer tubing coiled into a cylindrical draft-tube configuration (Figure 58.11). A two-bladed anchor impeller located inside the "draft tube" was used for agitation. For any given Reynolds number, the anchor impeller yielded higher values of Sherwood number relative to propellers and screw impellers. Equation 58.87 is for a protein-free medium. For microporous tubes, the k_L values in protein-containing media are about 20% lower than in water. Presence of protein does not seem to affect the mass transfer coefficient of nonporous tubing (44). Equation 58.87 may also be used for homogeneous silicone tubing.

Depending on the porosity of tubing and its diameter, 1.8–3.0 m of polymer tubing is needed per liter of culture volume to meet the $k_L a_L$ demands (44). This length of tubing is close to the technical limits of accommodation in a given volume; therefore, aeration through polymer tubes is useful only for specific cases. The tubing is susceptible to fouling and requires periodic replacement. Anchorage-dependent cells sometimes attach to the surface of silicone tubing; hence, oxygen transfer to bulk fluid is prevented.

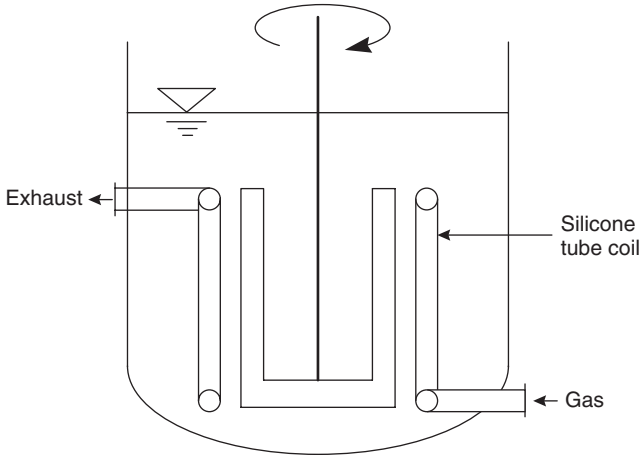

Figure 58.11. Oxygen supply via silicone tubing.

For transfer of carbon dioxide through nonporous silicone membranes and tubes (wall thickness of 1.5–2.0 mm), the diffusion coefficient (D) has been reported to be 1.92 ± 0.14 m^2/ min at 25°C (129). For mass transfer through such a tube to a highly agitated culture volume V_L, the transfer rate can be written as

$$\frac{dC_L}{dt} = \frac{AD(C^* - C_L)}{V_L \delta_w} \tag{58.89}$$

where A is the surface area of the tube, δ_w is its wall thickness, C_L is the instantaneous concentration of the diffusing gas in the liquid phase, and C^* is the saturation concentration of the diffusing component in a liquid sample that is in equilibrium with a gas phase having the same composition as in the silicone tube; C^* may be calculated using Henry's law. Note that Equation 58.89 assumes a constant composition of the gas within the tube (i.e. no diffusion of other dissolved gases from the liquid into the tube). This assumption may be valid for relatively short tubes and high flow rates within the tubes. Aeration through polymer tubing is discussed further by Aunins and Henzler (28).

58.6.11.3 Mass Transfer Effects in Membrane Processes. Membrane filtrations, particularly microfiltration and ultrafiltration, are commonly employed in bioprocessing to separate cells, particles, microemulsions, and macromolecules. Generally, a crossflow scheme is used in which the fluid being filtered flows parallel to the membrane but perpendicular to the direction of the permeate flux. The turbulence generated by the flow improves mass transfer at the membrane surface; consequently, the buildup of a solute layer or gel layer on the surface of the membrane is reduced to assure relatively high permeate or filtrate flux through the membrane. At steady state, a solute concentration profile develops on the upstream side of the membrane as shown in Figure 58.12. The permeate flux J is related to the concentration C_{Ge} of the solute in the gel layer, the concentration C_B in the bulk fluid, and the mass transfer coefficient k_L as follows:

$$J = k_L \ln \frac{C_{Ge}}{C_B} \tag{58.90}$$

The mass transfer coefficient depends on the Reynolds number on the slurry side of the membrane as follows:

$$Sh = \alpha Re^{\beta} Sc^{\frac{1}{3}} \tag{58.91}$$

where Sh and Re are based on the hydraulic diameter d_h of the flow channel. During ultrafiltration, β is 0.5 in laminar

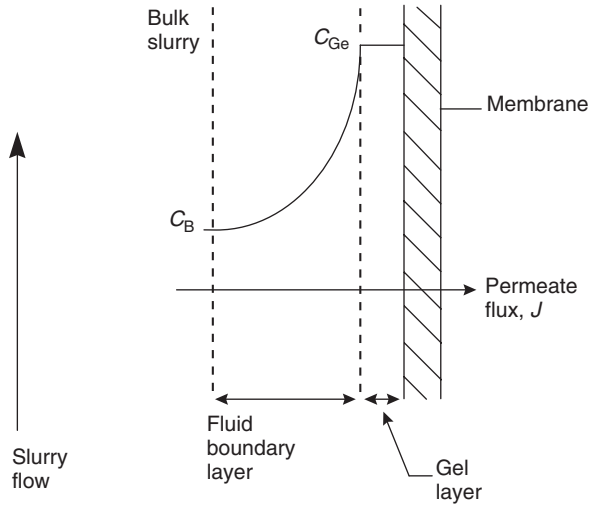

Figure 58.12. Steady state solute concentration profile in ultrafiltration and microfiltration processes.

flow and about 1.0 in turbulent flow. In crossflow microfiltration of particles and cells, β equals 0.8 in laminar flow, but increases to about 1.3 in turbulent flow (130). The α value is 0.023 in turbulent flow. Other expressions for Sherwood number are

$$Sh = 1.62\left(ReSc\frac{d_h}{L}\right)^{0.33} \tag{58.92}$$

$$Sh = 1.86\left(ReSc\frac{d_h}{L}\right)^{0.33} \tag{58.93}$$

and

$$Sh = 0.023Re^{0.875}Sc^{0.25} \tag{58.94}$$

Equations 58.92 and 93 are for laminar flow in tubes and channels, respectively; Equation 58.94 is for turbulent flow. For fully developed laminar flow in ultrafiltration, k_L may be related to shear rate γ by the Porter equation:

$$k_L = 0.816\gamma^{0.33}D_L^{0.67}L^{-0.33} \tag{58.95}$$

where L is the length of the flow channel and the shear rate depends on the channel geometry: $\gamma = \frac{8U_L}{d}$ for tubes with diameter d, and $\gamma = \frac{6U_L}{h}$ for rectangular channels of height h.

The crossflow velocity is the principal operating variable for enhancing the performance of a given filtration membrane module. The optimal crossflow velocity depends on the product and the configuration of the filtration module. For tubular microfiltration membranes with $\sim$ 5.5 mm inner diameter, the optimal crossflow velocity is about 2.5–5 m/s (131). The inner diameter of membrane tubes is usually 4–20 mm. Hollow fibers have much smaller diameters at 0.5–2 mm. Membranes are often deployed as flat sheets in a plate-and-frame configuration, in which the height of the flow channel is 0.5–1.5 mm (131).

Other methods for improving mass transfer in membrane processes include operation at higher temperature (i.e. higher diffusivity and lower viscosity), addition of large inert particles to the feed to agitate the gel layer, and use of pulsating flow. Module design may also be modified to enhance turbulence in the flow channel; hence, turbulence promoters such as static mixers (e.g. wire screens) may be used in tubes and channels, or membranes may be formed into a corrugated configuration. Another method of mass transfer enhancement is the use of dynamic filtration systems with rotating membranes, or agitators placed in close proximity to the membrane (8).

In both ultrafiltration and microfiltration, the mass transfer coefficient tends to be quite small because of the small diffusivities of the cells and macromolecules. Formation of the gel layer, also known as *concentration polarization*, reduces the permeate flux in microfiltration to only about 5% of the pure water flux. Unlike microfiltration and ultrafiltration, pervaporation processes use nonporous homogeneous membranes. Typically, the solute flux is low and the mass transfer coefficient k_L is relatively large in view of the higher diffusivities of small solutes such as ethanol. For additional information on mass transfer in membrane processes see Mulder (132), Ho and Sirkar (133), and Brindle and Stephenson (134).

58.6.11.4 Mass Transfer at Rough Surfaces. Compared to smooth surfaces, mass transfer from a geometrically similar rough surface is generally higher for otherwise identical conditions. Roughness induces an earlier transition to turbulence in flow past a surface. The effect of surface roughness on mass transfer coefficients in Newtonian fluids has been correlated by Kawase *et al*. (135) using the equation

$$Sh = 0.0093\left(\frac{e}{d}\right)^{0.15}ReSc^{0.5} \times \left(1.11 + 0.44Sc^{\frac{-1}{3}} - 0.70Sc^{\frac{-1}{6}}\right) \tag{58.96}$$

where e is the absolute roughness (mean height of projections from the surface) and d is pipe or channel diameter. The ratio e/d is known as *relative roughness*. Equation 58.96 is for the ranges: $5 \times 10^3 < Re < 5 \times 10^5$, $5 < Sc < 400$, and $0.003 \leq e/d \leq 0.056$.

Mass transfer in solid-state fermentation devices is relatively poorly understood. Relevant studies have been reviewed by Rahardjo *et al*. (120) and Mitchell *et al*. (121). Mass transfer in rotating drum solid-substrate bioreactors has been discussed by Hardin *et al*. (136) and Barrera-Cortes *et al*. (137). Mass transfer in biofilms under oscillatory flow conditions has been discussed by Nagaoka

(138). Surface mass transfer during air chilling and storage of food products is discussed by Kondjoyan (139).

58.6.12 Fluid–Solid Slurries

For mass transfer to or from suspended solids, energy dissipation in the vicinity of the particles is generally assumed to control mass transfer in an isotropically turbulent field. Under such conditions, the small energy dissipating eddies are independent of the nature of the bulk flow; the properties of those eddies depend only on energy dissipation rate per unit mass of fluid, E. In general, the liquid film mass transfer coefficient k_L at the solid–liquid interface is expressed in terms of E as follows (140):

$$Sh = \frac{k_L d_p}{D_L} = 2 + c\left(\frac{E^{1/3}\rho_L d_p^{4/3}}{\mu_L}\right)^a Sc^b \qquad (58.97)$$

where $(E^{1/3}\rho_L d_p^{4/3}/\mu_L)$ may be regarded as the energy dissipation Reynolds number (141). Notice that in a quiescent environment, purely diffusive mass transfer occurs and Equation 58.97 reverts to $Sh = 2$ as expected from theoretical considerations. Irrespective of the reactor configuration, solid–liquid mass transfer in slurries is not significantly influenced by the presence of gas bubbles. Solid–liquid mass transfer cases for the principal types of bioreactors are discussed in the following sections.

58.6.12.1 Stirred Tanks. Use the Calderbank and Moo-Young (12) Equation 58.35 noted earlier, or the Liepe and Möckel equations recommended by Hempel (142):

$$Sh = 2 + 0.67\left(\frac{P}{V_L}\frac{\rho_L^2 d_p^4}{\mu_L^3}\right)^{\frac{1}{8}} Sc^{\frac{1}{3}} \qquad (58.98)$$

which is valid when

$$d_p < 5.2\left(\frac{\Delta\rho}{\rho_L}\right)^{\frac{-5}{6}}\left(\frac{\mu_L^3 V_L}{P\rho_L^2}\right)^{\frac{1}{4}} \qquad (58.99)$$

When the particle diameter exceeds that given by inequality 99, the recommended equation is

$$Sh = 2 + 0.35\left(\frac{\Delta\rho}{\rho_L}\right)^{\frac{1}{3}}\left(\frac{P}{V_L}\frac{\rho_L^2 d_p^4}{\mu_L^3}\right)^{\frac{2}{3}} Sc^{\frac{1}{3}} \qquad (58.100)$$

Solid–liquid mass transfer coefficients in solid–liquid and gas–liquid–solid systems in stirred tanks have been reviewed by Pangarkar *et al*. (143).

58.6.12.2 Bubble Columns. The recommended correlation is

$$\frac{k_L d_p}{D_L} = 2 + 0.545 Sc^{\frac{1}{3}}\left(\frac{g d_p^4 \rho_L^3 U_G}{\mu_L^3}\right)^{0.264} \qquad (58.101)$$

which is due to Sänger and Deckwer (144). It is suitable for $137 \leq Sc \leq 50{,}000$.

58.6.12.3 Airlift Bioreactors. For typical operating conditions, solid–liquid mass transfer coefficient in airlift bioreactors is insensitive to the gas flow rate until such a point, where increasing the superficial gas velocity ceases to produce much increase in circulation of the slurry. If the aeration rate is increased further, the k_L increases rapidly (17,140). Pneumatic energy imparted to the slurry initially produces bulk circulation of fluid; only when circulation no longer improves, the energy is dissipated in microeddies that penetrate to the vicinity of the solid–liquid interface and enhance k_L. Slight variations in solids concentration (e.g. 0.2–4% wt/wt) do not affect k_L in airlift reactors (140,145).

Under similar conditions, solid–liquid mass transfer in external-loop airlift reactors exceeds that in stirred tanks and bubble columns; airlifts perform marginally better than fluidized beds (17). Performance of draft-tube internal-loop airlift devices also exceeds that of bubble columns. The solid–liquid mass transfer coefficient in both external- and internal-loop types of airlift reactors may be increased further by using static mixers. In draft-tube sparged reactors Kenics-type twisted ribbon static mixers placed in the draft-tube have been shown to enhance the mass transfer coefficient by about 20%, relative to operation without the mixers (17).

The various correlations developed for solid–liquid mass transfer coefficient in internal- and external-loop types of airlift reactors are noted in Table 58.19. These correlations require a knowledge of the energy dissipation rate per unit mass of fluid; E is calculated using the equation

$$E = \frac{g U_{Gr}}{1 + \frac{A_d}{A_r}} \qquad (58.102)$$

where U_{Gr} is the superficial gas velocity in the riser (6,90).

58.6.12.4 Fluidized Beds. Mass transfer coefficient for spherical particles suspended in a gas or liquid fluidized bed can be estimated using

$$Sh = \frac{0.4548 Re^{0.5931} Sc^{\frac{1}{3}}}{\phi} \qquad (58.103)$$

TABLE 58.19. Solid–Liquid Mass Transfer Coefficient in Airlift Reactors

Reactor Configuration	Correlation	Ranges
Internal-loop reactors (draft-tube sparged)	$Sh = 2 + 0.064\left(\frac{E\rho_L^3 d_p^4}{\mu_L^3}\right)^{0.165} Sc^{0.45}$ Kushalkar and Pangarkar (146)	0.5% wt benzoic acid granules, $d_p = 0.55$–3 mm, in air–water. $A_r/A_d = 0.17$–1.29, $U_G = 0.08$–0.35 m/s
Internal-loop reactors (draft-tube sparged)	$Sh = 2 + 1.01\left(\frac{E\rho_L^3 d_p^4}{\mu_L^3}\right)^{0.173} Sc^{0.33}$ Goto *et al*. (145)	Amberlyst 15 ion exchange resin, $d_p = 0.55$–0.92 mm, suspended in dilute aqueous sodium hydroxide. $A_r/A_d = 0.1$–1.4
Internal-loop reactors with static mixers (draft-tube sparged)	$Sh = 2 + 1.68\left(\frac{E\rho_L^3 d_p^4}{\mu_L^3}\right)^{0.133} Sc^{0.33}$ Gaspillo and Goto (147)	Kenics-type twisted ribbon static mixers were in draft-tube
External-loop reactors	$Sh = 2 + 0.48\left(\frac{E^{1/3}\rho_L d_p^{4/3}}{\mu_L}\right)^{0.72} Sc^{1/3}$ Mao *et al*. (140)	Benzoic acid coated particles, $d_p = 3.8$ mm, $\rho_S \approx$ 1080 kg/m^3, suspended in water

where ϕ is the void fraction of the bed. Equation 58.103 is suitable for $10 \leq Re \leq 4000$. Another correlation applicable only to liquid fluidized beds is

$$Sh = \frac{1.1068 Re^{0.28} Sc^{\frac{1}{3}}}{\phi} \tag{58.104}$$

which is suitable for $1 \leq Re \leq 10$. Gas–solid mass transfer in gas-fluidized beds has been discussed by Yusuf *et al*. (148).

Mass transfer from the vessel wall to the fluid in a liquid fluidized bed (no gas) is aided by suspended solids that disturb the boundary layer at the wall of the reactor. The liquid film mass transfer coefficient at the wall of such systems has been correlated (149) with the following equation:

$$\frac{k_L d_p}{D_L} = 0.14\left(\frac{d_p U_L \rho_L}{\mu_L}\right)^{1/3}\left(\frac{\mu_L}{\rho_L D_L}\right)^{1/3} + 0.13(1-\phi_f)(\phi_f - \phi_b)\left(\frac{\mu_L^2}{\rho_L^2 U_L d_p D_L}\right)^{1/3}\left(\frac{d_p^3(\rho_S - \rho_L)\rho_L g}{\mu_L^2}\right)^{1/3} \tag{58.105}$$

Equation 58.105 applies when $0.9 \leq \left(\frac{d_p U_L \rho_L}{\mu_L(1-\phi_f)}\right) \leq 1652$ and $151 \leq \left(\frac{\mu_L}{\rho_L D_L}\right) \leq 7021$. In Equation 58.105, ϕ_f is the bed voidage and ϕ_b is the void fraction of the settled bed.

58.6.13 External Mass Transfer and Heterogeneous Bioreaction

At steady state, the rate of mass transfer of a substrate being consumed at the surface of a nonporous particle equals the rate of consumption; thus,

$$k_L a_s (C_B - C_{Sb}) = R \tag{58.106}$$

where a_s is the solid–liquid interfacial area per unit liquid volume, R is the overall rate of reaction, and C_B and C_{Sb} are substrate concentrations in the bulk fluid and at the solid's surface, respectively. Because R is a function of the substrate concentration C_{Sb}, R tends to a maximum when the concentration at the interface approaches that in the bulk fluid, that is, the mass transfer rate or the $k_L a_s$ is large. In this situation, the rate of reaction is maximum and is controlled by the intrinsic kinetics and not by mass transfer effects. At the other extreme, when the mass transfer rate is low compared to the reaction rate, the substrate concentration at the interface approaches zero, and the reaction is mass transfer controlled. Because now $C_{Sb} = 0$, the reaction rate is

$$R = k_L a_s C_B \tag{58.107}$$

Thus, the observed rate of a mass transfer controlled reaction will be influenced by changes in C_B, k_L, or the specific solid–liquid interfacial area a_s. Indeed, observing influence of these variables on the reaction rate provides methods for determining if the reaction is mass transfer limited. In addition, because the activation energy for mass transfer is much smaller than that of biochemical reactions, the observed rate of a mass transfer controlled reaction is not as sensitive to temperature changes as the rate of reaction when it is not limited by transport effects. In a batch stirred vessel, an increase in the rate of a solid-phase catalyzed reaction with increasing agitation implies a mass transfer limited reaction. Similarly, in a packed bed reactor, the rate of a mass

transfer controlled reaction will increase as the flow rate is increased, but the contact time is kept unchanged (i.e. the depth of the bed is increased proportionately).

The solid–liquid mass transfer correlations given earlier in this chapter may be used to estimate k_L in bubble columns, packed beds, fluidized beds, and other geometries of bioreactors. External mass transfer in immobilized enzyme systems has been discussed in greater detail by Goldstein (150).

58.6.14 Intraparticle Mass Transfer

When a substrate is being consumed or a product is being produced inside a porous immobilization matrix or in homogeneous gels, an internal substrate (and product) concentration profile exists within the matrix at steady state. In microporous particles, in the absence of convective transport, the main internal mass transfer parameter is the effective diffusivity D_e in the particle. The effective diffusivity is related to the liquid- or gas-phase diffusivity in the pores as follows:

$$D_e = \frac{p}{\tau} D_L \tag{58.108}$$

In Equation 58.108, p is the porosity, and τ is the tortuosity of the immobilization matrix. The tortuosity corrects for changes in cross-sectional area of the pore. Equation 58.108 applies to gases and liquids when the ratio of the mean free path and the pore diameter (i.e. the dimensionless Knudsen number) is less than 0.01. Tortuosity of many porous solids (e.g. silica gel and alumina) are in the range $2 \leq \tau \leq 6$ (4). For activated carbon, $5 \leq \tau \leq 65$ (4). Intraparticle mass transfer is encountered in immobilized enzyme and cell particles, in chromatographic media, and during leaching of solubles from inert solids.

In macroporous particles, changes in local fluid velocity outside the particle create pressure fluctuations within the larger pores and this leads to some "agitation" of the fluid held in the pores. In this situation, the apparent effective diffusivity (D_{eap}) is greater than that predicted by Equation 58.108. For example, the apparent effective diffusivity of oxygen in pellets of *Aspergillus niger* has been reported to be $\sim 10^{-8}$ m^2/s, or about 10-fold greater than in water, which suggests a level of fluid movement within the pellet possibly because of turbulence induced elastic structural deformations of the loose floc.

For porous particles in packed beds, the apparent effective diffusivity has been observed to depend on the effective diffusivity (no convection) and the Peclet number; thus,

$$D_{e\,ap} = \frac{D_e}{\frac{3}{Pe}\left(\frac{1}{\tanh Pe} - \frac{1}{Pe}\right)} \tag{58.109}$$

where the Peclet number is given as

$$Pe = \frac{d_p U_L}{(1-\phi) D_e} \tag{58.110}$$

In Equation 58.110, d_p is the diameter of the particle, U_L is the superficial fluid velocity through the bed, and ϕ is its void fraction. More complete treatments of intraparticle mass transfer have been provided by Chisti and Moo-Young (8), Radovich (151), Willaert *et al*. (152), Pitcher (153), Bailey and Ollis (154) and Pilkington *et al*. (155). Mass transfer effects during osmotic dehydration of foods and other biological matrices have been discussed by Shi and Le Maguer (156). Mass transfer in frozen food matrices has been reviewed by Pham (157). Gervais and Beney (158) have discussed osmotic mass transfer in the yeast *Saccharomyces cerevisiae*. Combined heat and mass transfer during freezing processes such as those commonly encountered in the food industry, have been discussed by Delgado and Sun (159).

NOMENCLATURE

A	Surface area of tube (m^2)
A_d	Cross-sectional area of downcomer (m^2)
A_r	Cross-sectional area of riser (m^2)
A_s	Total solid–liquid interfacial area (m^2)
a_D	Gas–liquid interfacial area per unit volume of dispersion (/m)
a_L	Gas–liquid interfacial area per unit liquid volume (/m)
a_{Lc}	Liquid–liquid interfacial area per unit volume of continuous phase (/m)
a_s	Solid–liquid interfacial area per unit liquid volume (/m)
BOD	Biochemical oxygen demand
Bo	Bond number
C	Concentration (kg/m^3)
C^*	Saturation concentration of transferring gas or solute in liquid (kg/m^3)
ΔC	Concentration gradient (kg/m^3)
C_B	Solute or substrate concentration in bulk liquid (kg/m^3)
C_G	Concentration in the gas phase (kg/m^3)
C_{Ge}	Solute concentration in gel layer (kg/m^3)
C_{Gi}	Interfacial concentration of the diffusing component in the gas phase (kg/m^3)
C_L	Instantaneous concentration of transferring component in liquid (kg/m^3)
C_{L0}	Initial dissolved oxygen concentration at time t_0 (kg/m^3)
C_{Lc}	Equilibrium concentration of solute in continuous phase (kg/m^3)

C_{Ld}	Equilibrium concentration of solute in dispersed phase (kg/m^3)
C_{Li}	Interfacial concentration of the diffusing component in the liquid phase (kg/m^3)
C_S	Concentration of solids in slurry (% wt/vol or kg/m^3)
C_{Sb}	Substrate concentration at solid–liquid interface (kg/m^3)
C^*_{in}	Saturation concentration of oxygen in equilibrium with ingoing gas (kg/m^3)
C^*_{out}	Saturation concentration of oxygen in equilibrium with the exhaust gas (kg/m^3)
D	Diffusivity (m^2/s)
D_D	Diffusivity of dispersed phase (m^2/s)
D_e	Effective diffusivity in particle (m^2/s)
$D_{e\ ap}$	Apparent effective diffusivity in particle (m^2/s)
D_{gas}	Diffusivity of gas in liquid (m^2/s)
D_L	Diffusivity of gas or solute in liquid (m^2/s)
DMEM	Dulbecco's modified Eagle's medium
D_{oxygen}	Diffusivity of gas in liquid (m^2/s)
D_p	Diffusivity of small solute in protein solution (m^2/s)
d	Characteristic length dimension (m)
d^*	Diameter number defined by Equation 58.33
d_B	Sauter mean bubble diameter (m)
d_D	Diameter of drop (m)
d_F	Maximum diameter of flask (m)
d_H	Diameter of sparger hole (m)
d_h	Hydraulic diameter (m)
d_{hi}	Hydraulic diameter in packed bed as defined in Table 58.18 (m)
d_i	Diameter of impeller (m)
d_o	Outer diameter of tubing (m)
d_p	Diameter of particle (m)
d_r	Diameter of riser (m)
d_T	Diameter of tank or column (m)
E	Energy dissipation rate per unit mass (W/kg)
EDTA	Ethylenediaminetetraacetic acid
E_L	Overall axial dispersion coefficient of liquid (m^2/s)
e	Absolute roughness (m)
$\hat{e}$	Eccentricity of shaker platform
F	Mass flow rate of gas (kg/s)
Fr	Froude number
f	Parameter
Gr	Grashof number
g	Gravitational acceleration (m/s^2)
H	Dimensionless Henry's law constant
h	Height of channel (m)
h_D	Height of dispersion (m)
h_L	Height of gas-free liquid (m)
I	Ionic strength (kg ion/m^3)
J	Mass flux (kg/m^{2}s or kmol/m^{2}s) or permeate flux (m/s)
K	Consistency index of fluid (Pa s^n)
K_L	Overall mass transfer coefficient based on liquid film (m/s)
K_p	Mass transfer coefficient for plug (mol O_2/ atm/h)
K_p	Partition coefficient of solute defined by Equation 58.25
K_S	Mass transfer coefficient at surface (mol O_2/ atm h)
k	Mass transfer coefficient (m/s)
k_G	Gas film mass transfer coefficient (m/s)
k_i	Impeller-dependent constant in Equation 58.45
k_L	Liquid film mass transfer coefficient (m/s)
k_La_L	Overall gas–liquid volumetric mass transfer coefficient (/s)
$(k_La_L)_{r\ or\ d}$	Overall volumetric mass transfer coefficient in riser or downcomer (/s)
k_{Lc}	Liquid film mass transfer coefficient in continuous phase (m/s)
k_{Ld}	Liquid film mass transfer coefficient in dispersed phase (m/s)
L	Length of circulation loop, pipe, plate, or flow channel (m)
ℓ	Length of impeller blade (m)
M_L	Molecular weight of liquid (kg/kmol)
Mo	Morton number
N	Rotational speed (/s)
n	Flow behavior index
P	Power input (W)
PEG	Poly(ethylene glycol)
Pe	Peclet number
P_G	Gassed power input (W)
Po	Power number
Ps	Poiseuille number
p	Porosity of particle
p_{atm}	Partial pressure of oxygen in the atmosphere outside flask (atm)
p_L	Partial pressure of oxygen in liquid in flask (atm)
Q_G	Volume flow rate of gas (m^3/s)
q_{O_2}	Specific oxygen consumption rate (/s)
R	Overall rate of reaction (kg/m^3 s)
Ra	Rayleigh number
R_b	Ratio of bubble diameter to its width
Re	Reynolds number
Re_C	Reynolds number for the continuous phase
Re_d	Reynolds number based on d_{hi} as in Table 58.18
Re_G	Reynolds number of gas
Re_i	Reynolds number based on impeller

Re_L	Reynolds number of liquid
Re_t	Reynolds number based on terminal settling velocity of particle
Re_x	Local value of Reynolds number at distance x from leading edge
RPMI	Cell culture medium
Sc	Schmidt number
SDS	Sodium dodecyl sulfate
Sh	Sherwood number
Sh_x	Local value of Sherwood number at distance x from leading edge
Sh_G	Sherwood number of gas
Sh_L	Sherwood number of liquid
SLS	Sodium lauryl sulfate
St	Stanton number
T	Temperature (degree Celsius) or absolute temperature (K)
T_L	Turbulence factor defined by Equation 58.50 ($L^{-0.537}/s$)
t	Instantaneous time (s)
t_C	Contact time of droplets (s)
t_m	Mixing time (s)
t_R	Residence time of gas in liquid (s)
U_B	Bubble rise velocity (m/s)
U_G	Superficial gas velocity based on outer column cross-sectional area (m/s)
U_{Gr}	Superficial gas velocity in the riser (m/s)
U_L	Mean superficial liquid velocity in the reactor or pipe (m/s)
U_{Lr}	Superficial liquid velocity in the riser (m/s)
U_p	Velocity of particle (m/s)
U_t	Terminal settling velocity of a single particle in liquid (m/s)
V	Volume of shake flask (L)
V_L	Volume of liquid or slurry (m^3)
V_{Lc}	Volume of continuous phase (m^3)
V_M	Molar volume of solute at its boiling point (m^3/kmol)
W	Width of impeller blade (m)
We	Weber number
Wi	Weissenberg number
X	Viable biomass concentration (kg/m^3)
x	Distance (m)
x_i	Mass fraction of oxygen in inlet gas stream
x_o	Mass fraction of oxygen in exhaust gas

Greek Symbols

α	Parameter; parameter in Equation 58.72 ($m^{\beta}/s^{(\beta+1)}$)
α_M	Value of α (Eq. 58.72) in presence of static mixers ($m^{-\beta}/s^{(\beta+1)}$)
β	Parameter
γ	Parameter or shear rate (/s)
δ	Film thickness (m)
δ_G	Thickness of gas film (m)
δ_L	Thickness of liquid film (m)
δ_w	Wall thickness of tube (m)
ε_G	Overall gas holdup
ε_{Gr}	Gas holdup in the riser
ε_S	Volume fraction or holdup of solids in three-phase systems
θ	Parameter in Equation 58.79
λ	Characteristic time or relaxation time of viscoelastic fluid (s)
μ_{ap}	Apparent viscosity of non-Newtonian fluid (Pa s)
μ_C	Viscosity of the continuous phase (Pa s)
μ_D	Viscosity of the dispersed phase (Pa s)
μ_G	Viscosity of the gas (Pa s)
μ_L	Viscosity of the liquid (Pa s)
μ_{SL}	Viscosity of the slurry (Pa s)
μ_w	Viscosity of water (Pa s)
ξ	Association parameter
π	Pi
ρ_C	Density of continuous phase (kg/m^3)
ρ_D	Density of dispersed phase (kg/m^3)
ρ_G	Density of gas (kg/m^3)
ρ_L	Density of the liquid (kg/m^3)
ρ_p	Density of the particles (kg/m^3)
ρ_S	Density of solids (kg/m^3)
ρ_{SL}	Density of slurry (kg/m^3)
$\Delta\rho$	Density difference between phases (kg/m^3)
σ	Interfacial tension (liquid–liquid) (kg/s^2)
σ_L	Interfacial tension (kg/s^2)
τ	Tortuosity of pores
ϕ	Void fraction of the packed bed
ϕ_b	Voidage of settled bed
ϕ_f	Voidage of fluidized bed
ϕ_S	Volume fraction of solids in gas-free slurry
χ	Parameter

OXYGEN TRANSFER RATE DETERMINATION METHODS

Felix Garcia-Ochoa and Emilio Gomez
Dept. Ingenieria Quimica, Facultad Quimicas, Universidad Complutense, Madrid, Spain

59.1 INTRODUCTION

A properly designed bioreactor must provide a controlled environment and a concentration of nutrients sufficient to achieve optimal cell growth allowing the formation of products, either biomass or a metabolite or the substrate, under fixed specifications. Several phases are involved in the bioprocesses: the substrates, nutrients, and products must be transferred from one phase to the other therefore, mass transfer between phases may often become the limiting step of the overall process rate and be a relevant factor in scale-up. Mixing, by aeration and agitation, is used to improve mass transfer and also to insure homogeneous distribution of the nutrients in the liquid phase. Hence, gas–liquid contact is a matter of decisive importance for the design, scale-up, and operation of bioreactors to carry out bioprocesses. This is true not only in aerobic systems, where oxygen transport from the air is necessary and obviously focused, but also in the case of anaerobic systems where the transport of other gases such as methane or carbon dioxide usually takes place.

Oxygen is one of the most important nutrients for aerobic cells that need oxygen dissolved in the broth for maintenance, growth and production of bioproducts. Due to its low solubility in broths, which are usually aqueous solutions (approximately 9 ppm at 25°C and 1 atm in pure water), oxygen must be continuously supplied by a gas phase (air or oxygen) with the purpose of achieving acceptable productivities, independent of the physical operational modes (batch, semi-batch, and continuous cultures). Frequently, in aerated bioreactors the critical limiting factor to providing the optimal environment is the oxygen transfer rate (OTR).

In shake flask scale, oxygen transport is accomplished by the rotary or reciprocating action of a shaker apparatus. In laboratory and pilot scales, oxygen is generally supplied by compressed air and distributed by a gas sparging, and mechanical devices are used to improve mixing of the broth for better distribution of gas bubbles and to rupture large bubbles into small ones, obtaining a large interfacial area. Thus in mechanically stirred-tank bioreactors, the impeller is the main gas-dispersing tool and stirrer speed and its design both have a pronounced effect on OTR. In this type of bioreactor, it is possible to alter the stirrer speed and thereby allowing a greater flexibility to deal with rheological changes in the medium. Mechanical agitation is however restricted by biological constraints, because the cells may be damaged by hydrodynamics stress when agitation and/or aeration are too vigorous.

In order to avoid mechanical agitation and to obtain a sufficiently high OTR to ensure that dissolved oxygen (DO) concentration can be maintained above a critical level, others types of bioreactors have been extended, the majority of which are pneumatically stirred bioreactors (bubble columns and airlifts). In these bioreactors, the supply of oxygen depends mainly on aeration, which is also responsible for the homogenization of the medium and for sweeping out the carbon dioxide and any volatile by-products formed, and therefore the system is less flexible than the mechanically stirred bioreactor. The main advantages of airlifts over bubble columns are the improved mixing and the increase of OTR.

Consequently, there are diverse ways of achieving a sufficient OTR in bioreactors. Hydrodynamics conditions and energy dissipated into bioreactor play an important

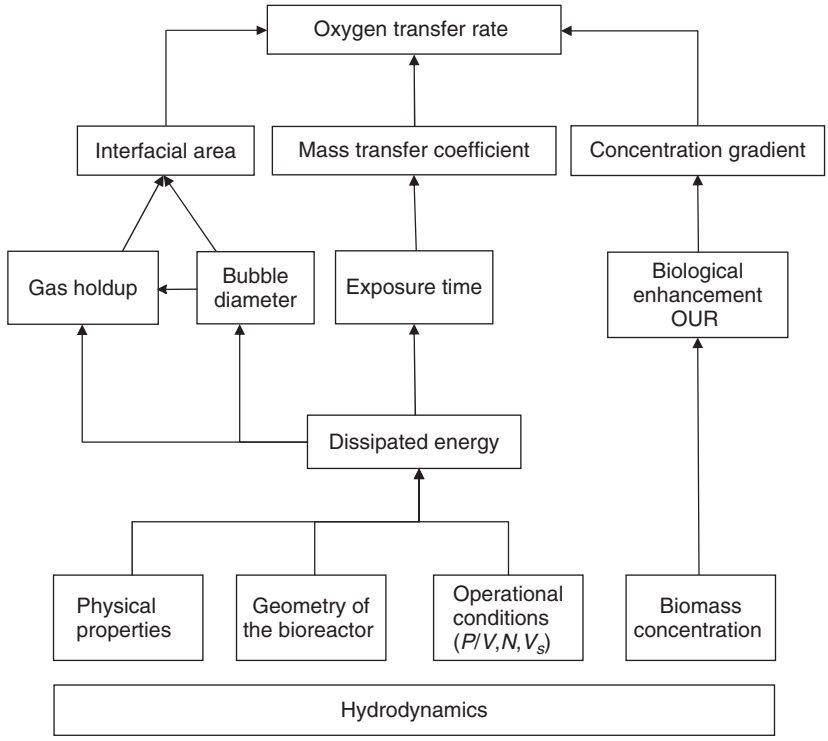

Figure 59.1. Factors influencing oxygen transfer rate at several levels in bioreactors. [Adapted from Garcia-Ochoa and Gomez (1).]

role because different phenomena are simultaneously taking place; also the relative importance of these phenomena changes with the scale, the type of bioreactor and so on. The interrelationship between factors influencing OTR is shown in Fig. 59.1.

Nonconventional methods for enhancing the oxygen supply to broth include introduction of chemicals (surfactants) (2,3), of an immiscible phase of inert hydrocarbons (4,5) or perflurocarbons with high oxygen solubility (6); coimmobilization or mixed culture of an oxygen-production photosynthetic alga (7,8); and by raising the oxygen partial pressure in the gas phase, using oxygen-enriched air (9) or increasing the pressure in the bioreactor head space (10).

Extensive literature on OTR in bioreactors is available and a considerable part of it has been published in recent years. Chapters of encyclopedias and books (11–14), several reviews (1,15–21), and many papers deal with different aspects of this phenomenon in stirred tanks (4,5,22–26), bubble columns, and airlifts (27–35). This chapter is devoted to the description of OTR in aerated bioreactors and to the different experimental techniques for the determination of k_La (the volumetric mass transfer coefficient). This information will be useful for better understanding the importance of OTR in aerobic microbial processes as well as for searching for better operational conditions for oxygen transfer and scale-up in bioreactors.

59.1.1 Oxygen Transfer Rate Description

Bioreactors carrying out microbial processes are gas–liquid–solid systems. In an aerated bioreactor, the oxygen is transferred from a gas bubble into a liquid phase, where it is taken up by the microorganism (which can be considered as a solid particle), and ultimately transported to the site of oxidative phosphorylation inside the cell. This transport can be represented by a number of steps and mass transfer resistances (36) at the following localization (schematized in Fig. 59.2): (r_1) transport from the interior of the bubble to the gas–liquid film; (r_2) movement at the gas–liquid interface; (r_3) diffusion in the liquid film surrounding the bubble; (r_4) transport in the bulk liquid; (r_5) diffusion through the relatively stagnant liquid film surrounding the cells; (r_6) movement across the liquid–solid interface and in the case of multicellular aggregates or solid particle, diffusion through the solid to the individual cell; (r_7) transport through the cytoplasm (r_8) at sites where biochemical reactions, involving oxygen consumption and production of carbon dioxide, take place.

It should be stressed that steps (r_1) to (r_7) correspond to physical phenomena that are in principle better known and easier to describe than biochemical phenomena and step (r_8), which is a complex reaction network. Not all these resistances are significant. Because oxygen is only slightly soluble in water, it can often be assumed that no

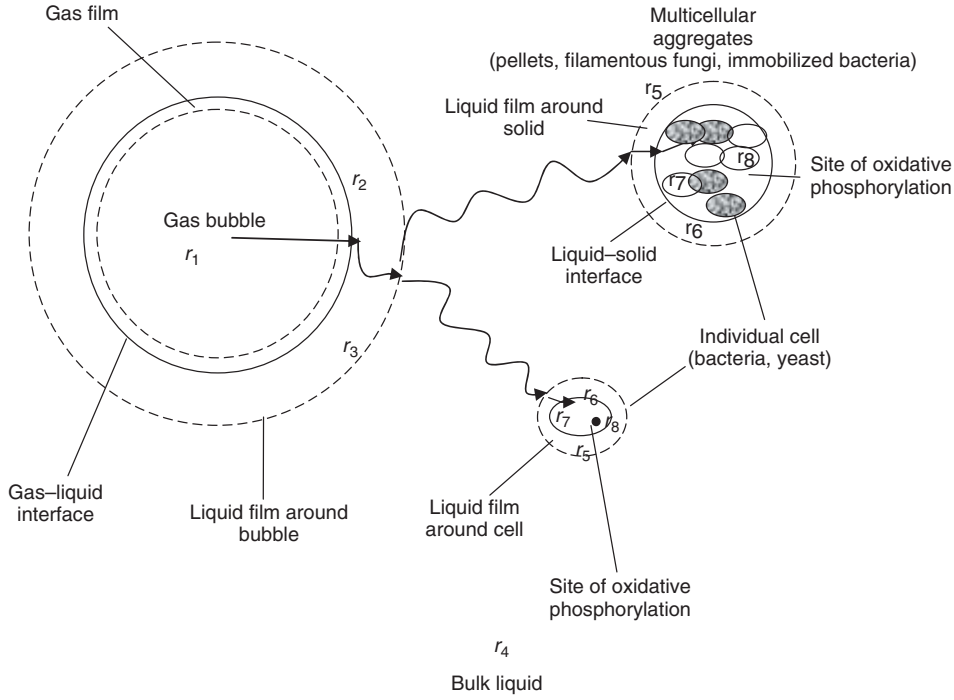

Figure 59.2. The pathway for transport of oxygen from gas bubble to cell in a bioreactor. [Adapted from Blanch and Clark (36).]

mass transfer limitation is observed within the gas phase. Provided that the liquid is well-mixed, transport through the bulk liquid is generally rapid and may be neglected as well. The resistance in the liquid film around the organism can be neglected since the organism (bacterium or yeast cell) is relatively small and thus, only an extremely small driving force is necessary to transport oxygen from the bulk liquid into the organism. Finally, in packed organisms (e.g. molds in pellet form, filamentous mycelia or immobilized bacteria) with a size comparable to that of a bubble, resistance in the liquid film surrounding the solid may dominate; also, the intraparticle resistance resulting from diffusion and oxygen consumption within the solid particles must be considered, but that is beyond the scope of this chapter. Intracellular oxygen transfer resistance must be negligible because of the short distances involved. The liquid film resistances around bubbles usually control the overall mass transfer rate and the oxygen transport problem is thus reduced to that of gas–liquid interfacial mass transfer (22,36).

The simplest theory on mass transfer is the two-film model (37) and usually the gas–liquid mass transfer rate is modeled according to this theory. In this model, the resistance to mass transfer in each phase is localized in the thin layer close to the interface, which is assumed to offer no resistance to transport. Mass transfer through the stagnant film of liquid around the bubble is transferred by molecular diffusion along a concentration gradient that can be assumed to be linear, as shown schematically in Fig. 59.3. In the steady state, the molar oxygen flux, J_0, through each of the two films, can be expressed as the product of the driving force times the mass transfer coefficient according to

$$J_0 = k_G \cdot (p_G - p_i) = k_L \cdot (C_i - C_L) \tag{59.1}$$

where k_G and k_L, are the local gas- and liquid-phase mass transfer coefficients, respectively; p_G is the oxygen partial pressure in the gas phase; and C_L the oxygen concentration in the liquid phase; index i refers to same magnitudes at the gas–liquid interface.

Considering Henry's law, an overall volumetric mass transfer coefficient can be used which includes the gas and liquid film resistances according to

$$J_0 = K_G \cdot (p_G - p^*) = K_L \cdot (C^* - C_L) \tag{59.2}$$

where K_G and K_L are the overall gas- and liquid-phase mass transfer coefficients, respectively; p^* is the oxygen pressure in equilibrium with liquid phase; C^* is the saturation oxygen concentration in the bulk liquid in equilibrium to the partial pressure of oxygen in the gas phase.

Combining Equations 59.1 and 59.2, the following relationship is obtained:

$$\frac{1}{K_L} = \frac{1}{H_e k_G} + \frac{1}{k_L} \tag{59.3}$$

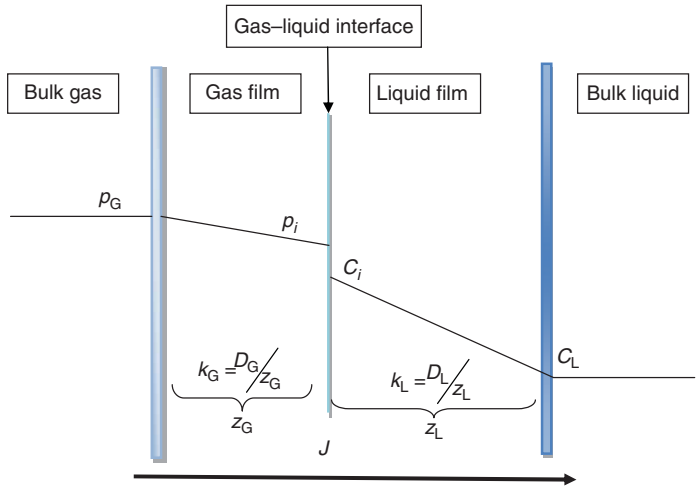

Figure 59.3. Schematic representation of the gas–liquid interface, concentrations, and mass transfer coefficients according to two-film theory. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

where H_e is the Henry constant. This last equation represents the additive contribution of gas- and liquid-film resistances. Taking into account that H_e is very large for oxygen, it is commonly accepted that the greatest resistance for mass transfer is on the liquid side of the interface and the gas-phase resistance can usually be neglected and $K_L \approx k_L$.

The OTR is obtained by multiplying the flux by the gas–liquid interfacial area per unit of liquid volume, a:

$$\text{OTR} = a \cdot J_0 = k_L a \cdot (C^* - C_L) \qquad (59.4)$$

where $k_L a$ is the volumetric mass transfer coefficient.

Equation 59.4 implies that essentially all resistance to oxygen transfer is located at the interface in the liquid film and that OTR is dependent on the mass transfer coefficient, the gas–liquid interfacial area, and the gradient between the concentration of the oxygen at the interface and concentration in the bulk liquid (average concentration). The maximum value of the concentration gradient is limited due to the low solubility of oxygen. Therefore, the maximum OTR from the gas to the liquid in the bioreactor can be estimated by the product $k_L a C^*$. Gas solubility is mainly dependent on the temperature, pressure, concentration, and presence of salts and organic solutes (38). The gas solubility, in electrolyte solutions and organic solutes, is usually smaller than the gas solubility in pure water (solubility data are available in handbooks). As fermentation broths contain different salts, substrates, products and surfactants, reduction in OTR must be considered. Some of these effects are shown in Fig. 59.4 as an example. Due to the difficulty of measuring k_L and a separately, usually the product $k_L a$ is experimentally determined, and this parameter characterizes the transport from gas to liquid phase. Some of the measuring methods of oxygen transfer are applied to other gases, as well. To quantify the OTR for another gas, the relationship between the volumetric mass transfer coefficients and the diffusion coefficients for two different compounds can be employed according to

$$\frac{k_L a(\text{O}_2)}{k_L a(\text{gas})} = \frac{D_{\text{LO}_2}}{D_{\text{Lgas}}} \qquad (59.5)$$

The above relationship indicates a direct proportionality between the volumetric mass transfer coefficient and the diffusion coefficient and it applies when the transfer can be ascribed to the mechanism of the two-film model. Using other models, such as the penetration theory or the surface renewal theory, a direct proportionality is not obtained. However, since the ratio of the diffusion coefficients is close to 1, the error from using Equation 59.5 is small. The correction is satisfactory only for mass transfer for identical liquids under identical hydrodynamic conditions and the diffusion coefficients used for the correction should be at the same temperature as the $k_L a$ data.

The transport and the consumption of oxygen have usually not been described together, and have often been measured in different ways in the past. However, now it is usual to obtain both experimental values using the same technique, that is simultaneous determination of both, OTR (or $k_L a$) and oxygen uptake rate (OUR) in the same experiment.

59.2 EXPERIMENTAL DETERMINATION OF $k_L a$

There are several approaches to determine OTR in bioreactors. The most common methods can be classified

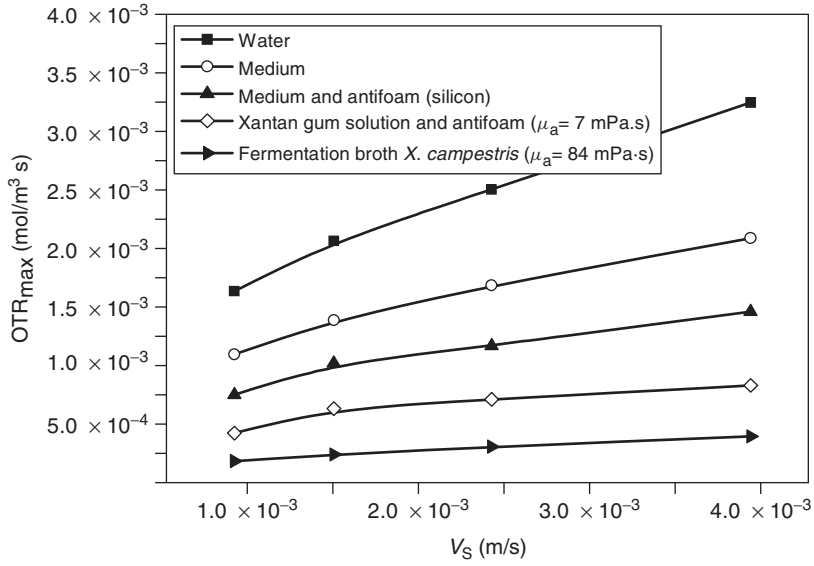

Figure 59.4. Comparison of oxygen transfer rate in different aqueous solutions for a 2 L bioreactor, and a stirrer speed of 350 rpm. Adapted from Garcia-Ochoa and Gomez (39).

depending on whether the determination is realized in the absence of microorganisms or with dead cells (chemical and physical methods) or in the presence of biomass that consumes oxygen at the same time that the measurement is carried out (biological methods). Chemical and biological methods require a reaction in the liquid phase to reduce the DO concentration to a level below saturation. In chemical methods it is usually a chemical oxidation, and in biological methods it is cellular respiration.

When selecting a method, several factors must be taken into account, mainly (i) the bioreactor type and its mechanical design, (ii) the aeration and mixing of the system (iii) the flow characteristics of gas and liquid phases, (iv) the composition of the fermentation medium, and (v) the type of microorganism and its morphology, due to the possible effect on measurements.

Whatever the method used for the experimental determination of $k_L a$, data generation is basically the same: the measured variable (usually oxygen concentration) is compared to the value predicted by a mathematical model that includes $k_L a$ as a parameter. It is thus obvious that the choice of the model is very important, and poor assumptions on flow characteristics of gas or liquid phases may lead to errors and deviations from the true values. All the models are a simplified description of the system and, therefore, $k_L a$ is not a property of the system, but a parameter of the model adopted (13).

The oxygen mass balance in the assumed well-mixed liquid phase can be written as

$$\frac{dC_L}{dt} = K_L a \cdot (C^* - C_L) - q_{O_2} \cdot C_X \qquad (59.6)$$

where dC_L/dt is the accumulation of oxygen in the liquid phase, the first term on the right-hand side is the OTR and the second term is the OUR. This last term is usually expressed by the product of the specific OUR of the microorganism, q_{O_2}, and the biomass concentration, C_X.

When biochemical reactions do not take place, OUR $= 0$, and the oxygen mass balance in the liquid phase can be simplified to

$$\frac{dC_L}{dt} = k_L a \cdot (C^* - C_L) \qquad (59.7)$$

Many methods for OTR determination are based on Equations 59.6 and 59.7 and different techniques from measuring the DO concentration can be used. Only the more useful and common chemical, physical, and biological methods will be examined here.

59.2.1 Chemical Methods

Chemical methods require a reaction in the liquid phase that consumes oxygen at a rate which is sufficiently fast so that transport of oxygen from the gas to the liquid phases through the liquid film around the gas bubbles is the limiting step of the overall process rate. Consequently, these methods cannot be applied to actual microbial processes. When a chemical is added to the system, there is the question of whether the addition has provoked changes in the physicochemical properties of the media, which have thus become different from the properties of the original system.

59.2.1.1 Sulfite Oxidation Method. This method is based on the reaction of sodium sulfite, a reducing agent, with the dissolved oxygen to produce sulfate, in the presence of a catalyst, usually a divalent cation (40); sulfite is oxidized according to the following equation:

$$2SO_4^{2-} - O_2 - 2SO_3^{2-} = 0 \qquad (59.8)$$

The kinetics of the sulfite oxidation is independent of the reactant concentration and sufficiently fast so as to assume that the overall rate is limited by OTR. The experimental procedure consists in first filling the bioreactor with sodium sulfite solution containing Co^{2+}, sparging the liquid with air, and allowing the oxidation reaction to continue for some minutes; after that, the air flow and the agitation are stopped and samples of the solution are removed at intervals of time. The concentration of nonreacted sulfite is determined by reaction of the sulfite in each sample with an excess of standard iodine reagent:

$$SO_4^{2-} + 2H^+ + 2I^- - SO_3^{2-} - I_2 - H_2O = 0 \qquad (59.9)$$

The amount of residual sulfite can also be estimated indirectly by the stoichiometry of the reaction (10) based on colorimetric determination of the iodine concentration (10) or by back-titration of the iodine with standard sodium thiosulfate solution ($Na_2S_2O_3$) to a starch indicator end point according to the following equation:

$$S_4O_6^{2-} + 2I^- - 2S_2O_3^{2-} - I_2 = 0 \qquad (59.10)$$

With respect to oxygen, the following balance can be written for a well-mixed liquid phase:

$$k_La(C^* - C_L) \cdot V - r \cdot V = 0 \qquad (59.11)$$

Once the sulfite concentration is measured versus time, the reaction rate is determined from the rate of sulfite disappearance, according to

$$-\frac{dC_{Na_2SO_3}}{dt} = 2 \cdot r \qquad (59.12)$$

The DO concentration in the bulk liquid C_L, will be essentially zero if the reaction rate is fast enough and k_La is calculated by measuring the observed reaction rate:

$$-\frac{dC_{Na_2SO_3}}{dt} = 2k_LaC^* \qquad (59.13)$$

This method is relatively easy to carry out and has been extensively used in the past but it has a number of drawbacks and several assumptions are involved in determining k_La in this way. First, the rate of reaction is assumed to be zero order with respect to sulfite concentration and catalyzed by heavy metal ions, usually Co^{2+}; the concentration of these ions must be kept carefully within narrow boundaries (5×10^{-6} M) in order to obtain an adequate reaction rate and avoid OTR enhancement due to the chemical reaction. Second, the physicochemical properties of the solution must be assumed to approximate the properties of the fermentation broth; this is an important limitation because some of its properties are very different from those of fermentation broths. The hydrodynamics of the solution is changed, mainly due to the influence on bubble size. This change makes k_La values obtained by this method bigger than those obtained by other techniques.

Linek and Vacek (41) and Ruchti *et al*. (42) have reviewed the use of the sulfite oxidation method, and its capacity for accurately determining mass transfer characteristics. This method has been criticized because the reaction rate is a complex function of the catalyst concentration (it is strongly dependent on the concentration and purity of the sulfite and catalyst employed) and the operational conditions that must be controlled in order to obtain reproducible measurements. However, the method has proved to be valuable in characterizing and comparing different aeration systems.

59.2.1.2 Chemical Absorption of Carbon Dioxide. The k_La can also be found by determination of mass transfer of carbon dioxide in different solutions. This method is similar, in principle, to the sulfite oxidation procedure.

59.2.1.2.1 Absorption in an Alkaline Solution. The technique involves the absorption of carbon dioxide in an alkaline solution (43). Carbon dioxide is considerably more soluble than oxygen and dissolution in water is more complex because of the liquid-phase reactions of CO_2. Alkaline solutions of CO_2 in water undergo two chemical reactions:

$$HCO_3^- - CO_2 - OH^- = 0 \qquad (59.14)$$

$$HCO_3^- + H^+ - CO_2 - H_2O = 0 \qquad (59.15)$$

According to Danckwerts (44), the reaction expressed by Equation 59.14 is of second order kinetics:

$$r = k \cdot C_{CO2} \cdot C_{OH^-} \qquad (59.16)$$

where the constant rate, k, takes a value of 5×10^3 L/mol/s (at 20°C).

On the other hand, Reaction 15 has a first-order kinetic equation:

$$r' = k' \cdot C_{CO_2} \qquad (59.17)$$

where the constant rate, k', takes a value of $2 \cdot 10^{-2} s^{-1}$ (at 20°C).

Therefore, in any solution in which the C_{OH}^- is higher than 10^{-4} mol/L (pH > 10), the rate of Reaction 59.14 will have a kinetic constant of pseudo-first order of, at least, 0.5 s^{-1}, 25 times higher than the kinetic constant of Equation 15. Therefore, it can be assumed that Reaction 15 is the limiting step controlling the absorption rate of carbon dioxide in alkaline solutions under pH > 10.

In order to be able to apply this method, it is necessary to work with a reaction of first order, whereas Reaction 59.14 is of second order. However, for gases in which the partial pressure of CO_2 is not high, the reaction behaves like one of pseudo-first order (45) and the mass transfer coefficient can be obtained from

$$-\frac{1}{2}\frac{dC_{CO2}}{dt} = k_L a \cdot C^* \sqrt{k \cdot C_{CO_2}} \tag{59.18}$$

In principle, this method uses a reaction more easily controllable than the sulfite oxidation technique. Nevertheless, it has disadvantages similar to the previous method, due to the need for using high concentrations of the ion OH^- that inhibits the coalescence of the bubbles and other reaction conditions need to be controlled to ensure that the reaction rate does not enhance the mass transfer rate.

59.2.1.2.2 Dynamic Measurement of pH. The change of pH by constant bubbling flow of carbon dioxide into the reactor can be used for measuring the overall mass transfer coefficient of carbon dioxide, as well. Upon dissolution in water, CO_2 undergoes three chemical reactions:

$$H_2CO_3 - CO_2 - H_2O = 0 \tag{59.19}$$

$$HCO_3^- + H^+ - H_2CO_3 = 0 \tag{59.20}$$

$$CO_3^{2-} + H^+ - HCO_3^- = 0 \tag{59.21}$$

The rates of reactions of Equations 59.19 and 59.21 are much faster than Reaction 20, which would be the rate-limiting reaction step determining the absorption rate of CO_2. Its equilibrium constant, K_1, is given by

$$K_1 = \frac{C_{H^+} C_{HCO_3^-}}{C_{H_2CO_3}} \tag{59.22}$$

The change of carbonic acid concentration (CO_2 and H_2CO_3 species) into liquid phase in a well-mixed reactor can then be modeled according to Hill (46):

$$\frac{dC_{H_2CO_3}}{dt} = k_L a \cdot \left(C^*_{H_2CO_3} - C_{H_2CO_3}\right) \cdot \left(1 - \frac{K_1}{K_1 + \left(K_1 \cdot C_{H_2CO_3}\right)^{1/2}}\right) \tag{59.23}$$

where $C^*_{H_2CO_3}$ represents the saturation carbonic acid concentration in the liquid phase.

Therefore, the following balance can be established:

$$C_{H^+} = C_{OH^-} + C_{HCO_3^-} + 2C_{CO_3^{2-}} \tag{59.24}$$

An equilibrium analysis shows that the CO_3^{2-} concentration is negligible for all partial pressure of CO_2 and taking into account that solution becomes acid, the OH^- concentration can also be overlooked. Under these conditions:

$$C_{H^+} \cong C_{HCO_3^-} \tag{59.25}$$

Since there is a simple relationship between carbonic acid and protons concentration, Equation 59.23 can be solved from the pH dynamics when carbon dioxide is bubbled into the reactor.

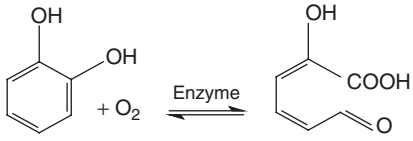
The experimental procedure consists in initially filling the bioreactor with water which is then brought to the correct temperature and stirring speed. At time zero, the gas flow is connected to the reactor and pH data are collected until a constant pH value is achieved. The pH probe response can affect the correct determination of the mass transfer coefficient if the time characteristic of the carbon dioxide transport is of the same order as the time response of the electrode.

59.2.1.3 Hydrazine Oxidation. Other techniques based on a chemical reaction have been proposed for measuring OTR, which improve some aspects of the above methods. One of them is hydrazine oxidation according to the following equation:

$$N_2 + 2H_2O - N_2H_4 - O_2 = 0 \tag{59.26}$$

In order to determine $k_L a$, a steady flow of hydrazine is fed into the bioreactor for maintaining a constant DO concentration. At steady state, the amount of hydrazine consumed per unit time equals the oxygen absorption rate

$$F_{Hy} - F_{O_2} = 0 \tag{59.27}$$



and $k_L a$ can be calculated from

$$k_L a = \frac{F_{Hy}}{V \cdot \Delta C_L} \tag{59.28}$$

Since at ambient temperature the hydrazine oxidation rate is very low, a catalyst is required. Onken *et al*. (47) developed a method based on homogeneous catalysis by several heavy metal complexes (Co, Cu, and Ni) and found that copper tetrasulfophthalocyanine (10^{-5} to 10^{-4} mol/L) was the best catalyst among those employed for $k_L a$ determination.

The applicability of this method is greater than others based on chemical reactions. The reaction rate is slow and it takes place in the liquid bulk, avoiding acceleration of oxygen uptake due to the chemical reaction. Hydrazine, a toxic chemical, is not accumulated. Thus this technique is more suitable for the k_La determinations in coalescing systems, because the reaction does not produce any ionic species which impact coalescence behavior, and the product is not accumulated.

59.2.1.4 Bio-oxidation of Catechol. The method involves the oxidation reaction of catechol forming 2-hydroxymuconic semialdehyde (2-HS) catalyzed by the enzyme catechol-2,3-dioxygenase, according to

(59.29)

If the enzyme concentration is in excess and the reaction rate is fast enough ($C_L = 0$), the kinetics of the biooxidation rate is zero order, and then the rate at which the product is formed will be equal to the OTR. With this assumption, k_La can be determined by measuring the rate of formation of brightly colored 2-HS, according to

$$\frac{dC_{2-HS}}{dt} = k_La \cdot C^* \tag{59.30}$$

The biooxidation of catechol is rapid and does not require any assumptions about its kinetic equations, but is limited to the evaluation of k_La in small-scale devices. Unlike sulfite oxidation, the biooxidation of catechol is controllable, kinetically robust, and simple to perform and yields similar k_La values when compared to the physical dynamic gassing-out method (48).

59.2.2 Physical Methods

The physical methods are based on the measurement of the oxygen concentration in the liquid or the exhaust gas during the absorption or desorption experiments in the absence of microorganisms (or nonrespiring systems that imitate the fermentation broth) under the unsteady state. The methods differ in the procedure of gas interchange (49–52), in the gas used (53), and in the model for the gas-phase description (54,55). Those methods based on the measurement of response of the DO probe during the absorption of oxygen in the solution are now the most commonly used methods of OTR determination.

59.2.2.1 Classical Dynamic Methods. The well-known dynamic techniques are based on oxygen mass balance in the liquid phase under unsteady-state conditions. After a step-change in the concentration in the inlet gas, the dynamic change in the DO concentration is analyzed. If the liquid phase is perfectly mixed and no chemical reaction takes place, Equation 59.7 can be integrated, yielding:

$$\ln \frac{C^* - C_{L1}}{C^* - C_{L2}} = k_La \cdot (t_2 - t_1) \tag{59.31}$$

where C_{L1} and C_{L2} are DO concentration at the beginning of experiment and at time t_1, t_2, respectively.

The dynamic desorption technique consists in supplying air until the saturation of oxygen concentration in the liquid is reached. Then, nitrogen is introduced downwards into the vessel and the decreasing DO concentration is recorded as a function of time. Under these conditions: $C_{L1} = C_{L0}$ at $t_1 = 0$, and from Equation 59.31, C_L can be expressed as

$$C_L = C_{L0} \cdot e^{-k_La \cdot t} \tag{59.32}$$

However, the most widely used dynamic technique is gassing out. The DO is first removed from the bioreactor by gassing out with nitrogen until the oxygen concentration falls to zero. The nitrogen flow is then stopped and bubbles are allowed to separate from the liquid. When the bioreactor has reached a hydrodynamic steady state, the system is then aerated and the increasing DO concentration, C_L, is measured as a function of time until the fluid becomes nearly saturated with oxygen. Now $C_{L1} = 0$ at $t_1 = 0$, and Equation 59.31 can be expressed as

$$C_L = C^* \cdot (1 - e^{-k_La \cdot t}) \tag{59.33}$$

Equations 59.32 and 59.33 describe the time course of DO concentration when it is removed from the media or from the restart of aeration (Fig. 59.5). In both cases, the slope of the straight line obtained from a plot of $\ln f(C_L)$ against time is numerically equal to k_La.

This technique has been widely employed (26,56–58) and the correct use of this method has been analyzed in depth by Linek *et al*. (59). It must be noted that in this method the dynamics of the oxygen electrode must be taken into account. The response time of the DO electrode, τ_r, is a critical parameter for the determination of accuracy values of oxygen concentration, because changes in the actual value of DO concentration in the media are not recorded until some later time. τ_r is defined as the time necessary to reach 63% of full response when exposed to a step-change of concentration (60) and it can be determined by transferring the oxygen electrode from a solution with sodium sulfite (whose oxygen concentration is zero) to another dissolution saturated with air (100% of saturation). When τ_r

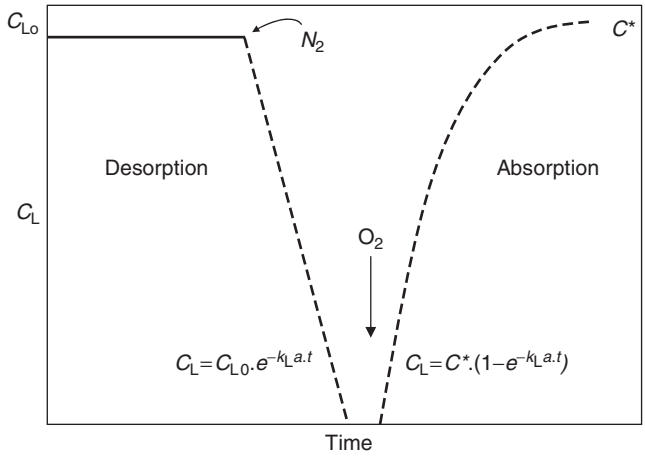


Figure 59.5. Schematic description of the dynamic technique of desorption–absorption of oxygen for inert condition measurements.

has a high value, the model of the dynamic behavior of the electrode should also be included for a correct analysis of measurement. A good approach is a first-order dynamic (61,62) according to

$$\frac{dC_{me}}{dt} = \frac{(C_L - C_{me})}{\tau_r} \tag{59.34}$$

Combining of Equations 59.7 and 59.34 permits the determination of the value of $k_L a$ from the DO concentration measurements; in the case of the gassing-out method, according to the following equation:

$$C_{me} = C^* + \frac{C^* - C_{L0}}{1 - \tau_r k_L a} \cdot \left(\tau_r k_L a \cdot e^{(-t/\tau_r)} - e^{(-k_L a \cdot t)}\right) \tag{59.35}$$

where C_{me} is the electrode output and C_{L0} is the DO concentration at the initial time of the aeration.

Assuming that the dynamic response of the electrode is of the first order, characterized by a constant time, a simple criterion for the suitable selection of the electrode, and despite this effect, would be $\tau_r < 1/k_L a$ (60,63). In pneumatically stirred bioreactors, when only one probe is used, this method is difficult to employ, because the results strongly depend on the modeling of probe dynamics, on the position of the probe in the reactor, and on the assumptions of the hydrodynamic conditions. These limitations have been discussed by Gourich *et al*. (64).

In order to simplify the above procedure, approximations based on the truncation of parts of the electrode response curve have been proposed. According to Merchuk *et al*. (65) for long time intervals ($t >> \tau_r$), the first term in the right-hand member of Equation 59.35 becomes irrelevant. As the electrode time constant approaches zero, Equation 59.35 further reduces to Equation 59.33. In addition, mass transfer data analysis for dynamic $k_L a$ determination can be simplified by truncation of the first part of the electrode response curve and applying the first-order approximation; nevertheless, truncating more than 30% of the lower end data is not recommended. It should be kept in mind that this simplification implies the loss of part of the information, and due care should be given to statistical analysis of the results.

59.2.2.2 Kr Method. This method is based on the injection of Kr-85 (a volatile radioisotope that emits β and γ radiation) into the medium and the measurement of the radioactivity in the outlet gas stream (53). To evaluate the response curve of radioactivity, a model for describing the concentrations of tracer in the liquid, bubble, and head space–gas is necessary. Two steps are involved in the gassing out of tracer. First, mass transfer from the liquid phase to the gas bubble and, second, mixing of the gas bubbles in the head space. The mass balance for the tracer in the liquid phase is given by Equation 59.7. Furthermore, the mass balance in the gas phase with the assumption of an ideally mixed head space is given by

$$V_G \frac{dC_L}{dt} = Q \cdot (C_b - C_G) \tag{59.36}$$

where V_G is the head space volume, Q is the gas flow rate and C_L, C_b, and C_G are the concentration of tracer in the liquid, bubble, and gas phase respectively.

To describe the concentration of tracer in the gas holdup, it is necessary to know the residence time distribution of the gas bubbles. Assuming a plug flow model, the Kr-85 concentration in the head space–gas of the bioreactor is given by

$$C_G = \frac{C_{L_0} \cdot V_L}{Q \cdot \xi - V_G} \cdot \left(e^{(t_b - t/\xi)} - e^{(Q(t_b - t)/V_G)}\right) \quad t \geq t_b \tag{59.37}$$

where C_{L0} is the concentration of tracer in the liquid at $t = 0$, t_b is the average residence time of gas bubbles, and the parameter ξ is defined by

$$\xi = \frac{1}{k_L a} + \frac{V_L}{Q \cdot H_e} \tag{59.38}$$

Equation 59.37 can be fitted to experimental response of radioactivity in the gas leaving the head space after the injection of Kr-85 pulse using a nonlinear regression with $k_L a$ as parameter. This method has been also used by Pedersen *et al*. (53) to obtain $k_L a$ values during bioprocesses involving different filamentous fungi, although the use of a radioactive isotope may cause some problems in an industrial application.

59.2.3 Biological Methods

Biological methods are those used while the microbial process is carried out; thus k_La values are directly determined in the suspension formed by the actual broth: substrates, nutrients, metabolites, products, and the cell population. In consequence, under suitable conditions, these methods provide values that are much more secure and realistic than others.

59.2.3.1 Biological Dynamic Gassing-Out Method. A modified physical gassing-out method is widely employed to determine both the k_La and the OUR values. The biological dynamic gassing-out method involves physical oxygen absorption combined with the oxygen consumption by microorganisms which are actively growing (and carrying out metabolic changes) inside the bioreactor. The application of the original method proposed by Taguchi and Humphrey (66), is illustrated in Fig. 59.6, and it requires the previous evaluation of the OUR by the culture. The air flow supplied to the fermentation broth is stopped (only for a short time in order to not affect the process evolution), and the decrease of DO concentration is recorded as a function of time. Under these conditions, during the nongassing period, the transport term disappears in Equation 59.6, being then simplified to

$$\left(-\frac{dC_L}{dt}\right) = q_{O_2} \cdot C_X = \text{OUR} \qquad (59.39)$$

obtaining OUR from the slope of the plot of DO concentration versus time after stopping air flow.

Before the DO concentration falls below the critical value, the air supply is resumed under the same previous operational conditions, thus ensuring equal OTR, and is then increased until the steady state is reached. The evolution of DO concentration is given by Equation 59.6, which can be rearranged to give

$$C_L = \frac{-1}{k_La} \cdot \left(q_{O_2} \cdot C_X + \frac{dC_L}{dt}\right) + C^* \qquad (59.40)$$

If DO where concentration is recorded as a function of time, the value of k_La can be obtained as the slope of the plot of C_L versus $(q_{O_2} \cdot C_X + dC_L/dt)$, and C^* value is obtained at the axis intersection. Due to the error accumulated by the necessary derivation of the experimental C_L versus time values, a better alternative is the integration of Equation 59.6, with the boundary conditions: $t = t_1 \therefore C_L = C_{L1}$ and $t = t_2 \therefore C_L = C_{L2}$, yielding

$$q_{O_2} \cdot C_x \cdot \Delta t + \Delta C_L = k_La \cdot \int_{t_1}^{t_2} \left(C^* - C_L\right) \cdot dt \qquad (59.41)$$

The k_La value is calculated by solving Equation 59.41 for each data set of experimental values of C_L versus time by an integration algorithm (67,68).

The biological dynamic method is now the most commonly employed, and it is used during an actual fermentation in large and small scales for determining k_La values due to its simplicity, reproducibility, and because gas analysis is not needed. The underlying assumption is that no interchange of oxygen between gas and liquid occurs during the nongassing period and that the culture is rapidly degassed when the air is switched off; but this is not always the case particularly for high viscous non-Newtonian fermentation broths. On the other hand, it is usually assumed that the change in hydrodynamic conditions associated with the stopping of the aeration stream does not affect the OUR; therefore, C_L must be sufficiently high so that q_{O2} value remains constant, and independent of DO concentration.

The probe characteristics are again crucial and, if the response time of the electrode is not negligible, it must be taken into account in the modeling and manipulation of the experimental data, as quoted above.

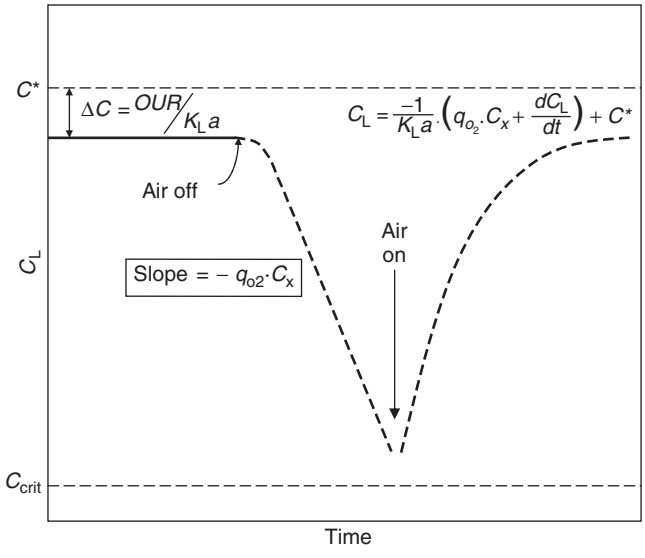

Figure 59.6. Schematic description of the direct measuring of K_La in bioprocess by the biological dynamic gassing-out method.

59.2.3.2 Biological Dynamic Method in Cultures with High OUR. In some cultures, oxygen demand is so high that the DO concentration decreases until it approaches zero and it is very difficult to increase it, even when OTR is improved (by increasing air flow, stirrer speed or the oxygen concentration in the gas phase). Consequently, the above technique can be difficult to apply. In this case, a modified dynamic method can be used. A possible modification consists in using a step-change of air to pure oxygen in the inlet gas stream or *vice versa*. Oxygen concentration changes as the result of both, physical oxygen absorption (or desorption) and oxygen consumption by the cells (69).

Assuming that OUR, C^*, and $k_L a$ are constants during the measurement time, Equation 59.6 can be expressed as

$$\frac{dC_L}{dt} = c - k_L a \cdot C_L \tag{59.42}$$

where c is given by

$$c = k_L a \cdot C^* - \text{OUR} \tag{59.43}$$

The integration of Equation 59.42, when oxygen is absorbed, with the boundary conditions: $t = 0 \therefore C^* = C_0^*$ and $C_L = C_{Lo}; t = t_1 \therefore C_L = C_L$, yields the following equation:

$$C_L = \left(C_0^* - \frac{\text{OUR}}{k_L a}\right) - \left(C_0^* - C_{L_0} - \frac{\text{OUR}}{k_L a}\right) \cdot e^{-k_L a \cdot t} \tag{59.44}$$

while, if the oxygen is desorbed, the integration of Equation 59.42, now with the boundary conditions: $t = t_1 \therefore C^* = C_1^*$ and $C = C_{L1}; t = t_2 \therefore C = C_L$, results in

$$C_L = \left(C_1^* - \frac{\text{OUR}}{k_L a}\right) + \left(C_{L_1} - C_1^* + \frac{\text{OUR}}{k_L a}\right) \cdot e^{-k_L a \cdot t} \tag{59.45}$$

Equations 59.44 and 59.45 describe the evolution in the time course of the DO concentration in the liquid phase from a starting concentration, C_{L0} or C_{L1}, after changing from air to pure oxygen or from pure oxygen to air for the gas flow through the bioreactor. According to the above procedure, $k_L a$ and OUR values can be determined during the bioprocess by fitting of the above equations to the experimental data using nonlinear regression techniques (Fig. 59.7).

Casas *et al*. (70) have discussed and compared this approach with the biological dynamic gassing-out method and found that $K_L a$ values are statistically identical. Therefore, this method can be a valuable tool for the determination of OTR in those systems and under operational conditions that would not tolerate the application of the classical dynamic gassing-out method.

59.2.3.3 Gaseous Oxygen Balance Method. The static method takes into account a gas oxygen balance in the bioreactor under steady-state conditions. This method uses a gaseous oxygen analyzer to measure the oxygen concentration in the gas streams, inlet and outlet, entering and leaving the bioreactor and a probe for measuring the DO concentration in the liquid phase. When the gas phase behaves like the liquid in a well-mixed bioreactor and there are no pressure variations, gas oxygen balance yields

$$F_{O_2}^{in} - F_{O_2}^{out} - V \cdot \text{OUR} = 0 \tag{59.46}$$

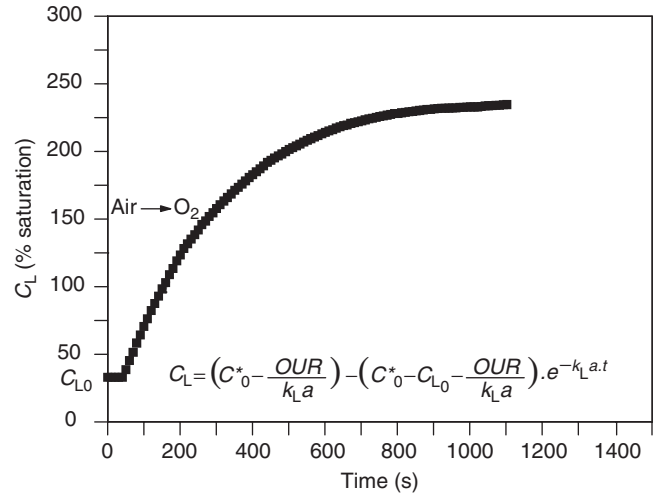

Figure 59.7. Evolution of DO concentration when the composition of the gas stream is modified changing from air to pure oxygen (absorption). [Adapted Gomez *et al*. (69).]

where F^{in} and F^{out} are the molar flow rates measured at bioreactor inlet and outlet, and V the bioreactor volume.

On the other hand, the OTR from the bubbles is equal to the rate of oxygen consumption by the cells:

$$k_L a \cdot (C^* - C_L) = \text{OUR} \tag{59.47}$$

Once the OUR is determined from the measurement of oxygen in the outlet gas and, at the same time, the DO concentration is measured in the broth, $k_L a$ can be calculated according to

$$k_L a = \frac{F_{O_2}^{in} - F_{O_2}^{out}}{V \cdot (C^* - C_L)} \tag{59.48}$$

This technique is very reliable under suitable conditions and it does not disturb the time course of fermentation by interrupting the air flow supply. However, accurate modeling of gas-phase mixing is required for the correct interpretation of data (60). It is also important to take into account the fraction of the oxygen consumed because, if OUR is low, the difference between F^{in} and F^{out} may be very small, and it becomes necessary to use very sensitive measuring equipment.

In this method, it is assumed that there is no significant variation of hydrostatic pressure within the bioreactor. In small-scale bioreactors there are insignificant static pressure differences and short mixing times, as a result of this C_L, C^*, and C_G values can be assumed to be constant in the whole reactor, and a single point determination of DO concentration will be sufficient, C^* can be determined using Henry's law, and C_G value can be assumed to be equal to the outlet gas concentration. However, in large-scale bioreactors (at $H > 1$ m), the hydrostatic pressure variation can

be relevant, and it may be necessary to read the DO concentration at several points and a logarithmic mean between the inlet and outlet gas streams must be considered. Moreover, due to the average bubble volume increase with height, the gas flow through the bioreactor can change (to approximate plug flow) and a combined model for the gas and liquid phase must be used to calculate OTR values (71).

59.2.3.4 Mass Balance from Growth Rate under Oxygen Limitation. Another method for the determination of OTR consists of the measurement of C_X versus time (growth curve) under oxygen-limited conditions (72). This technique employs the kinetic data for growth together with the biomass–oxygen yield (stoichiometric relationship).

According to Pirt (73), OUR can then be related with both oxygen necessary for biomass maintenance and oxygen necessary for growth, according to

$$\mathrm{OUR} = q_{O_2} \cdot C_X = m_{O_2} \cdot C_X + \frac{1}{Y_{XO}} \cdot \frac{dC_X}{dt} \qquad (59.49)$$

where m_{O_2} is the oxygen consumption coefficient for maintenance and Y_{XO} the yield of oxygen consumed for cell growth. From Equation 59.49, the rate of biomass growth during oxygen limitation (assuming no cell death and negligible maintenance requirement) can be written as

$$\frac{dC_X}{dt} = Y_{XO} \cdot \mathrm{OUR} \qquad (59.50)$$

As can be seen, the growth rate and OUR show a linear relationship. In steady-state conditions, OTR = OUR, and from Equation 59.50, the following relation is found:

$$\frac{dC_X}{dt} = Y_{XO} \cdot k_L a \cdot \left(C^* - C_L\right) \qquad (59.51)$$

and therefore

$$\mathrm{OTR} = k_L a \cdot \left(C^* - C_L\right) = \frac{\mu \cdot C_X}{Y_{XO}} \qquad (59.52)$$

In order to relate biomass growth rate with OTR, the yield of oxygen consumed for cell growth, Y_{XO}, must be known. This yield can be experimentally determined by an oxygen mass balance (73,74) or by an estimative model proposed by Heijnen and Roels (75). This method for OTR determination is very laborious and contains several doubtful assumptions.

59.3 COMPARISON OF $K_L A$ VALUES OBTAINED BY DIFFERENT METHODS

The different techniques for determination of $k_L a$ vary according to the accuracy required, and have advantages and disadvantages depending on the scale, availability of necessary analytical instruments and materials, assay time, and labor cost. In Table 59.1 a summary of different methods for $k_L a$ determination is shown. Chemical methods were the first to become widely accepted. In general, however, these methods are not recommended for $k_L a$ determination in the case of aerated bioreactors, due to the changes of physicochemical properties of liquids (especially decreasing the coalescence) produced by the addition of chemicals. High salt concentration as required for most chemical methods, which is known to lead to a lower solubility of oxygen, leads to systematic underestimation of the OTR values achievable in culture media. On the other hand, these methods can give values higher than the real ones, because the absorption rate may be enhanced by fast chemical reaction in the liquid phase, if the experimental conditions are not kept within certain limits. Thus, Pedersen *et al*. (53) found that $k_L a$ values were between 10–25% larger using the sulfite method as compared to values obtained using the Kr method.

Among physical methods to evaluate $k_L a$, the dynamic method has by far been the most commonly used in the last few decades due to its simplicity and relative accuracy. Both, the absorption and desorption measurements give equal values of $k_L a$ under identical hydrodynamic conditions (56) although, if the characteristic time for the oxygen electrode is of the same magnitude as the characteristic time for the oxygen transfer process ($1/k_L a$), the dynamic response of the electrode must be taken into account. Also, an incomplete modeling of the mixing and mass transfer in the bioreactor can give rise to inaccuracies in the determination of $k_L a$ (59).

In Fig. 59.8, for example, $k_L a$ values obtained by different methods as a function of stirrer speed in non-Newtonian solutions and 20 L vessels are compared from different studies ($V_S = 2 \cdot 10^{-3}$ m/s and $\mu_a = 8 \cdot 10^{-3}$

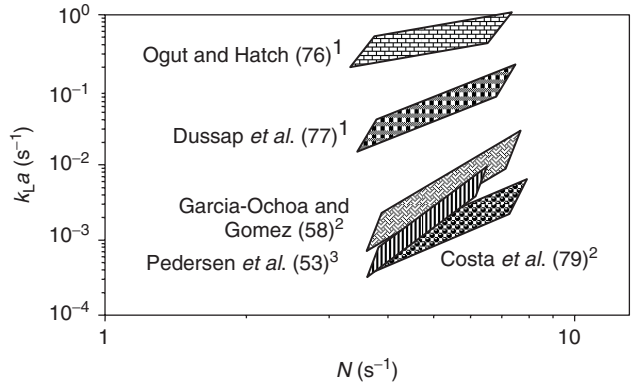

Figure 59.8. Comparison of $k_L a$ values obtained by different techniques as a function of stirrer speed in non-Newtonian liquids. Key: 1: sulfite oxidation method, 2: physical dynamic gassing-out method, 3: Kr method. [Adapted from Garcia-Ochoa and Gomez (58).]

TABLE 59.1. Summary of Different Methods for Volumetric Mass Transfer Coefficient Determination

Measuring Method			$k_L a \cdot 10^2$ Range (s^{-1})	Assay Time	Scale Applied	Assumptions/ Drawback
Chemical	Sulfite oxidation		0–0.3	Hours	Laboratory scale	The rate of reaction is assumed to be zero order in sulfite. Alteration of driving force, diffusion coefficient, and coalescence properties; complex kinetics boundary layer reduction. This method is fairly labor intensive
	Absorption of CO_2	Alkaline solution	0–0.1	Minutes	Laboratory scale	Assumptions about kinetic reaction must be made. Possible alteration of the driving force. Change of the coalescence behavior
		Dynamic measure of pH	0–0.03	Half an hour	Any scale	Assumptions about kinetic reaction must be made. Salt addition does not alter the mass transfer rate of CO_2
		Hydrazine oxidation	0–0.5	Minutes	Pilot plant	Hydrazine does not accumulate. No chemical enhancement
		Biooxidation of catechol	<0.8	Minutes	<100 mL	Available of oxidative enzyme; limited to small scales
Physical		Dynamic	0–0.1	Minutes	>100 mL	A nonrespiring system can be employed to simulate the fermentation broth. The response time of the electrode, τ_r, is a critical parameter. Gassing time can be significant at larger scales
		Kr method	0–0.3	Minutes	Any scale	The use of a radioactive isotope may cause some problems in an industrial application. Can be applied to microbial processes
Biological		Biological dynamic gassing out	0–0.1	Minutes	Any scale	High DO concentration is necessary. Nongassing period must be short and OUR independent of DO concentration. Invasive probes are necessary and response time must be considered. Hydrodynamic changes may disturb the microbial metabolism
		Biological dynamic method with high OUR	0–0.1	Minutes	Any scale	OUR independent of DO concentration. Invasive probes are necessary and response time must be considered
		Gas-phase analysis	0–0.3	Minutes	>100 mL	For large scales, the assumptions of well-mixed gas and liquid phase may not be valid. This method may not be the best choice in case of small bioreactors, where the difference between F^{in} and F^{out} may be very small because of the short contact time The accuracy depends on the precision of oxygen analyzer
		Mass balance from the growth rate under oxygen limitation	0.06–0.1	Hours	Any scale	Assuming a negligible maintenance requirement for the cells. The yield of oxygen consumed for cell growth, Y_{XO}, is required. Experimentally laborious

to $30 \cdot 10^{-3} Pa \cdot s \cdots$). It can be seen that $k_L a$ values obtained by Ogut and Hatch (76) and Dussap *et al*. (77), using the sulfite oxidation method, are much higher than those usually obtained for an electrolyte solution. The difference is greater for lower values of the stirrer speed; this is due in part, to the strong ionic state of the sulfite solution and in part, to the chemical reaction enhancement of transfer rate (78). The difference between the results obtained by other authors can be explained by the effect of certain distinctive features in the reactor used (e.g. D/T ratio, impeller and sparger type) on the $k_L a$ values (58). The next sections are devoted to anticipating variations of $k_L a$ among different systems and the equations for prediction of OTR will be presented.

59.4 CORRELATION OF $K_L A$ VALUES

In the literature, a high number of correlations for the volumetric mass transfer coefficient (in both dimensional and dimensionless equations) have been proposed. Values of $k_L a$ have been obtained by a variety of methods; as quoted above, there are considerable problems concerning the accuracy of $k_L a$ by experimental determination. Frequent discrepancies between experimental data and those estimated from these equations are found, mainly when $k_L a$ for actual broths are estimated from correlations proposed for aqueous solutions, that is in static systems with an invariable composition of the liquid media with time.

In mechanically stirred bioreactors, typical correlations for $k_L a$ have the form:

$$k_L a = C \cdot V_s^a \cdot \left(\frac{P}{V}\right)^b \cdot \mu_a^c \qquad (59.53)$$

where V_S is the superficial gas velocity, P/V is the power input per unit volume, and μ_a is the apparent viscosity of the liquid. Other authors have proposed substitute P/V by the stirrer speed, N. Some typical values given for the exponents are given in Table 59.2. As can be seen, the correlations show different influences of the operating variables, and the exponent values show a wide variation range in the different correlations: $0.3 \leq a \leq 0.7$; $0.4 \leq b \leq 1$; $-0.4 \leq c \leq -0.7$. This is due to the differences in the bioreactor geometry, fluid properties, and in power input range. Only in the equation proposed by Galaction *et al*. (25) is the biomass concentration considered as an alternative to viscosity. For nonviscous systems, the most frequently used correlation is that from Van't Riet (60).

One criticism of the dimensional equations is that no account is taken of all the properties of fluids and the geometric parameters of the bioreactor. There have been attempts to develop more complete relationships, using dimensional analysis. Dimensionless equations predict $k_L a$, included usually in the Sherwood number, as a function of other dimensionless numbers (Reynolds, Froude, Schmidt, Aeration, etc.), with the general form

$$\frac{k_L a T^2}{D_L} = C \cdot \left(\frac{\rho N T^2}{\mu_a}\right)^{\alpha} \cdot \left(\frac{N^2 T}{g}\right)^{\beta} \cdot \left(\frac{\mu_a}{\rho D_L}\right)^{\gamma} \cdot \left(\frac{NT}{V_s}\right)^{\delta} \qquad (59.54)$$

This approach presents certain advantages because, in principle, the correlation obtained for a known system can be used to estimate $k_L a$ in other bioreactors with different dimensions. Although a variety of dimensionless equations for $k_L a$ estimation are available, the complex correlations that have emerged have found few applications in microbial processes. Some of them, in mechanically stirred bioreactors for Newtonian and non-Newtonian liquids, are summarized in Table 59.3. The relationships may be divided into those which reflect the effect of the N directly and those which take into account the P/V effect. The correlation of Nishikawa *et al*. (82) is the only one to include both variables, differentiating between mass transfer resulting from stirring and from bubbling, although the latter contribution is usually negligible. Yagi and Yoshida (80) used various liquids and gases to deduce their correlations, although no effect of gas viscosity as implied in the equation of Perez and Sandall (90) could be observed. In addition, these authors take into account the effect of viscoelasticity by including the Deborah number (λN), but the method for the evaluation of characteristic material time (λ) from the shear rate, depending on the apparent viscosity, can be only applied to liquids approaching Newtonian flow behavior (91). The relationships proposed by Höcker *et al*. (92) and Schlüter and Deckwer (93) are the only approach considering the gas flow rate rather than superficial gas velocity. Finally, Garcia-Ochoa and Gomez (58) considered two rheological equations for liquid behavior (Ostwald–de Waele and Casson models), employing a similar approach to correlate $k_L a$ values in the production of the extracellular polysaccharide xanthan by *Xanthomonas campestris* (67).

In bubble columns, $k_L a$ is usually correlated by dimensional equations as Equation 59.55. For the internal loop airlift reactor, ascending flow by the circular and descendent crown by the central zone, Halard *et al*. (94) have verified that the equation proposed by Godbole *et al*. (61), for classic bubble columns, can be used for non-Newtonian fluids. In the case of external loop airlift reactor, expressions based on the ratio of down-comer to riser cross-sectional area (A_D/A_R), the effective viscosity of the dissolution and other fluid dynamic parameters have been proposed (95,96) as

$$k_L a = C \cdot V_s^{a} \mu_a^{b} \cdot \left(1 + \frac{A_D}{A_R}\right)^{c} \cdot V_{LR}^{d} \cdot \phi^{e} \qquad (59.55)$$

The (A_D/A_R) ratio is a key design parameter, which controls the hydrodynamics of the system, and thus also the

OTR in airlift reactors. Some values of exponents proposed in the literature for Newtonian and non-Newtonian fluids are noted in Table 59.4. As can be seen, the exponent on $1 + A_D/A_R$ is negative and therefore a decrease in k_La is predicted with increasing down-comer to riser cross-sectional area ratio (A_D/A_R). Furthermore, the correlations of Popovic and Robinson (95) and Li *et al*. (31) include a problematic definition of the apparent viscosity, defining shear rate as a linear function of the gas velocity. This approach can be questionable from a rheological point of view because it will predict the same shear rate for a certain superficial gas velocity, no matter which liquid is used (18,97).

On the other hand, in Table 59.5, a selection of dimensionless equations proposed for pneumatically stirred bioreactors is given; among these equations, that from Akita and Yoshida (103) is the most widely used, although it is limited to bubble columns with diameter less than 0.6 m and a simple gas sparger. The correlation proposed by Suh *et al*. (27) was successfully employed by these authors to correlate k_La values in the xanthan gum production by *X. campestris* (28). It should be emphasized that the validity and application of these correlations in non-Newtonian fluids depend very much on the measurements of the flow behavior of the liquid and also on the assumption regarding the estimation of a representative shear rate for predicting

the apparent viscosity. Although various correlations can be used to directly estimate k_La, the reliability of such predictions is often quite poor. The correlations are suitable only for initial estimates because the hydrodynamic and transport behavior of bioreactors depends on the scale and is quite sensitive to the flow behavior of the liquid, concentration and morphology of the cells, reactor geometry, and, in airlift designs, to the distribution of gas holdup in the various zones, and the induced liquid circulation rate. Thus, the initial expectation to obtain a general correlation valid for different systems has not been reached and is perhaps scientifically unfounded.

In recent years, other types of models based on artificial intelligence such as the neural networks (108), or using support vector regression (109) have been developed but also with an empirical base. Because of the numerous influences, fundamental approaches to prediction of OTR have also been developed. Such approaches tend toward

generalization and enlargement of the range of applicability of the conclusions. These general methods are discussed in the next section.

59.5 A GENERAL METHOD FOR OTR PREDICTION

Although most literature reports empirical and semi-empirical equations on OTR, attempts have been made to theoretically predict k_La in pneumatically stirred (56,97,105,110,111) and mechanically stirred bioreactors (39,84,110,112). As a first step, it is necessary to separate k_La into the two terms, k_L and a, and estimate them under the conditions of the bioreactor.

The mass transfer coefficient, k_L, is usually estimated according to Higbie's penetration theory:

$$k_L = 2 \cdot \sqrt{\frac{D_L}{\pi \cdot t_e}} \tag{59.56}$$

The exposure time, t_e, that characterizes the residence time of microeddies at the interface is generally unknown, but can be estimated by an adequate model. The evaluation of that time can be done according to the Kolmogoroff's theory of isotropic turbulence, as the time spent by the bubble to travel a length equal to its diameter, and it is estimated using the ratio between the eddy length and the fluctuation velocity of Kolmogoroff. If the rheological model of Ostwald–de Waele is adopted for the description of non-Newtonian flow behavior of fluids, the following equations for t_e and k_L are obtained (105,112):

$$t_e = \left(\frac{k}{\varepsilon \cdot \rho}\right)^{\frac{1}{(1+n)}} \tag{59.57}$$

$$k_L = \frac{2}{\sqrt{\pi}} \cdot \sqrt{D_L} \left(\frac{\varepsilon \cdot \rho}{k}\right)^{\frac{1}{2\cdot(1+n)}} \tag{59.58}$$

The specific interfacial area, a, is a function of the hydrodynamic parameters, which depend on the fluid physicochemical properties and on the geometric parameter. Assuming spherical bubbles, it can be calculated from the average bubble size, d_b, and the gas holdup, ϕ, by the following equation:

$$a = \frac{6\phi}{d_b} \tag{59.59}$$

Bubble size, d_b can be estimated from the equation

$$d_b = C \cdot \frac{\sigma^{0.6}}{\left(\frac{P}{V}\right)^{0.4} \cdot \rho_L^{0.2}} \cdot \left(\frac{\mu_L}{\mu_G}\right)^{0.1} \tag{59.60}$$

where the constant C depends on the kind of fluid (112–114).

For mechanically stirred bioreactors, gas holdup can be estimated from (84)

$$\frac{\phi}{1-\phi} = 0.819 \cdot \frac{V_S^{2/3} N^{2/5} T^{4/15}}{g^{1/3}} \left(\frac{\rho_L}{\sigma}\right)^{1/5} \cdot \left(\frac{\rho_L}{\rho_L - \rho_G}\right) \cdot \left(\frac{\rho_L}{\rho_G}\right)^{-1/15} \cdot \left(\frac{\mu_L}{\mu_G}\right) \tag{59.61}$$

For pneumatically stirred bioreactors, the gas holdup is necessarily related to the superficial gas velocity, and the mean bubble rise velocity according to (115) is

$$\phi = \frac{V_S}{U_S + \frac{1}{2}V_{LC} + \overline{V}_{LR}} \tag{59.62}$$

where U_s is the terminal rise velocity of the bubble, V_{LC} is the average velocity in the core region and V_{LR} is the average linear velocity. For bubble column bioreactors, both terms, V_{LC} and V_{LR} disappear.

Therefore, the volumetric mass transfer coefficient in bioreactors can be predicted by taking into account the above equations: Equation 58 for the mass transfer coefficient, k_L, and Equation 59.59 for the specific interfacial area, a. In order to estimate both parameters, the power input in the bioreactor must be calculated. Methods for estimating the power input in mechanically and pneumatically agitated bioreactors have been detailed recently by Garcia-Ochoa and Gomez (1). In Fig. 59.9, k_La values predicted in mechanically stirred bioreactors for 2 and 20 L are shown as a function of the power input per unit volume.

59.5.1 Influence of Oxygen Consumption on OTR

The study of oxygen mass transfer in bioprocesses has usually been separated into the parameters related to transport (OTR, k_La) and the oxygen consumption by the cells (OUR). However, correct prediction of OTR in a bioprocess must take into account the relationship between both of them. Thus, oxygen absorption into a culture broth can be considered as the absorption of a gas into a liquid where it reacts, the suspended cells being the consumers of the oxygen, and therefore an enhancement of OTR can take place. A number of works have reported an enhancement on oxygen transfer in microbial system (57,116–120).

To take into account the possibility of an OTR enhancement in a microbial system, a biological enhancement factor, E, is defined as the ratio of the absorption flux of oxygen due to the oxygen consumption by the cells to the absorption flux in its absence under the same hydrodynamic

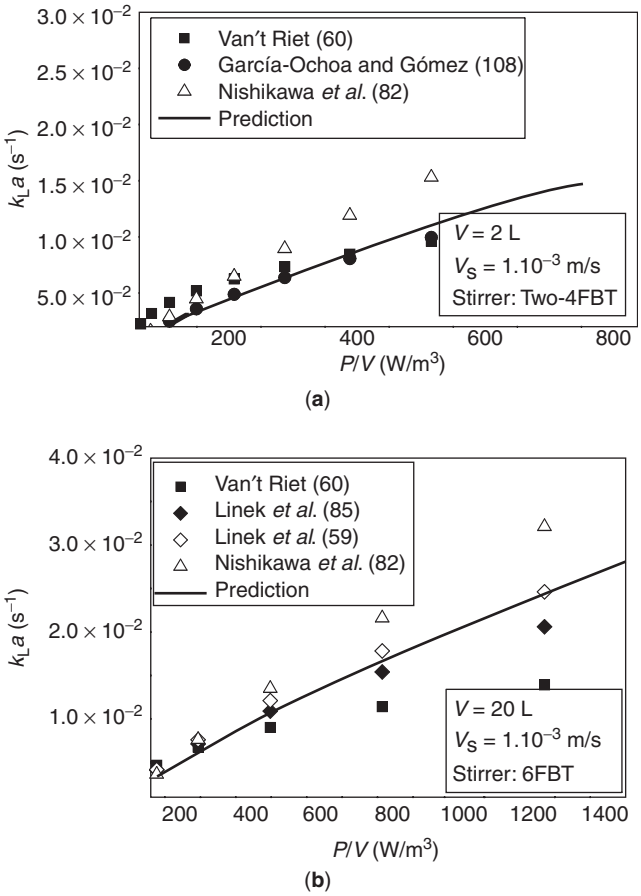

Figure 59.9. Comparison of k_La values predicted in mechanically stirred bioreactors for 2- and 20-L (4FBT and 6FBT = turbines of 4 and 6 flat blades, respectively). [Adapted from Garcia-Ochoa and Gomez (112).]

conditions and driving force according to

$$E = \frac{J}{J_0} = \frac{K_La}{k_La} \tag{59.63}$$

Some reports in the literature have discussed the biological enhancement factor for oxygen absorption into fermentation broths, and several models with different cell concentration distribution have been proposed (121–123). Garcia-Ochoa and Gomez (39) have proposed a model for estimation of the potential biological enhancement factor taking into account the substances usually added to the broths. This model considers three layers in series; therefore, to describe the oxygen mass transport, three mass transfer resistances are considered for the biological system: (i) the interfacial surfactant film resistance, (ii) the mono-layers of adsorbed microorganisms resistance, and (iii) the liquid film resistance. The different layer resistances are taken into account by the diffusion coefficient (D_i) and by layer thickness (z_i). According to this model, the biological enhancement factor, E, can be expressed as

$$E = \left[1 + \frac{q_{O_2} C_{X_m} z_m^2}{2D_m\,(C^* - C_L)} \cdot \left(1 + 2 \cdot \frac{z_l D_m}{z_m D_L} + \frac{2z_L^2}{3z_m^2}\right) + \frac{1}{3} \cdot \frac{q_{O_2} C_{X_L} z_L^2}{2D_l\,(C^* - C_L)}\right] \cdot \left[\frac{z_L / D_L}{\sum_i z_i / D_i}\right] \tag{59.64}$$

where C_X, i represents the cell concentration in the cell monolayer or in the continuous phase in liquid film; D_i is the molecular diffusion coefficient within a film of thickness z_i.

The first parenthesis in Equation 59.64 is always ≥ 1 and can be written as a function of the *Hatta* number, which takes into account the biological enhancement due to the oxygen consumption by the microorganisms in the different layers according to

$$\mathrm{Ha}_i = \frac{q_{O_2} C_{X,i} z_i^2}{2D_i \cdot (C^* - C_L)} \qquad (i = L, m) \tag{59.65}$$

The second parenthesis of Equation 59.64 is always ≤ 1, representing the resistance to diffusion exerted by each of the three films defined previously. Depending on the relative values of both terms in Equation 59.64, the enhancement factor E, can take values below, equal or above unity.

Now, the OTR can be determined as

$$\mathrm{OTR} = a \cdot J = a \cdot E \cdot J_0 = E \cdot k_La\,(C^* - C_L) \tag{59.66}$$

and

$$K_La = E \cdot k_La \tag{59.67}$$

Therefore, the overall volumetric mass transfer coefficient in the presence of a biochemical reaction, K_La, is a lumped parameter comprising the resistances to mass transport of oxygen due to several films around the gas–liquid interface and to the oxygen consumption; this last effect can be expressed by a biological enhancement factor, E. Figure 59.10 shows the evolutions of q_{O2} and E (experimental and predicted values by Eq. 59.64) with the biomass concentration of *Pseudomona putida* during a process-scale fermentation. As can be observed, the E values obtained in the presence of biomass can be higher than 1. The values $E < 1$ indicate that the OUR is low or that the transport resistance is high. In Fig. 59.11 the time course of biomass concentration and DO concentration are shown; here, experimental and predicted K_La values, according to Equations 58,59.59, and 59.64, are shown; it can be seen that the prediction method yields values of K_La close to the experimental ones.

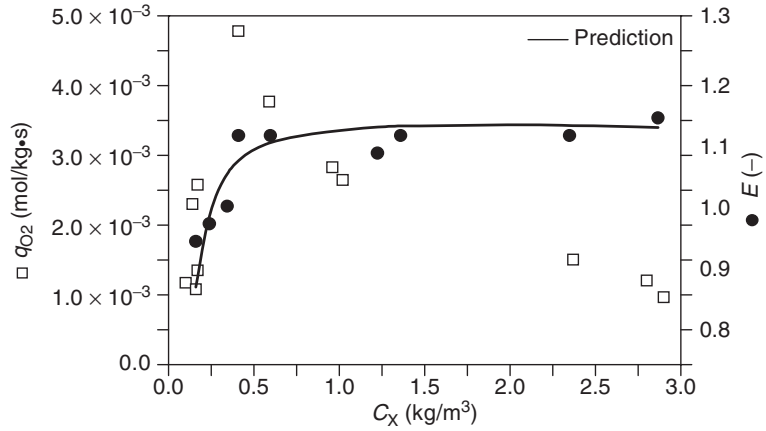

Figure 59.10. Evolution of specific OUR (□) and biological enhancement factor (experimental (•) and estimated (—) from Equation 59.64) in *Pseudomonas putida* culture applying the same stirrer speed (200 rpm) and gas flow rate (2 L/min).[Adapted from Gomez *et al*. (69).]

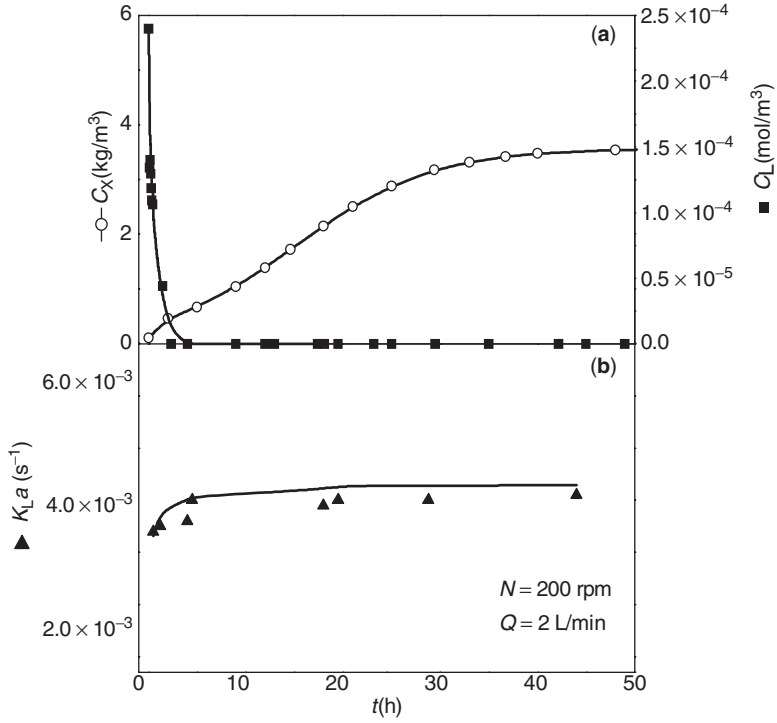

Figure 59.11. Time profile of biomass concentration (◯),dissolved oxygen concentration (■), and volumetric mass transfer coefficient (experimental (▲) and estimated (—) from Equations 58,59.59, and 59.64 of *Pseudomonas putida* culture applying the same stirrer speed (200 rpm) and gas flow rate (2 L/min). 59.6 OTR IN MINIATURE BIOREACTORS (MINI- AND MICRO- DEVICES)

Bioprocess development (strain selection, strain enhancement, formulation and preparation of media, process optimization, biocatalyst production, etc.) has traditionally required the screening of large numbers of cell lines. The need for carrying out a vast number of cultures has resulted in the increasingly widespread development of s*hake flask* and *microscale* bioreactors. These devices offer a miniaturized high throughput solution to bioprocess development. It is important that such devices be very reliable so as to

accurately mimic laboratory and *pilot-scale* bioreactors when used for bioprocess development. Therefore, growth, product formation rates, and oxygen transfer capability, optimized at the *microscale*, can be expected to be easily scaled-up.

Several types of mini- and micro-devices have been described in the literature, which ca be classified according to the agitation system or to the device geometry. The main types are shaken devices (flask, microtiter and spin tubes) and miniature stirred tanks and bubble columns. The most commonly used culture vessel in bioprocess development is the shaken Erlenmeyer flask (0.1–2 L) filled with low volumes of media (10–25%) which are shaken to promote fluid mixing and oxygen transfer via surface aeration. They have a simple mechanical design, requiring only small amounts of material and power, and thus are inexpensive to operate. Nevertheless, the major limitation is their dependence on surface aeration, leading to reduced OTR as compared to that achieved in mechanically stirred bioreactors. Further, the oxygen consumption of microbial culture may become limiting if the oxygen demand exceeds the oxygen transfer capability through the shake flask closure or/and the gas–liquid interface.

Chemical, physical, and biological methods have been applied for the determination of k_La in miniature bioreactors. Liu *et al*. (124), using the sulfite oxidation method, found that k_La decreases with the liquid volume in the flask and increases with the shaker speed, the correlation being

$$k_La = 0.141 \cdot N^{0.88} \cdot \left(\frac{V_L}{V_0}\right)^{-0.80} \tag{59.68}$$

The small difference in absolute values of the exponents on N and V_L implies that the two variables have a similar influence on the OTR.

As a novel alternative to shaken vessels at a *small scale* and high throughput cell culture, miniaturized bioreactors have been developed. Lamping *et al*. (125) have measured (using the dynamic gassing-out method) and predicted (using the Higbie's model with the exposure time obtained from the computational fluid dynamics) k_La in a miniature stirred bioreactor, obtaining values in the range of 0.028–0.11 s^{-1}, typical of those reported for large-scale bioreactors. Doig *et al*. (74) estimated k_La in a miniaturized bubble column by three methods (the dynamic gassing-out method, the gas oxygen balance method, and the oxygen-limited growth method in *Bacillus subtilis* cultures). They found that all three methods provided values that were within 15% of each other and experimental data of k_La was fitted to the following:

$$k_La = 0.65 \cdot V_S^{0.6} \tag{59.69}$$

However, due to the problems associated with the classical methods for k_La determination, other specific methods have been developed in small-scale devices. Thus, Duetz *et al*. (72) estimated OTR using the mass balance from the growth rate under oxygen limitation method in *P. putida* broths. Hermann *et al*. (126) developed an optical method for determining OTR based on sulfite oxidation. More recently, Duetz and Witholt (127) used the reaction of formation of gluconic acid (via enzymatic oxidation of glucose with oxygen in the presence of glucose oxidase) for the determination of OTR in microtiter plates, by measuring the rate of consumption of alkali that is needed to neutralize the acid. Finally, Ortiz-Ochoa *et al*. (48) developed a chemical method based on the biooxidation of catechol by the enzyme catechol-2,3-dioxygenase for small-scale vessels. In both cases the cost of the enzymes restricts the methods to small-scale applications.

59.7 CONCLUSION

A proper mechanical design of the bioreactor is aimed at maintaining the environmental and nutritional conditions (temperature, pressure, pH, nutrients concentration, mixing, hydrodynamic stress, etc.) for optimal growth and/or a product formation. Among the various environmental and nutritional factors that influence the aerobic bioprocess, oxygen is a critical parameter since it is the only nutrient that has to be provided continuously, even in batch cultures.

The determination of OTR in bioreactors is essential in order to establish the aeration efficiency and quantify the effects of the operation variables on the requirement of oxygen, since DO concentration is dependent on transport processes. Under these conditions, OTR and k_La are two of the key parameters involved in the design, operation, and scale-up of bioreactors.

Among the methods used to determine OTR experimentally, the most desirable are biological methods, which determine OTR (k_La) and OUR (q_{O_2}) in the same experiment. Sometimes when OTR from a physical method is determined, it must take into account the enhancement factor, E, because oxygen absorption into a culture broth can be considered as the absorption of a gas into a liquid where it reacts, the microorganisms suspended being the consumers of the oxygen, and therefore an enhancement of oxygen mass transfer rate can take place.

In recent literature, predictive methods have been proposed to calculate k_La and E, and thus find the value of OTR, although it is necessary to measure OUR experimentally. This approach is much more reliable than those based on the use of empirical equations, which are usually developed for other systems, other bioprocesses, and to be carried out in different types or sizes of bioreactors.

NOMENCLATURE

a	specific interfacial area (m^{-1})
A_D	down-comer cross-sectional area (m^2)
A_R	riser cross-sectional area (m^2)
C	concentration (kg/m^3)
c	parameter defined by Equation 59.43 (mol $O_2/m^3 \cdot s$)
CMC	carboxymethyl cellulose
C_X	biomass concentration (kg/m^3)
D	diameter of bioreactor, vessel or column (m)
d_b	bubble diameter (m)
D_i	diffusivity (m^2/s)
DO	dissolved oxygen
F	molar flow rate (mol/s)
g	gravitational acceleration (m/s^2)
H	height (m)
H_e	Henry's constant ($mol/m^3 \cdot atm$)
J	flux density molar (mol $O_2/m^2 \cdot s$)
k	consistency index in Ostwald–de Waele model (Pa s^n)
k_L	liquid-side mass transfer coefficient (m/s)
k_La	volumetric oxygen mass transfer coefficient (s^{-1})
K_La	volumetric oxygen mass transfer coefficient in presence biotransformation (s^{-1})
N	stirrer speed (s^{-1} or rpm)
N_l	normal stress (N/m^2)
n	flow behavior index in Ostwald–de Waele model
OTR	oxygen transfer rate (mol $O_2/m^3 \cdot s$)
OUR	oxygen uptake rate (mol $O_2/m^3 \cdot s$)
P	power input (W)
Q	gas flow rate (m^3/s)
q_{O2}	specific oxygen uptake rate (mol $O_2/kg \cdot s$)
r	reaction rate (mol $O_2/m^3 \cdot s$)
T	stirrer diameter (m)
t	time (s)
t_e	exposure time (s)
U_s	terminal rise velocity of bubble liquid circulation velocity (m/s)
V	volume of the liquid in the vessel (m^3 or L)
V_0	volume of flask (m^3)
V_{LR}	average liquid circulation velocity (m/s)
V_{LC}	average velocity in the core region (m/s)
V_S	superficial gas velocity (m/s)
Y_{XO}	biomass yield on oxygen (kg X/mol O_2)
z	film thickness (m)

Greek Symbols

ε	energy dissipation rate (W/kg)
ϕ	gas holdup
ϕ_v	gas holdup in viscous system
λ	characteristic material time (s)
μ	viscosity (Pa·s)
μ_a	apparent viscosity according to Ostwald–de Waele model (Pa·s)
μ_c	viscosity according to Casson model (Pa·s)
ν	kinematic viscosity (m^2/s)
ρ	density (kg/m^3)
σ	surface tension (N/m)
τ	shear stress (N/m^2)
τ_r	electrode response time (s)
ξ	parameter defined by Equation 59.38 (s)

Subscripts or Superscripts

b	relative to the bubble phase
CO_2	relative to carbon dioxide
Crit	relative to critical value
G	relative to gas phase
Hy	hydrazine
L	relative to liquid phase
me	relative to measure by electrode
max	maximum value
O_2	relative to oxygen
In	relative to inlet
Out	relative to outlet
2-HS	2-hydroxymuconic semialdehyde
	*Relative to equilibrium value in each phase

CNR, Istituto per lo Studio degli Ecosistemi, Firenze, Italy

60.1 INTRODUCTION

Photobioreactors (PBR) are reactors specifically designed for the cultivation of phototrophic microbes (anoxigenic photosynthetic bacteria, cyanobacteria, microalgae) and plant cells, or to carry out a photobiological reaction (1).

In the last decades, PBR have much evolved and plenty of new designs have been proposed, most of them for research in the laboratory or small scale applications. This review will focus on pilot PBR and large-scale systems used for commercial cultivation of microalgae (including the cyanobacteria).

With few exceptions (e.g. *Crypthecodinium cohnii* and *Schizochytrium* sp. cultivated in fermenters, and the green stage of *Haematococcus* grown in PBR), large-scale commercial production of microalgae is limited to species (belonging to the genera *Arthrospira*, *Chlorella*, and *Dunaliella*), which are cultivated in open ponds taking advantage of their high growth rate or of a selective growth medium that limits contamination (2). The reason for this is that large (commercial) open ponds are easier and less expensive to build and operate, and more durable than large closed reactors. However, the majority of microalgae does not require a specific growth environment or a selective medium, and cannot be cultivated for prolonged periods in outdoor open systems because other microalgae tend to dominate the culture regardless of the species inoculated (2). PBR provide a close environment that, although not sterile, protects the culture from direct fall-out and invasion by unwanted species. This, together with a more accurate control of culture conditions (pH, temperature, pO_2, etc.), ensures dominance of the desired species, even in the absence of a selective pressure.

PBR have been reviewed by Lee (3), Chaumont (4), Prokop and Erickson (5), Torzillo (6), Tredici and Chini Zittelli (7), Pulz and Scheibenbogen (8), Tredici (1), Pulz (9), and more recently by Tredici (10), Carvalho *et al*. (11), and Ugwu *et al*. (12)

60.1.1 Photobioreactor Definition and Classification

PBR can be defined as culture systems for phototrophs in which photons, the main source of energy for growth, do not impinge directly on the culture surface but need to pass through the transparent walls of the reactor before reaching the cultivated cells (1,10). In PBR direct exchange of gases, liquids (e.g. rain) and particles (microbes, insects, dust) between the culture and the atmosphere is thus excluded or strongly limited.

PBR can be classified on the basis of both design and mode of operation. In design terms, the main categories of reactors are (i) flat or tubular; (ii) horizontal, inclined, vertical or spiral; and (iii) manifold or serpentine. An operational classification of PBR would include (i) air- or pump-mixed, and (ii) single-phase reactors (filled with media, with gas exchange taking place in a separate gas exchanger), or two-phase reactors (in which both gas and liquid are present and continuous gas mass transfer takes place in the reactor

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

itself). Construction materials provide additional subcategories: (i) glass or plastic and (ii) rigid or flexible PBR. Axenic PBR are exclusively those reactors intended for operation under sterile conditions and require sterilization (e.g. by steam) before operation.

60.1.2 Design Criteria for Photobioreactors

The main requisites of a commercial PBR are a high productivity (resulting from a high efficiency of conversion of light energy) combined with the necessary reliability, stability and cost-effectiveness of the cultivation process. An efficient photobioreactor cannot be properly designed without knowing the physiology of the organism to be cultivated. Since phototrophic microorganisms are highly diverse in their morphology, nutritional and light requirements, and resistance to stress, PBR cannot be designed so as to adapt to all organisms and conditions (1). Besides, we should not forget that in artificial culture systems conditions differ substantially from those found in nature, in terms of average distance between the cells, velocity of displacement, light regime, nutrient availability, and shear stress (9).

The main design criteria for PBR include: shape and structure, construction material, surface-to-volume ratio (S/V), orientation and inclination, mixing and degassing devices, and systems for cleaning and for temperature regulation. Ease of operation and construction and operating costs also take on particular relevance in relation to commercial PBR.

60.1.2.1 Materials for Photobioreactors. Glass and different types of transparent plastic and resin [polyethylene, polyvinyl chloride (PVC), polymethyl metacrilate, Teflon, polycarbonate, fiberglass] can be used for PBR construction. Materials for PBR must have high transparency, high mechanical strength, durability, chemical stability, and low cost. Ease of cleaning and lack of toxicity are also important requisites. Advantages and drawbacks of the most common tubular materials used for PBR have been described (1).

60.1.2.2 Light Regime and Surface-to-Volume Ratio (S/V). Light (photons) is the basic energy source for phototrophic growth. Light used in algal photosynthesis (and growth) is the so-called photosynthetically active radiation (PAR), which lies in the wavelength range 400–700 nm and typically represents between 43% and 45% of total solar radiation. Understanding how light quality and intensity influence growth and biochemical composition of microalgae is a basic requisite for their successful cultivation in a PBR. A main goal of PBR design is achieving the maximum photosynthetic efficiency (PE), that is the maximum conversion of light energy into the chemical energy of biomass. Outdoors, the maximum PE achievable is about 10% of total solar radiation (13). Because of mutual shading between the cells, light regime inside reactors exposed outdoors is very complex. The light effectively available for each cell in the reactor, the average irradiance (I_{av}), depends on both the irradiance at the culture surface (I_o) and the biomass concentration. Methods to evaluate I_{av} in tubular reactors, based on the Beer–Lambert law, have been developed (14,15).

Besides irradiance, it is the S/V that is, the ratio between the illuminated surface area of a reactor and its volume, that determines the amount of light that enters the system per unit volume. Generally, the higher the S/V, the higher the cell concentration at which the reactor can be operated and the higher the volumetric productivity attained. As found by Richmond *et al*. (16), the S/V also influences productivity per unit of illuminated surface area. There is an optimal S/V (or light path) at which maximum productivity per unit of illuminated surface area is obtained, and it changes with the species cultivated (see section on flat photobioreactors). High S/V PBR are generally preferred since high cell concentrations reduce the cost of harvesting as well as that of medium preparation and culture handling. It must be emphasized, however, that high S/V reactors may become highly inefficient systems when scaled up to industrial size, as the failure of the PBL plant set up in Spain well demonstrates (see section on flat photobioreactors). At high S/V, volumetric activities such as O_2 evolution, CO_2 absorption, nutrient depletion, and metabolite excretion change at a high rate and may quickly disrupt the stability of the culture. Problems such as biofouling and cell damage are also magnified in high S/V reactors.

60.1.2.3 Orientation and Inclination. Unlike horizontal systems, elevated PBR may be oriented and inclined at various angles to the sun and thus offer the possibility to vary irradiance at the culture surface. The effect of photobioreactor inclination on productivity outdoors has been investigated by Lee and Low (17), Tredici and Chini Zittelli (7), and Hu *et al*. (18). Sun-oriented systems (south-facing and tilted so as to intercept maximum solar radiation) achieve higher productivities, whereas vertical systems that intercept sun rays at large angles, and thus dilute sunlight, attain higher efficiencies of solar energy conversion. High temperatures may become a problem in sun-oriented reactors in the summer. Experimentation is required to define the best arrangement at large scale, which with difficulty can be inferred from experiments with single units (see section titled "Flat Photobioreactors").

60.1.2.4 Carbon Dioxide Supply and Oxygen Removal. Carbon dioxide supply and oxygen removal are related to mixing and to the mass transfer capacity of the system (11,15). Nearly 50% of the dry algal biomass is made up of carbon; consequently carbon nutrition is a major component

of the production cost of autotrophic biomass, unless waste CO_2 from flue gas or fermentation is available. Automatic pH control, in which CO_2 is injected when pH is above a desired value, is the most common system employed to both regulate pH and replenish CO_2. Supplying carbon dioxide in shallow suspensions at near neutral pH is not an easy task, the low residence time of the bubbles being in general not sufficient for complete absorption and resulting in great losses of CO_2 to the atmosphere. Gas injection as minute bubbles by use of sintered porous stones into a column of down-coming culture, in which the culture velocity is adjusted to that of the rising CO_2 bubbles, may increase the efficiency of absorption up to 70% (15). The response to CO_2 injection is much improved and the losses reduced with the use of model-based predictive control systems (11). As alternative to bubbling, diffusion through hollow-fiber membranes or silicon tubing has been successfully applied in microalgae cultures (11).

Photosynthetic oxygen production and accumulation are directly correlated with the volumetric productivity of the culture. Dissolved oxygen concentrations equivalent to more than four times saturation with respect to air (~30 mg oxygen/L), toxic to many microalgae, may be easily reached in outdoor cultures, especially in high S/V reactors. At maximal rates of photosynthesis, a 1-cm diameter reactor may accumulate 8–10-mg oxygen/L/min (19). In high S/V tubular reactors, the maintenance of oxygen levels below the toxic concentration requires frequent degassing and very high flow rates, making the serpentine design difficult to scale-up (see section on tubular PBR"). Vertical reactors (columns or flat panels) mixed by air-bubbling offer a significant advantage in this respect. A useful model for predicting dissolved oxygen and carbon dioxide concentration profiles in serpentine reactors has been developed by Camacho Rubio *et al*. (20) and gas transfer in PBR has been thoroughly described by Carvalho *et al*. (11).

60.1.2.5 Mixing. Mixing in PBR is necessary to provide uniform dispersion of the cells within the culture, to prevent thermal stratification, to distribute nutrients and break down diffusion gradients at the cell surface, to remove photosynthetically generated oxygen and above all to ensure that cells experience alternating periods of light and darkness of adequate length. The fluid dynamics of the culture medium and the type of mixing influence the average irradiance and the light regime to which the cells are exposed, which in turn determines productivity (15,21). Increasing mixing increases productivity, but damage may occur when the fluid microeddy sizes approach cellular dimension (22). For this, the choice of the mixing device and of the intensity of mixing should be based on the characteristics of the organism to be cultivated. Although even air-bubbling may damage the cells at the level of bubble formation and break-up (23), air-mixing causes in general less damage compared to pump-mixing, and therefore is recommended for fragile organisms. Camacho Rubio *et al*. (20) have well described gas–liquid mass transfer and mixing in serpentine airlift bioreactors.

60.1.2.6 Temperature Control. Maximum productivity can be achieved only at the optimal temperature for growth. While open ponds are limited by low temperatures in the morning, PBR generally require cooling at midday. Immersion in a water bath, water spraying, or the use of internal heat exchangers are the most common solutions adopted for temperature regulation in PBR outdoors. Cooling by immersion in a water pool is efficient, but its cost-effectiveness is rather doubtful. Water spraying may be reliable and cost-effective in dry climates. Economic considerations seem to favor evaporative cooling over the use of heat exchangers, although the latter have been found more efficient for controlling the culture temperature in a disposable panel reactor (24).

60.2 PHOTOBIOREACTOR CATEGORIES

60.2.1 Sleeves and Vertical Columns

An inexpensive disposable vertical reactor can be easily built by cutting a suitable length of transparent polyethylene tubing and heat-sealing one end. This "bag" or "sleeve" reactor can be suspended from a framework or supported within a mesh frame. The culture is mixed by bubbling air from the bottom. Such reactors are used indoors with artificial illumination (generally vertically mounted fluorescent lamps) or outdoors under sunlight. Polyethylene bags, from 50 to 500 L in volume are widely used to produce marine microalgae in the hatcheries. Polyethylene sleeves hung on an iron structure have been used to grow *Porphyridium* and *Dunaliella* outdoors at the Institute for Applied Research (Beer–Sheva, Israel) obtaining significantly higher productivities compared to open ponds (25) (Fig. 60.1). In 2000 MinaPro Ltd. was established at Nevatim (Beer–Sheva, Israel) (26) to exploit this technology for production of natural products from microalgae. The company was closed in 2002 (27). At Ketura Kibbutz (near Eilat, Israel) a small plant made of polyethylene sleeves is in operation to produce *Porphyridium* for the cosmetic market. NOVAgreen GmbH (Vechta–Langforden, Germany) develops and provides bioreactors based on the "bag system" for the production of microalgae for the food, cosmetics, and pharmaceutical industry (28) (Fig. 60.1). Sleeve reactors are used for inocula production at GreenFuel Technologies Corp. (Massachusetts, USA) (29). The main drawbacks of sleeve reactors are low S/V, biofouling and the need of large number of units for scaling-up.

(a) (b)

(This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Vertical tubular reactors (or column reactors) are simple systems in which mixing is achieved by injecting compressed air at the bottom. The rigid vertical columns, typically 2–2.5 m in height and 30–50 cm in diameter, which are extensively used in hatcheries to produce algal biomass for feeding the larval stages of marine bivalves and fish must be included in this category. Most commonly, these systems are made of translucent glass fiber sheets formed into cylinders. Illumination is provided either by artificial or natural light.

Several vertical tubular PBR made of rigid material have been developed following Cook's first design set up at Stanford University in California in the late 1940s (30). Column reactors made of glass or Plexiglas® have been experimented with by Jüttner (31), Miyamoto *et al*. (32), Hu and Richmond (33), and García Camacho *et al*. (34). Volumetric productivities in the range of 0.5–1.5 g/L/d, mostly in inverse relationship with the column diameter, have been attained with different algae.

At the Department of Chemical Engineering of the University of Almeria, airlift and bubble-column vertical reactors, 9.6–19 cm in diameter and 2 m high were used to cultivate *Phaeodactylum tricornutum* outdoors (34–36). The systems compared favorably with horizontal serpentine reactors experimented with in the same location (22). On the other hand, when stress conditions (high pO_2, high irradiance) are required for the production of specific products (e.g. carotenoids) horizontal, higher S/V PBR may be necessary (37).

At the Energy Research Center of the Netherlands (ECN), a 64-L Plexiglas® bubble-column reactor, 21 cm in diameter and 2 m high, was used to cultivate *Monodus subterraneous* outdoors (38). The productivities attained (0.03 g/L/d in winter and 0.20 g/L/d in summer) constitute a good performance for *M. subterraneous* grown in this low S/V reactor under Dutch climate. Lu *et al*. (39) report comparable results for the same microalga grown in bubble columns of similar S/V under the climatic conditions of Southern Spain.

Vertical cylinders illuminated from inside, which may be considered a variation of the annular reactor devised by Jüttner (31), have been proposed for the production of marine microalgae in hatcheries. Internally lit cylinders typically attain higher volumetric productivities and greater efficiencies of light utilization compared to completely filled columns, since the photon flux provided is completely trapped by the culture (1).

A vertical annular column with internal illumination was developed at the University of Florence by Tredici and co-workers in 1997 (Fig. 60.2). The reactor consists of two 2m-high Plexiglas® cylinders of different diameter placed one inside the other so as to form a regular annular culture chamber, 3- to 5-cm thick and 120 to 150 L in volume. Compressed air is bubbled at the bottom of the annular chamber for mixing and gas exchange. CO_2 from cylinders is injected into the culture through a gas diffuser placed in an unaerated zone of the annular chamber to provide the carbon source and pH regulation. To operate the reactor with artificial illumination, lamps or fluorescent tubes can be placed inside the inner cylinder. These reactors have been used to cultivate various cyanobacteria and microalgae, among which bioactive *Nostoc* strains (40), *Nannochloropsis* sp. (41,42), *Isochrysis* sp. (T-ISO) (43), *Skeletonema* sp. (44) and *Tetraselmis suecica* (45) under artificial, natural or combined illumination. The potential of annular columns has been evaluated outdoors using units arranged to simulate a full-scale plant (45). High productivities (up to 38 g/m^2/d) and high PEs (up to 9.3% on PAR) were attained with *T. suecica* (45). The annular columns can produce high quality algae biomass on a regular basis, attaining 5–10 fold higher productivities and cell concentrations at harvesting than the traditional systems used in hatcheries. However, the small size and relatively high cost (more than €1000 for a 120-L unit) discourage the use of the annular column

(a) (b)

Figure 60.2. Plexiglas® (a) and polyethylene (b) annular columns commercialized by Fotosintetica & Microbiologica S.r.l. (from the company's web site). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

in large scale production of algae biomass. Recently, at the University of Florence this design has been modified in order to reduce its cost by using a polyethylene film for the culture chamber, which is enclosed in a cylindrical wire structure (46) (Fig. 60.2). Annular columns of 30–230-L volume are commercialized by Fotosintetica & Microbiologica S.r.l. (Florence, Italy) (47), a spin-off company of the University of Florence, mainly as small cultivation units for research and microalgae production for aquaculture.

Horizontal annular columns, in which mixing is induced by air-bubbling in a half of the culture chamber that thus acts as a riser, have been developed by Yamaha Motor Co. Ltd. (Iwata, Japan) for the cultivation of *Chaetoceros calcitrans* under natural and artificial illumination (48).

In this category, the sterilizable PBR known as *Medusa*, developed for monoseptic (axenic) cultivation of microalgae (49), may be also included. The reactor consists of a U-shaped loop made of borosilicate glass tubes, 2 m long and 5 cm in diameter, vertically arranged and connected at the top to a stainless steel or glass vessel that acts as a degasser and houses electrodes and probes. One arm of the loop is gassed with air, thus the culture is circulated by an airlift system. Illumination is provided by fluorescent lamps regularly interspaced between the culture tubes. The reactor can be sterilized by steam injection or by *in-situ* sterilization at 121°C and an overpressure of 1 bar, and is thus suitable for mixotrophic cultivation of microalgae (50,51). At the University of Erlangen (Germany) units of 10, 25, and 100 L have been developed by combining a number of loops (52).

60.2.2 Tubular Photobioreactors

60.2.2.1 Serpentine Photobioreactors. Serpentine PBR are systems in which several straight transparent tubes are connected in series by U-bends to form a flat loop (the photostage) that can be arranged either vertically or horizontally. Gas exchange and nutrient addition normally take place in a separate vessel. Circulation between the photostage and the gas exchanger is achieved by the use of a pump or an airlift. Typically, in serpentine reactors the culture is circulated at flow rates between 20 and 30 cm/s. Several reactors of this type have been developed following the original design by Tamiya (53). After several months of experimentation with *Chlorella ellipsoidea*, this author concluded that a significant increase of productivity could be attained through cultivation of algae exhibiting higher temperature optima and through vigorous mixing aimed at increasing growth by providing intermittent illumination. These concepts still guide our research.

In the early 1950s, the Arthur D. Little Company at the Massachusetts Institute of Technology (USA) developed a horizontal tubular unit for the cultivation of *Chlorella* that may be considered the first pilot plant for microalgae production (54). The reactor, of a total surface area of about 56 m^2, consisted of polyethylene tubes that, once filled with algal culture, assumed a more or less elliptic shape of 1.2 m width and a maximum depth of about 8 cm. Leakage and contamination were the major problems encountered. In a 40-day run an average areal productivity of 9 $g/m^2/d$ was attained.

Following these initial studies, little work was carried out with PBR for several years. In the early 1980s, Gudin and co-workers (4,55), working at the Centre d'Etudes Nucléaires de Cadarache (France), devised a horizontal serpentine reactor that was immersed in a water pond to obtain temperature control. It was composed of five identical 20-m^2 units, each of which consisted of 20 polyethylene tubes, 20 m in length and 6 cm in diameter. Initially, the culture was circulated by means of a pump, but later, airlift systems were adopted to limit damage to shear-sensitive cells and, at the same time, provide CO_2 and obtain O_2 degassing. Productivities from 20 to 25 $g/m^2/d$ were obtained with *Porphyridium cruentum*. The use of rigid rather than flexible tubes permitted operating a self-cleaning system consisting of two plastic balls, one with higher density than the culture medium and one lighter, which were hydraulically pushed through the system. Although flotation and immersion in a water basin can provide efficient thermoregulation, the cost of such a system is prohibitive for most applications.

In the early 1980s, Pirt and co-workers developed a vertical serpentine tubular reactor at the University of London's Queen Elizabeth College (56,57). The photobioreactor consisted of a photostage formed of 52 Pyrex® glass tubes (each approximately 1 m long and with a 1 cm internal diameter) horizontally stacked and connected to glass U-bends by silicone-rubber tubing to form a vertical loop. The loop outlet was connected through a vertical riser to a degasser. A second tube connected the degasser to the inlet of the loop. The culture suspension was circulated either by a peristaltic pump, a rotary positive-displacement pump or an airlift; the latter method was preferred because of the adverse effects observed with the pumps. The work carried out by Pirt and co-workers was remarkable for three reasons: It provided the first detailed analysis of the fundamental engineering parameters of a closed photobioreactor, introduced the concept of high S/V reactors (127 m^{-1} in this case), and attained extremely high light-conversion efficiencies. Pirt's analysis, however, ignored the light saturation effect, assuming that the efficiencies observed at low light intensity could be achieved in full sunlight as well. Although Pirt's serpentine reactor did deal with many of the problems encountered in closed systems, the concept of very high S/V reactors revealed all its practical drawbacks when the experimental set-up was scaled up to industrial level by Photo Bioreactors Ltd. (PBL) (see section on large scale commercial PBR).

Reactors of the type developed by Gudin have been thoroughly investigated by Molina Grima and co-workers in Spain (15). The Spanish group has carried out extensive research with serpentine reactors on the influence of the principal parameters that regulate growth of photosynthetic cells, among which are average irradiance, gas–liquid mass transfer, temperature control, fluid dynamics and mixing (15,22,58–60).

Torzillo and co-workers developed and experimented with a 145-L two-plane serpentine reactor (61). A maximum areal productivity of 27.8 g/m^2/d was achieved with *Arthrospira platensis* in the summer. This study addressed fundamental engineering parameters such as the effect of the rheological behavior of the algal culture on the mixing characteristics of the system and the energy requirement for turbulent flow.

A similar two-layer design has been recently adopted and optimized at the University of Almeria to maximize light capture, achieve better exploitation of the occupied area and reduce oxygen accumulation (62,63). In 2004, a 4000-L two-layer serpentine PBR has been set up by Cajamar in a greenhouse near Almeria (Spain) (64). The system, made of 10-cm diameter Plexiglas® tubes connected by U-joints to form a single 400-m long loop, occupies an area of 80 m^2 (Fig. 60.3). Temperature regulation is provided by circulating tap water through a heat exchanger placed in the degasser. The reactor has been

(a)

(This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

used for production of lutein-rich biomass of *Scenedesmus almeriensis* achieving a mean productivity of 290 mg lutein/m^2/d (65). More recently, a fence-type tubular photobioreactor (32,000 L total volume and 1000 m^2 occupied area) has been devised and set up for mass production of *S. almeriensis* (66).

A horizontal serpentine PBR cooled by immersion in a water pool is used to cultivate marine microalgae by Fitoplancton Marino S.L. (Cadiz, Spain). The company sells lyophilized biomass and slurries of several microalgae for aquaculture use (67).

A tubular photobioreactor that makes use of concentrated solar radiation has been devised at the Academic and University Centre of Nove Hrady (Czech Republic) (68). The photobioreactor is based on solar concentrators (linear Fresnel lenses), mounted in a climate-controlled greenhouse, that concentrate up to 3.5 times the direct component of incident sunlight on the cultivation tubes. The cultivation unit (a 24-m long loop made of six parallel horizontal glass

tubes connected by U-bends) is placed on a movable frame, which enables automatic focusing of direct solar radiation. The photobioreactor has been used to study acclimation of algae to supra-high solar irradiances.

60.2.2.2 Manifold Photobioreactors. In manifold PBR, a series of parallel tubes is connected at the ends by two manifolds, one for distribution and the other for collection of the culture suspension. The main advantages of these systems over serpentine loop reactors are the reduction of head losses and lower oxygen concentrations, two factors that facilitate scale-up to industrial size. As shown by Pirt *et al*. (57), more than 15% of the energy consumed for circulating the culture in serpentine reactors is spent in moving the culture suspension around the bends.

Richmond and co-workers (69) devised a system made of parallel sets of 20-m long tubes connected by manifolds in which the culture was circulated by an airlift. A productivity of 0.55 g/L/d was attained with *A. platensis*. A manifold elevated system called "α-type tubular photobioreactor" was developed and experimented with in Singapore (70).

Tredici and co-workers, working at the University of Florence (Italy), developed the near-horizontal tubular reactor (NHTR) (Fig. 60.3). Units made of rigid or flexible tubes of about 5 cm in diameter and ranging from 6 to 45 m in length have been built and used to grow different algal species outdoors (71,72). Typically, a NHTR consisted of 8–10 flexible tubes connected by two manifolds. The tubes were placed side-by-side on white corrugated plastic sheeting, facing south and inclined at a slight angle to the horizontal (4° to 6°). Mixing and degassing were achieved by injecting air at the base of 6–8 tubes (risers); the remaining unaerated tubes acted as return-flow tubes (downcomers). Temperature control was obtained by water spraying. The largest unit experimented with occupied an area of 60 m^2 and contained about 1200 L of culture. Volumetric productivities of up to 1.3 g/L/d and areal productivities of more than 28 g/m^2/d were obtained with *A. platensis* (7). A maximum productivity of 0.8 g/L/d was achieved with *Nannochloropsis* during the late spring (72). NHTRs can be scaled up by increasing the number and/or the length of the tubes. Adoption of tube lengths over 20–25 m are, however, not practical since it would require the preparation of land areas with a drop of more than 3 m in order to get the minimum inclination necessary for proper mixing through air-bubbling. Besides, low mass transfer may be a limiting factor in long NHTRs, unless mixing is improved (e.g. by static mixers) (73,74). A cost analysis for a large NHTR system developed for hydrogen production has been presented (75).

A vertical manifold PBR known as *BioFence* was developed by Applied Photosynthetics Limited (APL) (Manchester, UK) in the late 1990s. The BioFence consists of an array of rigid or flexible transparent tubes racked together in banks and connected by manifolds in a fence-like structure (76). The culture suspension is circulated between the photostage and a holding tank by a centrifugal pump or by an airlift. BioFence systems are currently commercialized by Varicon Aqua Solutions Ltd. (UK) (77), which offers several sizes of modular reactors that are used as small cultivation units for research and microalgae production for aquaculture (78). A BioFence unit of 1200 L was commercialized at about €36,000 (79).

Biofence PBR from 10 to 35,000 L are also distributed by B. Braun Biotech International GmbH (now incorporated in Sartorius Biotechnology Division). Industrial scale plants based on the biofence design have been built by Bioprodukte Prof. Steinberg GmbH (Germany) (80), Algaltechnologies Ltd. (Israel) (81) and, more recently, by Salata (Germany) (see section on large scale commercial photobioreactors).

60.2.2.3 Helical Photobioreactors. Helical PBR consist of small-diameter flexible tubes wound around an upright structure (biocoils). This design was used in the 1950s by Davis to grow *Chlorella* (82) and later adopted, in a flattened version made of glass tubes, by Setlik (83), Krüger and Eloff (84) and Jüttner (31).

A biocoil consisting of a photostage of polyethylene or PVC tubing (between 2.5 and 5 cm diameter) wound helically around a cylindrical support (typically 8 m in height with a core diameter of 2 m) was patented by Biotechna Ltd. (85). Several parallel bands of tubes were connected by manifolds to the pumping system, allowing more even flow and shorter tube length thus minimizing oxygen build-up.

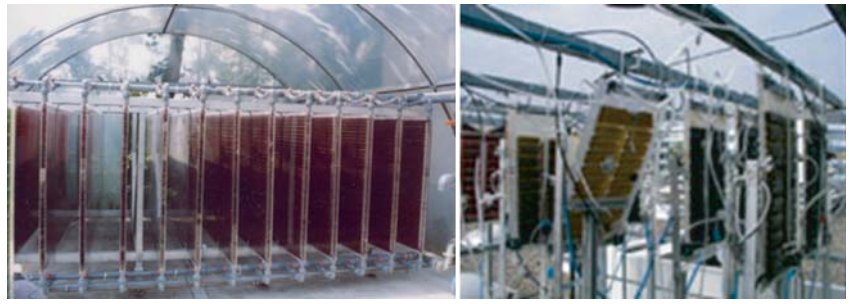
A 120-L helical bubble reactor was used to grow *Anabaena siamensis* and *A. platensis* outdoors at the University of Florence (71). With *A. platensis*, a mean volumetric productivity of 0.9 g/L/d and a photosynthetic efficiency of 6.6% (PAR) were achieved. The cost of a 120-L unit of this type was estimated to be about US$150 (1).

Addavita Ltd. (Chesterfield, UK) commercialized a coiled reactor called Advanced Algal Production System (AAPS). In this reactor circulation of the culture is achieved through a pump or by an airlift accordingly to the type of algae grown. The culture is pumped at the base of the tubes and flows in the helical photostage up to the top degasser. From the degasser the cultures descend down to a water bath for thermoregulation. The slope of the tubes can be varied for flow optimization (86).

A flat coiled glass reactor named VGPR, similar to that developed by Setlik (83), of about 1000 L volume has been built in Nanchang (China) and used to grow *Arthrospira maxima* and *Haematoccocus* (87). One single module is 5 m high, 5 m long and 0.8 m wide. The tubular photostage is connected to two glass towers, one for deoxygenation, the second for CO_2 supply and thermoregulation. The culture

is circulated by a pump at a speed of 0.5 m/s. The system can be sterilized.

60.2.2.4 Vertical Columns vs. Horizontal Serpentine Photobioreactors. Horizontal serpentine PBR, especially those characterized by a high S/V, reveal limited scalability because as tube length increases, pH and dissolved oxygen rise to very high values. It has been suggested that also an inadequate light climate strongly limits this design (22). Oxygen removal is governed by the magnitude of the overall gas–liquid mass transfer capacity, which in bubbled columns is about four folds the estimated value for a horizontal serpentine. Vertical bubble columns and airlift cylinders have substantially greater gas hold-ups than horizontal reactors and a much more chaotic gas–liquid flow, and consequently can attain substantially increased radial movement of the fluid that is necessary for improved light–dark cycling (22). A limitation of vertical bubble columns may be seen in their cost and in the fact that, since diameter and height cannot be much increased, a large number of units is needed to set up an industrial plant.



Vertical columns (and vertical reactors in general) are superior to horizontal reactors also in terms of PE, since they achieve higher light dilution because sun rays strike their surface with a large incidence angle. It has been demonstrated that light dilution reduces the negative effects of photosaturation and photoinhibition, leading to a significant increase of PE and productivity (71). Besides, the rear surface of a vertical reactor receives mainly disperse (diffuse and reflected) radiation of low intensity, which is known to be used with higher efficiency (16). In particular, during the central daylight hours, when the negative effect of excessive light upon outdoor cultures is maximal, the mean radiation incident on a vertical system undergoes about twofold dilution compared with that impinging on the horizontal. Besides, while the irradiance on the horizontal draws the well known bell-shaped curve centered at midday, the culture in a vertical column is exposed to a more homogeneous light environment for most of the day (45). However, the main advantage of this system (i.e. that around solar noon a large part of the direct radiation is reflected) can be seen also as a limitation, since it leads to significant losses of useful photons. These losses can be reduced at full-scale by closely spacing the different units so that a significant part of the photons reflected by the reactor walls (and then by the ground) are intercepted again by the reactors in the vicinity (45).

60.2.3 Flat Photobioreactors

Flat PBR have often been used in the laboratory because they are easy to be operated and provide a simple geometry that facilitates the measurement of irradiance at the culture surface. Despite their simplicity, few of such systems have been used for mass cultivation of algae until recently (1). Three main types of flat PBR have been experimented with at pilot level outdoors: alveolar panels, glass and acrylic plastic plates, and disposable panels.

60.2.3.1 Alveolar Panels. Interest in flat PBR sparkled in the 1980s when two groups working independently in France (88) and Italy (89) introduced alveolar panels for algae cultivation. The systems were constructed from commercially available, transparent PVC, polycarbonate or polymethyl methacrylate sheets internally partitioned to form narrow channels called *alveoli*. At the Centre d'Études Nucléaires de Grenoble (France) Ramos de Ortega and Roux (88) used 1.5 m^2, 4-cm thick, double layer PVC panels for growing *Chlorella*. The panels were laid horizontally on the ground; the upper layer of channels was used for algal growth, the lower for thermoregulation. The culture suspension was circulated through a pump. A productivity of 24 $g/m^2/d$ was achieved in the summer.

In 1988 Tredici and co-workers at the University of Florence developed vertical flat reactors made from commercially available, 16-mm thick Plexiglas® alveolar sheets (89). The sheets were placed vertically with the alveoli (and hence the culture flow) running parallel to the ground and pumps were used to circulate the algal suspension. A prototype of this design was presented at the exhibition ITALIA 2000 held in Moscow in 1988. In the same year, the Florence group started to experiment with a different design in which the panel was set up with the channels perpendicular or highly inclined to the ground so that mixing could be achieved by bubbling air at the bottom of the reactor (90). Several panels, with surface areas varying from 0.3 to 2.2 m^2 and different inclinations (from 20° to 50° to the horizontal) were experimented with by the Florence group and collaborating groups at Harbour Branch (Florida, USA), CSIRO (Hobart, Australia) and IFREMER (France) both under natural and artificial light with productivities of up to 24 g/m^2 (of illuminated panel surface) /d. The system proved adequate for growing different algal species, among which *A. platensis*, *Anabaena azollae*, *Isochrysis galbana*, *Pavlova lutheri*, *P. tricornutum*, *Nannochloropsis* sp., *T. suecica*, *Skeletonema* sp., and the fragile dinoflagellate *Alexandrium minutum* (7,44,71,90–94). Among the advantages of the system there is its high S/V (up to 160 m^{-1}), which allows to attain high volumetric productivities (> 2 g/L/d) and operation at high cell concentrations (4–6 g/L). Among the drawbacks, biofouling and the difficulty of scaling up seem to be the major ones. Besides, these systems, when placed near-horizontally (5°), have shown a lower performance compared to tubular reactors, which was attributed to the fact that tubular reactors achieve light dilution and reduce the negative effect of light saturation and photoinhibition (71).

(a) (b)

Figure 60.4. (a) alveolar panels at the IGV Institute für Getreideverarbeitung (Bergholz–Rehbrücke, Germany) (photograph by the authors). (b) airlift flat panel commercialized by Subitec GmbH (Stuttgart, Germany) (from the company's web site). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

The design developed in Florence with pump-mixing was brought to industrial level by Pulz and co-workers at the IGV Institut für Getreideverarbeitung (Bergholz–Rehbrücke, Germany), who used 32-mm thick alveolar panels (8) (Fig. 60.4). Difficulty in maintaining an adequate turbulent flow, build-up of oxygen and fouling were among the problems encountered. The main merit of the reactors developed in Germany was the close spacing of the plates that provided an illuminated surface area of about 500 m^2 on a ground area of only 100 m^2. This design may seem weak at first sight, since in this configuration the panels strongly shade each other. However, despite the unfavorable climatic conditions of Germany, a record output of 130 g/m^2 (ground area)/d was reported with *Chlorella* (8). This very high productivity, which exceeds the maximum theoretical photosynthetic efficiency, may be partially explained by the fact that peripheral effects were not considered. It should be noted, however, that this arrangement allows a fivefold dilution of solar irradiance at the culture surface, compared to an horizontal surface, an effect called *culture lamination*, which enhances the efficiency of conversion of solar irradiance into biomass (95,96). Reactors based on this design are commercialized by B. Braun Biotech International GmbH (now incorporated in Sartorius Biotechnology Division) in sizes varying from 10 to 2000 L.

60.2.3.2 Glass Plates. In the mid 1990s Richmond and co-workers (97) developed an inclined modular photobioreactor consisting of a series of flat glass chambers, 0.7 m high and 0.9 m long, connected in cascade and tilted at an angle to maximize solar radiation capture. Reactors with light paths (thickness) from 1.3 to 10.4 cm were tested in the cultivation of *A. platensis*, *M. subterraneus* and *A. siamensis*. At the optimal population density and adopting vigorous mixing by air-bubbling, record productivities of about 50 g/m^2 /d of front illuminated reactor surface were achieved with *A. platensis*. When the back surface (that receives mainly reflected and diffuse radiation) of panels placed vertically was covered, culture productivity diminished of more than 50%, confirming the role played by diffuse and reflected light in elevated systems (97). Using glass panels with a light path ranging from 1.3 to 30 cm, Richmond and co-workers elucidated the influence of the light path on areal productivity (98–101). It was found that there is a precise light path at which areal productivity is maximal and that the optimal light path changes with the species cultivated: For example, it is 1–2 cm for *A. platensis*, 10 cm for *Nannochloropsis* and 20 cm for *Chaetoceros muelleri* var. *subsalsum* and *I. galbana*. A 500-L glass plate with 10-cm light path attained with *Nannochloropsis* an average productivity of 12 g/m^2 (total illuminated surface)/d (102). The same reactor design, but of 5-cm light path has been recently used for the cultivation of the green stage of *Haematococcus pluvialis* (103). In the summer a productivity of 0.37 g/L/d (9.3 g/m^2 of total illuminated surface/d) was attained. Another important result of the researches of the Israeli group was clearing the role of autoinhibition. Ultra-high cell densities (over 50 g/L) were achieved with *Nannochloropsis* and *A. platensis* in narrow (1–2 cm) light path plates exposed to high irradiance and under vigorous stirring, only when the exhaust growth medium was regularly replaced with fresh medium to remove inhibitory substances and replenish nutrients (16,104).

Glass panels have several advantages. Glass is highly transparent, easy to clean and resistant to weathering. Using glass sheets, reactors of any desired optical path can be assembled and tailored to meet the specific requirements of any algal species. However, glass excessive weight, fragility and cost discourage its use in large scale plants. Zhang *et al*. (102) calculated that for a 2000 L glass reactor, construction cost was US$8000. The cost of *Nannochloropsis* biomass production in this system was estimated to vary between US$50 and US$110 per kg dry wt, the dominant input being the cost of labor (102).

60.2.3.3 Plastic Plates. Vertical plates made of acrylic plastic and resembling those realized by Richmond and collaborators have been experimented with by the group of Miyachi (105,106). In some designs, vertical and horizontal baffles were inserted into the culture chamber to provide rigidity and improve mixing (107,108). In the laboratory with *Chlorococcum littorale* a cell density of up to 84 g/L was reached in a 1-cm light path reactor under 2000 μmol/photons m^2/s and by daily replacing the culture medium (106). With *Synechocystis aquatilis* the influence of the distance between reactors, reactor orientation and reactor size on productivity was evaluated (108,109). The productivity in an N-S oriented (east-west facing) set of parallel plates placed at a distance of 0.5 m was higher than the productivity obtained with E-W oriented (north-south facing) plates. These results differ from those attained by Rodolfi *et al*. (110) at similar latitudes in a different season with *T. suecica* (see section on disposable panels).

Small flat panels built from polycarbonate sheets held together in a steel frame with two chambers, one for the culture and the other for thermoregulation, have been used for the A-stat cultivation of *Dunaliella tertiolecta* (111) and to study the influence of autoinhibitory substances in high density cultures of *M. subterraneus* (112).

An airlift flat panel with a defined circulation path was patented and tested in the indoor cultivation of *Chlorella vulgaris* (113) and *P. tricornutum* (114). The reactors, made of Plexiglas® or PVC, were divided in a small downcomer zone and a larger riser zone, in which compressed air was injected. The riser was subdivided into interconnected chambers by means of horizontal baffles attached alternately to the two wider sides of the reactor. This arrangement allowed a more regular and defined mixing that significantly enhanced productivity in comparison with randomly mixed bubble columns (113,114). This design (Fig. 60.4) is commercialized by Subitec GmbH (115), a company founded in 2000 as a spin-off of the Fraunhofer Institute for Interfacial Engineering and Biotechnology (Stuttgart, Germany). A similar design made by molded plastic sheets is offered by PetroSUN Inc. (Arizona, USA) for production of biofuels (116). These reactors are an interesting development of plastic panels. However, low scalability and high cost (a 5–9 L unit is sold by Subitec GmbH for €1000) (115) limit their commercial application especially in the biofuel field.

A multi-compartment flat plate reactor made from acrylic plastic sheets was developed by Grobbelaar and Kurano (117). The idea was to have separate culture chambers with algal cells acclimated to different light conditions in order to allow better utilization of the entire light gradient found in dense cultures and maximize PE. A continuous-flow panel was tested in which the compartment facing the light source contained high-light acclimated cells, whereas low-light acclimated cells grew in the back compartment. With *S. aquatilis*, the double compartment plate yielded a 37% higher productivity compared to a traditional plate with a single compartment.

A 500-L Plexiglas® plate, with a 20-cm light path, based on Richmond's design (102) was tested with different microalgae used in aquaculture and compared with vertical columns and biofence-like tubular reactors at the Oceanic Institute of the University of Hawaii (78). The authors found that the hydrostatically limited height, the narrow width, the large internal surface area that hinders cleaning, and the high cost (about US$5000) were major drawbacks of this system.

60.2.3.4 Disposable Panels. In the early 2000s, two groups working independently in Italy (University of Florence) and Israel (Ben–Gurion University) developed and patented the concept of the disposable panel: a flat reactor consisting of a plastic culture chamber enclosed in a rectangular metal frame or cage (46,118) (Fig. 60.5). As in many of the previous designs, a tube inserted at the bottom provides mixing by air-bubbling, and water spraying, or a heating exchange unit, ensures temperature control. Different reasons prompted the two groups to develop the disposable panel design. While the Italian group aimed at

(a)

(b)

Figure 60.5. Disposable panels developed at the University of Florence, Italy (a) (photograph by the authors) and at the Ben–Gurion University, Israel (b) (courtesy of Prof. S. Boussiba). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

a low-cost system for large scale applications, the main goal of the Israeli researchers was to have a clean and disposable culture chamber for the cultivation of those microalgae which suffer from contamination (Boussiba, personal communication). Disposable panels are simple to operate, have low construction cost and are capable to be scaled up. The plastic chamber can be either cleaned or replaced when necessary. They are currently used in hatcheries for microalgae feed production both in Israel and Italy.

In Italy, green wall (GW) panels, as the disposable reactors were called, 1 m high, 5 cm thick and from 2.5 to 10 m long (Fig. 60.5) have been used to grow *Tetraselmis*, *Isochrysis* and *Nannochloropsis* outdoors (93). These reactors have shown reliability, flexibility and good mass transfer capacity ($K_L a$ O_2 was 0.006 s^{-1} at an Ug of 0.004 m/s). With *T. suecica* it has been shown that while single units attain a higher productivity when they are N-S oriented (east-west facing), at full-scale an E-W orientation (north-south facing) is preferable (110). In the latter arrangement, overall areal productivities (OAP) (see section on evaluation of productivity) of about 30 $g/m^2/d$ were attained in a full-scale simulation with *T. suecica*, in September. With *Nannochloropsis* lipid productivities of more than 8 $g/m^2/d$ has been achieved, which represent a potential of more than 20 t/ha/y under the climatic conditions of Tuscany (Italy) and of 30 t/ha/y in sunny tropical regions (119,120).

Sierra *et al*. (24) evaluated the fluid dynamics and mass transfer characteristics of a 1.5-m high, 2.5-m long and 0.07-m thick disposable panel. The study concluded that the low power supply (53 W/m^3) and the high mass ($K_L a$ $O_2 = 0.007$ s^{-1}) and heat (500 W/m^2) transfer capacities were important advantages of the system, and make bubbled plates preferable to tubular PBR.

Recently the GW panel has been modified by the Italian group (119,120). A decrease of the culture chamber height from 1 to 0.7 m has permitted to use a much lighter metal frame and decreased construction cost from about €100 to about €30 for a 2-m long panel. Excluding accessory equipment (electrodes, tubing, valves, etc.), the cost of the new reactor (on a ground area basis) is within the range of construction costs of raceway ponds. The GW panels patented by the University of Florence are commercialized by Fotosintetica & Microbiologica S.r.l. (Florence, Italy) (47).

60.2.3.5 Critical Evaluation of Flat Systems. Vertical or inclined flat reactors represent very promising culture devices. Air-bubbling can be adopted attaining good mixing and high mass transfer capacity at relatively low power supply. Temperature control is efficient either through evaporative cooling by water spraying (in dry climates) or by heat exchangers. Some of the latter designs, especially the disposable panels, have shown good scalability. Disposable units of 1000–2000 L in volume have been built and successfully operated for long periods. Flat panels can be oriented and tilted at angles that maximize the amount of solar radiation intercepted and thus maximize productivity per reactor or, differently, inclined so as to reduce the amount of radiant energy impinging on the culture and increase the efficiency of light conversion and the productivity per unit of ground area. Which strategy is to be pursued depends on the objectives and local conditions. In contrast with horizontal reactors, the entire surface of elevated plates is illuminated. The front surface receives total radiation and the back surface is illuminated by a low energy photon flux made essentially of diffuse and reflected light, very effective for photosynthesis. They also offer the possibility to be closely packed together and thus attain, by a sort of "lamination" of the culture, high areal productivities.

60.2.4 Photobioreactors for Biofuels

Numerous companies have been established in the last 2–3 years in the field of microalgae biofuels, with interesting new ideas and innovative applications of old reactor designs. Here only three companies that have done some outdoor trials at pilot scale with proprietary designs will be shortly described. More information can be retrieved from http://peswiki.com/index.php/Directory:Biodiesel_from_Algae_Oil (121). The survey "Microalgae Biofuel & CO_2 Mitigation Ventures—Emerging New Business" (July 2006) prepared by Necton S.A. (Portugal) is also a useful source of information.

60.2.4.1 GreenFuel Technologies Corp. (GFT) (Massachusetts, USA) (122). GFT was founded in 2001 by MIT (Massachusetts Institute of Technology) and Harvard scientists. In 2004 its technology (the triangular airlift reactor) was tested at pilot level at MIT, and in 2006 a demonstration unit was set up at a coal-fired station in New York. The GFT bioreactor consisted of a series of riser tubes, gas separators and downcomers arranged in a triangular configuration (Fig. 60.6). GFT claimed the process was able to capture from the gas stream up to 82% CO_2 and reduce NOx by 86%. According to the reactor productivity, a biodiesel yield of up to 80 ton per ha per year was expected. Despite the high potential, this system has been not further developed and a different design, called the *3D Matrix System* (no details available at present), is currently under test at GFT facilities in the Arizona desert (Redhawk, Phoenix, Arizona). With the new technology in the summer 2007, an average areal productivity of 98 g (ash free dry wt) $/m^2/d$, with peak productivities of over 170 $g/m^2/d$ on good sunny days, was achieved (122). These numbers are unrealistic, even if

(a)

(b)

Figure 60.6. (a) GFT (Massachusetts, USA) triangular airlift reactor (from the company's web site). (b) AlgaeLink (The Netherlands) serpentine bioreactor (from the company's web site). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

the 3D Matrix System, which is reported to have an S/V of 1500–2000 m^{-1} (20 times higher than in most PBR), maximizes the "light dilution effect". On sunny days, during the experiment, irradiances of about 870 μmol photons/m^2 /s (daily average) were measured, which in energy terms amount to about 9 MJ/m^2/d in the visible range. Given the peak productivity and an average energy content of the algal biomass of 22 kJ/g, a photosynthetic efficiency on PAR of more than 40% was attained, while the theoretical maximum is 22% (13).

60.2.4.2 Valcent Products, Inc. (Vancouver, Canada) (123). Valcent has developed a vertical bioreactor (named *Vertigro*) for the mass production of oil-rich algae. The system consists of a series of closely spaced vertical bioreactors made from thin plastic film membranes. The culture is pumped at the top of the reactor and circulates by gravity to the bottom in a meandering way. During a 90-day test carried out at Valcent's research center located at El Paso (Texas, USA), an algal suspension at 1 g/L was continuously harvested (123). The measured productivity was equivalent to more than 680 tons of dry biomass per ha and year, which is impossible. The system is interesting for its simplicity and verticality. Problems, however, might arise at high cell densities, that favor biofouling, and because of oxygen build-up. The cost of the single bioreactor may be low, but the system needs a heavy support structure and to be protected inside a greenhouse. In July 2007, Vertigro and SGCEnergia, the biofuel division of the SGC Group of Portugal, have agreed to form a joint venture company to build a Vertigro pilot plant near Lisbon, Portugal.

AlgaeLink N.V. (The Netherlands) (124). AlgaeLink N.V., based in The Netherlands, that currently commercializes PBR (Fig. 60.6) from demo up to 100 ton per day plants, is a good example of a growing, successful enterprise in the field of microalgae biofuel. The company has already sold several plants, in the USA, Asia, Europe, Australia and South America, based on a PC-controlled, large-diameter serpentine photobioreactor. The 3.5-m^3 demo is made of 36-m long, 30-cm diameter tubes, costs €69,000, occupies an area of 40 m^2, and produces between 3.5 and 5 kg dry biomass per day. Productivity is thus assumed to be between 1 and 1.4 g/L/d. The large scale reactors are made of 64-cm diameter tubes assembled on-site from transparent sheets. The expected volumetric productivity is 1.5 g/L/d. The AlgaeLink reactor is an example of a well developed (and well advertised) technology which is marketed on the basis of wrong assumptions: in this case that the algae will achieve a volumetric productivity of 1.5 g/L/d, which is impossible in such low S/V reactors under autotrophic conditions. According to http://www.algaelink.com (124), the 1 ton per day plant requires a ground area of 3327 m^2 (the installation area needed is wrongly reported to be 1782 m^2 in http://algaefuels.org). This means that the reactor is expected to produce 300 g/m^2/d and thus achieve, in energy terms, a daily output of about 6.6 MJ/m^2 (at an energy content of the algal biomass of 22 kJ/g). Given an average summer day of 23 MJ/m^2, this productivity will be equivalent to a PE on total solar radiation of about 30%, that is, three times the theoretical maximum, without considering irradiance losses because of reflection at the tubes' surface and the non-active empty spaces between tubes. AlgaeLink N.V. sells a 100 ton per day plant at about €300,000 ha^{-1} (€30 m^{-2}). This is an interestingly low price, even in comparison with raceway ponds (which will not cost much less if lined with a durable liner), for a completely-controlled, self-cleaning, pump-mixed closed system. The company also sells a prefabricated automatically controlled 1000-m^2 raceway-pond at the price of €45,500 (€45 per square meter), including tanks, pumps, valves, tubing and sensors (124).

Many other companies have been formed recently to exploit the interest on microalgae originated by the dramatic

problems of climate change and oil increasing price. In reality, no company in the field has at present a mature technology to be on the market and compete with fossil fuels. However, some of the proposed designs are worth being improved and tested at larger scale. It is not to exclude that, after adequate R&D, one of these or another system, very likely in combination with open ponds, might in the not far future produce algae biomass with the necessary efficiency so as to become a competitive source of renewable fuels.

60.3 LARGE SCALE COMMERCIAL PHOTOBIOREACTORS

60.3.1 Present Enterprises

With the exclusion of the plant built in Hawaii (USA) by MicroGaia Ltd. (now BioReal, Inc.) large industrial PBR are tubular, pump-mixed, one-phase systems. The photostage is typically made of plastic tubes, as in the Mera Growth Module (MGM) built by Mera Pharmaceuticals, Inc. (Hawaii, USA) or of glass tubes, as in the two largest commercial systems currently in operation, BPS (Germany) and Algatechnologies (Israel) plants.

60.3.1.1 BioReal, Inc., (USA) (125). In 2000 Micro Gaia, Ltd. (now BioReal, Inc. a subsidiary of Fuji Chemical Industry Co., Ltd., Japan) installed on an area of about 8 ha on the island of Maui (Hawaii) a plant based on its patented "bio-dome" (126). This is a rather elaborate system made by coupling two hemispheric transparent domes placed one on top of the other, convex surface up, so as to create a hemispheric culture chamber, from 2.5 to 10 cm wide. The culture is mixed and degassed by air-bubbling and by an apparatus that moves "jumping" along the circular bottom of the bio-dome. The air-tube, inserted from a top opening and connected to the moving device, cleans the dome walls by scraping their surface during its circular motion. Cooling is obtained by water spraying from the top of the reactor. Complexity, the need to build and connect thousands of units to realize a commercial plant, and difficulty of cleaning represent severe drawbacks of this system. BioReal, Inc. utilizes these dome-shaped reactors to grow *H. pluvialis* for production of astaxanthin (125).

60.3.1.2 Algatechnologies Ltd. (Israel) (81). Algatechnologies Ltd. was founded in 1999 to develop and commercialize microalgae derived products for the nutraceuticals and cosmeceuticals market (81). The plant, spread on an area of about 1.2 ha, is located at Kibbutz Ketura, 50 kilometres north of Eilat (Israel) (Fig. 60.7). Both horizontal manifold and biofence-like tubular systems are used to grow *H. pluvialis* based on the technology developed by Prof. Sammy Boussiba at the Microalgal Biotechnology Laboratory of Ben–Gurion University (127). Differently from Cyanotech Corp. and Mera Pharmaceuticals Inc., which use open ponds for the red stage, Algatechnologies Ltd. carries out both the green and the red stage in their closed system. A high quality product is obtained through strict control of growth parameters and inocula production under axenic conditions. Compared to the BPS and Salata plants in Germany (see following paragraph), productivity in this system is much advantaged by the high solar radiation available in the Arava desert (Southern Israel). Algatechnologies Ltd. has recently started collaboration with GreenFuel Technologies Corp. (Massachusetts, USA) for developing fuels from microalgae cultures using carbon dioxide emissions (128).

Figure 60.7. Algatechnologies Ltd. plant at Kibbutz Ketura (Israel) (courtesy of Prof. S. Boussiba). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Bioprodukte Prof. Steinberg GmbH (Klötze, Germany) and Salata GmbH (Ritschenhausen, Germany) (80). Among the large scale commercial plants currently in operation, special mention goes to the 700 m^3 PBR built by ÖPA GmbH at Klötze near Wolfsburg (Germany) (Fig. 60.8), now owned and operated by Bioprodukte Prof. Steinberg GmbH (BPS) (80). This plant consists of 20 modules, 35 m^3 each, installed in a 12,000 m^2 greenhouse. The photostage is made of 500 km of 48-mm diameter glass tubes running horizontally in a fence-like structure.

Figure 60.8. BPS plant at Klötze (Wolfsburg, Germany) (company's brochure). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Each unit is provided with an on-line control system. Mixing is achieved through centrifugal pumps. Harvesting is accomplished by Westfalia separators, and the biomass is spray dried. The expected productivity with *C. vulgaris* was 100–130 tons per year, which means achieving a volumetric productivity of 0.6–0.8 g/L/d during an 8-month operation period. Quality control of the *Chlorella* biomass produced at BPS has shown lower levels of heavy metals, pesticides and contaminating microorganisms compared to products attained in open ponds.

A similar design has been recently put in operation at Ritschenhausen (Germany) by Salata in cooperation with the Institut für Getreideverarbeitung GmbH. Salata cultivates, in modules of sizes ranging from 15,000 to 25,000 L, microalgae (*Nannochloropsis*, *Scenedesmus*, *Chlorella*, *Porphyridium*) and cyanobacteria (*Oscillatoria*, *Lyngbya*) mostly for the cosmetic market. Productivity is in the range of 0.2–0.8 g/L/d. Cost of production is high since artificial illumination is used to integrate solar radiation and to achieve year round production.

60.3.1.3 Mera Pharmaceuticals, Inc. (USA) (129). A 25,000 L polyethylene PBR, called *Aquasearch Growth Module* (AGM), was developed for astaxanthin production from *H. pluvialis* by Aquasearch, Inc. (now Mera Pharmaceuticals, Inc., Hawaii, USA) (129–131). The AGM (now MGM) consists of an unusually large (38 cm in diameter) serpentine reactor made up of a low-density polyethylene tube laid on an impermeable surface of about 200 m^2. The tubing is doubled back on itself several times so as to create a series of parallel tubes that are connected through a single end assembly. The end assembly incorporates a pump or an airlift, pH and temperature sensors, and fixtures to connect the PBR to tanks with nutrient media and to open ponds. The pump generates a velocity of the culture flow sufficient to attain a Reynold's number in the range of 2×10^3 to 2×10^4. Temperature is controlled by immersion in a water pond, which is cooled by addition of cold seawater. The reactor is sterilized by chlorination prior to inoculation. The system was operated continuously for several years. In the final year of operation an average areal productivity of 10.2 g/m^2/d was achieved. Given the low S/V, volumetric productivity was rather low (around 0.08 g/L/d). The PBR was used to inoculate ponds that, surprisingly, obtained a significantly higher productivity (15.1 g/m^2/d) (131).

60.3.2 Attempts of the Past

Among the several industrial PBR built in the last two decades and failed (1), two are worth to be illustrated here because they provide useful examples of technical and marketing mistakes that should not be repeated.

Photo Bioreactors Ltd. (PBL), set up in southern Spain in the late 1980s and based on two different designs patented by Queen Elizabeth College (UK) (56), represents one of the biggest failures in the field of microalgal biotechnology (Fig. 60.9). Despite the high quality of the work done by John Pirt and his collaborators at Queen Elizabeth College, several major technical errors were done in the full-scale plant, which was built without adequate piloting. The polyethylene tubes, about 50 m long, degraded quickly under sunlight and the tube diameter (1 cm) was too small for effective mixing and oxygen removal. Besides, temperature of the culture and wall growth were not adequately controlled. Together with improper management, the poor design led to heavy contamination of the culture, and in 1991 PBL closed without ever entering into production (132).

In 1996 Hidrobiologica SA, located at about 15 Km south of La Rioja (Argentina), started to cultivate *A. platensis* in one of the largest PBR known at that time (1). The plant consisted of 96 polyethylene tubes 120 m long and 25.5 cm in diameter laid parallel on the ground and arranged like a manifold with feeding and collecting channels made of concrete. The surface occupied by the whole plant was about 5000 m^2 and the total culture volume was 600 m^3 (Fig. 60.9). Some problems were apparent after the first years of operation, among which a limited capacity to control temperature and inadequate mixing, both consequent to low flow speed and unequal distribution of the culture among the tubes. The problems were approaching toward a solution when the plant was closed in 1999, when a hail storm destroyed part of the installation (Abdulqader, personal communication). It seems that the main problem that discouraged continuation was not technical, but it was the difficulty to compete with American and Asian companies using open raceways.

60.4 CONCLUDING REMARKS AND PROSPECTS

60.4.1 Evaluation of Productivity

Productivity in PBR can be evaluated as: (i) volumetric productivity (VP), that is, biomass produced per unit reactor volume per unit time (expressed as g/L/d); (ii) areal productivity (AP), that is, biomass produced per unit of ground area occupied by the reactor per unit time (expressed as $g/m^2/d$); or (iii) illuminated surface productivity (ISP), that is, biomass produced per unit of reactor illuminated surface area per unit time (expressed as $g/m^2/d$). VP is an important operational parameter that illustrates how efficiently the unit volume of the reactor is used. Being a function of the number of photons that enter the unit reactor volume in the unit time, it strictly depends on the S/V of the reactor. The higher the S/V, the higher the VP, but not necessarily a high VP translates into an efficient PBR. Care should be taken to discern between AP and ISP. In the case of ponds and horizontal flat reactors, the ground surface area occupied by the system and its illuminated surface area coincide, and so do AP and ISP. In the case of horizontal tubular reactors placed with tubes in contact, the illuminated surface area is 1.57 times the occupied surface area, so ISP will be always lower than AP. In the case of tubular reactors with tubes set up at a distance, the empty space among the tubes must be accounted for, and should be considered as occupied area when AP is calculated. The performance of elevated systems (i.e. reactors set at a high angle with the horizontal) is not easy to evaluate with these three parameters. For this it has been suggested to use a fourth parameter (10), the overall areal productivity (OAP) (expressed as $g/m^2/d$), which is obtained by summing the production of the reactors that constitute the plant and dividing the result by the total (including empty spaces) ground surface area occupied by all the reactors, carefully considering peripheral effects (10). When a plant of significant size cannot be set up, a simulation can be done by surrounding the experimental unit by an adequate number of dummy reactors arranged as in the planned industrial plant (45). OAP has greater meaning for scale-up and permits comparison between different kinds of reactors, and between reactors and ponds.

Commonly, VP and ISP, and sometimes also AP, are calculated from data obtained from the operation of a single unit. AP of an elevated reactor calculated on the basis of the area it projects on the ground is a meaningless parameter and should be avoided. A vertical or highly inclined reactor intercepts a much higher amount of radiation than that impinging on an area equivalent to its projection on the ground, and expressing productivity of vertical systems in terms of AP leads to unrealistic figures. When a single unit is experimented with to obtain data for scaling-up the system (to be essentially achieved by setting up a large number of units), it is necessary to understand that the data collected are of limited value, since the performance at large scale will be much influenced by the mode (essentially the distance) in which the several units in the field will be set up. Placing the reactors far apart and so that they do not significantly shade each other will maximize VP and ISP, which will not be too far from the values attained by experimenting with the single units. The OAP in this arrangement will be low because of the large non-productive space between the systems. If the reactors are placed closely packed, they will heavily shade each other, and VP and ISP will be reduced, generally in an inverse relationship with the distance. OAP on the contrary will be increased. Which strategy is to be chosen depends on many factors, among which are the cost of land, and capital and operating costs of the reactor.

An economic analysis providing the cost of biomass production in the system under consideration offers the best

evaluation of the performance of a PBR. However, economics evaluations are not valid for all situations, since many cost factors that have large impact on the final cost of the biomass (e.g. cost of labor, land, materials) change considerably from site to site even when the same species is cultivated.

60.4.2 Photobioreactors versus Ponds

The debate that opposes PBR and ponds is a false one. There is diffuse perception that open systems have reached their limit and there is little room for technological improvement (11). Together with their open surface, the major drawback of ponds is the fact that for practical reasons (reduction of flow and turbulence) the water level cannot be kept much lower than 15 cm (150 L/m^2). Optimal standing crops for algae are generally well below 100 g/m^2, hence the cell concentration of the culture in a 15-cm pond must be maintained below 0.65 g/L. Unless we are in the presence of some selective pressure (e.g. a specific chemical or physical requirement such as a high pH, salinity or temperature), these diluted, highly variable environments become readily contaminated by fast-growing microalgae, bacteria and protozoa, and do not ensure a durable and stable cultivation of the selected strain. Besides being closed, PBR have a much higher S/V (typically from 20 to 200 m^{-1}) than ponds (from 5 to 10 m^{-1}) and can sustain much higher cell concentrations. Together with the protected environment and tighter control over growth parameters (pH, pO_2, pCO_2 and temperature), the higher population density makes closed reactors relatively safe from invasion by competing microorganisms. However, growing algae in large raceway ponds is much cheaper than growing them in PBR, thus ponds are the systems of choice when the organism's requirements allow its cultivation in an open culture. In some cases a combination of PBR and ponds is worthy of consideration: the PBR for inoculum production and the ponds for bulk cultivation lasting for a period not long enough for contaminants to prevail. It is generally thought that PBR are more productive than ponds. This is true when the two systems are compared in terms of VP, unless PBR of unusual low S/V are used. On the contrary, when AP is the basis of comparison, it is difficult to reach any conclusion, the result depending on the algal species, the climate, the type of PBR used, and several other variables. Indeed, maximum short-term areal productivities of about 50 g/m^2/d have been reported for both ponds and PBR operated outdoors (65,133).

60.4.3 The Photobioreactor of the Future

PBR efficiency cannot be defined in general terms: any PBR that brings a product to the market making a profit must be considered efficient. In the future many other PBR designs (more or less efficient, more or less new) will be developed and, in much less number, exploited. However, two emerging opposite strategies can be foreseen in the future scenario of algal biotechnology: (i) very low-cost and (ii) high-tech systems. An example of the first type are the disposable panels (see section on flat reactors). These culture systems can be scaled up to large scale and set up with a capital investment of less than €200,000 ha^{-1} (120), much less than previously estimated (75) and not far from the construction cost of ponds.

A completely different approach is, for example, that of fiber optical–based systems, in which light capture and use are physically separated (Fig. 60.10). Visible solar light is collected by mirrors, concentrated through lenses and delivered into the bioreactor via an array of flexible, optical fibers (which transmit light via total internal reflection) and distributor rods or plates (21,134,135). Because the solar collectors track the sun, the main significant variation in photon flux is cloud cover (136). Wijffels and his team at the Agrotechnology and Food Sciences Group of Wageningen University (The Netherlands) envisaged a 10-m high, 250 m^3 in volume optical-fiber PBR, with the capability to produce about 200 t of dry algal biomass per year (21). Solar light is collected by parabolic dishes from a 2-ha field and conveyed through optical fibers to

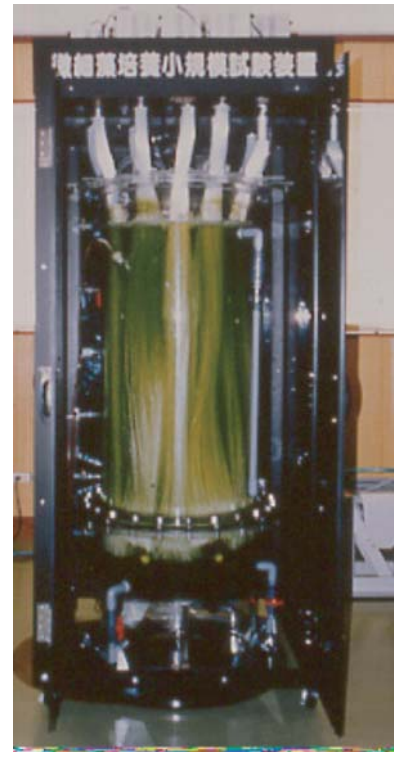

Figure 60.10. Optical fiber photobioreactor (courtesy of Prof. A. Richmond). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

eighty 3-cm thick plates that re-distribute visible photons inside the culture at an irradiance of 1200 μmol/m^2/s. One main limitation of this technology is the efficiency of solar energy collection and transmission, but thanks to the much higher efficiency of liquid based cables, the efficiency of solar concentrating systems has significantly improved in recent years, exceeding 45% (136). Cultivation of microalgae in optical fiber PBR has been demonstrated only at the laboratory scale, and the very high cost of solar tracking devices and distribution systems seem prohibitive for most applications, but the potential of this technology is high and worth of further R&D efforts. (See also Chapter 18 in volume 1)

60.5 CONCLUSIONS

PBR are considered to have several advantages: They minimize contamination, offer better control over culture conditions, prevent evaporation, reduce CO_2 losses due to out-gassing, attain higher cell concentrations and volumetric productivities. Elevated reactors can be oriented and tilted at different angles and can use diffuse and reflected light, which plays an important role in productivity. PBR can be built with various light paths, a key issue to reach very high productivities and efficiencies of solar energy utilization, and can be mixed by either pumps or by air-bubbling. Many different materials can be used for their construction and many different designs are available. In conclusion, closed reactors are flexible systems that can be optimized according to the biological and physiological characteristics of the algal species being cultivated. The ultimate and most important advantage of closed systems, however, is that they permit cultivating algal species that cannot be grown in open ponds. On the other hand, the adoption of closed systems for large scale cultivation of microalgae requires that solutions are provided to the many problems that limit the technology (overheating, oxygen accumulation, biofouling, mixing generated shear-stress, deterioration of the construction material) and can lead to failures when not duly considered and solved. In the last years, even at commercial scale, these problems have been efficiently solved and some recent analyses support the conclusion that algae biomass production at large scale will be soon less expensive using PBR than open ponds (137).

RHEOLOGICAL BEHAVIOR OF FERMENTATION FLUIDS

COLIN R. THOMAS AND GRAINNE L. RILEY
School of Chemical Engineering, University of Birmingham, United Kingdom

61.1 INTRODUCTION

Rheology is the study of the deformation and flow of matter, while rheometry is the experimental characterization of rheology. Rheometers or viscometers are the instruments used for this purpose. The rheological behavior of fluids or suspensions such as fermentation broths is described in terms of viscosity, which is the ratio between shear stress and shear rate. A Newtonian fluid is one in which the viscosity is constant, so that the shear stress is proportional to the shear rate, and furthermore the only stresses generated during flow are shear stresses. Fluids or suspensions that do not conform to these criteria are described as non-Newtonian. It has been long been known that some fermentation broths exhibit non-Newtonian behavior, and this can happen in industrial fermentations for two main reasons. The first is if the microorganisms excrete an "exo-biopolymer". An exo-biopolymer such as xanthan or gellan consists of large, long molecules that can change shape or entangle to resist the flow of the liquid in which they are dissolved. The second reason is that filamentous fungi or filamentous bacteria consist of hyphae that are long, often branched, structures. Mycelia consist of many hyphae, and like exo-polymers, they can become entangled.

The viscosity of non-Newtonian broths is not constant, but depends on the shear rate. In this case, the ratio of the shear stress to the shear rate is called the *apparent viscosity*. The viscosity of water (and most fermentation media not containing filamentous microorganisms or exo-biopolymers) is around 10^{-3} Pa s (1 cP), while the apparent viscosity of some fermentation broths can be orders of magnitude higher than this. It is therefore typical for a broth to be Newtonian at the beginning of fermentation, but for it to become highly viscous and non-Newtonian as the biomass or exo-biopolymer concentration increases. This usually has deleterious effects on mixing and mass transfer, and hence productivity. It is therefore essential to be able to characterize the rheology of fermentation broths, but this is difficult because broths are suspensions of cells rather than homogeneous liquids. The way this is done and practical correlations for relating key rheological parameters to the biomass concentration and the morphology (shape) of mycelia are the subject of this chapter. The effects of high and non-Newtonian viscosity on mixing and flow of fermentation broths are also discussed.

61.2 RHEOLOGICAL MODELS

The common rheological models used to describe fermentation broths are given in Table 61.1, and shapes of some of the stress–strain curves are shown in Fig. 61.1. It should be noted that Bingham plastics, and Herschel-Bulkley and Casson fluids, have a "yield stress," that is, there is no flow until a certain stress is exceeded. The behavior of Power law fluids depends on the value of the consistency index n. For non-Newtonian fermentation broths, this is typically less than 1, in which case the fluid is described as "pseudoplastic" or "shear thinning" because the apparent viscosity decreases as the shear rate increases. For non-Newtonian fluids or suspensions, it is meaningless to quote an apparent viscosity without a corresponding shear rate.

TABLE 61.1. Common Rheological Models Used to Describe Fermentation Broth Rheology

	Rheological model
Newtonian fluid	$\tau = \mu\gamma$
Bingham plastic	$\tau = \tau_y + \mu\gamma$
Power law fluid	$\tau = K\gamma^n$
Herschel–Bulkley fluid	$\tau = \tau_y + K\gamma^n$
Casson fluid	$\tau^{0.5} = \tau_y^{0.5} + K\gamma^{0.5}$

τ, shear stress; γ, shear rate; μ, viscosity for a Newtonian fluid or plastic viscosity for a Bingham plastic; τ_y, yield stress; K, consistency index; n, flow behavior index.

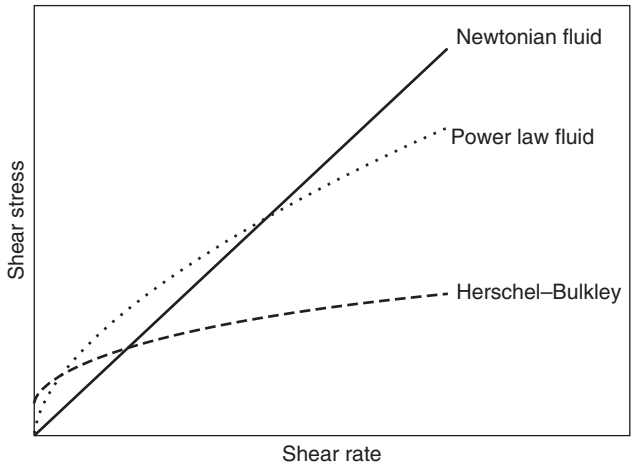

Figure 61.1. Some common models used to describe fermentation broth rheology.

Figure 61.2. Couette or cup and bob rheometer (Contraves Industrial Products Ltd.), sometimes called an annular gap rheometer because the bob fits concentrically in the cup leaving an annulus where the broth is sheared. Photograph: G. Wheeler, University of Birmingham.

It is important to recognize that the various rheological models are intended as empirical relationships between stresses and shear rates in the fluid or suspension. As such, more than one model may fit any given set of experimental data. The most commonly used model by far is the Power law because it has only two parameters, and fits most rheological data adequately.

61.3 RHEOMETRY

Conventional rheometers such as the "Couette" design, where a fluid or suspension is sheared in the annular gap between two concentric cylinders (Fig. 61.2), might be of limited value for suspensions of solids such as fermentation broths because of phase separation or "slip" at the smooth surfaces (1–3), and also because there might be gravity settling (3). Furthermore, geometries that have a narrow measuring gap such as cone and plate systems, where the material is sheared between a shallow cone and a flat plate, may incur the additional problem of particles of similar sizes to the gap jamming within it, destroying them and impairing accurate measurement. However, by careful design and choice of operating conditions, it may be possible to use such conventional rheometers to characterize fermentation broth rheology (4). A common industrial practice is to use very simple rheometers such as a flat disk rotating with a spindle (Fig. 61.3) in a beaker or cup of broth. The flows in these simple systems are usually ill-defined, and an empirical approach using test fluids must be used to calibrate the rheometer (5). That may be of little consequence in practice, because consistency and convenience of measurement often outweigh any need for fundamental understanding of the broth rheology, especially when monitoring an established fermentation.

To overcome the potential problems with conventional rheometers, the disk turbine impeller rheometer (Fig. 61.4) was developed (1,2). This is said to minimize particle settling and avoid particle jamming, and it might be particularly appropriate for fermentation broths as the flows might in some respects resemble those in a real fermenter (6). However, it is important that the flow remains laminar in this type of device, and this may limit the range of shear rates available. Even so, the flows around the impeller are too complex to model, and an empirical approach is used

Figure 61.3. Disk spindles (Viscometers UK Ltd.). The chosen spindle is rotated in a sample of broth, either in a cup supplied with the rheometer or in a beaker. Photograph: G. Riley, University of Birmingham.

Figure 61.4. Disk turbine impeller (purpose built). The impeller is rotated in a sample of broth, either in a cup supplied with a rheometer or in a beaker. Photograph: G. Wheeler, University of Birmingham.

to calibrate the rheometer. The calibration is based on the Metzner and Otto average shear rate concept (7). This proposes that the average shear rate near a disk turbine should be used to determine an average viscosity. The average shear rate is defined as

$$\gamma_{av} = k_s N \tag{61.1}$$

where γ_{av} is the average shear rate and k_s is a constant assumed to be dependent only on the geometry of the system, that is, independent of the rheology and impeller rotational speed, N. The shear stress corresponding to the average shear rate can be found from the torque on the impeller shaft as it rotates. The literature gives many descriptions of the method (e.g. (8)), although its validity has been criticized by some workers (4,9), particularly as it usually needs large sample volumes (10). It has recently been given a satisfactory theoretical underpinning, along with confirmation that k_s is a constant for Power law fluids in laminar flow (8). Turbine impeller rheometers have been used to give reproducible rheological measurements on various fungal fermentation broths (6,11–13). The calibration fluid is usually a viscous Newtonian fluid such as silicone oil or a pseudoplastic solution of a polymer such as Carbopol. At least for such calibration fluids, it has been confirmed that the assumption of an average shear rate is valid for the helical ribbon and disk turbine systems (12). It should be noted that the theory assumes a single phase fluid, and although this may be an acceptable approximation for mycelial suspensions, it might not be valid if gas bubbles are present in the broth. It may therefore be necessary to degas a sample before the measurements begin, for example, by sonication.

A common alternative to the turbine impeller rheometer is the vaned geometry (Fig. 61.5), which has become the universal choice for yield stress or very shear-thinning fluids (14), mainly in industries other than biotechnology.

It has been suggested that an impeller such as a helical ribbon (Fig. 61.6) with better mixing capabilities in the laminar flow region would be preferable to the disk turbine rheometer (4,15,16). An upward pumping helical ribbon impeller with a close clearance to the wall is used to create fluid motion all the way to the wall even for very viscous materials and to provide some top to bottom mixing, which is useful when suspended solids may settle. The use of this impeller can also increase the range of shear rates available for measurement by extending the laminar region. The determination of apparent viscosity for a helical ribbon rheometer is similar in method to that for the disk turbine (12).

Although it is probable that many non-Newtonian fermentation broths have a yield stress, it is often difficult to determine this without special techniques. It can be hard to distinguish between a highly shear-thinning fluid and one that yields, as can be seen in Fig. 61.1. This is another good reason for use of the Power law (Table 61.1), but it should be recognized that even small, nearly immeasurable, yield stresses may have deleterious consequences on fermenter mixing, as discussed later. Some workers use a "controlled shear stress" rheometer to attempt to measure yield stresses directly, but the geometry of such devices may well be inappropriate for broths containing larger particles. It is also

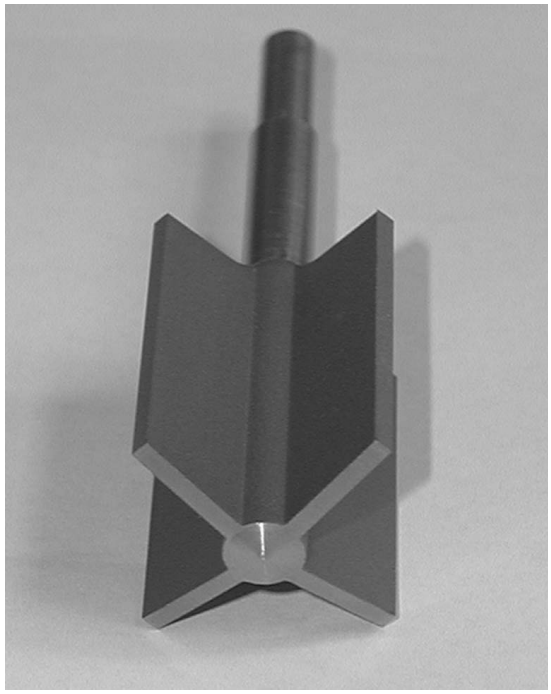

Figure 61.5. Vaned impeller (Bohlin Rheometers, Malvern Instruments Ltd). The impeller is rotated in a sample of broth held in a cup supplied with the rheometer, giving a close clearance. Photograph: G. Wheeler, University of Birmingham.

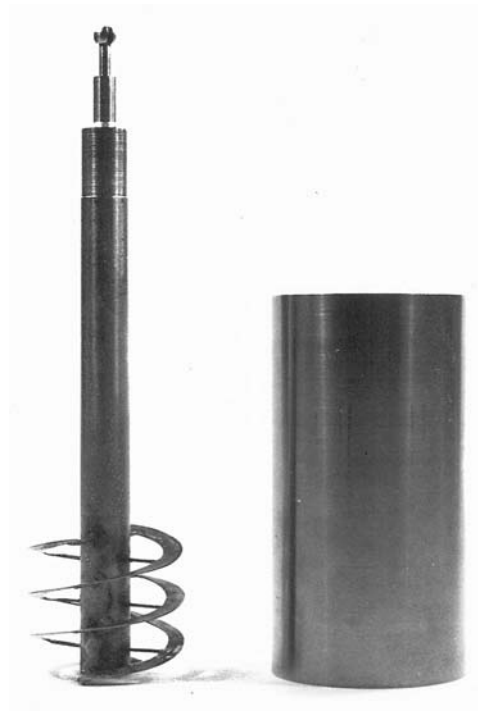

Figure 61.6. Helical ribbon impeller (purpose built). The impeller is rotated in a sample of broth held in a rheometer cup, giving a close clearance. Photograph: G. Wheeler, University of Birmingham.

possible that only the continuous phase (i.e. the medium) flows at very low shear rates, through any suspended solids, making it appear that there is no yield stress.

In rheometry in general, it is recognized that the temperature of the measurements may be important, as the (apparent) viscosity usually drops as the temperature rises. However, it is rare for the temperature to be quoted with rheological parameters for fermentation broths, and practical measurements are often at room temperature. Fortunately, many mycelial and exo-biopolymer fermentations are operated at or close to 25°C, and room temperature is adequate for rheological characterizations in these cases. This is because variabilities in sampling and rheological characterization are usually large enough to render temperature effects negligible or of the second order of importance. Furthermore, changes in apparent viscosity across mycelial and exo-biopolymer fermentations are usually orders of magnitude greater than any temperature effects.

It should be mentioned that on-line rheometry is possible (17,18), but has not been very popular in industrial fermentations, presumably because of contamination risks and the additional complexity. There are few published studies on the use of this method. A recent example was the use of such a rheometer as part of a process control strategy for an industrial, pilot-scale, fed-batch fermentation of *Aspergillus oryzae* (19).

61.4 EXO-BIOPOLYMER FERMENTATIONS

Xanthan and gellan are examples of microbial polysaccharides. Xanthan in particular is a major commercial biopolymer used extensively in the food industries (20) because its solutions are highly pseudoplastic and of high viscosity at low shear rates. This makes it an ideal suspending agent in food products. Gellan is an excellent gel-forming agent (20). The design of fermenters for production of these and other polysaccharides is very challenging, because high product concentrations are required to reduce downstream processing costs, and yet the resulting high viscosity, non-Newtonian, broths cause major mixing and oxygen transfer problems during the fermentations (20).

Mixing and oxygen transfer effects in fermentations of the bacterium *Xanthomonas campestris* have been studied in detail recently (21). The rheology of the broths was measured by cone and plate rheometer, and the Power law model was fitted to the data. In this application, the cone and plate rheometer is usable as the viscosity is caused by the dissolved polymer and there are no particles to jam in the device. Because of the production of xanthan to 26 g/L, the consistency index of the broth went from a very low value to over 30 Pa s^n and the value of the flow behavior index n dropped from 1 to 0.14 (shear rate range not

specified). This had serious consequences on the mixing and oxygen transfer in these stirred tank fermentations. The effects of changes in rheological behavior on mixing and mass transfer in fermentations are discussed later.

A comprehensive study of mixing and mass transfer conditions on gellan production by the bacterium *Auromonas elodea* (22) again showed that the fermentation broth was initially Newtonian and had low viscosity, but within a short time it had become highly shear thinning because of the excretion of the biopolymer. The broth had a yield stress, but this was difficult to determine and therefore the Power law (Table 61.1) was used to describe the rheology. It was discovered that the flow behavior index went from 1 to 0.3 within 9 h of a typically 32 h culture (shear rates ca. 2–200 s^{-1}) and the apparent viscosity could be as high as 20 Pa s (shear rate 0.1 s^{-1}).

A similar report of a low viscosity broth becoming viscous and pseudoplastic concerns scleroglucan production of *Sclerotium glucanicum* (23). In this case, there were deleterious effects on the performance of an airlift bioreactor with an internal circulation loop.

It is worth noting that highly viscous, non-Newtonian broths can also result from the release of deoxyribonucleic acid (DNA) from, for example, *Escherichia coli*, by alkaline cell lysis for plasmid recovery (24). Such suspensions have also been found to exhibit significant viscoelastic properties demonstrating the "Weissenberg effect" upon agitation. This is a phenomenon that occurs when entanglement causes polymer chains to be drawn toward a spinning agitator or spindle shaft, causing a surprising movement of the broth up the shaft. In DNA recovery, this viscoelasticity compounds the rheological challenges posed in processing.

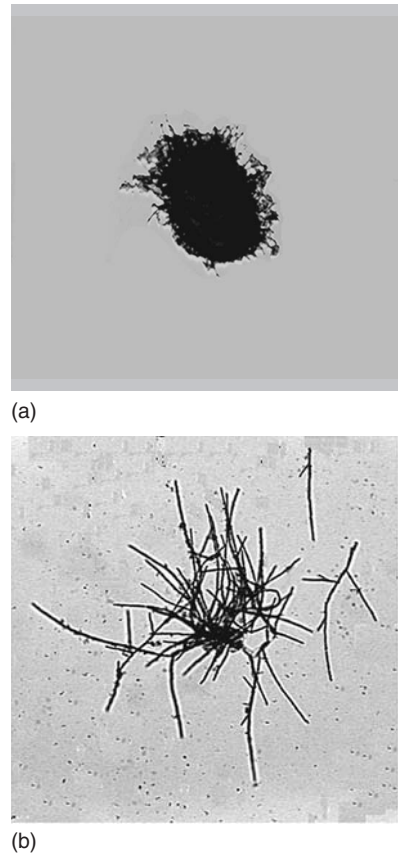

Figure 61.7. (a) Pellet of *Aspergillus niger*; (b) Dispersed forms of mycelia of *Penicillium chrysogenum*.

61.5 MYCELIAL FERMENTATIONS

Mycelial fermentations may be of filamentous fungi such as *Penicillium chrysogenum* (producing penicillin) or filamentous bacteria such as *Streptomyces* spp., from which come most antibiotics. In either case, the morphology has been shown to play a crucial role in submerged fermentations of these microorganisms. Most studies are on fungi, and the relationships between fungal morphology and metabolite production have been reviewed recently (25).

Commercial production of metabolites often requires that the microorganism is grown in one particular form, that is, morphology. In submerged culture, many filamentous microorganisms tend to aggregate into "pellets" (Fig. 61.7a), the size of which might be measured in millimeters or even centimeters. Although pelleted fermentation broths may remain Newtonian and of low viscosity throughout the entire time course of the fermentation, problems might arise with diffusion and transport of nutrients into pellet cores, thus reducing productivity. Nevertheless, the pellet form has been used traditionally for commercial production of citric acid and other metabolites. The dispersed form (Fig. 61.7b) can result in large increases in broth viscosity for only small increases in biomass concentration. Thus, even in the early stages of mycelial fermentations the broth can exhibit several non-Newtonian characteristics, possibly including a yield stress. This behavior of the broth is presumed to arise from the formation of complex entanglements of the mycelia (11). This may lead to difficulties with fermenter mixing, which in turn might affect mass and heat transfer deleteriously, causing a decrease in productivity and/or the production of undesirable metabolites (11,25). Problems with mixing can also affect process control, for example, pH control, by introducing a time lag between acid/alkali addition and the resulting signal from the pH electrode (11). These problems are compounded when a process is scaled up due to increased circulation times and generally lower agitation intensities. Nevertheless, dispersed mycelial fermentations are common and are found in the production of antibiotics.

The complex interactions between process conditions, morphology, productivity, growth, rheology, heat and mass transfer, mixing, and process control are summarized

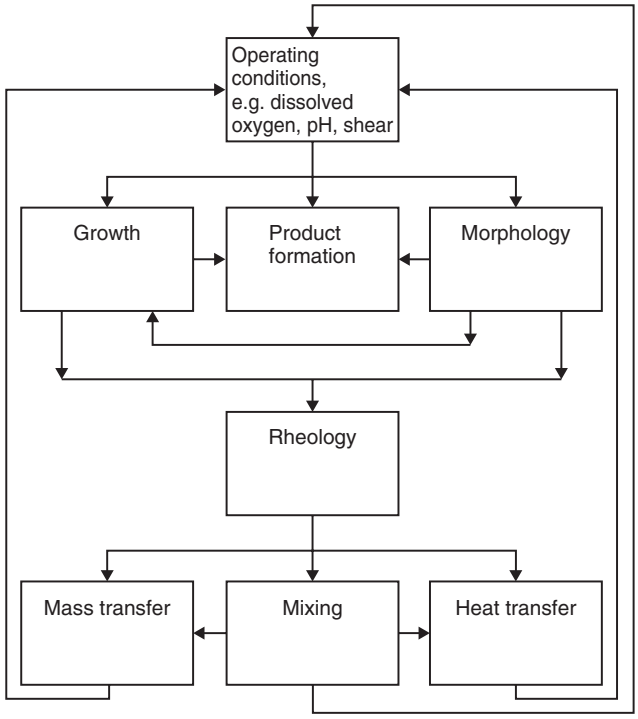

Figure 61.8. Complex interactions between process conditions, morphology, productivity, growth, rheology, heat and mass transfer, mixing and process control (after (11)).

in Fig. 61.8 (11). There is no doubt that the production of metabolites generally depends on the morphology (25), but the morphology depends on the process conditions including the agitation. The effects of agitation might be directly due to breakage of hyphae (26–30), or aggregation/disaggregation of mycelia (31), or might be indirect through changes in heat and mass transfer (particularly oxygen transfer). In either case, the morphology influences the rheology, and this in turn affects the mixing and transport processes, thus closing the loop, as shown in Fig. 61.8. Because of the complexity of this situation, the optimum process conditions for different fermentations vary considerably and are usually highly specific. Indeed, the optimum conditions may vary throughout a single fermentation. For example, conditions that are optimal for biomass growth may not be optimal for the production phase or *vice versa*. The means that has now been found to break into this loop is measurement of morphology by automatic image analysis (32–35). This method has allowed useful correlations to be sought between morphology and rheology, and studies on agitation effects on morphology to be undertaken, as described later.

61.5.1 Morphological Characterization

The development of image analysis techniques (32–35) has enabled methods for rapid and accurate characterization of mycelial morphology. These methods greatly extend the amount and type of data that can be obtained and have helped to describe the interactions between rheology and morphology more fully. Image analysis allows for the relatively rapid, fully or semiautomatic and reproducible extraction of quantitative data from mycelial broth samples, greatly extending the amount and type of data that can be obtained. In addition, the process allows a completely randomized field of view to be observed and measured thus reducing the dependency of the measurements on operator selection.

Some of the dispersed morphological forms found in mycelial cultures are illustrated in Fig. 61.9. Because the morphology usually requires microscopy and image analysis for its quantification, only two-dimensional projections of the objects are characterized. For example, the size of an object is often given as its "projected area," which is the area found in an image of the object as seen through a microscope. Pellets (Fig. 61.7a) are usually identified by the presence of a central core of highly entangled hyphae (34), and are sometimes classified into smooth and hairy types (34). The latter is sometimes described as "fluffy." Usually, the core of the pellet is identified and its size found

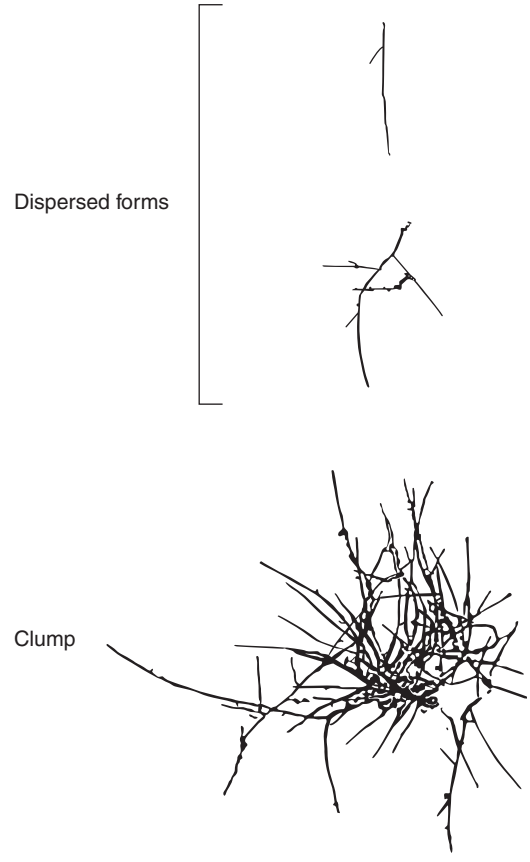

Figure 61.9. Dispersed morphological forms found in mycelial cultures.

as the projected area. This is probably a doubtful practice given pellets are not even approximately two-dimensional, but at least the characterization is consistent. For hairy pellets, the annular region is also characterized, often as a ratio of its projected area to the total projected area, sometimes called the *filament ratio* (36,37). Dispersed forms may be split into two groups; clumps and freely dispersed (Fig. 61.9). Clumps are loose aggregates of hyphae, which are not sufficiently tightly packed to be described as pellets (35). Hyphae are usually flexible enough for a clump to lie relatively flat on a microscope slide, and (except for hyphal overlapping) the projected area may indeed give a reasonable estimate of size. As clumps predominate in many mycelial fermentations (32,33), the characterization of this form is particularly significant. Typical morphological parameters for clumps beside projected area are roughness and compactness (35). In recent practice, it is usually considered better to have only one parameter to describe the morphology of all the dispersed forms. The obvious choice is the projected area, but the maximum dimension has also been suggested (13). These and other morphological parameters have been used in correlations of rheological parameters of mycelial fermentations, as described below.

61.5.2 Morphology and Rheology

61.5.2.1 Pelleted Forms. Lovastatin is an important cholesterol-reducing drug, which is made by fermentation of the filamentous fungus *Aspergillus terreus* growing in the pelleted form (36,37). In recent studies, large (ca. 2 mm) fluffy pellets gave high lovastatin titers but produced highly shear-thinning broths, which required the use of enriched oxygen to maintain sufficient oxygen transfer to the microorganism (36,37). Rheology was measured using a vane spindle device and it was assumed that the Power law was applied. Pellet morphology was quantified using the equivalent diameter of the total pellet projected area, that is, the diameter of the circle with the same area as the pellet, and the filament ratio. At low agitation rates (average shear rate of about 70 s^{-1}), which gave the desired morphology, the flow behavior index decreased and the consistency index substantially increased, as the biomass concentration and mean pellet size increased. However, at high intensity agitation where the pellets were much smaller, both the flow behavior index and the consistency index remained approximately constant with increasing biomass but decreasing pellet size. In the latter case, the flow behavior index exceeded 1, that is, the broths were shear thickening. Overall, it seemed that the main determinant of the rheological parameters was the pellet diameter (36,37). However, it was not clear from these papers whether there was little effect of biomass concentration (36) or that it was an important factor (37). In another work on *A. terreus* (38), the method of Tucker and Thomas (12), described later, was used to show the consistency index depended on the biomass concentration to the power of approximately 2. However, there was only a poor quality correlation if only the biomass concentration was considered. It seems essential that both the biomass concentration and the morphology are considered when trying to develop predictive correlations for rheological parameters.

Similar results have been obtained with *Aspergillus sojae* producing polygalacturonase (39), again showing dependence of the consistency index on the biomass concentration and pellet size, and the possibility that small compact pellets might lead to shear-thickening behavior. For this fermentation, it was found that careful choice of medium and seed culture could lead to high enzyme titers with a broth rheology close to Newtonian (40).

There is little reliable information on pelleted fermentations other than those of *Aspergillus* spp. The effects of morphology and rheology on neo-fructosyltransferase production by *Penicillium citrinum* have been reported recently (41). Once again, the rheology depended on the cell growth and morphology, but no correlations were presented.

Other workers have studied the rheology of pelleted fermentations, but have not characterized the morphology. Without such information, the results are difficult to interpret or use, except for a specific fermentation.

61.5.2.2 Dispersed Forms. Before the availability of comprehensive image analysis methods, there were a few attempts at correlating the rheological and morphological properties of mycelial broths. However, only the freely dispersed mycelia were characterized and there is no evidence that the morphology of hyphae within a clump is similar to that of the freely dispersed form. Indeed, no correlations between clump and freely dispersed morphologies have ever been found. Consequently, such work is generally flawed. However, it appears that some actinomycete fermentations contain only short, relatively unbranched, hyphae (42). In this case, it was possible to use the mean main hyphal length (the length of the longest or only hypha in a mycelium) as a reliable measurement of mycelial size. Rheological data were found using a disk-spindle rheometer, demonstrating a Power law relationship for shear rates from 0.3 to 100 s^{-1}. In all cases, the flow behavior index fell to 0.25 or lower, as soon as substantial growth occurred. The consistency index rose with the biomass concentration as the (fed-batch) fermentations progressed, and sometimes this was followed by a steep fall as cell lysis began. Unfortunately, it was concluded that there was no clear relationship between broth rheology and morphology.

The availability of comprehensive image analysis methods (32–35) now permits much more detailed studies of the effects of morphology on the rheology of mycelial

broths containing predominately dispersed forms. Most of this work has been on filamentous fungi. In an early study (12), the separate influences of biomass concentration and mycelial morphology on broth rheology was investigated, using an industrial strain of *P. chrysogenum*. To investigate the effect of biomass concentration separately to that of morphology, a large sample from the fermentation was split into a number of subsamples. These were reconstituted to a range of biomass concentrations by filtration and resuspension. The rheology and mycelial morphology of each subsample were then determined using a disk turbine impeller, assuming the Power law. By this procedure, sometimes called the *Tucker and Thomas* technique, each subsample possessed rheological properties due only to changes in biomass concentration. The rheological parameters could therefore be correlated with biomass concentration (X) assuming

$$\mathrm{RP} = \text{ constant} \times X^{\alpha} \tag{61.2}$$

where RP is a rheological parameter under examination and α is the exponent on the biomass concentration. Having established the effect of the biomass concentration, it was then possible to examine the effect of mycelial morphology independent of the biomass concentration. Table 61.2 shows some values of α found by direct correlations or the Tucker and Thomas technique. It should be noted that morphological analysis is not required to obtain such values. It can be seen that the value of α of around 2 is fairly typical. Figure 61.10 shows typical observations of the consistency index divided by the biomass concentration squared, that is, setting α equal to 2, for a *P. chrysogenum* fermentation broth (13). It is clear that the development of the rheology during such fermentations cannot be explained by changes in biomass concentration alone, and the morphology must also be considered. This is a common observation (e.g. 43,44).

Once α had been determined, morphological data from *P. chrysogenum* broths were used to estimate the constants in the correlation:

$$\mathrm{RP} = \text{constant} \times X^{\alpha} \times (\text{roughness})^{\beta} \times (\text{compactness})^{\gamma} \tag{61.3}$$

for each rheological parameter. The clump morphological parameters roughness and compactness were found by image analysis. The resulting correlations were fairly successful at predicting broth rheology for batch fermentations. It was later established that α was essentially constant throughout batch fermentations, and this allowed a mean value to be used. This method was also used on *Aspergillus niger* broths from chemostat cultures, and batch and fed-batch fermentations (17,18). The specific correlations are given in Table 61.3. In all these cases, the data were limited, and no indication was made concerning the statistical significance of the predictions made using the rheological parameter correlations. This lack is common to many published rheological correlations and makes the success of any particular correlation difficult to assess.

These problems were overcome in the subsequent extensive study on *P. chrysogenum* broths (13). No clear relationship between the flow behavior index and biomass concentration was found, at least for those phases of the fermentation in which the viscosities were high enough for the rheology to be characterized by a disk turbine

rheometer. The shear rate range was 3.5–75.8 s^{-1}, with lower rates impractical due to settling. The mean value of the flow behavior index was found to be 0.35 ± 0.1 (standard deviation) throughout both batch and fed-batch fermentations, although some significant deviations from this value were observed early and very late in the fermentations. Correlations for the consistency index, measured using a disc turbine rheometer and assuming the Power law, were based on the biomass concentration and the mean maximum dimension of the mycelia. These correlations were reasonably successful for both fed-batch and batch fermentations. The proposed correlation was

$$K = X^2 \times (5 \times 10^{-5}\ D - 10^{-3}) \qquad (61.4)$$

where K is the consistency index (Pa s^n), X is the biomass concentration as dry cell weight (g/L), and D is the mean maximum dimension (μm). Figure 61.11 shows a parity plot of the values of the consistency index K (Pa s^n) predicted from Equation 61.4 versus the experimentally determined values for three *P. chrysogenum* fermentations. The importance of Equation 61.4 is that it takes account of all dispersed morphological forms, not just clumps. This was a real advance on previous work. It was also shown by statistical analysis that the roughness and compactness of Equation 61.3 were not in fact independent variables, reducing the value of this correlation. It is clearly very important to consider the statistical validity of any proposed correlation between rheological and morphological parameters, although this is rarely done.

Mean maximum dimension, as used in Equation 61.4, is not the only morphological parameter that can collectively describe all the dispersed forms. Another possibility is the mean projected area (13). However, mean projected area measurements are significantly affected by the choice of magnification, unlike the mean maximum dimension. Therefore, correlations using the mean maximum dimension have been favored (13,46). This was especially significant when the correlations were extended to other fungal strains requiring different magnifications (46).

Given the wide range of rheometers used to measure mycelial broth theology, it is helpful that there has been a comprehensive comparison of the main choices (10). It was of particular value that broths were taken from production fermentations up to 19 m^3 scale.

In this work, the rheology of the broths of filamentous fungus *Glarea lozoyensis* was characterized using two spindles (Fig. 61.3) of different disk diameters, a disk turbine (Fig. 61.4), and a cup and bob device. The morphology of the fungus was dispersed and as might be expected, the broth was initially water-like, but eventually the apparent viscosity increased dramatically to over 10 times the value measured at the start of the fermentation.

For the smaller of the disk spindles, separation was observed around the spindle and there was some settling. On the other hand, values from the other disk spindle, the disk turbine, and the cup and bob were similar. Given the limited shear rate ranges available with the former two and their relative complexity, the cup and bob was chosen for further work. This was a very important observation and

TABLE 61.3. Correlations to Predict the Rheological Behavior of a Variety of Fungi, Measured Using Different Rheometric Techniques, from Measurements of the Morphology and Biomass Concentration

Reference	Correlation	Microorganism	Rheological Measurement Method
12	$K = X^{2.8} \times R^{0.7} \times C^{1.2} \times$ constant[a]	*Penicillium chrysogenum*	Disk turbine rheometer
43,44	$K = -0.56 + 0.0018 \times R \times X^{1.7}$ $K = 0.38 + 4.8 \times 10^{-5} \times R \times X^{2.9}$	*Aspergillus niger*	On-line impeller rheometer
13	$K = X^2 \times (5 \times 10^{-5} D - 10^{-3})$	*Penicillium chrysogenum*	Disk turbine rheometer

K, consistency index (Pa s^n); X, biomass concentration (gram dry cell weight per liter); D, mean maximum dimension ((13); μm) or average clump dimension ((44); μm); R, roughness; C, compactness. *Value of constant not given.

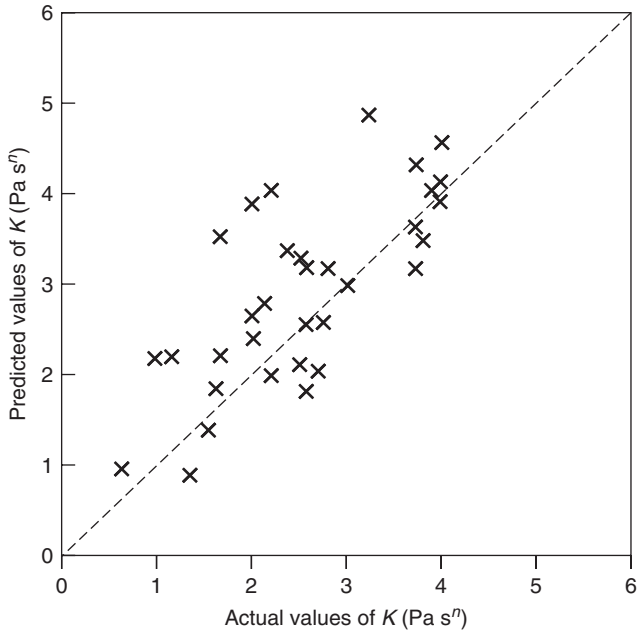

Figure 61.11. Parity plot of the values of the consistency index K (Pas^n) predicted from Equation 61.4 versus the experimentally determined values for three *Penicillium chrysogenum* fermentations (13).

conclusion, given that it is generally accepted that cup and bob systems are not appropriate for mycelial broths.

Yield stress experiments suggested that the Herschel–Bulkley model (Table 61.1) would fit the rheological data best, but because the Power law is in such common use, this was the eventual choice. Again this is important; essentially it was confirmed that the Power law is the most practical rheological model for mycelial fermentations.

There is limited morphological data from this study, but it is nevertheless an exemplar of good practice for rheological studies.

It is not necessary to use the Tucker and Thomas method to find α. An alternative approach is to gather a great deal of data and seek correlations directly. This was done in one of the few useful studies on an actinomycete, in this case *Streptomyces olindensis* (45). The morphology of all the dispersed forms in these fermentations was characterized by the average clump dimension (the average of the dimensions of the clumps in eight directions or "ferets"). The correlation for the consistency index K for a shear rate range of 0–330 s^{-1} was

$$K = 0.0043X^2D^{0.82}\text{dynes}s^n/\text{cm}^2 \qquad (61.5)$$

where X is the biomass concentration (g/L^1) and D is the average clump dimension (μm).

Image analysis is not the only way to characterize mycelial morphology; biomass particle size distributions may also be found by light scattering (47). This is an excellent, practical technique, which is fast and is inclusive as it does not classify particles into forms, and presumably can deal easily with other fermentation solids. This method was used to develop predictive correlations for the rheology of *A. oryzae* broths from 550 L fermentations (47). Principal component analysis was used to extract useful information from the data. The rheometer was a cone and plate system with a large gap width to "cope with the biomass particles in the broth". The shear rate range was 0–300 s^{-1}. The Herschel–Bulkley model was chosen (Table 61.1). It was discovered that the flow behavior index was not correlated with any other variables, and a constant value of 0.4131 (the mean measured value) was used. It was noted that estimates of other rheological parameters such as the consistency index were very sensitive to the choice of a value for n. This is an important practical point that should be considered when quoting consistency index values (for example).

Of course, to use this method one requires a suitable light scattering instrument, as no simple correlations are generated in this approach. It is probably best employed in a commercial environment, where its advantages outweigh any lack of a link to the detailed morphology of the microorganisms.

Finally, it is becoming clear that it may not be necessary to accept the morphology and hence rheology found in a conventional fed-batch, mycelial fermentation. Besides dilution of the broth with sterilized water, pulse-pause feeding (47,48) is known to reduce the viscosity of some fermentations by causing fragmentation of the mycelia.

61.6 MIXING

Some of the possible effects of high apparent viscosity and non-Newtonian broth rheology on fermenter mixing performance have been reviewed recently (49). For polysaccharide (exo-biopolymer) fermentations in which the polysaccharide concentration becomes high enough for the broth to have a yield stress, a "cavern" might form around the impeller. This is a region of relatively rapid motion, surrounded by a stagnant region. Its size can be predicted from the yield stress, but this requires careful determination. It might be that the Power law fits the rheological data well over a wide shear rate range, but a yield stress becomes apparent with more precise measurements over a narrower range. Of course, the existence of such a cavern may have a deleterious effect on oxygen mass transfer, thereby affecting productivity (50,51). In such a case, it might be preferable to use impellers with large diameters or novel impellers that improve bulk mixing (50).

As mentioned earlier, in an agitated mycelial fermentation, there are complex interactions between process conditions, morphology, productivity, growth, rheology, heat and mass transfer, mixing, and process control as summarized in Fig. 61.8. It might seem that reducing the broth apparent viscosity by increasing the impeller speed and hence the shear rate would be advantageous. However, an important issue here is the potential damage to mycelia caused by agitation. Fragmentation of mycelia can reduce the broth apparent viscosity, but may also reduce the fermentation productivity. It has been shown for several fungal fermentations that the (dispersed) morphology can be correlated using the "energy dissipation circulation" function (26–31). Again, much of this has been comprehensively reviewed elsewhere (49). Surprisingly, pellet sizes of *A. terreus* could also be correlated with this mixing parameter (36).

61.7 CONCLUSION

In choosing a particular rheometer, one has to consider both the intended use and prior art. In situations where consistency and ease of use are of paramount importance, for example, in routine monitoring of a well-established mycelial fermentation, a simple disk-spindle system might be the best choice. However, it is worthwhile reading the comprehensive comparison of the main choices that was mentioned earlier (10), from which it appears that a cup and bob system may also be feasible, with shear rates up to 100 s^{-1}. This may also be the best choice for a research environment, although the disk turbine rheometer has been in common use in laboratories for many years, and correlations with morphology obtained with this geometry are already available for some important fermentations.

It has been stated that "one of the most challenging tasks in the fermentation industry today is the design of bioreactors for highly shear-thinning, viscous fermentation broths" (49). It is through rheological studies on such broths, and the understanding of how the rheology is dependent on dissolved exo-biopolymers or suspended filamentous microorganisms, that progress is being made in understanding the complex interactions in such fermentations, with the prospect of their improved productivity.

NOMENCLATURE

C	compactness
D	mean maximum dimension or average clump dimension
k_s	constant in Metzner and Otto equation (Eq. 61.1)
K	consistency index
n	flow behavior index
N	impeller rotational speed
RP	any rheological parameter
R	roughness
X	biomass concentration
α	exponent on the biomass concentration (Eq. 61.2)
β	exponent on the biomass concentration (Eq. 61.3)
γ	shear rate or exponent on the biomass concentration (Eq. 61.3)
γ_{av}	average shear rate near an impeller
μ	viscosity for a Newtonian fluid or plastic viscosity for a Bingham plastic
τ	shear stress
τ_y	yield stress

RHEOLOGY OF FILAMENTOUS MICROORGANISMS, SUBMERGED CULTURE

Maria Papagianni
Aristotle University of Thessaloniki, Greece

62.1 INTRODUCTION

Rheology is the study of the deformation and flow of materials. The rheological characteristics of a fermentation broth directly affect its mixing behavior and all forms of mass and heat transfer (Fig. 62.1). This can have a profound influence on the course and outcome of fermentation as well as on the response of sensors used for monitoring and control. Beyond fermentation, the rheological properties of the final culture broth are a major determinant of the ease or difficulty of downstream processing.

Preinoculation media usually exhibit simple, water-like, Newtonian rheological behavior. With the progress of fermentation, broth rheology becomes more complex either by increases in biomass concentration or by both, increase of biomass and accumulation of high molecular weight products (e.g. extracellular polysaccharides) in considerable amounts. Biomass of most bacteria and yeasts, at the concentrations usually encountered, does not have much effect on rheological properties of culture broths (1). The effects of biomass are most pronounced for mycelial cultures (filamentous fungi and actinomycetes), in which the mycelia tend to give structure to the fluid (2). There are a number of economically important industrial processes that use filamentous microorganisms. Since the importance and influence of fluid flow properties on reactor performance is widely recognized, the physical properties of the suspensions involved in these processes should be accurately measured and correlated with the various transport phenomena.

The rheological behavior of mycelial suspensions arises from frictional and other energy losses which occur when suspensions are sheared. Mechanisms by which energy is dissipated include purely viscous frictional losses within the liquid phase and additional losses due to distortion of streamlines by the mycelial particles; flexing of hyphae resulting in distorted particle shapes; and fragmentation of hyphae or mycelial flocs (3). Mycelial morphology should therefore, exert a very profound effect on the nature of broth rheology. Morphology in submerged culture varies between two extreme forms: the filamentous and the pelleted (4,5). In the filamentous form, the mycelium has the form of hyphae with a varying degree of branching. Hyphae can be up to 500 μm in length and 2–10 μm in diameter. In the pelleted form, the mycelium develops as spherical particles of filaments intertwined around a core. These particles are stable and have a varying degree of compactness and roughness, while their diameters could be several millimeters (4,5).

In the first case of filamentous growth, a varying degree of filament entanglement is apparent. This may result in the formation of permanent aggregates without a core; they are referred to as mycelial clumps (6). A high degree of entanglement of filaments together with a high concentration of biomass in the reactor leads to very viscous suspensions in the order of several thousand centipoise (7–9). The rheological behavior in such cases is usually very non-Newtonian, leading to relatively low viscosities in regions of high shear rate (near the impeller) and very high viscosities in regions with low shear rate (near the

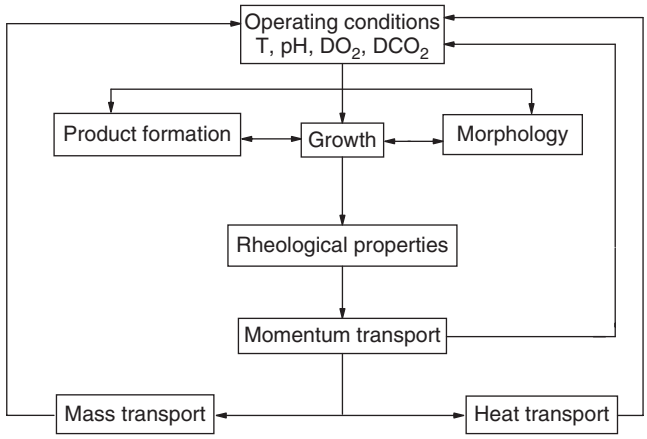

Figure 62.1. Interactions between process parameters in submerged mycelial fermentations.

wall). Suspensions of pellets are usually less viscous and their rheological behavior is more Newtonian-like although some degree of non-Newtonian response should be expected because the pellets are quite deformable or "hairy" (long filaments arise from the core) (1,7,10).

The effective size, shape, concentration, and size distribution of mycelial particles primarily affects the amount of energy dissipated through the particle–liquid interactions thus affecting the measured rheology. The analysis of rheological data is however, not a simple task and the superimposed effects of these parameters, and many others, on broth rheology can be difficult to simulate (11–13). Other parameters include the mode of fermentation, growth rate, dissolved oxygen concentration, pH, degree of mixing, and shear intensity as well as the presence of solid debris, impurities, additives, and surfactants (13). These parameters affect the properties of hyphae and the physicochemical interactions between them, and between hyphae and the continuous liquid phase. Disagreement in the area of rheology in filamentous fermentations is not uncommon, as well as difficulty in comparing results and a high level of ambiguity which makes it difficult to draw conclusions and establish useful generalities (14). Among the most important reasons for these difficulties are limited use of rheometry in fermentation processes, limited information on morphology, use of different types of viscometers and techniques by different investigators studying the same type of broth, the appropriate viscometer is not always used, and, instrument operating problems. Although considerable work has been done in recent years on fungal morphology and modeling in submerged fermentations, systematic studies which involved rheometry have been very limited. The wide range of parameters that affect both morphology and rheology have prevented construction of general predictive equations and modeling. These uncertainties have their impact on process design and scale-up.

This chapter discusses the factors that affect the rheological behavior of filamentous fermentation broths, rheological measurements, rheological models, control of the rheological properties of filamentous fermentations, and instrumentation.

62.2 RHEOLOGICAL MEASUREMENTS IN FILAMENTOUS FERMENTATION BROTHS

Deindorfer and Gaden (15), Chain and Gualandi (16), and Brierly and Steel (17) were among the first who reported a significant reduction of oxygen transfer rates in *Aspergillus* and *Penicillium* cultures as the mycelial concentration increased. Deindorfer and West (18), and Richards (19) discussed the influence of broth rheology on oxygen transfer rates and power consumption and reported differences on the type of rheological behavior of various fermentation broths. Deindorfer and West (18) pointed out the need for design and scale-up correlations for non-Newtonian broths as well as correlations of rheological properties with biomass concentration and mycelial morphology. A decade later, in 1971, Taguchi (20) discussed in his review chapter the rheology of fermentation broths but it seemed that no solutions had been found in the meantime to the problems addressed by Deindorfer and West (18).

The reviews of Blanch and Bhavaraju (21), Charles (1), and Metz *et al*. (7), give fundamental information on rheology of filamentous fermentation broths and still make the basis for any work in this area. Metz *et al*. (7) presented ways of relating the biomass and morphology of fungal cultures to broth rheology and discussed the factors that affect the behavior of viscometers with mold suspensions. Bongenaar *et al*. (22) and Roels *et al*. (2) were the first who pointed out the difficulties of using conventional viscometers in measuring the rheological properties of filamentous fermentation broths and presented new impeller viscometers which would prevent settling of the hyphae in the measuring cylinder and destruction of the flocs in the annulus of the apparatus. Problems with settling of hyphae however, were not avoided (7).

Online instruments for continuous automatic measurements of rheological properties were developed and presented by Kemblowski *et al*. (23,24). The first *in situ* instruments were also developed but not used with mycelial fermentations (25,26). The online system developed by Kemblowski *et al*. (23) was then used by Olsvik in the early 1990s (11,13,27) in the most important studies ever since in the area of online rheological measurements and control in fungal fermentations. Although the system developed by Kemblowski *et al*. (24) gives empirical results, these were consistent and reproducible. Based on the original instrumentation by Kemblowski and

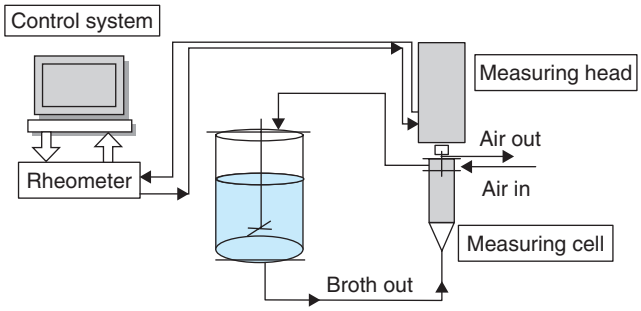

Figure 62.2. Schematic representation of an online rheometer system. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Kristiansen (12), Badino *et al*. (28) constructed a device for online rheological measurements which again produced experimental results of high accuracy that were successfully used for modeling purposes (29). Figure 62.2 gives a schematic representation of the setup for online rheological measurements.

For the study of flow properties, one has to experimentally develop the flow curve, or shear diagram, which is a plot of shear stress τ against shear rate γ in the laminar region. This information is usually obtained in a conventional laboratory viscometer, such as the concentric cylinder or a cone-and-plate viscometer. The difficulties in measuring rheological properties of a mycelial fermentation broth (and other biological suspensions) result from the fact that it is not a homogeneous liquid. Measurements with conventional viscometers are of rather limited value because of gravity settling of the suspended mycelia. In rotational rheometers, concentric cylinder or cone-and-plate instruments, additional difficulties arise from the fact that large particles may be of the same size as the measuring gap of the instrument and this causes destruction of particles in the shear field, impairing accurate measurements. In such cases useful rheological data can be generated indirectly in laminar flow by using a calibrated, scaled-down, "engineering" viscometer such as an instrumented pipe-flow viscometer or an impeller viscometer. Bongenaar *et al*. (22) were the first to propose the impeller type of viscometer, where the measuring unit consisted of a standard six-blade Rushton turbine or some other type of impeller rotating in a beaker, for rheology measurements in viscous fermentation broths. A Haake–Rotovisko rheometer was used for the measurement of impeller torque as a function of rotational speed. The same measuring technique was used by Roels *et al*. (2) and a similar approach was adopted by Kemblowski and Kristiansen (12). Engineering viscometers are used in research (11,13,27,29–32) and in the biochemical industry for flow characterization and they are essentially cup-and-bob viscometers except that the rotating inner cylinder is replaced by a mixer, such as a turbine, paddle, disc, or helical ribbon.

The basic problem with using engineering viscometers is that they do not provide a well-defined and uniform shear field and individual elements in the fluid may undergo periods of exposure to different levels of shear during measurements (33). In the case of the impeller viscometer, the evaluation of the average shear rate in the cup is based on the empirical technique originally developed by Metzner and Otto (34) for mechanically agitated vessels. The average shear rate around the impeller may be written as:

$$\gamma_{av} = kN \tag{62.1}$$

where N is the rotational speed of the impeller, and k, a constant that depends on the geometry of the system.

The viscosity, η, is by definition equal to the ratio of shear stress to shear rate and the shear-dependent viscosity can be expressed as:

$$\eta = \frac{2\pi M}{CNd^3} \tag{62.2}$$

with M, the torque on the impeller; C, a constant (shape factor) that depends on the geometry of the system; and d, the diameter of the impeller.

The average shear stress can be expressed as:

$$\tau_{av} = \frac{2\pi KM}{Cd^3} \tag{62.3}$$

In most early studies, shear rate was correlated with the rotational speed of the impeller as in Equation 62.1, or with the power input that depends on impeller speed. Recently, Sánchez Pérez *et al*. (35) proceeded to a rigorous theoretical analysis of the shear rate in stirred tank and bubble column bioreactors and showed that for both Newtonian and non-Newtonian power law fluids agitated mechanically, the average shear rate γ_{av} in the fluid is a function of the rotational speed N of the impeller, as follows:

$$\gamma_{av} = \text{constant } N, \text{ for laminar flow} \tag{62.4}$$

and

$$\gamma_{av} = \text{constant } N^{3/2}, \text{ for turbulent flow} \tag{62.5}$$

In turbulent flow and in the case of power law fluids, the constant depends on the flow behavior index and the consistency index of the power law fluid (refer to section titled "Rheological Models"). These equations were found to be in excellent agreement with the long-established empirical equation (Eq. 62.1) of Metzner and Otto (34), thus revealing a previously unknown theoretical foundation for that equation.

Sánchez Pérez *et al*. (35) extended their theoretical analysis to bubble column bioreactors for which the following

equation was given:

$$\gamma_{av} = \text{constant } U_g^{1/(n+1)} \tag{62.6}$$

where, U_g is the superficial gas velocity and n, the flow behavior index of the power law fluid. The constant in the above equation for bubble columns is a function of the flow index, the consistency index, and the density of the fluid.

A practical consideration of great importance is the selection of the appropriate type of rheometer (e.g. a rotating viscometer or a capillary flow rheometer). Flow-through cells for rheological measurements have been developed using a Rushton turbine (12,23) or a helical ribbon impeller (24,36) to get a uniform treatment of samples before measurement and to minimize aligning and settling of hyphae in the measuring cell. Rheological measurements are carried out under laminar flow conditions and in this context, the helical ribbon impeller system has been an improvement on the Rushton turbine version because the laminar shear rate is increased, thus allowing more accurate measurements (13,24). Pipeline systems have also been used for online measurements of the rheological properties of fungal fermentation broths (30,37). Of the applied systems, the flow field in an impeller system is more homogeneous and closer to what is found in the reactor itself. This should not be significant, as the rheological properties are intrinsic properties of the fluid and should not be influenced by the measuring system. This however, appears not to be the case with filamentous fermentation broths, with significant divergence in the classification of the fluids when based on their measured rheological properties. It must be remembered however, that determination of rheological properties in non-Newtonian broths are related to the measuring system and its calibration. Different methods give different results because the flow fields are different in different devices and the response of a non-Newtonian liquid depends on the flow field to which it is exposed. It is difficult therefore to compare results on rheological measurements from different publications.

In situ measurements of rheological properties during a bioprocess would be valuable, especially in terms of process control. Available literature on filamentous microorganisms is limited to the work of Wang and Fewkes (38) in which the bioreactor itself was used as a rheometer. Using a technique similar to Bongenaar's method to measure the rheological properties of a *Streptomyces niveus* culture *in situ*, they stated that effective measurements were accomplished by reducing the agitator speed to ensure "laminar" flow and then measuring the power input as a function of the agitator speed. Discussing their results, Charles (1) found the method promising but mentioned a number of parameters that did not allow for consistent measurements or for valid correlations; for example the failure to shut off the air flow during measurements, the applied narrow range of shear rate at the impeller tip, or the execution of the measurements themselves which influenced the mixing pattern and hence the reactor performance. Although instruments for *in situ* measurements are available today for commercial process applications, no reports have been published on their use in bioreactors.

Rheological characterization of filamentous fermentation broths remains a difficult task in biochemical engineering studies. Despite the industrial importance of viscous fermentations and in particular filamentous fermentations, few studies have considered the systematic characterization of filamentous broth rheology, particularly during scale-up, and its effect on process performance. Online measurements have been limited in the studies of Olsvik and coworkers (11,13,27,31) and Badino *et al*. (28). Most recent work, such as the studies by Müller *et al*. (39,40), and Pollard *et al*. (41) were based on data from off-line measurements. The applicability of the reported studies is limited by the practical difficulties encountered in rheological measurements, with no standard methodology and the use of elaborate devices.

62.3 RHEOLOGICAL MODELS

Newton's law is the simplest rheological model. It describes viscosity η as the ratio of shear stress to the applied shear rate:

$$\eta = \tau\gamma^{-1} \tag{62.7}$$

where η, viscosity (Newton per square meter per second); τ, shear stress (newton per square meter); and γ, shear rate (per second).

Viscosity in this model is defined as the relationship between the applied shear stress and the resulting movement (shear rate) of the fluid. The viscosity of a Newtonian fluid is independent of the shear rate.

Mycelial broths generally have pronounced non-Newtonian rheological characteristics showing shear-thinning or pseudoplastic behavior (15,18,42). Pseudoplastic fluids exhibit a decrease in viscosity with increasing shear rate. The viscosity of pseudoplastic fluids is therefore shear-dependent, and is referred to as apparent viscosity. A number of different mathematical models have been proposed to describe the rheology of mold suspensions. Most models describe a time-independent shear-thinning rheological behavior which can be described adequately by a two-parameter power law equation (8,30,43). Only a few researchers have reported time-dependent rheology and viscoelastic behavior for filamentous fermentations (2,18,21,22,41,44). Since it is impossible to have complete knowledge of shear

stress or shear rate relations and the elastic properties in the different flow fields for non-Newtonial fluids (7), rheological models may be regarded as an empirical fit for the experimental data (43). Reviews on rheological models have been given by Blanch and Bhavaraju (21), Metz *et al*. (7), and Charles (1). The three models most often used to describe the rheological properties of mycelial fermentation broths are the following:

62.3.1 Bingham Model

A number of authors (15,18,45–47) have described the rheological behavior of mold suspensions in terms of the so-called Bingham plastics. The Bingham model includes the often observed yield stress which has to be exceeded before the fluid will flow. The existence of yield stress is important because it determines whether there is flow in regions of low shear (47). At higher shear stresses, flow behavior is Newtonian. In mathematical terms, the Bingham model is expressed by the following equation:

$$\tau = \tau_o + \eta\,\gamma \tag{62.8}$$

where τ_o is the yield stress (newton per square meter).

62.3.2 Pseudoplastic Model

This model is very commonly used to describe the rheological behavior of filamentous fermentation broths (1,7,8,11,18,41,48–50). It is expressed by the equation:

$$\tau = K\gamma^n \tag{62.9}$$

where K is the consistency index (N s^n per square meter), and n is the power law index ($n < 1$).

This model does not include a yield stress and certain authors (18,51) modified the above equation and included the yield stress:

$$\tau = K\gamma^n + \tau_o \tag{62.10}$$

62.3.3 Casson Model

This model, originally formulated by Casson (52) for pigment-oil suspensions, has been applied successfully to a large variety of suspensions (7). Bongenaar *et al*. (22) and Roels *et al*. (2) were the first who applied the Casson model to mycelial suspensions. The mathematical expression for the model is the following:

$$\sqrt{\tau} = \sqrt{\tau_o} + K_c\sqrt{\gamma}$$

where K_c is "Casson" viscosity $(N/m^2\ s)^{1/2}$.

In many reported cases, the Casson model gave better fits to experimental data at lower shear rates than the power law model (2,7,22,41,43,53).

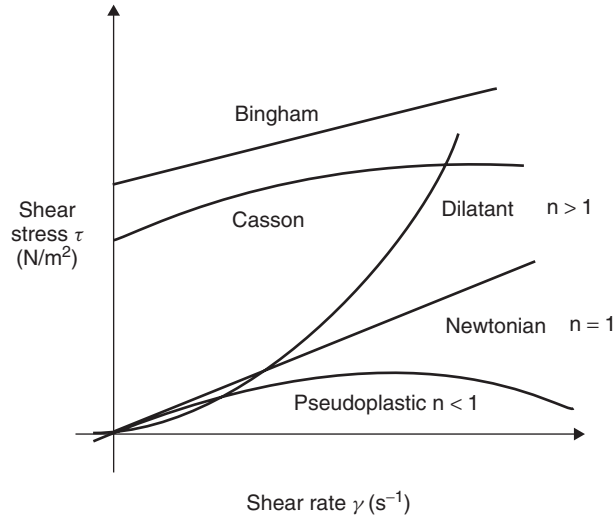

Figure 62.3. Rheological models.

The different rheological models are shown in Fig. 62.3.

Flow equations recommended for filamentous fermentation cultures based on the Bingham, Casson, or Herschel–Bulkley models include a yield stress parameter that needs to be evaluated from experimental data. However, in the case of a low shear rate, it becomes difficult to differentiate between the power law and models that contain a yield stress parameter. Scott Blair (54) demonstrated through statistical testing, that in cases in which the data ranges over only one or one and a half decades, alternative models can be used since they can describe the data equally well. Comparisons between the Casson, Herschel and Bulkley, and the power law models for the apparent viscosity of *P. chrysogenum* suspensions made by Reuss *et al*. (55), showed that in the small range of shear rates that can be measured with an impeller viscometer, discrimination between models was almost impossible. Very accurate data at low shear rates would be required to prove or disprove the existence of a true yield stress (43,56). Therefore, in the absence of such information it seems reasonable to use the power law model to describe rheological data of filamentous fermentations over a specified range of shear rates.

62.4 VISCOSITY AS AN ENGINEERING PROBLEM IN FILAMENTOUS FERMENTATIONS

The viscosity of a fluid influences the turbulence as expressed by the Reynolds number:

$$R_e = \frac{D^2 N\rho}{\eta_\alpha} \tag{62.11}$$

where R_e, is the Reynolds number; D, impeller diameter (meter); N, impeller speed (per second); ρ, broth density

(gram per liter); and η_α, shear-dependent viscosity (newton per square meter per second).

High turbulence in a fermentation system is needed to promote mass and heat transfer, and the lower the turbulence, the poorer the heat and mass transfer rates (14). As the viscosity in fungal fermentations may increase a hundredfold through the course of a batch process, the mass and heat transfer rates and the degree of mixing are adversely affected. The most critical transfer operation in aerobic fermentations is supplying enough oxygen to the microorganisms. The solubility of oxygen in water systems is very low and it can be assimilated by the organisms in a few seconds. The high viscosity of the suspension causes problems with the transfer of oxygen from the gas to the liquid phase. Coalescence of air bubbles in the reactor vessel is very pronounced and therefore, effective oxygen transfer takes place only in the impeller region. Another mass transfer problem arises from the tendency of the mycelia to agglomerate. Nutrients and oxygen must diffuse into the agglomerates and limited diffusion rates may result in a loss of productivity (57). The low DOT in the reactor may itself affect the morphology which in turn affects the rheological behavior. However, reports on the effect of oxygen on fungal morphology are contradictory (4).

The shear rates and power dissipation rates are very high near the impeller and decrease rapidly with distance from the impeller in viscous fermentation broths. Therefore, oxygen supply in the periphery of the vessel must be achieved by mixing. A higher viscosity causes longer mixing times and stagnant zones in the vessel (7). Mycelial microorganisms may thus experience severe oxygen starvation in viscous fermentation broths where the mixing times may be in the order of minutes. Apart from oxygen transport, mixing is important for sugar transport especially in continuous or fed-batch cultures operated at low sugar concentration levels in which sugar exhaustion can take place within a minute. Nutrient depletion can easily affect the process productivity. Mixing is also important for pH and temperature control in the bioreactor. In viscous fermentation broths, difficulties in mixing can cause instabilities in the control system due to a lag period between acid or alkali addition and the resulting signal from the pH electrode. Similarly, temperature control becomes difficult due to the fact that viscosity is highest in regions of low shear, where cooling coils are normally placed.

62.4.1 Oxygen Transfer Correlations ($K_L\alpha$-Correlations) in Filamentous Fermentation Broths

Oxygen transfer is a critical parameter that determines the outcome of aerobic fermentations. Methods for measurement and evaluation of the volumetric oxygen transfer coefficient K_La and the development of correlations useful for design and scale-up of industrial processes are always of great interest. Carcia-Ochoa and Gomez (58) in their most recent review give extensive information on literature and examine the oxygen transfer in microbial processes in different reactors, for example, stirred tanks and bubble columns, taking into account the effects of changes in viscosity, addition of substances that affect the hydrodynamics of the systems, and other aspects such as the consumption of oxygen by the microorganism. Owing to the importance of $K_L\alpha$ in the performance and scale-up of conventional bioreactors, the literature describing various correlations for $K_L\alpha$ in Newtonian fluids is rather extensive. However the situation is different with non-Newtonian and in particular filamentous fermentation broths.

Most published correlations for the calculation of $K_L\alpha$ in non-Newtonian fluids that incorporate a term for rheology have the following general form (59–65):

$$K_La = (P/V)^a (V_s)^\beta (\eta_a)^c \tag{62.12}$$

where K_La is the overall oxygen transfer coefficient (per hour); P, power consumption (Watt); V, volume (liter); V_s, superficial gas velocity (meter per second); η_α, shear-dependent viscosity newton per square meter per second); and a, b, and c, constants.

Correlations like Eq. 62.12, do not make use of any dimensional criterion but another type of correlation for $K_L\alpha$ is based on dimensional analysis. This approach presents certain advantages because the correlations obtained for a system can be applied for K_La estimations in other systems with different dimensions. Yagi and Yoshida (66) proposed the following correlation for the standard six-bladed turbine impeller in a vessel of 0.25-m diameter:

$$Sh^* = 0.060(R_{e_m})^{1.50}(Sc)^{0.50}(Fr)^{0.19} \times \left(\frac{\mu_{ap} v_s}{\sigma}\right)^{0.60} \left(\frac{N D_i}{v_s}\right)^{0.32} \tag{62.13}$$

where Sh^* is the modified Sherwood number $K_L\alpha\ D_i^2/D_{O_2}(-)$; R_{em}, modified Reynolds number (–); Sc, Schmidt number $\mu_{ap}/\rho D_{O_2}(-)$; Fr, Froude number $D_iN^2/g(-)$; μ_{ap}, apparent dynamic viscosity (Pascal second); V_s, superficial gas velocity $4Q/(\pi D_t^2)$ (meter per second); σ, surface tension (newton per square meter); N, impeller speed (revolutions per minute); and D_i, impeller diameter (meter).

Equation 62.13 was valid for Newtonian and non-Newtonian fluids and fitted the experimental data to a reasonable extent. Li *et al*. (67) proposed a relationship for $K_L\alpha$, the impeller speed, and apparent viscosity for fermentation broths of *Aureobasidium pullulans* in a 100-L reactor which correlated well a variety of experimental

data:

$$Sh^* = 5.40 \times 10^4 (Fr)^{0.45} \left(\frac{\mu_{ap}}{\mu_w}\right)^{-0.33} \quad (62.14)$$

where all terms are as in Eq. 62.13 and μ_w is the viscosity of water (Pascal second).

Zlokarnik (68) also applied dimensional analysis and suggested the following relationship:

$$K_L a \left(\frac{Q}{V_i}\right)^{-1} \alpha \left[\left(\frac{P_{gi}}{Q}\right)^*\right]^{\alpha^3} (Sc)^{b^3} (\sigma^*)^{c^3} (S_i^*)^{d^3} \quad (62.15)$$

where Q is the air flow rate (cubic meter per second); V_i, broth volume per impeller (cubic meter); α, constant of proportionality; P_{gi}, gassed power consumption per impeller (Watt); and S_i^*, dimensionless group.

The important characteristics of the relationship described by Eq. 62.15 are the term P_{gi} which is not found in any other proposed correlations, the dimensionless group S_i^*, which is related to the coalescence behavior of solutions, and the estimation of various terms per impeller which make possible its application in systems with different numbers of impellers and therefore, different geometries.

Badino and co-workers (29) applied four classical correlations, two of the first group that do not make use of any dimensionless criterion and two correlations based on dimensional analysis, in investigations of the influence of operating conditions on the rheological properties of *A. awamori* broths. These correlations were the proposed by Cooper *et al.* (65) and Ryu and Humphrey (66) for the first case, and the proposed by Yagi and Yoshida (67) and Zlokarnik (69) for the second case. In order to obtain accurate and reliable data, the authors developed their own methodologies for online rheological measurements and for determination of power consumption and $K_L\alpha$. Good fits were obtained for all four correlations tested with quite distinct operational conditions. The fits however were better with the more complex correlations which take into account the physical properties of the broth. The authors pointed out that good fits were obtained as a consequence of the quality and accuracy of the generated experimental values which were the result of the applied methodologies.

In their review, Garcia-Ochoa and Gomez (58) give a number of dimensionless correlations available in the literature for Newtonian and non-Newtonian fluids. In general, these can be divided into those which reflect the effect of the stirrer speed directly (N) and those which take into account the power input (P).

As in stirred tank bioreactors, many empirical equations have been proposed to estimate $K_L\alpha$ values in bubble columns and airlift reactors. Dimensional equations establish relationships between $K_L\alpha$ and superficial gas velocity, the properties of the fluid, and geometric factors of the bioreactor although the last two seem to have relatively little influence (58). The volumetric mass transfer coefficient is expressed by dimensional equations generally in the form:

$$K_L a = C \cdot V_s^a \cdot \mu_a^b \quad (62.16)$$

where C is constant, V_s superficial gas velocity, and μ_α the apparent viscosity.

In the same way as in stirred tanks, a number of dimensionless correlations have been proposed to express $K_L\alpha$ in bubble columns and airlift bioreactors (58).

Oxygen transfer rates increase with the superficial gas velocity, V_s, or with increasing impeller speed until maximum oxygen transfer rates are reached for the studied system (17,68). Increasing the gas flow rate has been reported to be less effective in increasing $K_L\alpha$ with increasing mold concentrations and viscosity due to coalescence of air bubbles and the consequent reduction in the interfacial gas–liquid area. Deindorfer and Gaden (15) noted an 85% reduction in $K_L\alpha$ as the mycelial biomass concentration increased. This was explained by the 100% increase in the viscosity of broth during fermentation. Decrease in oxygen transfer rate with increasing mycelial biomass concentration has been shown in many cases (6,7,11,15).

Despite the importance of oxygen transfer, there is considerable shortage of experimental data in filamentous fermentations. To develop reliable oxygen transfer and rheology correlations, mixing conditions and the development of morphology cannot be ignored and this represents the serious problem that results in the available data being limited. Difficulties involved in quantifying the rheological properties of fermentation broths may result in widely different values obtained from the $K_L a$ correlations (1,7,32,33) and difficulties involved in quantifying the morphology of a filamentous culture in real time make the task of developing such correlations very complicated and difficult. The use of model media in earlier studies (30,69,70), such as homogeneous polymer solutions, to simulate the flow behavior of heterogeneous fermentation broths offered no solution to the problem since none of these media could simulate well the course of $K_L\alpha$ in fungal fermentations. Moo-Young *et al*. (70) have, however, reported that the correlations obtained from model media may agree with data from fungal fermentation broths if no yield stress exists in culture broths.

62.5 VISCOSITY AS A FUNCTION OF SUSPENSION CHARACTERISTICS

During the first hours of a mycelial fermentation, viscosity is low while the rheological behavior of the broth is

Newtonian. Later during the process, viscosity increases and the rheological behavior of the broth becomes highly non-Newtonian. These are caused by the growth of the microorganism and the increase of the concentration of biomass, its morphology which develops into various forms and by changes in the composition of the broth. The latter may have a pronounced influence on the rheological characteristics of the broth in the case of production of biopolymers (e.g. extracellular polysaccharides).

62.5.1 Influence of Biomass Concentration

Several studies have shown that fermentation broths containing high concentrations of filamentous microorganisms are highly viscous and characterized by shear rate-dependent viscosities and by yield stress (1,13,20,27,48,55,71,72). Several authors have also proposed correlations between the biomass concentration and viscosity. Some of them are shown in Table 62.1.

The effects of biomass and mycelial morphology on rheology cannot be separated easily. Morphology effects were ignored in early studies and as shown in Table 62.1, the proposed correlations did not include any terms related to mycelial morphology. Roels *et al*. (2) included a general term δ for morphology, but later, the equations given by Metz *et al*. (7) included both, the effect of the length of hyphae L_e and the length of the hyphal growth unit L_{hgu} (hyphal length per branch) on the Casson model parameters τ_o and K_c. However, these equations were found to be inadequate for continuous culture experiments and that was attributed to differences in the flexibility of hyphae caused by the differences in culture conditions in batch and continuous experiments.

Tucker and Thomas (74) investigated the separate effects of biomass concentration and mycelial morphology on broth rheology of *P. chrysogenum* cultures. They proposed that rheology should be related mainly to clump properties since clumps account for almost 90% of the morphological forms in free filamentous broths. To investigate the effect of biomass concentration separately from that of morphology, a sample was divided into subsamples with biomass ranging from 10 g/L to 35 g/L and for each one the rheology and morphology were determined. The procedure allowed the evaluation of the biomass effects and rheological parameters (RP) that were correlated with biomass concentration with the equation given in Table 62.1, where RP is the rheological parameter under examination and α is the exponent on biomass concentration. The relationship was later complemented with terms related to morphological characteristics, like the roughness and compactness of the mycelial clumps of *P. chrysogenum*. Later, Tucker (76), via multiple reconstitution experiments, established that α was essentially constant during batch fermentations and a mean value was calculated.

Another correlation shown in Table 62.1 is the one proposed by Olsvik *et al*. (31) for *A. niger* in chemostat cultures operated at various dilution rates and dissolved oxygen concentrations. Image analysis studies revealed that more than 89% of the mycelia were in the form of clumps and apart from biomass concentration, clump roughness was the other determinant of rheological properties. Changes in the rheological properties of the broths were represented by the power law consistency index. Later, Olsvik and Kristiansen (77) presented a similar correlation for batch and

Biomass is denoted either as X or as $\boldsymbol{C_m}$.

fed-batch *A. niger* cultures (Table 62.1). Mohseni and Allen (56) also examined the influence of biomass concentration and mycelial morphology on the rheological properties of *Streptomyces levoris* and *A. niger* and proposed a set of correlations with the freely dispersed form using the biomass concentration, the mean dimensionless length, and the mean hyphal growth unit (Table 62.1).

Several authors have presented plots of the rheological parameters n and K versus the biomass concentration for various filamentous fermentations (30,48,72,78). Figure 62.4 gives the plot presented by Goudar *et al*. (48) of the apparent viscosity versus the shear rate of a *P. chrysogenum* fermentation broth at different biomass concentrations (5.07, 10.55, and 17.71 g/L). The flow behavior of the system (batch fermentations) was characterized at various fermentation times and was adequately described by the power law model. The apparent viscosity of the fermentation broth was significantly affected by the concentration of biomass in the reactor. Broths containing 17.71 g/L biomass had an apparent viscosity of 0.25 Pa s at a shear rate of 50 s^{-1}. Biomass concentration also affected the power law flow behavior index and the consistency index, which ranged from 0.002 Pa s^n at 0.1 g/L biomass to 6.14 Pa s^n at 17.71 g/L biomass concentration. The flow behavior index decreased from the initial value of 1 to the final value of 0.17. The relationship between K and the biomass concentration X was described by the three-parameter logistic equation shown in Table 62.1, where K_0 and K_f were the initial and final values of K, and c, a constant. Using experimental K and X values for *P. chrysogenum*, K_0, K_f, and c were estimated by nonlinear least-squares analysis. Experimental data obtained in that study were accurately described by the empirical correlation shown in Table 62.1. The general applicability of the relationship was assumed after testing with previously published rheological data on *A. awamori* and *A. niger* broths and obtaining good agreement between the experimental data and the equation-derived predictions. Ju *et al*. (72) however, reported that plotting the apparent viscosity versus biomass concentration could not be used to obtain a general relationship between the biomass concentration and viscosity since different plots could be obtained under different fermentation conditions; the differences were due to changes in morphology.

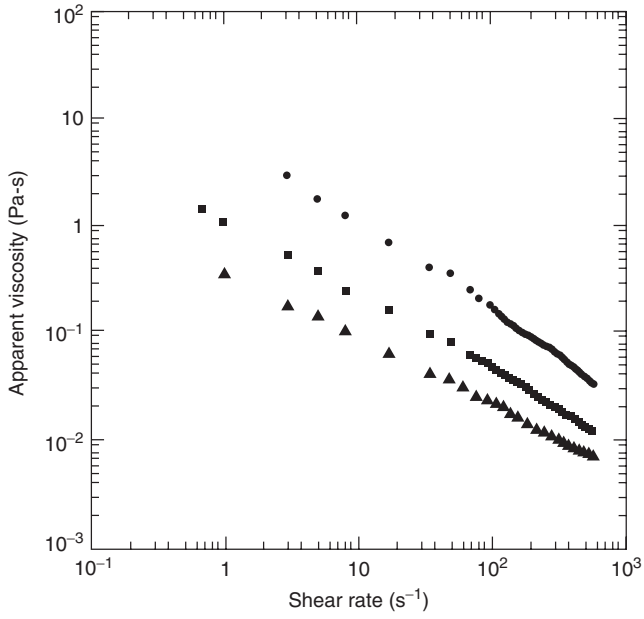

Figure 62.4. Apparent viscosity of a *Penicillium chrysogenum* broth at different biomass concentrations. ▼ 5.07 g/L, ■ 10.55 g/L, • 17.71 g/L. [From Goudar *et al*. (75)].

The relationship between the rheological behavior of *P. chrysogenum* fermentation broths and biomass concentration in batch and fed-batch cultures was studied extensively by Riley *et al*. (71). From the results of multiple reconstitution experiments, the consistency index was found to correlate strongly with the biomass concentration. The values of the exponents on the biomass concentration, α, were found to be constant throughout batch and fed-batch experiments and the use of an average α value permitted the separation of the effects of biomass and morphology. The value of the term K/C_m^a was found to be changing during fermentation and that confirmed that use of correlations to predict rheological characteristics of mycelial broths which are based solely on biomass concentration are intrinsically flawed. The proposed correlation for the consistency index K, biomass concentration, and morphology of *P. chrysogenum* in batch and fed-batch cultures is shown in Table 62.1. In that correlation, a mean maximum dimension D (micrometer) (the longest feret across the convex area of a mycelial particle) was used instead of the compactness and roughness of the aggregates. The correlation proposed by Riley *et al*. (71) was found to be successful with both batch and fed-batch fermentations. The authors pointed out that small changes in the exponent on the biomass concentration may dramatically affect any predictions.

62.5.2 Influence of Morphology

van Suijdam (79) used the terms microscopic and macroscopic morphology to refer to the external form and structure of an organism and to the nature of the microbiological system, consisting of the mycelial network and the homogeneous phase respectively. Microscopic morphology can be determined by microscopic examination, while macroscopic morphology involves determination of viscosity. In submerged culture, a large number of factors contribute to the development of any particular morphological form. Such factors include the

type and concentration of the carbon source, the levels of nitrogen and phosphate, trace minerals, dissolved oxygen and carbon dioxide tension, the pH and temperature, and the type and amount of the inoculum. Physical factors that affect mycelial morphology include the bioreactor geometry and agitation system, the degree of mixing, the viscosity of the broth, and the culture mode (batch, fed-batch or continuous). Microscopic and macroscopic morphology may respond differently to changes in some of these factors. Fungal morphology is related to metabolite production and this relationship has been discussed extensively (4). There are many fermentation cases in which particular morphological forms are associated with increased productivities. The large number of parameters that affect mycelial morphology in submerged fermentation and the interrelationships between them make it a very difficult task to deduce unequivocal general relationships between process variables, product formation, and mycelial morphology. However, the use of image analysis systems during the 1990s provided a valuable tool for characterization and quantification of complex morphologies, physiological states of mycelia, and relationships between morphology and productivity. Systematic morphological studies of fermentation broths through image analysis also made possible the development of correlations between morphological parameters and rheological behavior of the broths.

The influence of morphology on the viscosity of a culture was first reported by Deindorfer and West (18). Carilli *et al*. (80) found viscosity in a filamentous *A. niger* broth to be 3 times higher than in a broth containing large pellets. Similar observations were made by Takahashi and Yamada (73). As discussed in the previous section of rheology and biomass concentration, correlations between parameters describing the rheological properties of a broth and its biomass concentration have been suggested by many investigators. For the dispersed (free filamentous) growth forms, it has been suggested that in case the broth has power law-like behavior, the consistency index K will vary with biomass concentration, typically to the power of 0.3 to 3.3 (30,31,74,77,81,82). However, the large variability in morphological forms as well as the lack (in most reported cases) of appropriate instrumentation for performing morphological measurements resulted in comparatively fewer reports on correlations between morphological parameters and broth rheological properties. Using image analysis, Paul and Thomas (83) showed that for many strains of *P. chysogenum*, aggregated mycelia in the form of clumps may account for more than 90% (in terms of percentage projected area) of the biomass within the broth and this is also true for other fungi (4,6). It was suggested therefore, that the rheology of fungal fermentation broths should be related to clump properties rather than to morphology of the free filamentous mycelia that are dispersed in the broth in small amounts (74).

The microscopic morphology is determined by geometric descriptions of the hyphae and the mycelial aggregates. Information is extracted automatically by various image analysis techniques (84,85). Morphological parameters that have been used in rheology and morphology studies include the length and diameter of individual filaments, the branching frequency, the size and shape of aggregates (clumps and pellets), and various combinations of individual dimensions. By using image analysis techniques it is possible to differentiate quantitatively the freely dispersed from the aggregated mycelium (74,84).

Quite often, the term K/X (the consistency index divided by the biomass concentration), is used in plots against fermentation time or other variables and can be regarded as a simple description of the structure or morphology of the mycelia. By dividing K with the biomass, the effect of biomass concentration is eliminated and the term K/X represents the pure effect of the impeller speed on the system. Since morphology of filamentous microorganisms is directly affected by the impeller speed (4), morphological changes are included. The term K/X has been used by Roels *et al*. (2), Metz *et al*. (7), Olsvik and Kristiansen (27), and other investigators. Figure 62.5 shows the course of K/X as a function of fermentation time for three different impeller speeds, as presented by Olsvik and Kristiansen (27). It appears from these plots that the "morphology" parameter K/X is lowered by increasing the impeller speed.

Quantitative studies on morphology and rheology include the work of Roels *et al*. (2), Metz *et al*. (7), Fatile (81), Kim and Yoo (82), Liu and Yu (86), Olsvik *et al*. (31), Tucker and Thomas (74), Olsvik and Kristiansen (27), Olsvik (11), Tucker (76), Mohseni and Allen (56), Johansen *et al*. (9), Bocking *et al*. (87), Riley *et al*. (71), Sinha *et al*. (88,89), and Pollard *et al*. (41).

Metz *et al*. (7), based on batch fermentations, suggested the correlations shown in Table 62.1 between the Casson parameters τ_o and K_c and the morphological parameters of the freely dispersed form length of hyphae L_e, and length of hyphal growth unit L_{hgu}. These correlations gave a close fit for a number of strains in batch experiments in different bioreactors and under different mixing conditions, in different media with different pHs, but were not adequate for describing the relationship between morphology and rheology in continuous cultures. Morphological changes encountered were not quantified because of the lack of appropriate instrumentation then and the failure of the correlations to describe continuous cultures was attributed to changes in hyphal flexibility. This may be due to changes in cell wall composition, changes in the diameter of hyphae or changes in their degree of branching.

In Roels *et al*.'s (2) correlation (Table 62.1), the morphology parameter denoted as δ, was determined from

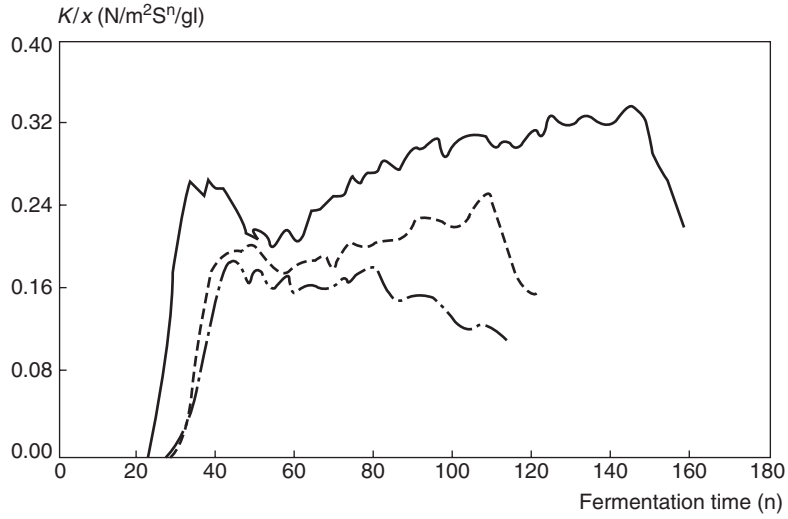

Figure 62.5. K values for three 10-l batch experiments run at different impeller speeds: (—) 300 rpm, (---) 360 rpm, (—.—) 420 rpm. [From Olsvik and Kristiansen (27).]

viscosity measurements of undiluted fermentation broth combined with mycelial dry weight determinations. van Suijdam (79) also included a general morphological parameter, which is defined as the apparent morphology factor M_F:

$$M_F = \lim_{x \to 0} (\eta/\eta_0 - 1)/x \tag{62.17}$$

The M_F factor was estimated through viscosity measurements of the broth which was diluted to biomass concentrations at which hyphal–hyphal interactions could be excluded.

Fatile (81), using the power law model, correlated the rheological properties of the fermentation broth with the biomass concentration X and the diameter of the mycelial aggregates d_p in the following equations:

$$K = 0.3X^{0.3} \times d_p^{0.2}, \tag{62.18}$$

and

$$n = 0.5X^{-0.06} \times d_p^{-0.08} \tag{62.19}$$

Apart from the diameter of the aggregates, which was measured according to Roels *et al*. (2), no other morphological parameters related to aggregated mycelia were considered.

Tucker and Thomas (74) having established the effect of biomass concentration on RP, the rheological parameter under examination, as shown in Table 62.1 and discussed in the previous section, proceeded in the estimation of the exponents β and γ, and the constant in the following correlation:

$$RP = \text{constant} \times C_m^{\alpha} \times (\text{roughness})^{\beta} \times (\text{compactness})^{\gamma} \tag{62.20}$$

Exponents β and γ, and the constant were estimated in 75-h samples of *P. chrysogenum* fermentation broths. The resulting correlations were fairly successful in predicting broth rheology for batch fermentations.

Olsvik *et al*. (31) correlated the shape of mycelial aggregates with the rheological properties and the biomass concentration for continuous fermentations of *A. niger* (Table 62.1). Changes in the roughness R of clumps were found to correspond to changes in the measured consistency index K. Later, Olsvik and Kristiansen (77) proposed a similar correlation for batch and fed-batch *A. niger* fermentations (Table 62.1). Values for the roughness parameter R were in the range of 15 to 40. As already discussed, the consistency index depends on biomass concentration. The exponent on biomass was found to vary according to the cultivation mode within the range of 0.7 to 4 as had been suggested by Metz *et al*. (7) and Allen and Robinson (30).

The studies made by Mohseni and Allen (56), Olsvik *et al*. (31), Olsvik and Kristiansen (77), Tucker and Thomas (74), and Tucker (76), established that clump morphology and in particular the roughness of clumps, is an important factor in determining broth rheology of fungal fermentations. Riley *et al*. (71) introduced error analysis and increased the amount of data to propose the correlation shown in Table 62.1. From the broader range of experimental data available and statistical analysis (F-test carried out at the 0.05 significance level), it became obvious that clump compactness and roughness were not independent

from each other and therefore they cannot be included in a single correlation. A new relationship had to be developed that took this into account, but also used morphological variables averaged over both clumped and freely dispersed forms. Having first determined the influence of the biomass concentration C_m, the authors looked for a correlation between morphology and the values of K/C_m^a. Mean values of roughness, compactness, projected area, and maximum dimension were measured for the combined, freely dispersed, and clumped forms and the following correlations were proposed:

$$K = C_m^a \times (\beta_1 \times A + \gamma_1), \tag{62.21}$$

and

$$K = C_m^a \times (\beta_2 \times D + \gamma_2) \tag{62.22}$$

where A, is the mean projected area (square micrometer); D, the mean maximum dimension (micrometer); β_1, β_2, γ_1, and γ_2, the constants of the regression lines in the plots of K/C_m^a against the mean projected area and the mean maximum dimension.

The plots of K/C_m^a against the mean projected area and the mean maximum dimension presented by Riley *et al*. are shown in Fig. 62.6. According to the data presented there, the value of K/C_m^a appeared to be nearly constant up to a mean projected area of about 5000 μm^2 or a mean maximum dimension of about 200 μm, suggesting that below a critical size this value is not a significant determinant of broth rheology. Both correlations of equations 62.21 and 62.22 were successful in describing the rheological behavior in batch and fed-batch fermentations. However, the second one that included the magnification-independent mean maximum dimension was preferable by authors. As a morphological parameter, the mean maximum dimension is more robust than other magnification-sensitive parameters and it is easy to measure even without image analysis equipment.

62.6 CONTROL OF THE RHEOLOGICAL PROPERTIES OF FILAMENTOUS FERMENTATION BROTHS

62.6.1 Influence of Operating Parameters on Broth Rheology

Different reactor configurations such as stirred tank, airlift, and loop reactors involve different flow patterns and mixing regimes which induce the development of different morphological forms and thus influence the viscosity of fermentation broths (90–92). The level of the applied agitation, either as impeller speed in stirred tank reactors, or as circulation time in loop reactors, has a great impact on the characteristics of the fermentation broth and hence, rheology. Agitation applied during fermentation creates shear forces which can affect microorganisms in several ways; for example, damage to cell structures, morphological changes, as well as variations in growth rate and product formation. The pellet size is influenced to a large extent by the level of agitation applied to the mycelial suspension. Strong agitation results in smaller and more compact pellets. The magnitude and variation of shear and other forces

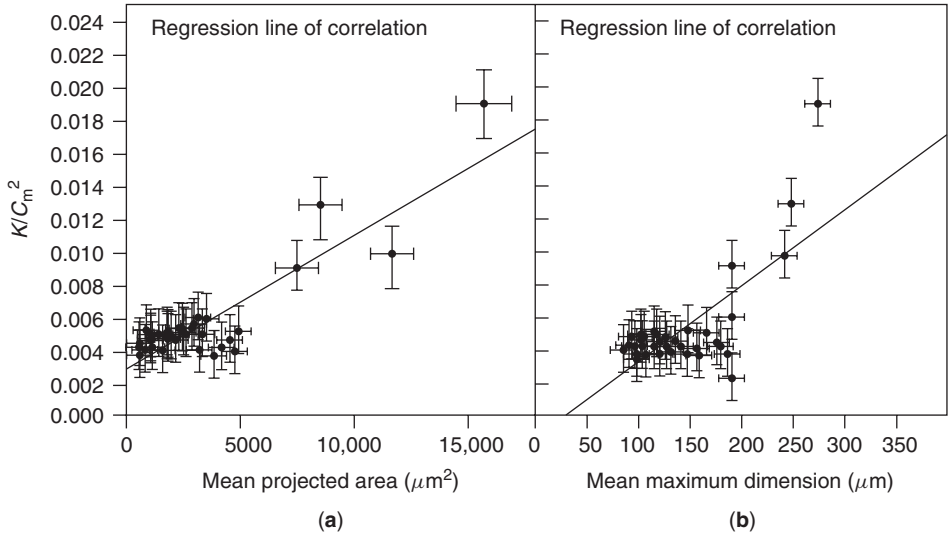

Figure 62.6. The consistency index K divided by the squared biomass concentration versus (a) the mean projected area and (b) the mean maximum dimension of clumps and freely dispersed hyphae. [From Riley *et al*. (71).]

in submerged mycelial fermentations have been discussed extensively in the literature (4).

For a stirred tank bioreactor, high viscosity and non-Newtonian behavior result in decreased homogeneity and poor process performance. Since good bulk mixing of mycelial cultures is important but difficult to achieve, it has been demonstrated earlier by several authors such as Phillips and Johnson (93), Maxon (94), and Steel and Maxon (95) that development of correlations between mixing parameters, impeller characteristics, and broth rheological properties would be valuable. Such correlations however, have been rare and the relevant literature has been very limited. The type of bioreactor employed and its mixing device influence the mixing and rheological properties of a fermentation fluid. The use of bioreactor designs other than the conventional stirred tank has received considerable interest. On the other hand, the application of alternative impeller configurations in mycelial fermentations has attracted little research interest (96); the subject has been reviewed by Charles (1) and more recently by Gibbs *et al*. (96). It is a general perception that for industrial production, increasing the mixing and the oxygen transfer rate by lowering the broth viscosity may be more profitable than trying out mechanical improvements (77).

Attempts have been made to influence the viscosity of a fermentation broth by diluting it (14,21,51,97,98). A 10% to 15% dilution of an *Endomyces* spp. broth in the work of Taguchi and Myamato (97) resulted in a significant reduction in viscosity with reducing the consistency index to a half. Similar results were presented by Sato (51) and Buckland *et al*. (98) with several actinomycete fermentation broths. For a shear-thinning broth of *Nocardia*, Buckland *et al*. (98) observed a large improvement in $K_L\alpha$ by addition of water to reduce broth viscosity. Sato achieved a 20% increase in product yield (kanamycin) by diluting the fermentation broth with water to 5% v/v. Blanch and Bhavaraju (21) suggested a strategy for dilution of viscous fermentation broths: periodic addition of water followed by removal of the same volume of broth was suggested as being more appropriate than continuous dilution. But these studies do not mention whether the observed improvements in viscosity were temporary or permanent. Olsvik and Kristiansen (27) working with *A. niger* showed that the effect of dilution on broth viscosity was only temporal and an inverse relationship between the initial broth viscosity and the duration of viscosity reduction existed.

Addition of salts is known to lower the viscosity in solutions of polyelectrolytes (99) and also to affect pellet formation in mycelial fermentations (57). Sodium salt additions have been shown to reduce significantly the viscosity in *P. chrysogenum* broths (7). Viscosity reductions mediated from the addition of various salts are always the result of morphological changes.

Other process parameters, such as the pH, dissolved oxygen and carbon dioxide tensions, and antifoam agent addition, also affect broth rheological properties and their effect is again through mediating morphological changes. The effects of these parameters on mycelial morphology are long-known and extensively discussed (4).

62.6.2 Influence of Operating Parameters on Mycelial Morphology

The development of a particular morphological form in submerged fermentation is the result of a genetic background that is influenced by a number of process parameters. These parameters can be controlled to a certain extent in most fermentation processes and include shear stress, pH, medium composition, dissolve oxygen tension, and growth rate. Both micro- and macro-morphology are affected by most operating parameters. In their classical review, Braun and Vecht-Lifshitz (57) distinguished the factors that affect mycelial aggregation in submerged culture between microbiological and physicochemical ones. The first include genetic factors, cell wall composition, size of inoculum, growth rate, nutritional factors, carbon to nitrogen ratio, and carbon dioxide tension. Physicochemical factors include the shear forces, pH, ionic strength, temperature, surface-active agents, Ca^{2+} ions, and presence of suspended solids. Some of these factors may be more important than others for mycelial aggregation. Such factors are the composition of cell wall, presence of suspended solids and surface-active agents, and divalent cations such as Ca^{2+} ions. Mycelial morphology in submerged fermentation has been the subject of a large number of studies (4). In this chapter, discussion will be limited to the most important process-engineering parameters, the influence of which has been studied with respect to both morphology and rheology.

62.6.2.1 Effects of Shear Stress. Shear induced micromorphological changes include reduced length of filaments, increased diameters, and increased branching frequencies while macromorphological changes include reduction in size of aggregates, increased compactness, and decreased roughness (92,100–103). Mycelial fragmentation is also induced by shear forces (104) and it is more intense in cases of increased vacuolation that results from aging of hyphae and limited nutrition (e.g. carbon exhaustion) (105,106). Badino *et al*. (29) observed a sharp decrease of the consistency index K in *A. awamori* cultures after exhaustion of the carbon source as a consequence of both hyphal fragmentation and autolysis. Although a large amount of information exists on the effects of shear stress

on mycelial morphology, only a few studies included rheological measurements.

Olsvik and Kristiansen (27) observed a small reduction in *A. niger* broth viscosity with increasing impeller speed in batch culture. Reduction of the process operating volume from 10 to 6l, and subsequent increase of the intensity of mixing, resulted in significant reductions of K/X. Morphology was not studied and the authors attributed these effects mainly to changes caused in the hyphal network or hyphal–hyphal interactions and to a lesser extent, to changes in the length of filaments assuming it to not be very sensitive to impeller speed changes as according to van Suijdam and Metz (101). However, both van Suijdam and Metz (101) and Smith *et al*. (102) reported a decrease in the mean length of filaments with increased power input per unit mass for a *P. chrysogenum* culture. A decrease in the mean length of hyphae with increasing impeller speed was also reported by Dion (103) for *Aspergillus* and *Penicillium* cultures. van Suijdam and Metz (101) reported that the effect of increasing shear stress on the hyphal growth unit is small and therefore they considered it to be of limited value in increasing the power input per unit mass as a means of reducing viscosity. The report by Johansen *et al*. (9) who observed that a 3-fold increase in hyphal length caused an increase in apparent viscosity by a factor of 7 is contradictory but this was independent of the stirrer speed. In experiments with *Aspergillus* and *Penicillium* and stirrer speeds ranging from 100–1100 rpm the authors noticed that the average hyphal length increase was independent of the stirrer speed.

Another important observation made by Olsvik and Kristiansen (27) was that the effect of changing the impeller speed on broth rheology was influenced by the composition of the medium. In an oxygen-limited culture, increasing the impeller speed resulted in an increased oxygen supply to the culture, an increase in the biomass concentration, and an increase in the consistency index K. In a nitrogen-limited culture, increasing the impeller speed led to a small reduction in broth viscosity.

62.6.2.2 Effects of Growth Rate. The growth rate of fungi in submerged culture is influenced by genetic factors, nutritional factors (e.g. the carbon source, nitrogen, and phosphate), growth temperature, dissolved carbon dioxide tension, culture mode, and perhaps other factors (5). The influence of the growth rate on mycelial morphology has been the subject of many studies but results are often contradictory as it appears that the same change in the growth rate can lead to either an increase or a decrease or even have no effect at all on morphological parameters, depending on strain and operating conditions (107). Growth rate was varied by varying the temperature, incorporating inhibitors in the medium, or changing the carbon source. The method used for altering the growth rate may have influenced the morphology and/or the viscosity of the broth. Therefore it is rather difficult to isolate the effects of growth rate on the rheological properties of a mycelial broth from the effects of the factors affecting the growth rate itself. Many earlier studies on the effects of the growth rate on fungal morphology in submerged cultures have not considered rheological measurements.

It appears from the literature that only Olsvik (11) and Olsvik and coworkers (13,27,31) studied the effects of growth rate on morphology and culture viscosity on mycelial cultures (*A. niger*). From continuous culture experiments, it was observed that the specific growth rate influenced the viscosity of the culture but the consistency index K was found to be very dependent on the dissolved oxygen tension (DOT) of the broth. The growth rate and the DOT were found to influence the roughness and compactness of the clumps and these influenced the consistency index. However, both K and clump roughness increased with time in one experiment and decreased in another. A close relationship between clump roughness and viscosity was suggested and also that prediction of viscosity based on the length and branching frequency of the hyphae is process-specific and not as universal as often suggested. By changing the DOT in the broth, the compactness of clumps appeared to change while no changes were observed in the hyphal geometry.

62.6.2.3 Effects of Dissolved Oxygen Tension. Industrial production of various metabolites by filamentous fungi is susceptible to regulation by the DOT of the medium. As these products are produced in most cases by differentiated cells, it is evident that the critical DOT for growth and the critical DOT for product formation are distinct parameters and in general, the latter is significantly higher (4). The described effects of DOT on mycelial morphology vary considerably among various reports, but it appears that in most cases morphology remains unaffected by changes in DOT. van Suijdam and Metz (101) varied the oxygen tension in continuous experiments with *P. chrysogenum* and observed no effect on the measured morphological parameters. Zetelaki and Vas (108) also found that morphology of *A. nidulans* remained unaffected by DOT changes while the apparent viscosity of the culture was reduced when increasing the DOT. This was attributed by the authors to changes in cell walls (thinner walls under increased DOT conditions) and thus, in hyphal flexibility that in turn constitutes macromorphological changes.

Metz *et al*. (7) suggested that low DOT in the reactor's vessel would result in changes in the mycelial properties and an increase in broth viscosity. This would result in a further drop of DOT, initiating a negative feedback loop. Similar observations were made by Olsvik and Kristiansen (13). They observed that in continuous *A. niger* fermentations, an increase in the consistency index K resulted in a

reduction of DOT which led to a further increase in K even if biomass concentration was kept constant. Also, shifts from low to high DOT in continuous cultures resulted in decreases of K while shifts from high to low DOT resulted in increased K. This large effect of DOT on K led to the need for a strict control of the DOT in continuous culture experiments. At low growth rate and DOT, a 2% change in DOT resulted in a 25% change in the consistency index.

62.6.2.4 Effects of Cell Wall Changes. As it represents the major determinant of the rheological behavior of mycelial submerged fermentations, attempts have been made to engineer the morphology of mycelial microorganisms. Such an approach could offer the desirable morphological form without altering the operating conditions in the bioreactor. Traditional screening and selection procedures would tend to select for less viscous and less highly branched cultures, as in the work of Warren *et al*. (8) with the actinomyces *Saccharopolyspora erythracea*, *Actinomadura roseorufa*, and *S. rimosus*. Bocking *et al*. (87) selected through mutagenesis highly branched strains of *A. oryzae* that appeared to give less viscous broths than the parental strains. This seems to be contradictory, but it is not the degree of branching alone that contributes to the rheological properties of the broth; the length of hyphae and the degree of interaction between them also play a role.

Another option to the approach of engineering the properties of cell walls is manipulation of the expression of genes associated with morphology. Deletion of chitin synthase genes (*chsB* and *csmA*) in *A. oryzae* by Müller and coworkers (39,40) resulted in lower values of K without affecting the overall process productivity. As the authors pointed out, the applicability of their results to other fungal strains remains to be proved. If proven, manipulation of chitin synthases can represent a simple, efficient, and inexpensive means to reduce viscosity during industrial filamentous-fungal fermentations.

62.7 EQUIPMENT USED FOR MEASURING RHEOLOGICAL PROPERTIES OF NON-NEWTONIAN BROTHS

62.7.1 Research Viscometers or Rheometers

Concentric cylinder or the cone-and-plate are the most commonly used types of viscometers in determination of rheological properties of mycelial fermentation broths, but the value of the results these instruments give is limited. The main problems associated with these viscometers are (2,22) as follows:

- particles in the suspension (e.g. pellets) may be of the same order of magnitude as the annulus of the apparatus, resulting in the destruction of pellets and other aggregated material;
- formation of layers of different densities such as less dense layers next to the surface of the measuring bodies;
- settling of particles and particle–particle interactions produce heterogeneous suspensions.

Tube viscometers with large pipe diameters handle larger volumes of samples and cope with the first of the listed problems, but the others may still be significant (2,7,22). The impeller type viscometer (2,22) provided a solution to the problems of settling and water layers next to the surfaces. According to Metz *et al*. (7), treatment of samples before measurement and the lag time between sampling, as well as the sampling timing, would all influence the results in turbine impeller rheometers. Settling of the mycelia was also observed during measurements. The disadvantages of using impeller systems, such as helical ribbon or Rushton turbine, is that they establish complex flow patterns with no straightforward calculation of shear, and results arebreak empirical.

Flow-through cells for rheological measurements have been developed using a Rushton turbine (23,24) or a helical ribbon impeller (36) and the problem of settling of hyphae was minimized. Pipeline systems have also been used for online measurements of the rheological properties of fungal fermentation broths (30,37).

Allen and Robinson (30) compared different types of viscometers with *A. niger* fermentation broths and found that measurements with Rushton-type impellers gave higher readings than helical ribbon impeller systems, concentric cylinder systems, and pipeline viscometers. The effect was more pronounced at high biomass concentrations. A problem with slip-in pipeline viscometers was shown to be that measurements were effective only at very low pipe diameters. Allen and Robinson's work was carried out using online pipeline systems, while the other tested types of viscometers were all off-line. Blakebrough *et al*. (78) also found significant differences between pipeline measurements and Rushton impeller measurements. The explanation given was that pipe-flow instruments make the measurements at the wall of the measuring device, whereas the turbine systems do so in the bulk of the fluid. Pace (3) suggested that high readings in impeller viscometers may be due to distortion of streamlines which then leads to energy dissipation.

In situ measurements of rheological properties have been reported by various investigators but the only work involving mycelial fermentations was the work carried out by Wang and Fewkes (38) who used the fermenter itself as a viscometer (discussed in the section "Rheological Measurements in Filamentous Fermentation Broths").

62.7.2 Commercial Viscometers or Rheometers

Brookfield, Rheomat, Haake, Bohlin, Rheomatrics, Paar Physica, are just a few of the manufacturers of devices used for rheological measurements on fluids. Viscometers are available in laboratory and portable forms and some are suitable for online applications (e.g. Brookfield). Major technology improvements over the past two decades have led to the development of instruments of various configurations, which can perform a variety of measurements including controlled stress and controlled strain, or yield measurements. Such devices are therefore suitable for a variety of applications with complex types of motion imposed on samples, such as oscillatory motion from which information can be extracted on the viscoelastic properties of a fluid. In studies with non-Newtonian fluids, these rheometers can be used to develop flow curves directly over a wide range of shear rates of interest to most process-engineering operations. A wide variety of viscometers or rheometers is available in the market today, from simple, easy-to-use devices to more sophisticated ones with a large choice of accessories, built-in thermometers and temperature control facilities, and software options to automate data collection, plotting and so on, and in some cases, process control.

62.8 CONCLUSION

The performance of a submerged mycelial fermentation process is greatly influenced by the rheological properties of the broth. These properties are determined mainly by the concentration of biomass and morphology. The filamentous growth form is the dominant morphological form in most processes. Long, thin, branched filaments create a network that gives very viscous fermentation broths with a pronounced non-Newtonian character. Although the influence on the rheological properties of the broth on bioreactor performance is widely recognized, systematic studies of the rheological properties and the use of rheometry in fermentation processes are still limited. Advances made in image analysis techniques in the early 1990s permitted the extraction of quantitative information on mycelial morphology and in combination with online rheological studies, resulted in a better understanding of the relationship between rheology and morphology. Comparison of rheological data from various sources is rather problematic. The main reasons for this are the different types of instruments used, the different methods applied, and the different morphological parameters evaluated or unstated differences in the morphology of a culture. Control of broth rheology has been attempted by either diluting the broth or by manipulating the morphology. Broth dilution offers only a short-term reduction of apparent viscosity and it is of little value for process control purposes. The latter approach has been extended beyond manipulation through varying process parameters, to genetic engineering of the genes associated with morphology. Further investigations with different microorganisms are needed to ensure the general validity of such attempts. A wide variety of rheometers is available in the market today but in research, measurements are still normally taken off-line introducing the added problem of sample treatment that influences measurements. These could be overcome with dynamic, online measurements which unfortunately have not found widespread application in fermentation technology. It is also possible and expected, that the area of fermentation broth rheology will be benefited in the future from advances in micro- and nano-fluidics applications. Such applications are expected to provide precise control over experimental conditions and in-depth rheological information on the studied systems (109,110).

NOMENCLATURE

a, b, and c	Constants in Eq. 62.12
C	Constant, shape factor in Eq. 62.2
C_m^a	Biomass in eqns of Table 62.1 (g/l[1])
d (or d_i, D, d_i)	Impeller diameter (m)
d_p	Diameter of mycelial aggregates (mm)
Fr	Froude number ($D_i N^2/g$)
K	Consistency index ($N/m^2 s^n$)
K_c	Casson viscosity $(N/m^2 s)^{0.5}$
k	Coefficient in Eq. 62.1
$K_L\alpha$	Overall oxygen transfer coefficient (h^{-1})
L_e	Length of hyphae (μm)
L_{hgu}	Length of hyphal growth unit (μm)
M	The torque on the impeller
M_F	Morphology factor
N	Impeller speed (s^{-1})
N	Flow behavior index
P	Power consumption (W), power input
P_{gi}	Gassed power consumption per impeller (W)
Q	Air flow rate (m^3/s)
R	Roughness of mycelial aggregates
R_e	Reynolds number
R_{em}	Modified Reynolds number
RP	Rheology parameter
Sc	Schmidt number ($\mu_{ap}/\rho D_{O_2}$)
Sh^*	Modified Sherwood number ($K_L a D_i^2/D_{O_2}$)
S_i	Dimensionless group in Eq. 62.15
U_g	Superficial gas velocity (m/s[1])
V	Volume (l)
V_i	Broth volume per impeller (m^3)
v_s	Superficial gas velocity (m/s[1])

X	Biomass (g/l^1)
γ	Shear rate (s^{-1})
γ_{av}	Average shear rate (s^{-1})
δ	Morphology factor
η	Viscosity (N m^{-2} s)
η_α	Sheardependent viscosity ($N/m^2/s^1$)
μ_{ap}, μ_α	Apparent viscosity (Pa s)
μ_w	Viscosity of water (Pa s)
ρ	Broth density (g/l^1)
σ	Surface tension (N/m^2)
τ	Shear stress (N/m^2)
τ_{av}	Average shear stress (N/m^2)
τ_0	Yield stress (N/m^2)

SAMPLING AND SAMPLE HANDLING FOR PROCESS CONTROL

Bo Mattiasson and Martin Hedström
Department of Biotechnology, Lund University, Lund, Sweden

The need for process control in biotechnology is increasing. The initiative by FDA to stimulate the use of process analytical technology (PAT) among the pharmaceutical industries has strongly contributed to the growing interest. With PAT, the main emphasis is to encourage the implementation of advanced and innovative process-monitoring solutions within pharmaceutical manufacturing (1).

Another factor that contributes to place efficient sampling and sample handling in focus is the development of industrial biotechnology where bulk chemicals are being produced using biocatalytic processes either by using whole cells or separated enzymes. In order to obtain economy in such processes, it is imperative to efficiently utilize the substrate and also to obtain high volumetric productivities. Besides these two areas, several others can be mentioned from, for example environmental monitoring and food processing. Thus, sampling and sample handling are essential operations and more interest is now being focused on developing these into efficient and convenient operations that anyone can utilize.

Sampling and sample handling can be divided into several steps:

- taking a representative sample;
- sampling under sterile conditions;
- treatment of the sample in order to prepare it for analysis.

The sampling challenges are more or less the same over time, but the sample handling has changed with the increased interest in monitoring compounds present at low concentrations.

Monitoring and control is very often used during development of a process, during optimization, and when evaluating proper media components. However, when the process comes in production, fewer analyses are often done since, at this stage, the process will be well known. However, because of the need for better documentation of industrial processes, more monitoring is introduced in the production stage also.

The present review summarizes the state of the art and also indicates some trends in the development.

Process monitoring and control involves many different steps. It is, sometimes, difficult to discuss one separate step without mentioning the others since they are often interconnected. However, focus in this review lies on sampling and sample handling.

63.1 SAMPLING

63.1.1 The Sterility Barrier

In Table 63.1 some typical examples are listed on how the sterility issue has been treated over the years.

There are essentially three main strategies—the mechanical, the chemical/physical, and the heat barrier. The mechanical barrier has been dominating and it often involves the use of membranes as sterile barriers through which a particle-free solution can be taken out for future analysis. These membranes can be applied in many

different modes, either within the bioreactor or in close proximity to the bioreactor connected via a sampling loop. Figure 63.1 illustrates some of the different membrane configuration applied.

63.1.1.1 Dialysis Membrane. The dialysis probe was initially developed to be used in medical studies where only very small samples could be taken. Thin dialysis tubing was connected to a continuous flow system and the tubing was continuously perfused with dialysis solution (10). When placed in the tissue/body cavity that was to be analyzed, small molecules were diffused through the membrane and then were transported away with the perfusion solution.

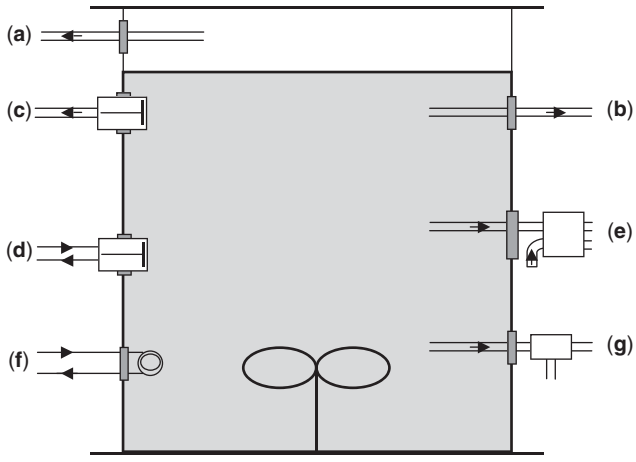

Figure 63.1. Modes of sampling from a bioreactor (a) sampling of headspace, (b) direct sampling, (c) membrane unit for sampling of particulate-free solution, (d) membrane dialysis probe with pumped-through receiving buffer, (e) sampling with an external filtering step outside the reactor, (f) dialysis, (g) sampling via filtering with collected permeate.

This latter was used for *in vivo* analysis of neurotransmitters in human brain tissue (3).

Besides being utilized in biomedical applications, the dialysis probe has also been applied in bioreactor surveillance with good success (2). Its characteristics are that the device is relatively slow, it takes very small volumes and it is only suitable for sampling low molecular weight compounds (Fig. 63.2). However, when utilizing the microdialysis equipment in an automated fashion, it is possible to gain real-time process information and hence the opportunity to eliminate the potential for contamination and error induced by the operator, as well as to reduce labor and improve yield (11).

63.1.1.2 Membrane Probe. Some different devices of membrane probes have been developed and presented. The ABC-probe seems to be the most reliable one and it is based on a mechanically robust membrane mounted in a holder that is inserted in the fermentor via one of the holes in the lid.

63.1.1.3 Membrane with High Shear Force in Order to Avoid Fouling. Sometimes it is needed to sample from very viscous media and then fouling is a serious problem.

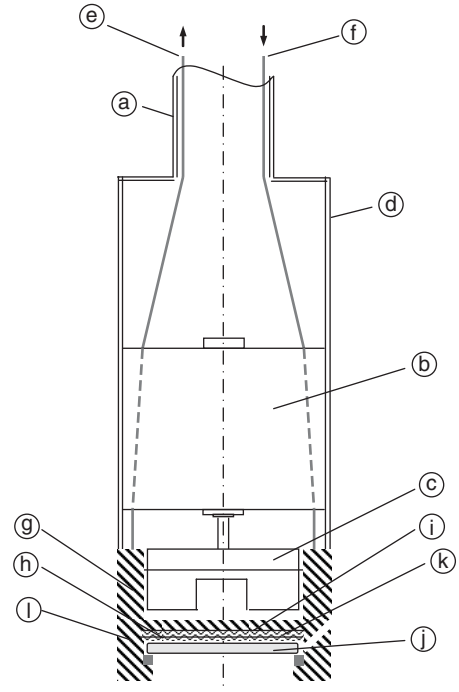

Figure 63.2. Cross-section of dialysis probe (a) stainless steel shaft, (b) autoclavable motor, (c) magnet, (d) stainless steel housing, (e, f) in- and outgoing dialysis solution, (g) polycarbonate membrane holder, (h) membrane, (i) membrane support with spiral groove, (j) magnetic stirrer bar, (k) thin Teflon washer, (l) channels for improved circulation. [Source: Reproduced with permission from Ref. 2].

Fouling will retard the passage over the membrane, thereby affecting the reproducibility of mass transfer of the analyte and later on give false values in the analysis. Fouling is a common phenomenon that appears on all membrane devices in contact with solutions containing macromolecules. The soluble molecules may form a secondary layer on the membrane thereby changing the characteristics of the membrane and thus of the sampling device. To compensate for such effects, one is trying to operate with shear forces. This could be to place the membrane probe close to the impeller where the shear forces are strong, or alternatively, may use a membrane probe with a built-in stirring that generates strong shear forces.

When biomass hydrolysate is being converted into biofuels and/or chemicals, it is important to operate with as concentrated solutions as possible, and then the risks of fouling of membrane units will be especially pronounced. The device shown in Fig. 63.2 was proven to function very well even when sampling from a hydrolysate of willow with a dry matter content of up to 15% (2).

63.1.1.4 Membrane Loop Outside the Bioreactor. When membrane filtering of fermentation broth was first used as a sampling method, the membrane was used for treating discrete samples, and later on it was applied in an external loop to the fermentor. This latter case was causing frequent sterility problems.

63.2 CHEMICAL MEANS

Beside the mechanical hindrance as sterility barrier, use of chemicals is efficient. There are at least two different methods presented:

63.2.1 The Coaxial Catheter

The coaxial catheter is based upon use of a double lumen catheter with the inner part slightly shorter than the outer part, thereby creating a small volume at the tip of the catheter. The sample is sucked into the inner catheter while an inhibiting solution is pumped in the reverse direction in the space between the inner and the outer catheter. Thus, one liquid stream with inhibitor is fed toward the tip of the coaxial catheter while the main stream is the sample being pumped in the other direction. By adjusting the flow rates such that the inhibitor stream is a fraction of that of the sampling stream, the two liquids will mix in the small volume created at the tip of the catheter, after which they are jointly sucked into the inner catheter for further treatment. The concept has been used in medical applications when continuously sucking blood from patients for on-line monitoring of blood glucose, and then heparin is fed as inhibitor of the blood-clotting process. When it comes to fermentation, it is fully possible to operate with toxic compounds that will arrest the metabolism of cells in the sample instantaneously. In one example, potassium cyanide (KCN) was successfully used to stop metabolism of yeast cells (12). An attractive feature with this concept is the instantaneous interaction between the sample containing cells and the inhibitor. There is, in some of the cases studied, a total volume at the tip of the catheter of approximately 20 μL, and when operating with a sampling rate of 1 mL/min, there will be a very short time for metabolism to continue after the sample is taken from the bulk (13). Potential leakage of inhibitor was carefully evaluated by FDA before the system was approved for continuous sampling from humans, and similar studies have been carried out on fermentation broth (13). A security system has been used in the sense that if the sampling tubing breaks, then the pump feeding the other channel will also stop.

63.2.2 Sanitation of Sampling Port

When sampling is done for off-line analysis, it is very common to use special procedures in order to secure that sterility is maintained during and after sampling. The sample is most often withdrawn from the bioreactor via a port and the zone of the port that might have been infected is sterilized in order to avoid backward infection and also to have a sterile port for the next sampling occasion (8).

63.3 PHYSICAL MEANS

63.3.1 Heat

The most common method to sterilize the sampling port is the use of steam. Such heat treatment might, of course, be automated so that a standardized procedure is connected to each sampling event. Figure 63.3 shows a steam-sterilized sample valve connected to regular fermentation equipment. The automated refrigerated sampling control unit is in close proximity to the fermentor (Fig. 63.4). Steam sterilization eliminates the often-used needle-puncturing system thereby improving the operator safety.

63.4 CHEMICAL MEANS

Strong oxidative toxic compounds are used to sterilize the sampling port. This is especially the case when automatic sampling is done and frequent intermittent assays are to be performed. Toxic chemicals can also be used as a chemical barrier to prevent infection of the bioreactor via the sampling port. In one system studied, a part of the tubing at the sampling port was intermittently filled with 5% formaldehyde, a concentration enough to kill any microbe (8). Similar effects were also obtained when using 3–6% hydrogen peroxide as sterilizing medium.

63.5 SAMPLING FROM GAS PHASE

When volatile samples are to be analyzed, it is possible to sample from the gas phase in the bioreactor. This is relatively easy to do, since one can draw out a sample from the airspace and connect the flow to a gas chromatograph (GC) or a mass spectrometer (MS).

Volatile compounds may also be dissolved in the liquid phase and then sampling can be done from there. It has been shown that, it takes quite some time for equilibration between the aqueous phase and the gas phase, so that if a process is to be followed, it might be preferable to sample from the liquid phase.

A device for such sampling was developed and applied in monitoring ethanol fermentation. The device is relatively simple in the sense that it is a Teflon tubing that is immersed in the fermentation broth and that an inert gas, usually nitrogen, is flushed inside the tubing. Volatile compounds are dissolved in the Teflon material and are diffused through the walls and are then carried away by the flushing nitrogen gas. The sample containing the compound to be analyzed is transported to a semiconductor sensor where it reacts and gives rise to a signal, the amplitude of which is proportional to the concentration of the substance in the gas phase. By using calibration solutions, it is possible to determine the actual concentration in a fermentation broth (14).

The same device was later used to quantify the amounts of hydrogen produced during anaerobic digestion of organic material (15).

Problems with such a sampling device are the potential risk of fouling. When dealing with relatively well-defined media, that is not a major problem but when it comes to anaerobic digestion of, for example, sludge from wastewater treatment plants, it was shown that the fouling became a problem already after 6 h, and the device had to be cleaned.

Another approach to monitor volatile compounds in complex media was developed for analyzing the content of volatile fatty acids in digesters treating pig manure. There, a sample was taken and the aliquot was acidified thereby pushing the volatile fatty acids to the gas phase. Analysis of the gas phase gave reliable readings (16).

63.6 REPRESENTATIVE SAMPLES

No analysis is better than the sampling preceding it. When sampling is done from bioreactors, there are obvious problems in taking representative samples. Heterogeneity in the fermentation broth may be severe and will thus cause variations in the samples and thus in the analytical results. This is something that cannot be avoided, but the effects can be minimized by proper routines.

The heterogeneity in a broth during active fermentation is well studied (17). An often used strategy is to sample in the medium close to the impeller since that is an area where mixing is intense. If the sample is not perfectly representative of the whole reactor volume, it will anyway be relatively reproducible over time, and then any error will be more or less constant over time.

For solid substrates or heterogeneous material with liquid as well as solid material, the sampling becomes even more complex (18). Then, it is possible either to take one big sample and homogenize it before analysis, or one may take several smaller samples, pool them, and then treat them as one sample.

63.7 REPRODUCIBILITY IN SAMPLING

It is important to get reproducibility in the sampling process, such that if no reaction is on-going in the sample, the analytical result from samples taken at different occasions should be constant. This would be expected if no reaction takes place and no physical obstacles appear. However, heterogeneity in a bioreactor due to improper mixing might give misleading results with scattered data over time (19). Still another possible disturbance might lead to successive decrease in the analytical result, even if the concentration is constant. Very often, fouling of membranes involved in the sampling will cause a decreased mass-transport over the membrane thereby resulting in nonreproducibility in the sampling.

As discussed above concerning membrane-based sampling devices, it is important to operate with tangential flow in order not to allow fouling layer to be formed.

Still another potential problem is that, on continuous processing, there might be risks of microbial on-growth of the inner surface of the sampling device, and when a subsequent sample is transported through the device, metabolism might occur and then change to analytical read out. Such a case was reported on when yeast cells were growing as a dense biofilm inside the sampling device used for monitoring a cultivation of Baker's yeast (20).

The most common error is by far heterogeneity in the reaction medium, and that is also the most difficult problem to deal with.

63.8 SAMPLE HANDLING

Any sample taken from a complex medium needs some kind of treatment before being analyzed. Often, additions are used in order to arrest any metabolism going on in the sample. When particulate matter present will disturb the readings, then filtration or centrifugation is carried out, and when cells are present and intracellular compounds are to be analyzed, cell breakage must take place and the cell debris being removed.

63.8.1 Discrete Sample Handling

All unit operations, as described above, can be carried out on discrete samples. Time consumption is often too high and the reproducibility in the assays may be strongly influenced by many manual handling steps.

63.8.2 On-Line Handling

When a sample has left the reactor, a range of possibilities to handle it is available. Very much depends on the character of the sample and on the nature of the analyte to be quantified. In Fig. 63.5 is schematically illustrated the treatment needed for a sample taken from a fermentation and in which one is interested to analyze an intracellular protein in the microorganism. As seen from the figure, there is a whole sequence of activities that need to take place, and each of them will represent inaccuracy in handling and thus affecting the accuracy in the final reading of the analytical outcome. Provided, this could be done automatically, it would be possible to reduce the inaccuracies caused by the human factor, and one could expect a far better accuracy and reproducibility. That it is advantageous to eliminate many manual steps and to try to introduce automation was clearly shown for ELISAs. While the standard variation of the manual analyses was in the order of $\pm 15\%$ for the inexperienced person and $\pm 7\%$ for a skilled laboratory technician, it was possible to carry out the same analyses in an automated fashion with a standard variation of $\pm$ 1.5–2% (21).

63.8.3 Flow Injection as a Tool in Sample Handling

When flow injection analysis (FIA) was first introduced, it was claimed to have a great advantage in the sense that additions of an aliquot of liquid could be done very accurately and be reproducible. Later on, it was shown to be suitable for on-line dilution in a reproducible way (22) and for dialysis, and even for incubation for a fixed period of time before the sample was read could be carried out using the FIA-approach. Different unit operations can be integrated into a continuous flow system, thereby simplifying sample handling even if it consists of many different steps. In Table 63.2 are listed some of the different operations that have been reported to be integrated in the continuous flow system.

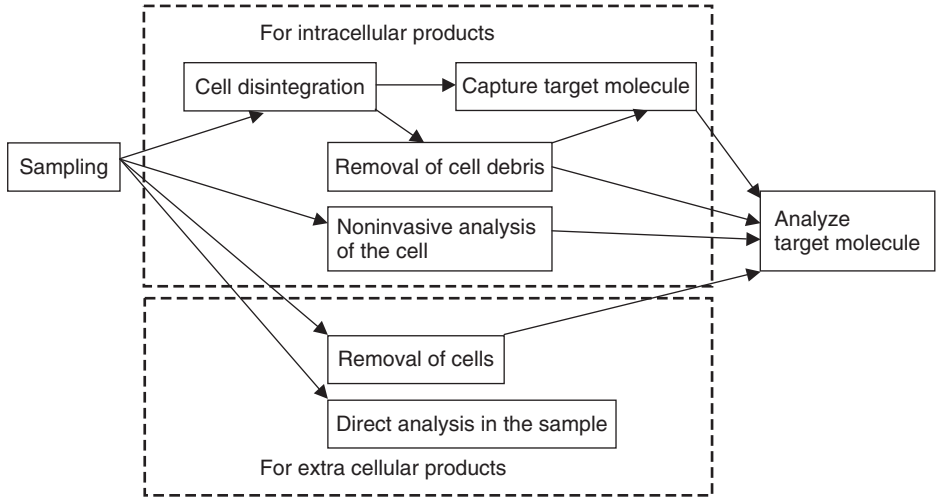

Figure 63.5. Schematic presentation of different options for analysis after sampling has been done.

TABLE 63.2. Unit operations in Sample Handling Integrated with Flow-Injection Systems

Unit Operation	Analysis	References
Dialysis	Penicillin V	23
Dilution	Many different	22

Cell homogenization	β-Galactosidease	28
	Plasmid DNA	29,30
Permeabilization	Plasmid DNA, alkaline phosphatase, intracellular target protein	31

63.8.4 Substances Present at High Concentrations: Dilution

When industrial processes are monitored, there may be situations when the target molecule is present in far too high concentrations to allow accurate assay. Then dilution is necessary, and that can easily be achieved using a flow-injection system (22).

The need for dilution is especially obvious when the assay falls far outside a linear range of a standard curve. This may be the case for immunoassays, since often such assays are set up to monitor low concentrations of substances (21). As long as it is the target molecule, one can expect high concentrations and needs for dilution. However, for impurities, especially impurities in pharmaceutical products, there is a need for enrichment.

63.8.5 Substances Present in Very Low Concentrations: Enrichment

When a substance is present in very low concentrations, it might be advantageous to enrich it on an adsorbent before analysis. Such adsorbents might be selective and then the substance is released by a less selective elution, or in some cases a nonselective adsorbent and a specific elution is used. Still, there might be a nonselective adsorbent and a nonselective elution and then a selective analysis. Some examples are given in Table 63.3. Examples on substances that are analyzed using enrichment strategies are listed in Table 63.4.

63.8.6 Cell-Free Solutions

The membrane units described above for sampling inside a fermentor, or from an external loop are all suitable to create cell-free solutions that can be used for further analysis.

63.8.7 Special Arrangements for Intracellular Substances

When intracellular substances are to be quantified, the cell walls need to be destroyed in order to release the intracellular material. There are many options on how to carry out such cell destruction. A crucial point is, of course, not to destroy the intracellular compounds that are of interest to analyze. When choosing suitable strategy for cell disruption, one needs to consider possible effects of addition of chemicals on the subsequent analysis.

In one example, a fermentation broth containing cells of *E. coli* was treated with lysozyme in order to enzymatically modify the cell wall before the pretreated cells were exposed to an ultrasound treatment as shown in Fig. 63.6

TABLE 63.3. Adsorbents Used for Enrichment of Analyte

Drugs

(28). All this was carried out in an integrated flow system and the results were analyzed in an immunochemical binding assay. A difficult task in such a situation is to know when the cell breakage is sufficient, since if the treatment is too brutal, then the proteins of interest to analyze will be denatured. On the other hand, if the destruction of cell walls is not complete, then a lower value of the intracellular target will be observed in the subsequent assay.

An interesting new methodology for on-line monitoring of intracellular products involves laser-induced disruption of the microbial cells. This technique, even not fully explored yet, has proven both rapid and efficient as well as clean for use as sample preparation in bioanalytical detection systems (36).

63.9 NONINVASIVE MONITORING METHODS

A dream for any biotechnologist would be to be able to follow the bioprocess without having to take samples and to carry out a range of analytical procedures. Novel sensing devices are being developed and some of them are possible to use *in situ* in the reactor and to read data that later on can be processed to a form that will give information about the physiological statues of the cells studied. Such methods are, for example, near-infrared spectroscopy (NIR), fluorescence spectroscopy, and to some extent NMR.

These methods do not yet have resolution enough to make it possible to register many specific metabolites. However, some useful information can certainly be achieved,

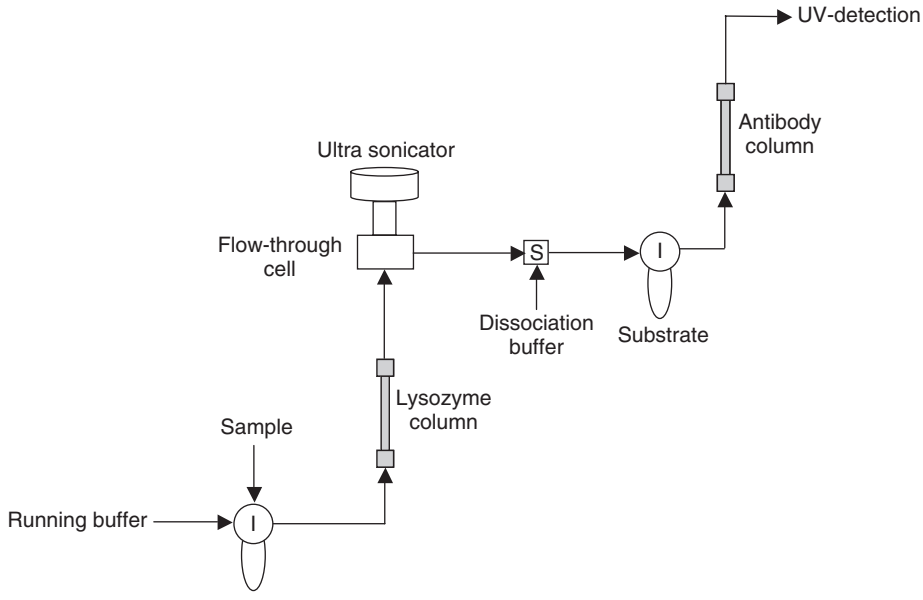

Figure 63.6. Schematic setup of the analytical system. I, injectors; S, switch valve [Source: Reproduced with permission from Ref. 28].

and the forecast is that such nonspecific analytical procedures combined with powerful computer programs will grow in importance in the future.

63.10 INTEGRATED PROCESSES

Flow-injection systems offer many attractive features. After sampling from the bioreactor has taken place, it is easy to retract well-refined and reproducible volumes of the aliquot for further processing. Moreover, the use of sample loops with fixed volumes could reduce sample volume inaccuracies in this step to a minimum (37).

A range of unit operations can be combined, and that makes it possible to build almost any kind of sample-handling procedure. Dialysis and/or dilution can be made in reproducible manners. A range of reports are available on these unit operations and it is obvious that they operate to satisfaction in most cases (23,28). Figure 63.7 illustrates one method for sampling from a bioreactor using a sample carousel. The samples collected are refrigerated at 4°C for later analysis.

When it comes to separation of macromolecules from a heterogeneous sample, it may be a little more problematic. Here dialysis will not do. If cells and cell debris are present, then an adsorption step might be useful for capturing the target molecules while the particulate matter is washed away. This can be done by using expanded bed adsorbents (38), or by using supermacroporous adsorbents connected in-line with the analysis system (39). By using selective adsorbents, it may even be possible to enrich the target molecule while most of the other molecules are removed.

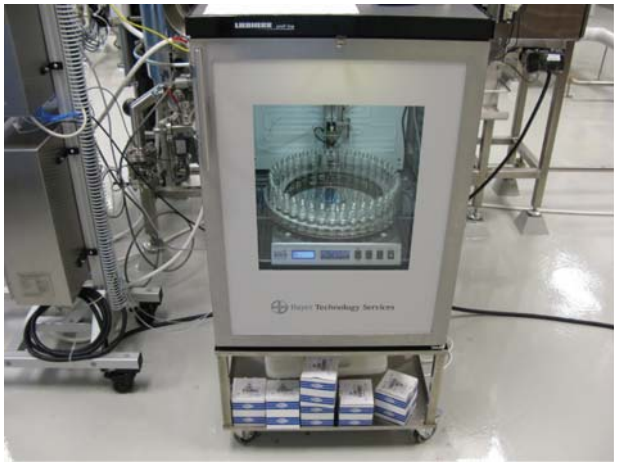

Figure 63.7. Automatic refrigerated aseptic sampling unit (BaychroMAT®, Bayer Technology Services) [Source: Courtesy of Golden LEAF Biomanufacturing Training and Education Center (BTEC), North Carolina State University, Raleigh, NC USA]. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Still, other possibilities in this connection would be to use magnetic trapment, that is, to have adsorbents with certain functionalities to trap the target molecule and at the same time have magnetic material in the adsorbent such that it will be possible to add the adsorbent to the sample and after binding has taken place, isolate the magnetic particles with their bound target molecules.

When it comes to monitoring intracellular compounds, very little on-line experience exists. However, a few reports in literature clearly show the possibility. Breaking the cells is the crucial step and depending on the type of cells different strategies may be used. When dealing with *E. coli*, it turned out to be efficient to let the organisms pass through a column with immobilized lysozyme and a subsequent step with ultrasound (39). When establishing this unit operation, it was a bit problematic to properly optimize the step. When is the optimum number of cells opened to release their content to the environment, without the effect that the target molecules get denatured by the ultrasound treatment? One has to make some trials and just decide the conditions yielding the best activity.

When nucleic acids are to be quantified, alkali treatment combined with adsorption chromatography turned out to be successful. This was exploited when monitoring the content of plasmids during a cultivation (29,30).

A different strategy based on sample handling in a flow-injection system involves the use of permeabilization of the cell walls and then monitoring of intracellular activities when substrate is supplied from outside. This was utilized in a model study when quantifying plasmids carrying the gene for alkaline phosphatase as well as cell density in the samples were studied. It was found that, there was a good correlation between the plasmid copy number and the monitored activity of the indicator enzyme. When one more enzyme was cloned into the plasmid, the expression of the target gene could be monitored (31).

There is always a risk that fouling and other disturbances might ruin the analyses. Calibration of the system is needed, preferably, all the way from the sampling point to the detector. In most cases, only some of the separation steps are evaluated, but not the whole system. However, when using a coaxial catheter (Fig. 63.8) for sampling, it turned out to be practically feasible to add a calibration solution to the system at the sampling point and then let it pass through all the different unit operations before being analyzed (40).

Besides flow-injection analysis, sequential injection analysis seems very attractive and useful. However, this later technique is of more recent date and not so many applications have been presented. The inventor of this technology is the same as of flow-injection analysis. Dr Ruzicka and his group have shown it possible to handle cells and to carry out a range of different unit operation in the sequential injection analysis.

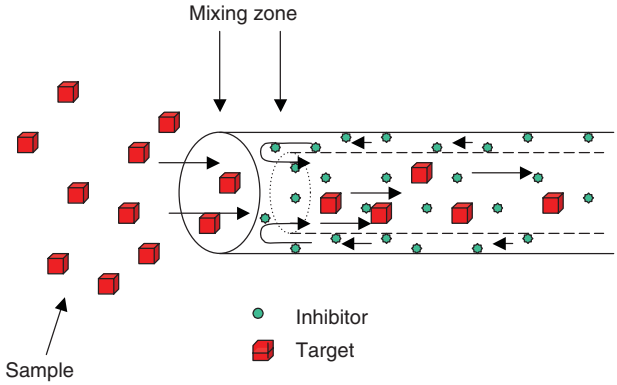

Figure 63.8. Schematic operation of a coaxial catheter unit during the *in situ* sampling step from a bioreactor [Source: Reproduced with permission from Ref. 13]. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

63.11 COMMERCIAL SYSTEMS

With an increasing demand for time-efficient ways of extracting specific information from each step in the process, the development of techniques for direct sampling in bioprocess situations has shifted from being a typical academic discipline to become a factual concern to the industry. Typically, pharmaceutical production is performed by batch processing with concomitant off-line analysis of collected samples from the different steps throughout the purification process. However, rising public demands for shortened time-to-market for the development and production of critical drugs and accessibility to more affordable medicines have put strains on both regulatory agencies and manufacturers to change this situation.

There are, at present, only few methods offered for direct and noninvasive sampling from a bioreactor. Some systems have, however, been commercialized and are today used as tools in industrial large-scale bioproduction**:**

63.12 CONCLUSION

Much effort has been put into developing biotechnological processes, both with regard to upstream and downstream. There is, however, a lack of suitable analytical information concerning on-line monitoring of the processes. This is, especially, clear in the downstream area.

When more efficient and better controlled bioprocesses are to be set up, improved process control is a must. To reach that, one must have better analytical systems and well-functioning sampling and sample-handling routines. It seems that the industry is starting to realize the problem, and the potential benefits from improving process monitoring and control, and therefore, one can expect that focus for the development will shift from the academic laboratories toward industrial units. With such a development, it is expected that this part of analytical activities will become more in focus, thereby attracting more interest, and therefore develop faster.

The technology presented in this review forms a sound basis for future development, but what is required now is that the analytical systems are implemented on real industrial processes, thereby making it possible to get figures on the impact of applying suitable sampling, sample handling, and subsequent analysis and control.

SOLID STATE FERMENTATION, KINETICS

David A. Mitchell

Robert D. Tanner
Vanderbilt University, Nashville, Tennessee

64.1 INTRODUCTION

Solid-state fermentation (SSF) involves the growth of microorganisms on moist solid substrates in the absence of free water. The absence of free water makes the system quite different from submerged liquid fermentations and makes SSF superior for the production of some products. However, compared with submerged liquid fermentation, relatively little is known about how to design and operate bioreactors for large-scale SSF processes.

Despite this, there are commercially successful large-scale SSF processes for the production of soy sauce koji and other traditional fermented foods, citric and gluconic acids, and fungal enzymes such as cellulases, amylases, lipases, and pectinases (1,2). In addition, fungal spores have been produced by SSF for use in steroid transformations and as inocula for production of blue-vein cheeses (2). Composting is another SSF application that is widely practiced, although composting is different from other SSF processes, because self-heating of the fermenting substrate is desired in composting processes, whereas avoidance of overheating is a key problem in most SSF processes.

In addition to these commercial processes, over the last 20 years there has been a growing interest in other SSF applications (2), including the following:

- Upgrading of solid wastes from agriculture and food processing for use as fermented animal feeds. In some cases the microorganism is used to enrich the protein content; in other cases it is used to degrade toxic substances in the waste.
- Production of fungal spores for use as mycopesticides. SSF is superior for the production of fungal spores because most fungi do not sporulate well in liquid culture, and even when they do, spores produced in SSF tend to be more robust.
- Production of other enzymes such as dehairing enzymes, fungal rennets, beta-glucanases and xylanases.
- Biopulping of woodchips during the production of paper.
- Production of various other products such as gibberellic acid, aroma and flavor compounds, antibiotics, and ethanol.

Unlike the situation with submerged liquid fermentations, there is no systematic framework guiding the design and operation of large-scale bioreactors for SSF. As a result, there has been relatively little success in developing successful large-scale processes for these newer SSF products, although large-scale bioreactors have been used to make

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

soy sauce koji. Intermediate-scale processes can be carried out using tray fermentations, but such operations are quite labor intensive. Mathematical models of bioreactor operation will be key tools in the development of strategies for the design and operation of large-scale SSF bioreactors. This chapter summarizes the current state of development of modeling of SSF processes.

64.2 AIMS OF THIS CHAPTER

This chapter addresses the importance, to the development of large-scale SSF technology, of understanding and modeling microbial growth kinetics and transport phenomena, which combine to determine the overall performance of a solid-state bioreactor. Transport phenomena are of special importance in SSF due to the unavoidable heterogeneity of SSF systems. Good reactor performance will be achieved only through an understanding of these transport phenomena and how they interact with the microbial growth kinetics. Mathematical models represent a convenient, concise, and powerful way of describing these phenomena and their interactions and provide a sound foundation for process development, control, and optimization. They can also guide us in learning where the problems are and how to attack them.

The main message of this chapter is that modeling of phenomena in SSF and of the performance of SSF bioreactors has not yet progressed to a stage where it can be usefully applied to industrial applications. In fact, it was only in 1990 that the first model was proposed for SSF bioreactor operation (3). Although advances have been made since then, currently we still do not have mechanistic models of SSF that are able to make accurate predictions based fully on independently determined parameter values. To date the focus has been on appropriate model structures. Relatively little attention has been given to parameter estimation, with many parameters being borrowed from other systems, systems that often involve different substrates, organisms, and cultivation systems. As a result, none of the models has been properly validated against experimental data, and although the models are now being used to predict improved operating conditions, they have not yet been used to improve operation of actual bioreactors. In most cases some of the model parameters have been estimated by adjusting them to enable the model to fit the experimental data. Furthermore, although the ultimate aim of SSF processes is to produce useful products industrially, to date models have focused on growth. In fact, in some cases the main aim has been to predict temperatures rather than growth itself.

The aim of this chapter is to draw together the basic principles from the work that has been done so far, to show the general concepts that underpin all models, to identify the features that will make models most useful for application in industrial processes, and thereby to provide a foundation for continued progress in the modeling of SSF.

64.3 ORGANIZATION AND SCOPE

Filamentous fungi are the most important group of microorganisms used in SSF, and most processes are aerobic. Most of the work discussed in this chapter addresses this type of system, although other systems are mentioned as appropriate.

The chapter begins by describing the biological and transport phenomena occurring in an SSF bioreactor and identifying the various phenomena that can potentially limit the kinetic performance of the bioreactor:

- Microbial growth phenomena
- Local transport phenomena (occurring at the level of a single particle)
- Bulk transport phenomena (occurring at the level of the whole bioreactor)

Current models of SSF address the influence of either local or bulk transport phenomena on growth and are therefore labeled as microscopic or macroscopic models. The general aims and usefulness of these two types of models are discussed. The mathematical expressions appropriate for describing the three types of phenomena that may be incorporated into these models are discussed in turn.

Readers interested in modeling of SSF processes are urged to consult the original references because no attempt has been made to present the complete models of individual workers. The original chapters do that better than we could hope to do. Rather we have organized this chapter around the ways in which the various kinetic and transport phenomena have been handled. Therefore, where we present equations, these have been separated from the author's discussion of their underlying assumptions and the notation and units they have used.

64.4 DESCRIPTION OF KEY FEATURES OF SOLID-STATE FERMENTATION

Growth in an SSF bioreactor results from and is influenced by processes operating at different scales (Fig. 64.1): microbial processes and local and bulk transport processes. Figure 64.1 also highlights some of the complex interactions between these phenomena during SSF. This chapter addresses the approaches that have been made to modeling the various phenomena shown in Figure 64.1, and the interactions between the various phenomena. Thermodynamic phenomena, such as the ability of solid substrates to absorb

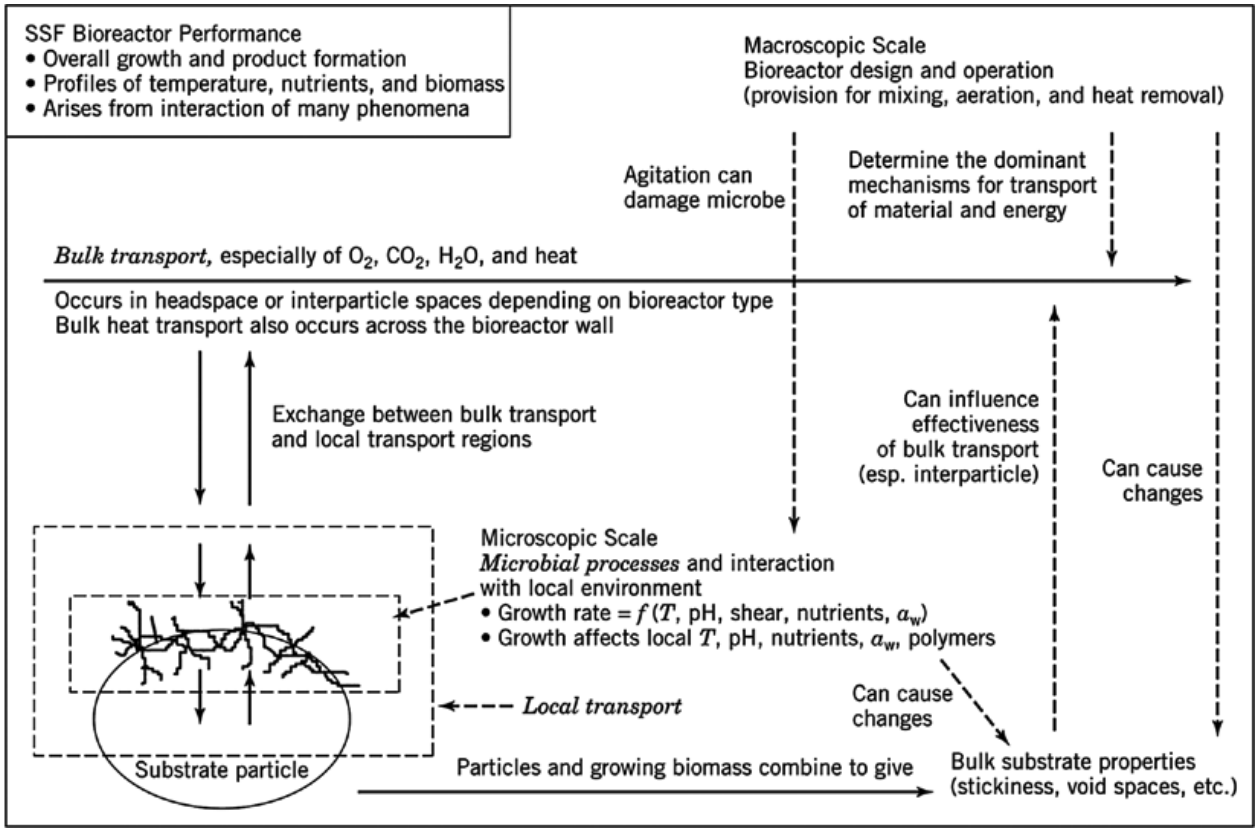

Figure 64.1. An overview of the microscopic and macroscopic processes that combine to determine the overall performance of an SSF bioreactor. This diagram describes transport processes in general terms and does not identify all the individual mass and heat transfer processes occurring. Although the diagram represents an SSF bioreactor, it is not drawn to scale. The nature and extent of the local and bulk transport regions depend on the particular bioreactor and how it is operated.

heat and the ability of gases to carry water vapor, also affect the overall bioreactor performance; however, these phenomena are not addressed in this chapter.

In developing a mathematical model, it is important to identify the processes occurring before attempting to describe them mathematically. This focuses attention on the processes that are potentially rate limiting. An understanding of the rate-limiting processes facilitates development of strategies to overcome the limitation, although SSF processes can be difficult to optimize because the limiting step might be different under different conditions, and at different stages of an SSF process the growth rate may be limited by different phenomena. Therefore this section provides a qualitative description of our current understanding of the phenomena occurring in SSF.

64.4.1 The Physical Nature Of Solid-State Fermentation Systems

From a macroscopic viewpoint, up to four subsystems are apparent (Fig. 64.2), depending on the bioreactor type:

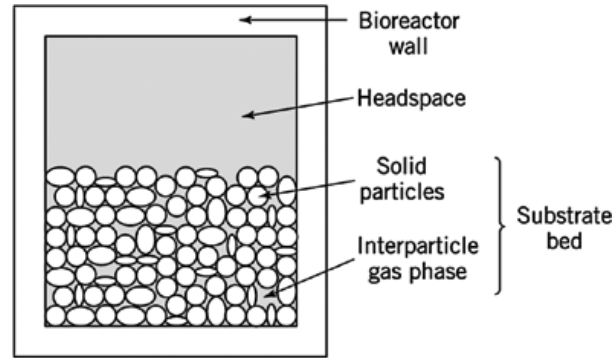

Figure 64.2. Subsystems within a solid-state fermentation bioreactor.

the material from which the bioreactor is constructed, a headspace containing gases, the solid particles themselves, and the interparticle gas phase entrapped between the solid particles. It is often appropriate to think of the solid particles and interparticle gas as a pseudohomogeneous "substrate bed."

From a microscopic perspective the system is considered in greater detail. The description focuses on the region near an individual particle and can include (Fig. 64.3) the following:

- The biomass, the majority of which is concentrated as a layer at the particle surface. Part of the fungal mycelium is immersed in the liquid film at the surface, but many hyphae extend into the gaseous region. These aerial hyphae may support films or droplets of water. Other hyphae may penetrate into the substrate particle. In contrast, yeasts and bacteria form a compact moist layer on the particle surface.
- The solid matrix, which provides the physical support for the liquid and biomass phases, and which may or may not be degraded during the fermentation.
- A liquid phase consisting of a stagnant liquid film at the substrate surface and the moisture inside the particle. This phase may be continuous, depending on the internal structure of the substrate particle.
- A gaseous phase. Although this gas phase is continuous, it may be conceived as comprising up to three regions. First, the aerial hyphae of the biomass are surrounded by regions of stagnant gas, and there will be a stagnant gas film adjacent to the liquid film. Second, there may be a stagnant gas region above the biomass region (i.e., part of the interparticle space). Third, there

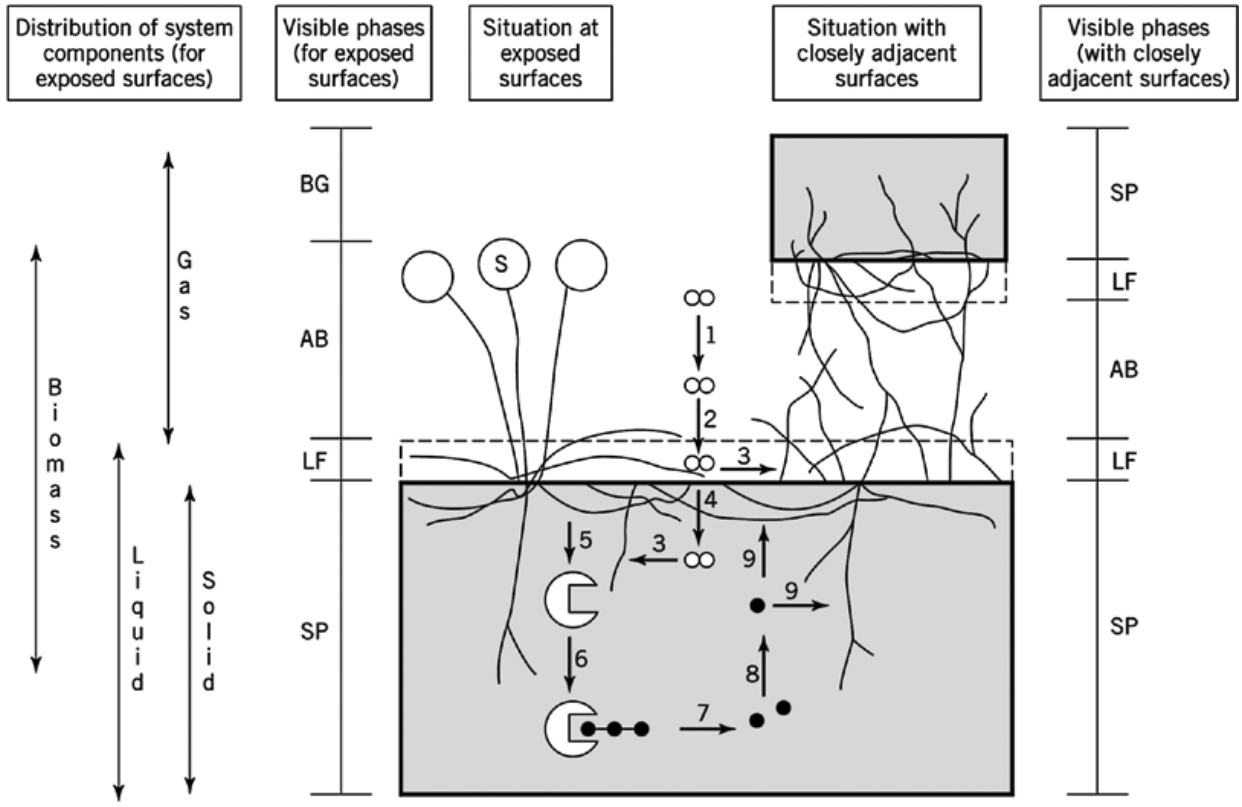

Figure 64.3. Structure of SSF systems at the microscopic scale and local mass transport processes. The example is for growth of a filamentous fungus, such as *Rhizopus* sp., on a starchy substrate. The diagram represents a cross-sectional view near the surfaces of the substrate particles and indicates the difference between substrate particles exposed to the bulk gas phase and substrate particles that are packed closely together. Simplifications, such as the absence of penetrative hyphae, and the liquid film as the only site of O_2 uptake, have been used in modeling studies. ∞, oxygen; •, glucose; •—•—•, starch; S, sporangium; SP, substrate particle; LF, liquid film; AB, aerial biomass; BG, bulk gas. The processes occurring are 1, bulk transport of oxygen; 2, diffusion of O_2 through stagnant gas regions and diffusion across the gas–liquid interface; 3, uptake of oxygen by hyphae; 4, diffusion of oxygen through the liquid phase of the substrate; 5, release of glucoamylase from the hyphae; 6, diffusion of glucoamylase through the solid substrate particle; 7, hydrolysis of starch by the glucoamylase; 8, diffusion of the released glucose through the solid substrate particle; 9, uptake of glucose by the hyphae.

may be a mobile region in which there is bulk flow. The locations and extents of the stagnant and mobile gas regions will depend on whether the substrate bed is agitated and how it is aerated. For example, in static packed beds the interparticle spaces are filled with a network of hyphae, but there is still bulk gas flow through parts of this region. On the other hand, in tray bioreactors, the gas phase within the substrate bed is relatively stagnant, although there may be some free convection due to thermal gradients.

64.4.2 The Processes Occurring During Solid-State Fermentation

Aufeuvre and Raimbault (4) described the changes in morphology during growth of the filamentous fungus *Aspergillus niger* in a packed bed bioreactor, on a granular substrate prepared from cassava flour. Initially, the spores used as inoculum are spread across the substrate surface. During the germination period of about 8 h, the spores swell and then extend germ tubes across the substrate surface. These germ tubes extend for up to 50 μm before branching begins. Branching of these germ tubes then rapidly leads to a loose covering of hyphae across the whole surface. As branching continues, the hyphal density increases, and it is soon impossible to distinguish individual mycelia. The network of hyphae increases in thickness, so that many hyphae are not in contact with the substrate surface. Some hyphae form together into multihyphal filaments, which can extend up to 80 μm above the substrate surface. These filaments form bridges between the substrate granules and bind the whole bed of substrate particles together into a single compact mass.

This description addresses only the features of the growth process that can be seen with a microscope. Many less obvious processes are occurring and influencing growth (Fig. 64.3). The growth activities of the microbe are determined by the local environment experienced by the microbe, especially the local temperature, pH, water activity (a_w), oxygen concentration, and nutrient concentrations. In turn, growth processes also affect the local environment, for example, hydrolytic enzymes are secreted, carbon and nitrogen substrates are absorbed into the mycelium, oxygen is consumed, and various products are excreted. In addition, waste metabolic heat is released by the microorganism. Therefore the temperature, pH, water activity, and oxygen and nutrient concentrations in the local environment are affected by the microorganism. This induces the transport processes, which tend to equilibrate chemical potential and temperature throughout a material. Within solid particles and within stagnant gas regions, mass transfer is limited to diffusion and the exchange of gases (O_2, CO_2, and water vapor) at gas–liquid interfaces, and heat transfer is limited to conduction, free-convection, and evaporation of water at the gas–liquid interface. These dissipative processes can be relatively slow compared with the rate of the microbial processes, leading to the establishment of local concentration and temperature gradients around the microbe.

The purpose of a bioreactor is to maintain an optimal local environment for the desired microbial activity, within the limits of physical and economical constraints. In SSF the ability to control the local environment is largely limited to manipulating either the bulk gas flow or agitation of the substrate, or both, providing oxygen for aerobic processes, removing carbon dioxide and evaporated water, and removing heat. Almost nothing can be done during the fermentation to prevent nutrient concentration gradients within individual substrate particles, because it is not possible to have bulk mixing below the scale of the substrate particles. This is an intrinsic consequence of the physical form of SSF systems.

Given that control of the environment is achieved by manipulating the bulk phases, the rate of removal of heat and the rate of supply of oxygen can be maximized by minimizing gradients within the bulk gas phase and minimizing the thickness of the stagnant gas film that separates the bulk gas phase from the local environment. Different reactor types enable this to be achieved to different extents. In bioreactors with bulk flow of air past the solids, due either to forced airflow or to mixing of the substrate bed, gases diffuse from the stagnant gas regions into the bulk flow and are carried away. Heat can be removed by convection and by evaporation of water into this air. Evaporative heat removal can be maximized by aerating with dry air, but this will tend to dry the substrate. Depending on the bioreactor operation there might be significant gas concentration gradients and temperature gradients in the bulk air phase across the bioreactor. Plug flow of gas (and maybe substrate) will tend to favor macroscopic gradients, whereas mixing of the gas phase and of the substrate bed will tend to minimize such gradients. In bioreactors without bulk flow of air past the solids (i.e., trays), mass transfer and heat transfer occur mainly by diffusion and conduction, respectively. In addition to heat and mass transfer within the bioreactor, there are also heat transfers between the substrate bed and the bioreactor wall, the headspace gases and the bioreactor wall, and the bioreactor walls and the surroundings (Fig. 64.1).

During microbial growth in SSF, growth activities and the aeration and agitation strategies can affect the bulk substrate properties, which in turn can influence the bulk transport processes, as indicated in Figure 64.1. For example, in an unstirred packed bed, fungal mycelia grow in the interparticle spaces and can significantly increase the pressure drop through the bed, affecting airflow patterns within the bed (5). Microbial activities on the substrate

may decrease the strength or increase the stickiness of the particles, leading to compaction or cohesion of particles when the substrate is agitated, thereby eliminating interparticle spaces and preventing bulk transport to or from the microbes within the bed.

In conclusion, there can be significant profiles of temperature, nutrients, and biomass at both the microscopic scale (looking at a single particle with a microbe growing on it, as shown in Figure 64.3) and the macroscopic scale (looking across the bioreactor as a whole, as shown in Figure 64.1). The success of transport processes at both these scales in dissipating thermal and concentration gradients determines how readily the local conditions can be maintained near the optimal state for the desired microbial activity. Therefore, the overall performance of an SSF bioreactor arises from the interaction of biological growth kinetics, local transport processes, and bulk transport processes. The next section discusses the nature of models of SSF in general terms, whereas the remaining sections address how the underlying phenomena have been described in mathematical models of SSF processes.

64.4.3 Approaches to Modeling Solid-State Fermentation

A fully mechanistic description of the bulk and local transport processes occurring within SSF (Figs. 64.1 and 64.3), when combined with the growth kinetics, would lead to a very complex model of the system. Models of SSF to date have focused on either local or bulk transport phenomena, and therefore it is convenient to classify the models as being either microscopic models or macroscopic models. Microscopic models concern themselves with growth at the level of individual particles, whereas macroscopic models describe overall bioreactor performance. Both types of models have a role to play in the development of SSF technology. However, in the future, models should be developed that integrate mechanistic descriptions of both local and bulk transport phenomena, although this will depend on further advances in computing power and methods for constructing and solving complex dynamic models. Such models will describe performance under a wide range of operating conditions. This trade-off between the power of the model and the ease of model solution should be kept in mind. As well, the purpose of the model and the ability to estimate parameters should be considered when developing models that incorporate both microscopic and macroscopic phenomena. Because microscopic and macroscopic models are currently developed separately, the modeling work usually has related but different aims.

Microscopic models combine local transport phenomena (Fig. 64.3) and the effect of the local environment on growth, in an attempt to identify the mechanisms by which these may control the growth rate and the total amount of growth that occurs during SSF. For example, due to the absence of mixing at the microscopic scale, diffusive phenomena within the substrate particle can limit the growth rate (6). Microscopic models tend to consider the biomass in more detail than do macroscopic models, and it may be appropriate to describe variations in hyphal density in space, or the presence of differentiated forms of biomass. However, for the modeling of bioreactor performance, it is not appropriate to describe the extension and branching of individual fungal hyphae. Models incorporating these growth phenomena are powerful tools for fundamental studies aimed at understanding the mechanisms of fungal growth but are not discussed in this chapter.

Macroscopic models attempt to describe the performance of the whole bioreactor (Fig. 64.1). Such models may be developed to contribute to various aspects of bioreactor development such as design, operation, scale-up, control, and optimization. The main aim is to describe growth, although this may require prediction of temperature or nutrient or oxygen concentrations, or properties of the substrate bed. Their level of sophistication is in keeping with the ability or lack of ability to measure fermentation parameters such as biomass, nutrient concentrations, gas concentrations, temperature, and pH. Macroscopic models should describe the phenomena controlling the bioreactor performance, but current macroscopic models simply combine bulk transport phenomena with empirical descriptions of microbial growth. They do not address local transport phenomena, because of the complexity that these introduce. Simple empirical descriptions of growth may subsume biological and local transport limitations on growth but conceal the mechanisms of the limitation. Therefore, current macroscopic models are most useful for determining whether bioreactor performance is limited by gas or heat exchange, and guiding bioreactor design and operation to overcome any such limitations.

Several other characteristics of SSF lead to common features of models:

- The vast majority of SSF processes are batch processes, and the few continuous processes involve plug flow systems rather than well-stirred vessels. Therefore dynamic models are most useful for describing SSF. Steady-state models are usually not appropriate.
- The presence of mass and thermal gradients means that in most cases it is desirable to include spatial coordinates in addition to the temporal coordinate. Unfortunately this makes the equation sets more complicated to set up and solve.
- Balances are commonly set up over more than one of the subsystems shown in Figure 64.2.

- Depending on what is expected to limit growth, either heat or mass transfer may be described. Models incorporating both of these transport phenomena will be most flexible in describing what controls the rate of growth under a wide range of operating conditions.
- Due to the complexity that transport phenomena introduce into problems, plus the difficulties of measuring biomass and metabolic states, the majority of models for SSF are unstructured and nonsegregated, although some do have very simple structure or segregation.

The remaining sections discuss the various expressions that have been used within models of SSF to describe microbial, local transport, and bulk transport phenomena in SSF.

64.5 MODELING OF MICROBIAL PHENOMENA

This section addresses microbial phenomena and how models of SSF have treated these phenomena. It focuses on studies of either SSF itself or similar systems involving overculture on solid nutrient media. Overculture occurs when a fungus is inoculated across the whole surface, and therefore the mycelium develops simultaneously from many points. This contrasts with colony growth, where the organism is inoculated at one point, and a colony spreads outward across the surface. The kinetics of colony growth on agar plates are not considered in this chapter. Note also that the word biomass is used here in the restrictive sense of microbial biomass, and not in the broad sense of agricultural biomass. This distinction is important because many substrates are of agricultural origin.

A word of warning is appropriate about modeling growth kinetics. The basis for expression of the microbial biomass must be clear (e.g., total biomass in the bioreactor, or biomass per kilogram of initial dry substrate, or biomass per kilogram of wet substrate present, etc.), and conservation equations must originally be formulated on a conserved quantity (i.e., absolute amounts of biomass rather than biomass concentrations). This is crucial in SSF because there is a significant decrease in substrate mass due to conversion of dry matter to CO_2, and therefore increases in biomass concentration result from two effects: the increase in the overall amount of biomass, plus the decrease in the overall amount of dry matter. Water transfer between the substrate and gas phases causes further complications if concentrations are expressed on a wet substrate basis. Due to the wide range of ways that different workers have expressed biomass, we have used general equations in which the variables X and S represent absolute amounts of biomass and substrate respectively, whereas the variables C_X and C_S represent concentrations. Rates are expressed as mass or energy per unit time and are represented by the symbol r with a subscript. Readers should refer to original chapters to find the units and nomenclature used by the authors.

64.5.1 Substrate-Independent Growth Kinetic Equations

Sangsurasak *et al*. (7) note that four general shapes of growth kinetic profiles in SSF have been reported. In SSF models the simplest kinetic expressions describing these profiles relate the growth rate (r_g) directly to the biomass:

- Linear growth kinetics, described by

$$r_g = \text{constant} \tag{64.1}$$

  where r_g is the rate of growth.
- Exponential growth kinetics, described by

$$r_g = \mu_m X \tag{64.2}$$

  where μ_m is the observed maximal specific growth rate.
- Early acceleration followed by deceleration, with the rates of acceleration and deceleration being nearly equal, such that the biomass profile is symmetrical by rotation around the transition point. These kinetics are described by the logistic equation

$$r_g = \mu_m X \left(1 - \frac{X}{X_m}\right) \tag{64.3}$$

  where X_m is the maximum possible amount of biomass.
- Early rapid acceleration, followed by an extended period during which growth decelerates slowly. This profile can be approximated by raising the ratio X/X_m to an exponent n to give the power-law logistic model (8,9)

$$r_g = \mu_m X \left(1 - \left(\frac{X}{X_m}\right)^n\right) \tag{64.4}$$

This allows the logistic curve to be skewed (i.e., for the rates of acceleration and deceleration to be different). The value of n is a measure of the relative sensitivity of the culture to self-inhibition at high biomass densities (8). For values of n less than 1, the organism is relatively sensitive to self-inhibition, and self-inhibition occurs for quite low values of X. For $n = 1$ the logistic equation is obtained. Finally, for values of n greater than 1 the organism is relatively resistant to self-inhibition, and significant self-inhibition occurs only at values of X close to X_m. The exponent n may have biological significance. The mycelium

arising from a spore undergoes a maximum number (k_m) of branching events before growth ceases, and mycelia arising from a large number of different spores have a distribution of k_m values. If n is less than 1 then many of the mycelia have low k_m values, whereas if n is greater than 1 then many of the mycelia have high k_m values (8).

The expressions for both the linear and exponential growth kinetics do not describe any limitation on growth and are of little use for incorporating into models of growth in SSF. On the other hand, the logistic equation (and by extension, its power-law modification) describes a limitation on growth, and for this reason has quite commonly been incorporated into models of growth in SSF (10–12), especially macroscopic models. However, the significance of X_m is not clear. Growth might potentially be limited by the amount of substrate or diffusional limitations, but it can also be limited sterically.

Assumption of symmetric branching enables a simplified description of the mycelial mode of growth and enables the macroscopic parameter μ_m in the logistic equation to be related to the specific growth rate of a segment of biomass just before it is about to divide (μ'_m). The value of μ'_m can be determined from microscopic observation of extending hyphae. After a few branching events the following equation holds (8,9):

$$\mu_m = \mu'_m \frac{(X + X_c)}{2X} \approx \frac{\mu'_m}{2} \tag{64.5}$$

where X_c is the biomass in one hyphal segment just prior to a branching event. The approximation arises because X_c is small compared with the total biomass. This relationship between the two specific growth rates occurs because, after a few symmetric branchings, the biomass in the actively extending segments of a mycelium comprises approximately half the total biomass. The remaining biomass is in the older section of the mycelium where there are no actively extending hyphal tips. The microscopic growth parameters (X_c and μ'_m) can be determined by image analysis, which might even be used to monitor growth during SSF itself (9). If the effect of environmental parameters on growth and branching is known, some prediction can be made about how the environment will influence macroscopic growth kinetics.

64.5.2 Substrate-Dependent Growth Kinetic Equations

Kinetic expressions that rely only on biomass are simple but lack flexibility in describing different systems because new values for the parameters must be determined for each new system. Another approach is to assume that growth is related to the concentration of a growth-limiting substrate (such as a soluble sugar or oxygen) by the Monod equation (6,13,14),

$$r_g = \mu_m X \left(\frac{C_S}{K_S + C_S} \right) \tag{64.6}$$

where K_S is the saturation constant for the substrate. The models of Muck *et al*. (13) and Kaiser (14), which are based on the Monod equation, are relatively complex because they describe composting processes involving several organisms and several substrates. Muck *et al*. have four microbial groups (fungi and yeasts, each of which is divided into thermophilic and mesophilic subgroups), each with different Monod growth parameters, and there are several substrates that are assumed to be used sequentially.

The substrate concentration in the Monod equation must be the actual concentration that the microorganism experiences, which may not be simple to define due to the presence of both solids and water. Due to the concentration gradients that arise during growth, substrate concentrations at the surface of a substrate where the microorganism is located can be quite low compared with the average concentration (6). Therefore the effect of substrate concentration should be incorporated into kinetic models only if the growth equations are coupled with local transport equations. Neither Muck *et al*. (13) nor Kaiser (14) modeled local transport, which limits the usefulness of their models.

Various modifications of simple Monod kinetics have been used by different workers:

- Simultaneous limitation of growth by oxygen according to Monod kinetics and self-inhibition by the biomass according to the logistic equation (15)

$$r_g = \mu_m \left(\frac{C_{o_2}}{K_{o_2} + C_{o_2}} \right) X \left(1 - \frac{X}{X_m} \right) \tag{64.7}$$

- Simultaneous limitation by oxygen and glucose (16)

$$r_g = \mu_m X \left(\frac{C_{o_2}}{K_{o_2} + C_{o_2}} \right) \left(\frac{C_G}{K_G + C_G} \right) \tag{64.8}$$

- Self-inhibition of growth by biomass late in growth (according to logistic kinetics) combined with substrate inhibition kinetics (17)

$$r_g = \mu_m \left(\frac{C_S}{K_S + C_S + C_S^2/K_i} \right) X \left(1 - \frac{X}{X_m} \right) \tag{64.9}$$

where K_i is the inhibition constant for the substrate.

64.5.3 Modeling Effects of Microbial Activities on the Environment

Microbial activities affect the environment in SSF, and the changes in the local environment in turn affect growth. The effect of microbial activities on the local pH and water activity in SSF have received almost no attention, with the exception of Muck *et al*. (13) who related pH changes to acetic and lactic acid production rates and the buffer index of the solids. This section therefore is restricted to describing how workers have modeled consumption of nutrients (either the carbon source or oxygen), the generation of metabolic heat, and effects of growth on porosity in the substrate bed.

In models that describe the dependence of the growth rate on substrate concentration, it is also important to describe the effect of the growth activities on the substrate (i.e., substrate consumption). Sometimes a constant growth yield coefficient has been assumed,

$$r_s = -\frac{1}{Y_{XS}} r_g \tag{64.10}$$

where Y_{XS} is the observed yield coefficient. The negative sign indicates that substrate is consumed during the growth reaction. However, many workers have assumed that substrate is used for both growth and maintenance and have assumed the relationship

$$r_s = -\frac{1}{Y'_{XS}} r_g - m_s X \tag{64.11}$$

where Y'_{XS} is the true growth yield on the substrate, and m_s is the maintenance coefficient. This equation has been applied both to nutrients within the substrate and to oxygen.

If the particle structure is provided by a macromolecule that is degraded by the microorganism, such as during the utilization of predominantly starchy materials by amylolytic microbes, or the degradation of cellulosic substrates by cellulolytic organisms, then the particle will shrink during the fermentation. This can affect bioreactor performance through effects on bulk transport. For example, a decrease in particle size caused the substrate bed in a packed-bed bioreactor to pull away from the walls, allowing the air to bypass the bed and reducing the availability of oxygen within the bed (18). A simple model for particle size reduction assumes that oxygen is the limiting substrate and that it is consumed at the substrate–biomass interface (19,20). As the fermentation proceeds, the oxygen must diffuse through a biomass layer that increases in thickness, lowering the rate of diffusion and therefore the rate of reaction. Further developments of shrinking-substrate models are necessary because most substrates have complex compositions, and microbes can produce a range of enzymes, often in sequential order according to preferences for different macromolecules.

The generation of large amounts of metabolic waste heat can cause overheating of the substrate, and the kinetics of waste heat generation must be described in models of heat transfer in SSF. The simplest approach is to assume a constant relationship between the rate of production of new biomass and the rate of generation of metabolic heat, r_Q (11,15):

$$r_Q = Y_{QX} r_g \tag{64.12}$$

where Y_{QX} is the differential yield coefficient for waste heat production during growth. However, if maintenance metabolism is significant, then a growth and maintenance model is appropriate (21),

$$r_Q = Y'_{QX} r_g + m_Q X \tag{64.13}$$

where Y'_{QX} is the differential yield of heat from the metabolism associated with growth, and m_Q is the maintenance coefficient for heat production.

The rate of metabolic heat production does not have to be directly related to the growth rate. Saucedo-Castaneda *et al*. (3) related heat generation to the carbon dioxide evolution rate, which in turn was related to the substrate utilization rate by a constant yield,

$$r_Q = Y_{QCO_2} r_{CO_2} = Y_{QCO_2}[Y_{CO_2S}(-r_s)] \tag{64.14}$$

where Y_{QCO_2} is the differential relationship between heat released and CO_2 evolved (J/g), and Y_{CO_2S} is the yield of carbon dioxide from the substrate (g/g). This equation was indirectly related to the growth equation because logistic growth kinetics were assumed, and substrate consumption was modeled by a growth and maintenance model.

Instead of simply using experimentally determined heat yield coefficients (e.g., Y_{QX}) several workers have applied a bioenergetic approach. Gutierrez-Rojas *et al*. (17) proposed a stoichiometric equation for microbial growth on sucrose and estimated the enthalpy change associated with the growth reaction from the enthalpies of formation of the reactants and products. Larroche and Gros (22) considered the energetics of growth in SSF in even greater detail, estimating ATP generation and expenditure during growth. Muck *et al*. (13) related the rate of energy release to the rate of consumption of each of four substrates (water-soluble carbohydrate, ethanol, lactic acid, and acetic acid), estimating the fraction of the energy of combustion of the substrates that is actually released as waste metabolic heat. Finally, Rodriguez Leon *et al*. (23) estimated the heat yield coefficient from considerations of the degree of reductance of the substrate and biomass.

The growth of the microorganism into the interparticle voids affects the porosity of the substrate bed according to the relationship (24)

$$E = E_0 - X/(\rho_x W_s V_r) \tag{64.15}$$

where ρ_x is the wet biomass density (g/cm^3); W_s is the biomass dry matter content (g/g); V_r is the reactor volume, and E_0 is the initial porosity. This reduction in void fraction affects the pressure drop through packed beds (5) and reduces the effective diffusion coefficient within the substrate bed in tray bioreactors (24).

64.5.4 Death Kinetics

Overheating is a common problem in SSF, and several models have attempted to describe both growth and death of microorganisms. To date, death kinetics have largely been assumed to be first order (11,12),

$$r_d = k_d X_v \tag{64.16}$$

where the specific death rate, k_d, is a function of temperature. The effect of temperature on the parameters in growth and death kinetic expressions will be discussed later. The incorporation of death kinetics into a model divides the population into viable (X_v) and dead (X_d) subpopulations, representing a very simple level of segregation. On the other hand, Sargantanis *et al*. (21) assumed that their organism was killed instantly when the temperature reached 43°C. Not all models considering the effect of temperature actually have death kinetics in them; some describe only a decrease in net growth rate with temperature (3).

64.5.5 Effects of Environmental Variables on Growth and Death Kinetics

The effect of the environment on kinetic parameters is quite important because it is difficult to control environmental variables; some may change quite significantly during growth, and some might limit growth. The effect of nutrient concentrations (including O_2) have already been considered. Of most interest here are temperature, water activity, and pH. Of these, temperature has received most attention due to the overheating problems that are commonly encountered in SSF. For bioreactors with large temperature gradients, heat transport equations must be built into the model if growth is to be adequately described.

Regarding the effect of temperature, most attention has been given to the effect of the temperature on the rate constants μ_m and k_d. Simple empirical equations are normally fitted by least squares regression to growth rate data collected between the minimum and maximum growth temperatures. Polynomial expressions (11,14,15) or double exponential expressions (3,17) have been used to describe the variation in specific growth rate with temperature. Arrhenius-type relationships have also been used to describe the effect of temperature on both the specific growth rate and the specific death rate (12),

$$\mu_m = \mu_{mo}\exp\left(\frac{-E_g}{RT}\right) - k_{do}\exp\left(\frac{-E_d}{RT}\right) \tag{64.17}$$

where R is the universal gas constant, T is the absolute temperature, E_g and E_d are the activation energies for growth and death, and μ_{mo} and k_{do} are rate constants. Least squares regression usually allows an adequate fit of such equations, although the biological significance of the parameters is not clear because the equations are not formulated on any theoretical basis.

Other growth parameters may be expressed as functions of the environmental conditions. Sargantanis *et al*. (21) expressed not only μ_m but also X_m in the logistic equation as empirically fitted functions of temperature and moisture content. Saucedo-Castaneda *et al*. (3) expressed the maximum biomass, X_m, in the logistic equation as an empirically fitted fourth-order polynomial function of temperature.

The model of Muck *et al*. (13) has described the effect of the environment on growth in most detail. In addition to using Arrhenius-type equations to describe the specific growth and death rates, with different parameter values for the different microbial groups, they also described the effect of pH and water activity on growth. However, for both these environmental variables the effects on the specific growth rates of the various microbial groups were incorporated simply by using empirical equations, fitted to experimental kinetic data, to modify the maximum specific growth rate. Gervais and Simatos (25) have addressed the effect of water activity on growth on solid surfaces in greater depth, although they consider the radial extension rates of fungal colonies. The effect of water activity on the overculture situation in SSF has not been addressed.

64.5.6 Modeling Branching, Penetration, and Differentiation

Fundamental phenomena in the growth of filamentous fungi on solid surfaces have received some attention. Some models address extension of the hyphal tip at a very fundamental level, but these models have not been extended to describe morphological development. Others can describe branching and certain aspects of hyphal morphogenesis but have not been extended to describe overall growth kinetics (8). In any case, models describing the extension and branching of individual hyphae describe the system in far more detail than is required in models of bioreactor performance, where only overall mycelial concentrations are of interest.

However, models describing hyphal phenomena might be useful if they concern themselves with the overall population of hyphae or hyphal tips, and this section addresses such models briefly. The equations are not presented but can be found in the original chapters.

The symmetric branching model of Viniegra-Gonzalez *et al*. (8,9), described earlier in conjunction with the logistic equation, makes many simplifying assumptions about the branching process, essentially that all hyphae branch after reaching a certain length, and the two branches arising are identical. These do not happen in practice but may be approximated on average in the large population of hyphae within a mycelium. As shown in equation 64.5, on this basis the relationship between some microscopic and macroscopic growth parameters can be derived.

Edelstein and Segel (26) used a modeling approach based on average tip and hyphal concentrations per unit area of substrate surface and describing the generation of tips by branching and the movement of hyphal tips across the surface due to hyphal extension. Growth of tips depended on the local nutrient concentration. This approach avoids the great complexity that would be involved in constructing a model on the basis of intracellular events, tip extension, and branching events, and some of the parameters such as tip densities can be estimated experimentally (27). Laszlo and Silman (28) used a cellular automata approach to model mycelial densities during fungal colony expansion over solid surfaces. In this approach a matrix of small squares is superimposed on a flat substrate surface. Initially, one or more squares are designated as living, to represent an inoculum. The fungus can then grow into adjacent squares, with simple rules based on the number of occupied squares adjacent to a vacant square being used to determine whether that vacant square will be colonized. This approach can give insights into density patterns within fungal colonies (28) but otherwise is of limited usefulness for modeling growth kinetics in bioreactors. Edelstein (29) developed a model describing colony expansion, assuming no nutrient limitations, but based on processes of branching, anastomosis, tip death, and hyphal death. Only the average frequencies of these processes need to be known. Different frequencies for the various processes can lead to very different colony morphologies. These approaches could be adapted to describe growth during overculture in SSF.

Penetration into the substrate is an interesting aspect that has not received much attention, although Jurus and Sundberg (30) gave a qualitative account of the penetration of *Rhizopus oligosporus* into soybeans. More recently Ito *et al*. (31) observed an exponential decrease in the concentration of hyphae below the surface of the rice in koji. Experimentally they observed that the quality of the koji was strongly correlated with the degree of mycelial penetration: at lower degrees of penetration, the activities of undesirable enzymes was high, leading to poorer quality koji. Although they proposed a mathematical equation to describe the decrease in hyphal concentration with depth, it was simply fitted to the data collected at each time point. A dynamic model describing the increase in concentration of penetrative hyphae as a function of time and distance was not proposed. Such dynamic models might be important because penetration into the substrate has the potential to increase substrate degradation.

Differentiation can be quite important in SSF processes as an essential step in the production of spores or secondary metabolites (32). Georgiou and Shuler (33) modeled growth and differentiation of *Aspergillus nidulans* on a solid medium containing glucose. The model could predict the increases in density of the various types of biomass (vegetative, competent, differentiated, and conidial) during overculture.

64.6 MODELING OF LOCAL TRANSPORT PHENOMENA

Local mass transfer processes have the potential to limit the rate of growth in solid-state fermentation. Most of the local transport phenomena occurring in SSF, such as diffusion through porous media and stagnant films, have been well studied in other systems. However, the translocation of nutrients within the fungal mycelium itself is poorly understood. The work done on nutrient diffusion during radial expansion of colonies on agar surfaces will not be described here because SSF usually involves overculture of the organism across the whole surface, for which nutrient diffusion horizontally toward the organism is not important. In overculture the key spatial dimension is the one passing vertically through the substrate (Fig. 64.3).

This section indicates how modeling of these local transport phenomena has improved our understanding of what controls growth in SSF. Emphasis is placed on the mathematical descriptions of the phenomena. Model predictions about system behavior are mentioned but not discussed in detail. This section concentrates on mass transport phenomena because local heat transfer has not been considered in any mathematical model of SSF to date. Indeed, local heat transport is less likely than local mass transfer to limit SSF performance, although it might have unknown significance, for example, through indirect effects on mass transfer coefficients.

64.6.1 Diffusion and Reaction

Early modeling studies relevant to SSF considered the overculture of microorganisms on solid agar media, with

glucose as the substrate (33,34). Two growth periods are predicted: an early period during which the glucose concentration at the substrate surface is relatively high and consequently the microbe grows at its maximum specific growth rate (i.e., exponential growth), followed by diffusion-limited growth during which the glucose concentration at the substrate surface is very low and the growth rate depends on the flux of glucose to the surface. The duration of the exponential growth phase depends strongly on the initial concentration of glucose because this determines how long it takes for the surface glucose concentration to fall to limiting levels. Analytical solutions to the diffusion equation can be obtained for short time periods but cannot describe the whole growth period. In any case, the usefulness of these models is limited because relatively few SSF processes contain a soluble sugar as the major carbon source.

Mitchell *et al*. (6) proposed and solved numerically a model for growth of *R. oligosporus* in overculture with starch as the carbon source. This allows some insight as to how mass transfer within the substrate itself can limit growth. In the experimental system a membrane filter prevented penetration of hyphae into the substrate. Five steps in the growth process were modeled (these correspond to processes 5 to 9 in Figure 64.3):

- Glucoamylase release into the substrate by the fungus located in a plane at the substrate surface; an empirical equation was used
- Diffusion of glucoamylase through the substrate according to Fick's law
- Hydrolysis of starch by the glucoamylase according to Michaelis–Menten kinetics
- Generation of glucose by the glucoamylase according to Michaelis–Menten kinetics and the diffusion of the glucose through the substrate; this is a process of simultaneous reaction and diffusion
- The uptake of glucose by the fungus at the substrate surface according to Monod kinetics based on the surface glucose concentration.

The expression of interest here is that for simultaneous reaction and diffusion. For diffusion in an overculture system in which net diffusion occurs only in the vertical direction, as shown in Figure 64.3, the balance equation for compound A has the general form

$$\frac{\partial A}{\partial t} = r_a + D_a \frac{\partial^2 A}{\partial z^2} \tag{64.18}$$

where r_a is the rate of generation of compound A, D_a is the diffusivity of A, and z is the vertical spatial coordinate. This equation, with the appropriate sign on the reaction term, can refer to the generation and diffusion of hydrolysis products within the substrate, or to the diffusion and consumption of nutrients within a biomass layer.

Microscopic models incorporating local transport equations are useful tools for understanding the role of local transport phenomena in limiting growth in SSF. The model of Mitchell *et al*. (6) predicts a short phase of exponential growth during the early period when the glucoamylase is still near the surface and the surface glucose concentration is much higher than the saturation constant for growth. As the biomass at the surface increases, the increased glucose uptake rate causes the surface glucose concentration to fall below the saturation constant. This is followed by a period of slow deceleration of growth. This kinetic profile has been observed in SSF by several workers. The model is able to explain how such kinetics might arise from interactions among the processes of glucoamylase diffusion, starch hydrolysis, and glucose diffusion.

Recently, Rajagopalan and coworkers have made two extensions to this model. Rajagopalan and Modak (16) incorporated an expanding biomass film of constant density, with simultaneous reaction and diffusion of oxygen from the bulk air above the biomass layer and of glucose from the substrate below the biomass layer. This model suggests that at different times during growth either glucose or oxygen may be limiting, but that overall oxygen limitation might be more important than glucose limitation. They ran simulations under different bulk oxygen concentrations, such as might occur in different positions in a bioreactor, foreshadowing the linking of both local and bulk transport equations in a single model. Rajagopalan *et al*. (35) then further modified the model to describe a decrease in particle size as glucose is used up. Their predictions agreed reasonably well with the experimental data of Nandakumar *et al*. (20), who measured decreases in particle size during growth of *Bacillus coagulans* on wheat bran particles. The predictions also confirm the observations of Mitchell *et al*. (6) that glucoamylase diffusion plays a crucial role. At low diffusivities most of the glucoamylase remains near the surface. This quickly depletes the starch at the surface, leaving much of the enzyme without substrate to act upon. As a consequence, the rate of glucose production within the substrate particle falls, and growth becomes limited by the rate of glucose production in the deeper regions of the particles.

These modeling studies have used homogeneous gel substrates with very high water contents in which diffusion is the major mass transport phenomenon. However, SSF substrates may have high solute concentrations and contain cellular structures. Sorption phenomena may restrict diffusion (25), capillary action may occur, and cell walls may present an impermeable barrier. The mechanisms of mass transport within real solid substrates deserve greater attention.

64.6.2 Film Transfer of Oxygen

Another important local transport process is that of diffusion of oxygen across the stagnant gas film into the thin liquid film at the substrate surface (Fig. 64.3). If the biomass is assumed to be surrounded by a thin liquid film that offers the major resistance to mass transfer, then the oxygen transfer rate, N, can be expressed as (36)

$$N = K_{\mathrm{L}}a(C^* - C) \tag{64.19}$$

where C^* is the concentration of oxygen in the bulk gas phase, C is the concentration of oxygen at the biomass–liquid interface, a is the area over which mass transfer occurs, and K_{L} is the mass transfer coefficient. This equation was used to estimate the overall mass transfer coefficient ($K_{\mathrm{L}}a$) for a packed-bed bioreactor. It can be applied also at the microscopic scale, although it can be difficult to measure local oxygen consumption rates and oxygen concentrations (36).

Alternatively, the biomass film can be assumed to be directly in contact with the gas phase, with the transport resistance residing in a stagnant gas film. In this case the variable C in the above equation is replaced by $HC_{\mathrm{O_2,F}}$, where H is Henry's constant, and $C_{\mathrm{O_2,F}}$ is the concentration of oxygen in the biomass film. This expression has been used to describe oxygen transfer to the biomass in a tray bioreactor (15). Film transfer of oxygen in SSF needs more attention because significant amounts of fungal mycelium are in direct contact with the air phase and are not immersed in the liquid film at the substrate surface (37).

64.7 MODELING OF BULK TRANSPORT PHENOMENA

64.7.1 Recognizing Subsystems within SSF Bioreactors

In developing a model of bulk transport phenomena occurring during SSF, we must consider the level of detail to be modeled and identify simplifications of the model structure. As pointed out earlier, at the macroscopic scale, up to four subsystems can be identified in SSF bioreactors: the bioreactor wall, the headspace gases, the solid particles themselves, and the interparticle gases (Fig. 64.2). The presence and arrangement of these various subsystems and whether the subsystems themselves are homogeneous or have concentration or temperature gradients depend on the particular bioreactor and how it is operated. Macroscopic models contain transport equations to describe the heat and mass transfer processes within and between the subsystems recognized by the model, and between the subsystems and the surroundings.

It is often convenient to ignore the bioreactor wall in order to simplify the model. This may be appropriate if the wall is maintained at a constant temperature by a cooling system, making the bioreactor wall part of the surroundings. Alternatively, if the resistance to heat transfer between the bioreactor wall and the outside air is much greater than the resistance to heat transfer from the substrate material to the bioreactor, the overall heat transfer coefficient can be assumed to be similar to the outside heat transfer coefficient. This also has the implicit assumption that the energy stored in the bioreactor wall is negligible.
