VOLUME I: EXPRESSION SYSTEMS & PROCESS DEVELOPMENT

PREFACE xi

CONTRIBUTORS xiii

PART I INTRODUCTION 3

PART II INDUSTRIAL CELL GROWTH AND GENE EXPRESSION SYSTEMS 7

1 Animal Cells, Suspension Culture 9
John R. Birch

2 Baculovirus Expression Systems 19
Robert D. Possee, Richard B. Hitchman, and Linda A. King

3 Baculovirus Kinetics, Insect Culture 33
Leslie Chan, Steve Reid, and Lars Keld Nielsen

4 Cell Culture, Aseptic Techniques 49
John M. Davis and Kevin L. Shade

5 Cell Cycle in Bioprocesses 71
Mariam Naciri and Mohamed Al-rubeai

6 Cell Growth and Protein Expression Kinetics 85
Dhinakar S. Kompala

7 Cell Viability Measurement **97**
Ning Wei and Benjamin Sommer

8 Contamination Detection in Animal Cell Culture **105**
Carol Mclean and Colin Harbour

9 Culture Collections and Biological Resource Centers (BRCs) **131**
David Smith

10 Culture Preservation **153**
Robert L. Gherna

11 Expression and Secretion of Heterologous Proteins, *Bacillus* and Other Gram-Positive Bacteria **163**
Boyke Bunk, Rebekka Biedendieck, Dieter Jahn, and Patricia S. Vary

12 Gene Expression in Human Cells **181**
Marco A. Cacciuttolo, Gene Lee, John Chon, and John Lewis

13 Gene expression in *Pichia* and other methylotroph yeast **195**
Koti Sreekrishna

14 Gene Expression in Recombinant Animal Cells and Transgenic Animals **213**
Richard M. Twyman and Bruce Whitelaw

15 Inoculum Expansion Methods, Animal Cell Lines **297**
Claudia Kloth, Glenn Maclsaac, Haile Ghebremariam, and Alahari Arunakumari

16 Insect Cell Culture **311**
Someet Narang, Erik M. Whiteley, Sunyia Hussain, and Michael J. Betenbaugh

17 Kinetics of Microbial Growth **331**
Nicolai S. Panikov

18 Microalgae, Mass Culture Methods **371**
Emílio Molina Grima, Jose María Fernández Sevilla, and Francisco Gabriel Acién FernáNdez

19 Microbial Growth Measurement **399**
Arthur L. Koch

20 Microbial Media Composition **413**
Rosalie J. Cote

21 Microscopic Characterization of Cells **437**
Erwin Huebner

22 Mycoplasma Contamination of Cell Cultures **467**
Cord C. Uphoff and Hans G. Drexler

23 Protein Glycosylation: Analysis, Characterization, and Engineering **489**
Mikael R. Andersen, Jong Hyun Nam, and Susan T. Sharfstein

24 Secretion of Heterologous Proteins, Gram Positive Bacteria **543**
Eric Morello, Isabelle Poquet, Philippe Langella

25 Soluble Protein Expression in Bacteria **557**
Catherine H. Schein

PART III MEDIA, CELL LINES AND PROCESS DEVELOPMENT **579**

26 Animal Cell Culture Media **581**
Natarajan Vijayasankaran, Jincai Li, Robert Shawley, Aaron Chen, Masaru Shiratori, Martin Gawlitzek, Feng Li, Robert Kiss, and Ashraf Amanullah

27 Animal Cell Culture, Effects of Osmolality and Temperature **599**
James C. Warren and Shyamsundar Subramanian

28 Animal Cell Stability **617**
Martin S. Sinacore, Timothy S. Charlebois, Denis Drapeau, Mark Leonard, Scott Harrison, and S. Robert Adamson

29 Animal Cell Types, Hybridomas **635**
K. Heilmann and B. Micheel

30 Antibody Production, Human Recombinant **645**
Stefan Dübel

31 Antifoams and Pluronic Polyols, Cell Protection **663**
David W. Murhammer

32 Biominiaturization of Bioreactors **669**
Michael A. Hanson and Govind Rao

33 Inoculum Preparation **699**
Craig J.L. Gershater

34 Microcarrier Culture **711**
Susan T. Sharfstein and Christian Kaisermayer

35 Monoclonal Antibody Production, Cell Lines **733**
Julia F. Markusen and David K. Robinson

36 Plant Cell Culture, Laboratory Techniques **747**
Mark Richard Fowler

37 Scale-Up of Biotechnological Processes **759**
Marko Zlokarnik

VOLUME II: EQUIPMENT, PROCESS DESIGN, SENSING, CONTROL, AND cGMP OPERATIONS

CONTRIBUTORS xi

PART IV BIOREACTOR DESIGN, ENGINEERING, PROCESS SENSING AND CONTROL 789

38 Aeration, Mixing, and Hydrodynamics in Animal Cell Bioreactors 791
Ruben Godoy-Silva, Claudia Berdugo, and Jeffrey J. Chalmers

39 Biocatalytic Membrane Reactors 821
Lidietta Giorno and Enrico Drioli

40 Bioreactor Scale-Down 847
Laura A. Palomares, Alvaro R. Lara, and Octavio T. Ramírez

41 Bioreactor Scale-Up 863
Laura A. Palomares and Octavio T. Ramírez

42 Bioreactors: Airlift Reactors 887
J.C. Merchuk and F. Garcia Camacho

43 Bioreactors, Continuous Culture of Plant Cells 955
H.J.G. Ten Hoopen

44 Bioreactors, Fluidized-Bed 963
Winfried Storhas

45 Bioreactors, Gas-Treatment 979
Graham Andrews and William Apel

46 Bioreactors, Perfusion 995
Wei Wen Su

47 Bioreactors: Rotating Biological Contactors 1013
Susana Cortez, Pilar Teixeira, Rosário Oliveira, and Manuel Mota

48 Bioreactors, Stirred Tank for Culture of Plant Cells 1031
Pauline M. Doran

49 Cell Immobilization, Engineering Aspects 1069
Ronnie Willaert

50 Fermenter/Bioreactor Design 1101
Marvin Charles and Jack Wilson

51 Gas-Holdup in Bioreactors 1137
Christian Sieblist and Andreas Lübbert

52 Immobilization of Proteins and Enzymes, Mesoporous Supports **1147**
Martin Hartmann and Dirk Jung

53 Immobilized Cells **1179**
Manojlović Verica, Bugarski Branko, and Nedović Viktor

54 Immobilized Enzymes **1201**
Jose M. Guisan, Lorena Betancor, and Gloria Fernandez-Lorente

55 Impeller Selection, Animal Cell Culture **1219**
Alvin W. Nienow

56 Mammalian Cell Bioreactors **1233**
Weichang Zhou, Gargi Seth, Maria J. Guardia, and Wei-Shou Hu

57 Mammalian Cell Culture Reactors, Scale-Up **1245**
J. Bryan Griffiths

58 Mass Transfer **1261**
Yusuf Chisti

59 Oxygen Transfer Rate Determination Methods **1303**
Felix Garcia-Ochoa and Emilio Gomez

60 Photobioreactors **1327**
Mario R. Tredici, Graziella Chini Zittelli and Liliana Rodolfi

61 Rheological Behavior of Fermentation Fluids **1347**
Colin R. Thomas and Grainne L. Riley

62 Rheology of Filamentous Microorganisms, Submerged Culture **1359**
Maria Papagianni

63 Sampling and Sample Handling for Process Control **1377**
Bo Mattiasson and Martin Hedström

64 Solid State Fermentation, Kinetics **1387**
David A. Mitchell, Deidre M. Stuart, and Robert D. Tanner

65 Solid Substrate Fermentation, Automation **1413**
Mario Fernández-fernández and J. Ricardo Pérez-correa

66 Stainless Steels **1427**
C.P. Dillon

67 Static Mixing, Fermentation Processes **1435**
Radu Z. Tudose and Maria Gavrilescu

68 Transfer Phenomena in Multiphase Systems **1451**
Rodica-Viorica Roman

PART V PROCESS ANALYTICAL TECHNOLOGIES (PAT) **1469**

69 Bioprocess and Fermentation Monitoring **1471**
Michael Pohlscheidt, Salim Charaniya, Marco Jenzsch, Christopher Bork, Tim L. Noetzel, and Andreas Luebbert

70 Flow Injection Analysis in Industrial Biotechnology **1493**
Elo Harald Hansen and Manuel Miró

71 Fluorescence Techniques for Bioprocess Monitoring **1511**
Fabienne Anton, Carsten Lindemann, Bernd Hitzmann, Kenneth F. Reardon, and Thomas Scheper

72 Off-Line Analysis in Animal Cell Culture **1523**
Heino Büntemeyer

73 Process Analytical Technology: Strategies for Biopharmaceuticals **1543**
Anurag S. Rathore and Gautam Kapoor

74 Vent Gas Analysis **1567**
David Pollard and Jens Christensen

PART VI UPSTREAM cGMP OPERATIONS **1585**

75 Antibody Manufacture, Disposable Systems **1587**
Regine Eibl and Dieter Eibl

76 Bioreactor Operations **1595**
David R. Gray

77 Bioreactors, Cell Culture, Commercial Production **1635**
Tan-Che Zhou, Wen-Wen Zhou, Weiwei Hu, and Jian-Jiang Zhong

78 Biotransformation, Process Optimization **1665**
Lutz Hilterhaus, Andreas Liese, and Udo Kragl

79 Foam Formation and Control in Bioreactors **1679**
Frank Delvigne and Jean-Paul Lecomte

80 Pilot Plants, Design and Operation **1695**
Beth H. Junker

81 Shear Sensitivity **1719**
Yusuf Chisti

82 Sterilization and Decontamination, Bioprocess Equipment **1763**
Peter L. Roberts

INDEX **1781**

PREFACE

Upstream Industrial Biotechnology is a compilation of essential in depth articles, organized topically and listed in alphabetical format, for biopharmaceutical, bioprocess and biologics process scientists, engineers and regulatory professionals from the comprehensive seven volumes of the *Encyclopedia of Industrial Biotechnology*. Process development for the manufacture of complex biomolecules involves solving many scientific, compliance and technical problems quickly in order to support pilot, preclinical and clinical development, technology transfer and manufacturing start-up. Every organization develops new processes from accumulated process knowledge. Accumulated process knowledge has a very significant impact on accelerating the time to market (and reducing the financial resources required) of products manufactured using recombinant DNA and living microbes, cells, transgenic plants or transgenic mammals. However, when an entirely new upstream platform is needed, there are few books that will quickly provide the depth of industry-relevant background. *Upstream Industrial Biotechnology* can fill this void as a 2 volume advanced desk reference. These volumes include relevant biology, protein purification and engineering literature with abundant process examples provide by industry subject matter experts (SMEs) and academic scholars. This desk reference will also be useful for advanced biomanufacturing students and professionals to quickly gain in depth knowledge on how to design processes (and facilities) capable of being licensed to manufacture enzymes, biopharmaceutical intermediates, human and veterinary biopharmaceuticals or vaccines. The opportunity is yours to leverage the combined knowledge from scores of industry professionals from around the world who have contributed to *Upstream Industrial Biotechnology* to reduce the time and cost to deliver engineered proteins, biomolecules and cost-effective biologics to the market and especially to millions of patients worldwide.

Volume 1

Expression Systems & Process Development

PART I

INTRODUCTION

INTRODUCTION

Volume 1: *Expression systems & Process Development*
Volume 2: *Equipment, Process Design, Sensing, Control and cGMP Operations*

Upstream biomanufacturing processes are designated on the basis of volume or surface area (liters, gallons, cubic meters, square meters etc.). As the process is developed and optimized, it is scaled up in volume or area and optimized for biocatalyst specific reactivity to match the market demand for the product. Therefore, close integration of the characteristics of the biological system that produces the product with the engineering and optimal performance of the manufacturing scale bioreactors is essential. This means that engineers, life scientists, and manufacturing operations staff with broad expertise all need to work and communicate effectively as a team to design an upstream process that can be scaled from the laboratory bench and transferred to the manufacturing scale.

Designing the upstream process requires focusing on the biochemistry of the final product (peptide, protein, hormone, and low-molecular-weight metabolic intermediate) *and working backwards* to design living cells or enzymes that will generate the product in the precise form for optimal biological activity or clinical efficacy. Many peptides and proteins are post-translationally modified or are synthesized on a multienzyme complex and the biological catalysts that carry out these modifications differ from cell line to cell line. This results in different degrees of modification or mixtures of partially modified products depending on the choice of cell line used and the growth conditions. The enzymes in some cell lines or microorganisms also inactivate or degrade the product as it is being produced. Fortunately, the range of these modifications can now be minimized or precisely altered by strategic host cell line engineering. These same concepts also apply when the product is more complex such as in the manufacture of biologics (cells, virus particles, virus-like particles, and complex antigens) used as vaccines or artificial tissues. In some cases the products are isolated from living tissues (eggs, blood, whole organs, milk, and fluids from individual patients) and this isolation step is considered as a component of the upstream manufacturing process. Fortunately, the genes encoding many complex biologics can now be cloned from their tissue of origin and expressed in microorganisms, fungi, mammalian or insect cell lines thereby diminishing or eliminating the need for direct tissue isolation. Regardless of their biological source, the precise biochemical characteristics of all of these products must be carefully defined at the beginning of the process design and these characteristics are often expressed as target product profiles (TPPs).

The first section of Volume I of *Upstream* provides indepth information on industrial cell gene expression systems and methods to quantify cell growth in order to design processes that are highly reproducible. Choice of the gene expression platform (host cell line, vector, promoters, the site of protein accumulation, and optimal expression conditions) has a major impact on the overall process design and final product yield. This is often determined by in-house gene expression expertise, existing process equipment as well as intellectual property restraints (composition of matter or process patents, licensing agreements, and freedom to operate).

How cells grow and the extent to which they grow are affected by media composition, growth conditions, and upstream process design (batch, fed-batch, continuous, cell recycle, immobilized biocatalysts, illumination, and heat transfer), which are included in Section III. For some cells

that require attachment to a surface, the chemistry of the surface and the available surface area are critical to optimizing growth. Upstream process design and development, even at the laboratory bench scale, must also consider eventual scale up to manufacturing scale. Scale-up approaches are included in Volume 1 Section III, and in Volume 2 Section IV.

Volume 2 includes important engineering information on the materials and design of specific types of bioreactors that have been found by the industry to be optimal for the growth of specific types of microorganisms and cells. Also included are reactors engineered for immobilized biocatalysts (whole cells, enzymes, and photo reactive cells). Each type of bioreactor must be designed to grow cells at optimal rates to a desired concentration and, therefore, methods for calibrating bioreactors for oxygen transfer, cell illumination, mixing, shear, foam formation, design of aseptic sampling systems, culture fluid rheology and effective sterilization/decontamination are included in Sections IV and VI.

As stated above, the eventual goal of bioreactor design is to scale up to the total volume needed on the manufacturing scale to meet market demand. However, there are critical regulatory considerations that need to be included in upstream process design and process operations for products manufactured under current Good Manufacturing Practice (cGMP) mandated by USFDA federal regulations (CFRs) and guidelines. These include monitoring of the process to obtain detailed process knowledge used to determine multivariant design space for optimal performance of each unit operation. Methods are included for these Process Analytical Technologies (PAT) as well as upstream cGMP operations in Volume 2, Sections V and VI. While these cGMP regulations may vary from country to country, a significant international harmonization effort has resulted in common global guidance documents (ICH, International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use) referred to in these sections.

Optimal biopharmaceutical product yield is *the mathematical product* of the number of cells used to generate the product, the amount of product produced per cell, *multiplied* (most importantly) by the yield of recovered product in the appropriate final biologically active form and purity. Each upstream process decision impacts downstream product recovery and purification. Therefore, the companion volume *Downstream Industrial Biotechnology* should also be consulted when designing an upstream process.

PART II

INDUSTRIAL CELL GROWTH AND GENE EXPRESSION SYSTEMS

1

ANIMAL CELLS, SUSPENSION CULTURE

JOHN R. BIRCH
Lonza Biologics plc, Berkshire, United Kingdom

1.1 INTRODUCTION

Mammalian cells can be distinguished by their requirement to grow when attached to a surface (anchorage dependence) or in free suspension. The ability to grow in suspension is frequently associated with cell lines that demonstrate an "immortal" or infinite lifespan phenotype. Suspension culture systems are preferred for most large-scale manufacturing processes because scale-up is more straightforward. Relatively homogeneous conditions can be achieved in a suspension bioreactor, allowing efficient monitoring and control of key process parameters.

Suspension culture technology for animal cell culture started in the 1950s, with the demonstration that several types of cells could be grown in simple agitated systems such as tumbling tubes and shaken flasks (1,2). By the end of the decade, methods had been developed for growing cells in magnetically stirred spinner vessels (3,4) and in bioreactors similar to those used for microorganisms (5,6). By the 1960s, pilot plant reactors at scales of hundreds of liters were in operation (7).

The initial drive to develop an industrial process based on mammalian cell suspension culture came from the need to produce very large volumes of vaccines against foot-and-mouth disease (FMD) virus. Processes were developed using baby hamster kidney (BHK) cells growing in stirred-tank reactors up to 3000 L (8–10). Subsequently, stirred-tank reactors of up to 8000 L were used for the production of interferon α from human Namalwa cells (9). The industrial application of animal cell culture has increased significantly over the last 20 years, driven by the need to produce monoclonal antibodies and recombinant proteins in addition to vaccines. It is the demonstration that these products can be made safely in immortal cell lines that has made possible their large-scale manufacture. In the case of monoclonal antibodies, requirements can be as high as hundreds of kilograms or tons per year. To meet this demand, bioreactors with working volumes up to 20,000 L are now used (11) and global reactor capacity is expected to increase from ~2.3 million L in 2004 to ~3.7 million L in 2011 (12).

1.2 TYPES USED FOR LARGE-SCALE PRODUCTION IN SUSPENSION CULTURE

Cell types used for large-scale production in suspension culture and those that are most commonly used industrially are described below.

1.2.1 Cell Types Used for Protein Production

1.2.1.1 CHO. The CHO line is the most commonly used cell type for recombinant protein production. Approximately 70% of all licensed biotherapeutic proteins are produced in this cell line (13). CHO cells have been used to produce a wide range of therapeutic proteins (hormones, growth factors, thrombolytics, blood clotting factors, and immunoglobulins). The choice of the CHO cell is based on several factors: compatibility with efficient gene expression systems leading to good productivity, ability to carry out important posttranslational modifications of proteins, and freedom from detectable pathogenic agents. In addition, the cell type can be grown in large-scale suspension

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

bioreactors. CHO cells can also grow as attached cultures, and in fact, growth in suspension traditionally required a period of adaptation after the production cell line had been created. This requirement for adaptation, which can take several weeks or months, can be circumvented by using host cells for gene transfection that have been preadapted to grow in suspension (14). Kurano *et al*. (15) isolated several anchorage-independent sublines of CHO, one of which grew in suspension even in static flasks. A CHO variant, CHOK1SV, has been described, which grows spontaneously in suspension in chemically defined medium (11). A different approach was taken by Renner *et al*. (16), who demonstrated that expression of recombinant cyclin E (a cell cycle regulator) in CHO cells prevented surface attachment and additionally permitted growth in protein-free medium.

1.2.1.2 Hybridomas and Myeloma Cell Lines. Rodent monoclonal antibodies are typically produced in hybridoma cells, which can be readily grown in suspension culture (see, e.g. Ref. 17). In general, rodent antibodies are used in diagnostic and research applications and are required only in modest quantities. For the vast majority of therapeutic applications, antibodies are now genetically engineered and produced in CHO cells or in mouse lymphoid cell types (particularly NS0 and SP2/0), which, like CHO, can be grown in large-scale suspension culture (13).

1.2.1.3 Other. BHK cells are used for the production of recombinant blood clotting factors VIIa and VIII (18,19). Immortalized human cell lines such as PER.C6® are also being developed for the production of recombinant proteins (20).

1.2.2 Cell Types Used for Vaccine Production

Many vaccines are produced in anchorage-dependent cell systems, but suspension culture is also used, particularly where the scale of production is large. BHK cells have been used for large-scale production of FMD vaccine because of their ability to propagate the virus and their capacity to grow in large-scale suspension culture (10). Rabies vaccine for veterinary use is also manufactured in BHK cells (21).The availability of cell lines that can be grown in large-scale suspension culture is leading to a shift in technology in some key areas of human vaccine manufacture. In the case of influenza vaccine in particular, the new cell culture processes may be an attractive alternative to the traditional egg-based processes (22,23). Examples of cell lines that have been developed for the production of large-scale human vaccine include the PER.C6 cell line derived from human retinal cells by immortalization with adenovirus E1 genes (20), the canine cell line MDCK (23), and EBx™ diploid cell lines derived from avian embryonic stem cells (24). There are also examples of suspension cultures of insect cells being used in the development of virus vaccines (25).

1.2.3 Cell Lines for Transient Production of Proteins

Transient expression technologies are frequently used for the rapid production of research quantities (milligrams to grams) of protein. The human HEK293 cell line has been very widely used for this purpose and suspension culture processes up to 100-L scale have been described (26). A process at similar scale for transiently transfected CHO cells has been described (27). Insect cells are also used for the rapid production of research materials using baculovirus expression technology (e.g. see Ref. 28).

1.3 SUSPENSION CULTURE REACTORS

Bioreactors up to 20,000-L scale are now used in the manufacture of recombinant therapeutic products from mammalian cells (11); the most commonly used systems being based on stirred tanks. Airlift reactors are also used, but much less frequently. The principles underpinning the design and scale-up of animal cell bioreactors have been reviewed by several authors (29–31). In addition to stainless steel systems, a variety of simpler technologies are used at smaller scales (<100 L) including spinner flasks and, more recently, disposable bag reactors.

1.3.1 Stirred Reactors

The majority of products made using large-scale mammalian cell culture are produced in stirred-tank reactors (see Ref. 32 for description of reactors used for a range of licensed products). Stirred bioreactors up to 20,000-L scale are now in use particularly for the production of monoclonal antibodies, which can be required in very large quantities. Birch and Racher (11) provide details of the process flow for 20,000-L scale reactors. Typically, reactors are stainless steel with height-to-diameter ratios in the range 1:1–3:1. In some cases, mammalian cell bioreactors have been developed by retrofitting microbial vessels, usually by changing the agitators and aeration system. Backer *et al*. (17) described the retrofitting of 150- and 1300-L reactors. Rushton impellers were replaced with marine propellers, and the agitator drives were altered to allow operation between 25 and 250 rpm. Air was sparged through a sintered stainless steel sparger with 10-μm pore size. Garnier *et al*. (28) describe the retrofitting of a 150-L microbial bioreactor (height-to-diameter ratio 3). They used two large pitched-blade impellers (45°), three surface baffles, and a polypropylene porous sparger (80-μm pore size). Agitation was controlled at 60–120 rpm. Nienow *et al*. (33) found

that Intermig impellers improved mixing times in a mammalian reactor compared with the Rushton turbines commonly used in microbial reactors. Impellers may be directly driven via a shaft or indirectly driven through a magnetically coupled drive (34,35). Magnetic drives remove the potential for microbial ingress through mechanical shaft seals. The operation of mammalian reactors differs from that of microbial reactors in one very important respect: power inputs are very low to minimize the risk of damage to cells. For an 8000-L reactor, it has been reported (33) that a maximum agitator speed of 1.5 rev/s is used, giving a maximum power input of 30 W/m^3. This is around two orders of magnitude less than the value typically achieved in microbial fermentations. Similarly very low aeration rates are used in animal cell reactors compared with microbial cultures. This combination of low power input and low aeration rate means that particular attention has to be paid to the design (impellers, spargers, and aspect ratio) and operation of vessels to ensure good bulk mixing and adequate mass transfer of gases (especially oxygen and carbon dioxide). Nienow *et al*. (33) describes a study of mixing characteristics and oxygen uptake rates in an 8000-L reactor and discuss ways of improving reactor performance. Ma *et al*. (36) provide an in-depth review of aeration, mixing, and hydrodynamics in bioreactors.

1.3.2 Airlift Reactors

The airlift reactor is used less commonly than the stirred reactor for cell culture and was originally developed for microbial fermentation. Sparging of air or other gas mixtures is used to aerate the culture and to provide mixing. Mixing is achieved by separating the vessel into riser and down comer sections using a draught tube, divider plate, or external recirculation loop. The presence of gas bubbles in the riser section creates a density difference between the riser and the down comer that causes the fluid to circulate, providing mixing. Airlift reactors tend to have larger height-to-diameter ratios than stirred reactors (typically as high as 10:1). Their advantage is simplicity (no mechanical agitators) combined with good mass transfer and low shear characteristics (42,43). A disadvantage of the technology is lack of flexibility in working volume. The basic design features of airlift reactors have been described in reviews (44,45). Airlift reactors have been used for the culture of BHK and human lymphoblastoid cells (46), insect cells (47), and at scales up to 5000 L for a variety of cell types including CHO, hybridomas, and myelomas (48,49).

1.3.3 Disposable Reactor Systems

Increasing use is being made of disposable, plastic film, bioreactors for suspension culture, particularly at small to medium scale where they offer significant flexibility and simplicity of operation compared with conventional stainless steel plants. This is particularly relevant where multiple products are being handled. Farid *et al*. (50) have described a decision-support tool for assessing disposables versus stainless steel plants under different scenarios. Disposable bags up to 500-L scale are increasingly used for small-scale production and for inoculum preparation. One of the most widely used systems (Wave Bioreactor™) exploits wave-induced agitation in disposable bag reactors to maintain cell suspension and oxygen transfer (51). Disposable stirred reactors have also been developed (52,53) at a range of scales up to 1000 L (Table 1.1).

1.4 OPERATING MODES FOR REACTORS

Although the type of vessel used for suspension culture is usually a stirred reactor (occasionally airlift), the mode of reactor operations can vary significantly. Production methods have been developed based on batch, fed-batch, and continuous (perfusion) systems. The choice of process will be dictated by several factors. Batch and fed-batch culture have the advantage of simplicity, reliability, flexibility, and reduced timescales for development and validation (compared with continuous systems). On the other hand, continuous systems may offer an advantage for less stable products, since residence time in the bioreactor is reduced. For most products, the ultimate decision comes down to process economics. Lim *et al*. (54) have described a decision-support tool to help compare the production economics of continuous (perfusion) versus fed-batch.

1.4.1 Batch and Fed-Batch Culture

Batch and fed-batch culture are the most widely used in production processes. Cells and medium are added to the reactor, and the culture is harvested after an appropriate period of culture. The time of harvest will depend on the kinetics of product accumulation and, in some cases, on the stability of product within the reactor. A commonly used variation on this type of culture is repeated batch or "draw and fill" culture. This is a batch culture in which a proportion of the culture is retained in the reactor as an inoculum, and fresh medium is added. This allows repeated batch growth cycles within the reactor, obviating the need to repeatedly clean, sterilize, and reinoculate the vessel. Backer *et al*. (17) described such a system, which was operated for several months at a time, for monoclonal antibody production in a 1300-L reactor. Every 84 h, the reactor was harvested, leaving 10% of the culture in the reactor as inoculum for the next culture.

A further commonly used variant on batch culture is fed-batch culture in which small volumes of selected nutrients are fed to the culture during the growth cycle

TABLE 1.1. Examples of Industrial-Scale Mammalian Cell Suspension Culture Processes

Product	Cell Line	Reactor	References
Foot-and-mouth disease vaccine	BHK 21	3,000 L	Pullen *et al*. (9)
Interferon	Namalwa	8,000 L	Pullen *et al*. (9)

to improve growth and productivity. Feeding strategies can be used to increase maximum cell population density and IVC (time integral of the viable cell concentration in the reactor). On the basis of an understanding of the nutrient requirements and metabolism of cells, feeds have been designed to avoid nutrient depletion and excessive accumulation of toxic by-products such as lactate and ammonia. The approaches taken in developing feeding strategies have been reviewed by Xie and Zhou (55). Progress with fed-batch technology has probably been the single most important factor contributing to the 100-fold increase in recombinant protein titers since the mid-1980s (56). This progress has been driven particularly by the need to produce very large quantities of therapeutic monoclonal antibodies. Initially, feeding methods were based on relatively simple supplementation strategies (reviewed in (57)). Subsequently, more sophisticated methods were developed, including techniques based on a stoichiometric model of the demands of nutrients for growth and product formation. This strategy aimed at providing nutrients based on their rate of utilization and reducing the formation of toxic products of metabolism such as ammonia and lactate, by avoiding excess concentrations of the nutrients that give rise to them. Application of this approach to hybridoma cells was described by Xie and Wang (58). They demonstrated that in fed-batch cultures of hybridoma cells the method resulted in very high cell densities (1.7×10^7 cells/mL), extended culture spans, and a 50-fold increase in monoclonal antibody concentration compared with batch culture (58). Although most methods have been based on off-line measurements, progress has also been made in the use of on-line measurement to estimate nutrient utilization rate and feed stoichiometric amounts of nutrients to support growth and reduce accumulation of toxic metabolites. Zhou *et al*. (59) demonstrated such a system using on-line measurement of oxygen uptake rate to automatically control the feed to a 500-mL hybridoma culture. Maximum cell concentrations were increased ca. sevenfold and lactate production was reduced. Kurokawa *et al*. (60) used on-line HPLC measurement of glucose and glutamine to control the concentration of these nutrients in fed-batch culture at low levels (0.2 and 0.1 g/L, respectively). This strategy reduced the accumulation of lactate and ammonia and gave an approximately twofold increase in cell growth and antibody production.

In the literature, there are now several descriptions of fed-batch strategies applied to culture of recombinant cell lines, particularly those used to make monoclonal antibodies.

A significant number of licensed antibodies are produced in mouse NS0 and SP2/0 cell lines. Burky *et al*. (61) describe a platform fed-batch process for making antibodies in NS0 cell lines using protein and cholesterol-free chemically defined medium and feeds. Optimization of this process led to antibody titers of 2.64 ± 0.19 g/L and volumetric productivity of >200 mg/L-day in a 13-day process for one cell line. Zhou *et al*. (62) reported antibody titers of >2.7 g/L for a fed-batch process using an NS0 cell line. Sauer *et al*. (63) have described a platform fed-batch process for SP2/0 cells.

In the case of CHO cells, antibody titers of >1 g/L are now routinely obtained in manufacturing processes. Birch and Racher (11) described the evolution of a fed-batch process for a GS-CHO cell line making an antibody. A titer of 5.5 g/L was obtained in a protein-free, chemically defined process. Maximum cell population densities in excess of 10^7/ml were realized. A contributory factor in the achievement of this high titer was the introduction of a new cell strain based on a variant of CHO, CHOK1SV, a cell line that grows spontaneously in suspension in chemically defined medium and appears to have improved growth characteristics compared with the parent CHOK1. The authors note that for this particular antibody the titer was a 100-fold increase compared with a CHO suspension process used to make the same antibody in 1990. Growth and product generation during fed-batch culture of a GS-CHO cell line making a recombinant monoclonal antibody are shown in Fig. 1.1.

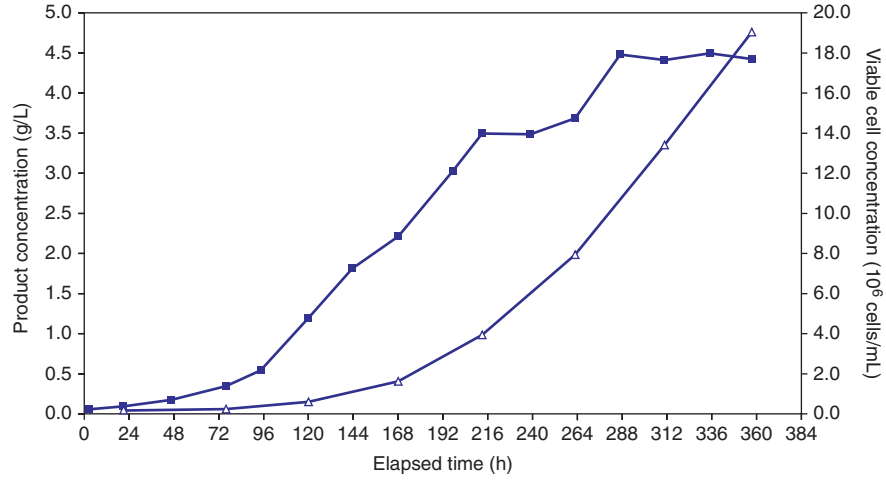

Figure 1.1. Production of a recombinant antibody from a GS-CHO cell line growing in protein-free, chemically defined medium in a bioreactor. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Although fed-batch technology has been driven significantly by the requirement for monoclonal antibodies, it has been applied to other proteins. Zhou *et al*. (64) described a feeding strategy that led to a 10-fold increase in productivity for large-scale mouse myeloma cultures, producing recombinant mouse and rat growth hormones. Wong *et al*. (65) developed a dynamic on-line fed-batch process for making interferon gamma, based on maintaining low glucose and glutamine concentrations to minimize accumulation of lactate and ammonia. Interferon levels were increased 10-fold compared with batch culture.

1.4.2 Continuous Culture Systems

Continuous (perfusion) suspension culture systems are used in several large-scale manufacturing operations for the production of recombinant proteins including monoclonal antibodies (66). Reactors up to 4000 L are in operation or being constructed (67). For a discussion of perfusion culture technology and the engineering issues involved in designing and operating such systems, the reader is referred to the review by Kompala and Ozturk (66). Perfusion culture uses a continuous supply of culture medium to the reactor and a continuous off take of spent culture fluid containing product. By retaining cells in the reactor (by preventing them leaving the vessel or by an external recycle device), very high cell densities and consequently very high product throughput can be achieved. The earliest device of this kind was the spin filter culture developed by Himmelfarb (68). A spinning filter within the reactor allowed cell retention, and with continuous perfusion of culture medium, cell densities approaching 10^8/mL were achieved. A wide range of cell retention devices have been described in the literature, based on filters, settlers, centrifuges, acoustic resonators, and hydrocyclones. Retention devices have been reviewed in detail by Voisard *et al*. (69) and Kompala and Ozturk (66)

At industrial scale Bodeker (19) describe the use of a perfused 500-L bioreactor with an external cell retention/recycle system to manufacture recombinant factor VIII from BHK cells. This is apparently the first approved biopharmaceutical from recombinant mammalian cells made using perfusion culture. Bodeker discusses the advantages of perfusion culture for factor VIII production, which requires the generation of greater than one million liters of harvest. These advantages include a high degree of culture control compared with batch operation (operates in steady-state conditions) and reduction in reactor size (hence easier to operate, clean, and sterilize). The main disadvantage reported was the extended process validation required. This validation included process stability, stability of product characteristics, and genetic stability of the cell line over the duration of the culture, which was up to 185 days. Several full-length campaigns were run to establish process consistency.

Deo *et al*. (39) described the design and operation of a 500-L perfused spin filter reactor for monoclonal antibody production. They note that continuous perfusion generally gives an ~10-fold greater volumetric productivity in comparison with batch and fed-batch processes. Hence, less reactor capacity is required. At an antibody titer of 400–500 mg/L, the 500-L reactor is capable of producing more than 1 kg of antibody per week, which they estimate would require a 5000- to 10,000-L bioreactor operating in batch or fed-batch mode. Successful operation of spin filter systems depends on careful optimization of the filter system to prevent fouling (39)

Another approach to continuous culture is to use a chemostat in which growth rate is controlled by the supply of a single limiting nutrient. The advantage of this system

is that true physiological steady-state conditions can be maintained indefinitely, allowing very precise control of culture conditions, and this can be extremely valuable in a variety of research applications for studying cell physiology (see, e.g. Refs 70–72). To date, however, the technique has not been applied in industrial processes.

1.5 PROCESS MONITORING AND CONTROL

The key parameters that are usually monitored and controlled in industrial-scale suspension cultures are pH, temperature, and dissolved oxygen. There is also increasing interest in the use of devices that allow real-time monitoring of biomass concentration (73). Such devices will allow improved monitoring and control of fermentations, particularly where fed-batch and perfusion strategies are adopted. Instrumentation and process control of bioreactors has been reviewed by Riley (74).

1.5.1 pH Control

Mammalian cell growth metabolism and productivity can be profoundly influenced by even small changes in pH of the culture. Ozturk and Palsson (75) found that the growth rate for a hybridoma was optimum at pH 7.2 but that the specific antibody production rate increased twofold at pH values below 7.2. They also showed that glucose and glutamine uptake rates and production rates for lactate and ammonia increased at higher pH values. Wayte *et al*. (76) reported that differences in pH of as small as 0.1 units could profoundly affect cell growth and/or productivity of hybridoma and myeloma cell lines. The effects observed were cell line specific. pH may also influence product characteristics, especially glycosylation. Borys (77) showed that pH affected the glycosylation pattern and specific expression rate of a recombinant lactogen protein made in CHO cell culture. Hence, it is essential to establish the optimum pH for a given cell line and to measure and control pH precisely. pH is typically controlled at a value in the range 7.0–7.5. Most cell culture media rely on a bicarbonate–CO_2 buffering system. Hence, when a bioreactor is sparged with air, the pH can be controlled by injecting a controlled flow of CO_2 on demand to maintain a constant pH value. It is frequently found that lactic acid accumulates to levels that cannot be controlled by sparging with air and CO_2; it is then common practice to control the pH by addition of a sterile base solution such as sodium bicarbonate (17) or sodium carbonate (33). Care is needed in designing bioreactors to avoid pH gradients during the addition of base solution. Regions of high pH may arise, especially if the base is added to a poorly mixed zone (often the upper region) in both stirred reactors (33) and airlift reactors (76). The problem can be minimized by adding base to a well-mixed region of the reactor. Osman *et al*. (77,78) studied the response of GS-NS0 cells to pH shifts and perturbations in stirred reactors.

1.5.2 Dissolved Oxygen Concentration

Animal cells have an absolute requirement for oxygen. There are several ways in which it can be provided to cultures, but the most common method is to bubble or "sparge" air or oxygen into the reactor. Dissolved oxygen concentrations can be measured *in situ* with a dissolved oxygen electrode and controlled automatically by adjusting the flow rate of air or oxygen to the reactor. The optimum dissolved concentration varies from one cell line to another, although most cell types will grow over quite a wide range of dissolved oxygen concentrations. Boraston *et al*. (72) found that the growth of a hybridoma cell was relatively unaffected over the range 8–100% air saturation. Ozturk and Palsson (75) showed that growth rates of hybridoma cells were not influenced at dissolved oxygen concentrations in the range 20–80% air saturation. Specific death rates were lowest in the range 20–50% air saturation. Nienow (33) found that a CHO cell line producing recombinant interferon γ grew well and had similar productivity over the range 20–80% saturation, but growth and productivity were reduced at 5% and 100% saturation. The oxygen uptake rate of animal cells is typically in the range 0.05–0.5 mmol $O_2/10^9$ cells/h (79). It is, of course, necessary to ensure that oxygen transfer into the culture is sufficient to meet the uptake rate of the cells, and this becomes an increasingly important issue as higher cell densities are achieved through improvements in process design. Factors influencing oxygen transfer include height-to-diameter ratio for the vessel, sparger and impeller designs, and gas flow rates. Tramper (80) has pointed out that gradients of dissolved oxygen concentration may occur in large bioreactors. It is not clear what impact such gradients have in practice, but they should be borne in mind and minimized when designing reactors. Aeration in cell culture bioreactors has been reviewed in detail by Aunins and Henzler (81).

1.5.3 Dissolved Carbon Dioxide Concentration

In addition to CO_2 added to the culture as part of the pH buffering system, account must be taken of CO_2 generated by cell metabolism. Although systems for *in situ* monitoring and control of CO_2 are not yet commonly used, it is useful to measure CO_2 levels off-line, for example, using a clinical blood gas analyzer. In recent years, it has become apparent that in some large-scale processes CO_2 can accumulate to levels that inhibit cell growth and recombinant product formation (28,79–82). It has been suggested (82) that CO_2 accumulation may be the factor that will ultimately limit the

reactor scale for some processes. Kimura and Miller (83) point out that inhibition may be caused by an effect of CO_2 on intracellular pH (even if the culture pH is controlled). Accumulated CO_2 may also lead to inhibition of growth due to an increase in osmolarity caused by the additional base required to maintain pH.

Gray *et al*. (84), working with CHO cells in a high density perfused process, showed that productivity of a recombinant product was maximized when CO_2 was maintained in the range 30–76 mm Hg. Levels greater than 105 mm Hg resulted in inhibition of growth and productivity. CO_2 concentration may also influence glycosylation of recombinant proteins (83). Aeration systems designed for efficient oxygen transfer will not necessarily be efficient at stripping out CO_2. Gray *et al*. (84) found that sparging with microbubbles of pure oxygen gave very efficient oxygen transfer but was inefficient for CO_2 removal because the bubbles dissolved before reaching the surface of the culture. Sparging with large bubbles (2–3 mm diameter) improved CO_2 removal while retaining adequate oxygen transfer. Zhou *et al*. (64), working with GS cell lines making recombinant mouse and rat growth hormones in a 250-L fed-batch reactor, also found that the use of a sintered steel frit delivering pure oxygen gave good oxygen transfer, but CO_2 accumulated to 200 mm Hg, depressing cell growth. By using a less efficient sparger generating larger bubbles, CO_2 accumulation was reduced to a noninhibitory level. Goudar *et al*. (85) addressed the issue of elevated pCO_2 levels in high density cultures of BHK cells by eliminating bicarbonate addition to the culture. MOPS–Histidine buffer replaced the $NaHCO_3$ in the medium and Na_2CO3 was used in place of $NaHCO_3$ for pH control. The resultant reduction in pCO_2 (by 63–70%) to 68–85 mm Hg led to increased growth rates of 68–123% and increased specific productivity of 58–92%.

1.5.4 Temperature

Temperature is typically controlled at around 37°C. Bloemkolk *et al*. (86) studied the effect of temperature on growth and antibody production of a hybridoma in suspension culture; 37°C was the optimum temperature for cell growth and antibody production. At 39°C growth was completely inhibited. In some instances, the optimum temperature for product accumulation may be below 37°C. The effects of temperature seem to be cell line and possibly product specific. Yoon *et al*. (87) found that lowering the temperature from 37 to 30 or 33°C had no beneficial effect on the production of a recombinant antibody from CHO cells. The result was in contrast to the improved production seen for erythropoietin in the same host cell. It may be advantageous to shift process operating parameters during the period of culture. Trummer *et al*. (88) described a biphasic culture process for Epo-Fc production in CHO cells in which they enhanced volumetric productivity by shifting both pH and temperature.

1.6 CULTURE MEDIA FOR SUSPENSION CULTURE

In general, media for suspension culture are similar to those used for other processes, with the exception that an agent to protect against mechanical damage is frequently added. For reactors that are aerated by sparging, it may also be necessary to use an antifoam agent, which is usually a silicone emulsion (81,89). In some instances, changes in nutritional requirements have been observed in suspension as opposed to static culture. For example, Murakami *et al*. (90) showed that a myeloma cell line in suspension culture had a requirement for a phospholipid component that was not required in static culture.

Significant progress is being made in the optimization of media composition as well as of nutrient feeds for fed-batch culture (see earlier section). Brown *et al*. (41) described how an iterative program of medium development gave a six- to sevenfold improvement in productivity of antibody from a recombinant myeloma cell line. The addition of a feed gave a further twofold increase in productivity. Jo *et al*. (91) increased maximum cell concentrations significantly for several cell lines by increasing the nutrient concentrations in RPMI 1640 medium.

There is an increasing drive to remove animal-derived raw materials from cell culture processes to reduce the risk of inadvertently introducing adventitious agents. Encouraging progress has been made, and there are now several examples in the literature of industrially important cell lines being grown in chemically defined protein-free medium. Keen (92) described the growth of myeloma and hybridoma cell lines in a protein-free medium in shake flask culture and Burky *et al*. (61) described a protein-free fed-batch process for recombinant NS0 cells. Zang *et al*. (93) developed a protein-free culture medium for the growth of CHO cell lines making recombinant proteins. A fed-batch process using protein-free, chemically defined medium for recombinant GS-CHO cells has been described (11).

1.6.1 Protective Polymers

Two mechanisms have been identified that can potentially cause cell damage in bioreactors; the first is the interaction of cells with bubbles in sparged reactors (reviewed by Chisti (94), and the second is the stress created by impellers at high agitation rates in stirred reactors. In practice, given the low impeller speeds used in animal cell reactors, interaction with bubbles is the only likely source of damage in aerated cultures (81,95). It seems probable that damage occurs when cells are attached to bubbles that burst

at the surface of the culture. The energy released by bubble bursting kills cells. The problem is readily overcome by incorporation of a protective polymer such as the nonionic surfactant Pluronic® F68 into the culture medium (96). Protective polymers seem to act by preventing cells from attaching to bubbles.

1.7 CONCLUSIONS

Animal cell suspension culture has become an extremely important industrial technology driven mainly by the need for biopharmaceutical products. With the steadily increasing number of biotechnology products in clinical trial (96), this trend seems set to continue, driven particularly in the short term by the need for large quantities of a significant number of therapeutic antibodies. Developments in other areas including vaccines are likely to expand the use of suspension culture technology even further. The requirement for large volumes of some animal-cell-derived pharmaceuticals, notably antibodies, has been a driver for improving productivity and cost efficiency of production processes. The most frequently used system for therapeutic protein production is the fed-batch bioreactor, which has been scaled up to >20,000 L. For recombinant antibodies, titers of grams per litre are now frequently reported, and protein-free, chemically defined media and feeds have been developed for a number of processes. Continuous perfusion culture is also used at reactor scales up to 4000 L for a number of products and is particularly favored for products that are relatively unstable.

2.1 INTRODUCTION

Insect baculoviruses have been developed as successful expression vectors of foreign genes. This owes much to a very late phase of gene expression that is unique to the replication cycles of some insect viruses. In this phase, which occurs after the production of infectious progeny, large quantities of two virus proteins are produced in infected cells. This feature is exploited for expressing recombinant proteins using baculoviruses. They are also highly attractive as a virus-based gene expression system as baculoviruses cannot replicate in mammalian cells, which renders them a very safe system to use in low containment laboratories. Before outlining the baculovirus expression system in more detail, it is worth describing the basic elements of virus replication in insect cells so that the advantages and also the limitations of this vector can be understood more thoroughly.

2.2 BACULOVIRUS STRUCTURE AND REPLICATION

Baculoviruses comprise a family of insect viruses (Baculoviridae) that have large, double-stranded DNA genomes ranging in size from 80 to 170 kb p. They are divided into two genera: the Alphabaculoviruses, which contain the nucleopolyhedroviruses (NPVs) and the Betabaculoviruses containing granuloviruses (GVs) (1). Only NPVs have been extensively developed as expression vectors. All baculoviruses have covalently closed, circular, double-stranded DNA genomes packaged in a rod-shaped nucleocapsid. This structure, usually about 30 nm wide and 100 nm long, appears to be able to expand in length to accommodate more DNA as required. Baculovirus genome size varies considerably from 80 to 180 kbp. The prototype member of the family, *Autographa californica* multicapsid nucleopolyhedrovirus (AcMNPV) has a genome of 134 kbp and is the virus most commonly used as an expression vector. The nucleocapsid is enclosed in a lipoprotein envelope to form virus particles. These may contain more than one nucleocapsid. Numerous virus particles are then occluded within a proteinaceous matrix mostly comprising a 29 kDa polyhedrin protein. These structures are known either as occlusion bodies or polyhedra (2). They are very resistant to degradation and are thought to serve as a survival mechanism for the virus in the environment. This is essential as their susceptible hosts, which are most commonly larvae of various lepidopteran species, are not normally available continuously.

Polyhedra are consumed by insect larvae as they feed on leaf surfaces. In the midguts of these insects, which are highly alkaline, the polyhedra quickly dissolve and liberate the virus particles. These fuse with the midgut epithelial

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

cells and release capsids into the cytoplasm. These move rapidly to the nucleus and release DNA to initiate virus replication. Virus genes are expressed in an ordered cascade of early, late, and very late phases (3). Early genes are transcribed by host RNA polymerase II and encode a number of late expression factors (19 in total), such as a virus-encoded alpha amanitin-resistant RNA polymerase, that are required for late gene expression from about 8 hours postinfection (hpi) (4). Prior to the late phase, however, virus DNA replication must be initiated. This seems to be essential for subsequent high level virus gene expression.

In the late phase, virus structural proteins are produced. These package virus DNA into capsids in the nucleus, which then exit this organelle, move to the plasma membrane, and bud from the cell to spread infection to other cells in the insect. A feature of this budded virus (BV) phenotype is that its envelope contains a major glycoprotein known as *GP64*. This serves as the attachment protein for the virus to bind uninfected cells and subsequently mediate dissemination of virus particles between cells (5). In contrast to the enveloped virus from the polyhedra, the BV does not fuse immediately with the plasma membrane but is taken up by receptor-mediated endocytosis before this vesicle fuses with an endosome. The acidic environment within the resulting structure causes fusion of the virus envelope with that of the endosome to release the capsid into the cytoplasm. This moves to the nucleus and replication continues. Within the original virus-infected cell, however, BV synthesis is replaced very late in infection by production of an enveloped virus form that remains within the nucleus. Although bounded by a lipoprotein envelope, these virus particles lack GP64. They are frequently known as occlusion-derived viruses or ODV. Their envelope contains several ODV-specific proteins, including glycoproteins that appear to be essential for attachment and entry of the virus to the insect gut (6).

From about 15 hpi, the virus-infected cell begins to produce two very late proteins: polyhedrin and *P10* (7). Both are synthesized to very high levels. The polyhedrin protein occludes a number of ODV within a crystalline matrix to form the polyhedron. Each cell nucleus may contain up to 100 polyhedra (Fig. 2.1). The role of the P10 in this process is unclear. If the *p10* gene is deleted from the virus genome, polyhedra are still formed but they appear more fragile and rupture when mechanically agitated (8). They also lack a polysaccharide envelope that normally surrounds them, which may confer on polyhedra their structural integrity (9). When most cells of the insect have been infected, the host dies and in the case of AcMNPV the cadaver liquefies. This process appears to result from the action of virus-encoded chitinase and cathepsin proteins that act in concert to reduce the structural integrity of the insect cuticle (10). The liquefaction process is important for the efficient release of polyhedra from the host. This is assumed to increase the chances of the virus encountering a new host.

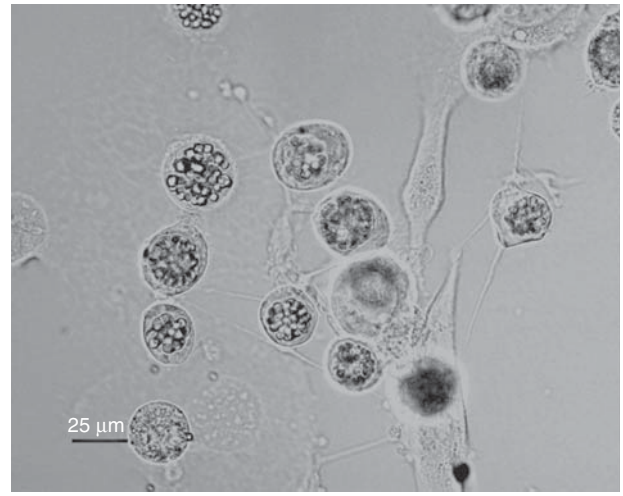

Figure 2.1. *Trichoplusia ni* 368 cells infected with AcMNPV at 60 hpi. Note the polyhedra in cells and how the nuclei have expanded to occupy most of the cytoplasm.

Baculoviruses, therefore, are unusual in that they produce two structural forms of enveloped viruses and an occluded form that packages one of these. The BV is never packaged within polyhedra and serves merely for cell to cell transmission within insects. In cell culture, only the BV phenotype is required to continue the replication cycle. Since there is no mechanism whereby polyhedra can be dissolved at physiological pH to release occluded virus, these structures are redundant in cell culture. By deleting the polyhedrin or *p10* gene coding regions and replacing them with heterologous sequences, it is possible to produce recombinant proteins in virus-infected cells (11,12).

2.3 PRODUCTION OF RECOMBINANT BACULOVIRUSES

Manipulation of baculovirus DNA is complex because of its size, which renders direct insertion of foreign genes in the manner of bacterial plasmids difficult. Despite polyhedrin and P10 proteins being synthesized to similar levels in virus-infected cells, polyhedrin has been most commonly used as a site for the insertion of foreign genes. This is a consequence of its easily visible phenotype of occlusion bodies in virus-infected cells, which is removed after insertion of a foreign coding region to render the virus polyhedrin-negative. Subsequent to this original selection system, a variety of ingenious methods has been developed to facilitate this process and some of these are summarized below.

2.3.1 Circular Virus Genomic DNA

The original methods for producing recombinant baculoviruses required the cotransfection of insect cells with circular AcMNPV DNA and a transfer vector, based on the polyhedrin gene region, which contained a foreign coding sequence (11,12). Homologous recombination between virus DNA and plasmid resulted in the replacement of the polyhedrin coding region with that of the foreign gene. This process was inefficient and required the careful separation of recombinant viruses from parental stock with the use of plaque assays. In insect cells, these can be difficult to perform and isolating a single recombinant virus could take many months of effort. The method was not easy for the nonspecialists and was a significant factor in slowing the wider adoption of the technology by non-virologists. Although p10 has a very effective gene promoter, the lack of a readily identified phenotype associated with the protein rendered it difficult to use as a site for foreign gene insertion. Clearly, if baculovirus expression vectors were to be adopted by a wider user group better methods for recombinant virus production were required.

2.3.2 Rescue of Linear Baculovirus DNA

Baculovirus DNA must be circular to initiate an infection after transfection of insect cells. However, mixing AcMNPV DNA linearized at the polyhedrin gene locus with an appropriate transfer vector resulted in the proportion of recombinant viruses rising to 30% after cotransfection of cells (13). This made their subsequent isolation in a plaque assay relatively simple. The linear virus DNA appeared to be restored to an infectious circular form after recombination with the homologous sequences in the plasmid transfer vector. Whether or not virus gene expression is required for this process is not clear. Although linearization of the virus DNA was estimated to be near 100%, a relatively high background of parental viruses suggested some religation of digested DNA within transfected cells.

This system was improved further by introducing the *Escherichia coli lac*Z coding region in lieu of polyhedrin and adding *Bsu*36I restriction enzyme sites upstream within ORF603 and downstream within ORF1629 (14). There is also a *Bsu*36I site within *lac*Z. Digestion of purified virus DNA (BacPAK6) with *Bsu*36I removed the complete *lac*Z and portions of ORFs 603 and 1629. While the putative ORF603 product is nonessential for virus replication, the protein encoded by ORF1629 is a virus structural protein (p78/80) and must be present for infectious virions to be formed. Hence, digested virus DNA, even if it relegates in transfected cells cannot initiate infectious virus production. When a transfer vector is mixed with *Bsu*36I-digested BacPAK6 DNA prior to cotransfection of insect cells, the resulting progeny virus consists of nearly 100% recombinant expression vectors.

While BacPAK6 almost guaranteed production of a recombinant virus, there was still a need to do a plaque assay and isolate clones to ensure no background contamination with the parental genome. This last obstacle to a plaque assay free recombinant expression vector selection system based on using DNA from virus particles was overcome by using *E. coli* bacmids to amplify a defective AcMNPV genome in bacteria (15,16). Essentially, this comprised the large DNA fragment generated by *Bsu*36I digestion of BacPAK6, inserted into a very low copy number bacmid vector. The bacmid DNA recovered from these cells is unable to produce infectious virus in insect cells unless mixed with a plasmid transfer vector prior to cotransfection. Consequently, all infectious virus recovered is recombinant expression vectors. A further advantage of this approach is that production of recombinant viruses can be automated using robotic liquid handling devices. This modified BacPAK6 DNA is now marketed as *flash*BAC™ by Oxford Expression Technologies, Ltd., Oxford, UK.

2.3.3 Selection of Recombinant Viruses within a Bacterial Host

Prior to the development of *flash*BAC, an alternative technology permitted the production of recombinant baculoviruses without the need to use a plaque assay for selection. A mini-F replicon, selectable antibiotic marker gene and a Tn7 transposition site were inserted into a baculovirus genome to permit low copy amplification of the virus DNA in bacteria (17). A customized plasmid transfer vector encoding Tn7 transposase functions and a foreign gene was then used to transform bacteria containing this modified genome. Transposition of DNA sequences from the plasmid to the virus genome results in foreign gene insertion at the polyhedrin locus of AcMNPV between the left and right arms of Tn7. The recombinant clones are then selected on agar plates containing appropriate antibiotics. Subsequent amplification of the bacteria and recovery of recombinant virus DNA via a simplified alkaline lysis method facilitates transfection of insect cells to produce infectious BV. This system has been a mainstay in many laboratories using baculovirus expression systems for many years. It is marketed as Bac-to-Bac™ by Invitrogen Ltd. The transfer vectors used for transposition in bacteria are not compatible with the systems described above in the section Rescue of Linear Baculovirus DNA.

2.3.4 Manipulation of Baculovirus DNA *In Vitro*

Digestion of baculovirus vectors with restriction enzymes and subsequent direct insertion of foreign genes to place them under the control of the polyhedrin gene promoter

was explored as a method for construction of recombinant viruses (18,19). However, since ligation reactions are rarely 100% efficient, plaque assays of virus progeny was still required to ensure genetic homogeneity of the recombinant expression vector.

The most successful system to date for making recombinant baculovirus genomes *in vitro* is the BaculoDirect, marketed by Invitrogen Ltd. It is also compatible with Gateway® clones since the parental virus contains *att*R sites. The system is based on the use of ganciclovir (9-[1,3-Dihydroxy-2-propoxy)methyl] guanine). Ganciclovir is a nucleoside analog, which is phosphorylated by the product of the herpes virus simplex virus type 1 (HSV-1) thymidine kinase (*tk*) gene. The phosphorylated active analog incorporates into DNA and inhibits DNA replication. If a baculovirus is used to express *tk* in insect cells, virus replication is sensitive to ganciclovir. The parental baculovirus genome contains the *att*R sites for Gateway recombination flanking the HSV1-*tk*, which is regulated by the AcMNPV *ie-0* promoter. This promoter is active in the early phase of virus replication with transcription initiated immediately after entry of virus DNA to the insect cell nucleus. Also flanked by the *att*R sites is a copy of the β-galactosidase coding region regulated by the p10 promoter, which is active in the very late phase of virus gene expression. The BaculoDirect linear DNA is mixed with a donor Gateway vector in a 1 h enzymatic reaction and replacement of both HSV1-*tk* and β-galactosidase with the foreign gene is achieved. Removal of HSV1-*tk* causes the virus to be insensitive to ganciclovir after the genome is used to transfect insect cells (20). Removal of β-galactosidase provides another level of selection. The advantage of this system is that baculovirus genome manipulation is done *in vitro* without the need to use bacterial cells. Plaque assay purification of virus after transfection of insect cells is also not required.

2.4 BACULOVIRUS TRANSFER VECTORS

A very important component of baculovirus expression vectors are the plasmid transfer vectors used to convey the desired foreign gene into the virus genome, either in insect or bacterial cells or *in vitro* via BaculoDirect. These may contain a range of baculovirus gene promoters, sequences encoding peptide tags to aid downstream protein purification, and protease cleavage sites for removal of such tags at the appropriate time. Such regions are flanked by other sequences homologous to the baculovirus genome, so that recombination can direct their insertion into the recipient virus. Most have been developed for use with either circular or linear baculovirus DNA but some of the recombinant virus selection systems, such as Bac-to-Bac and BaculoDirect require a different set of plasmids. Many of the transfer vectors currently available commercially are summarized in Table 2.1. Some of the key vectors are described in the sections below. Care must be taken to use them with the appropriate parental virus DNA. Others were developed in the 1980s and 1990s in academic laboratories but may be difficult to obtain now.

2.4.1 Vectors for Use With Circular or Linear Virus Genomes

The original AcMNPV transfer vectors consisted of partial or complete deletions of the polyhedrin coding region. The polyhedrin gene promoter and transcriptional terminator sequences were left largely intact. However, it is interesting that the very first polyhedrin transfer vector described had all of the promoter removed but was still able to produce recombinant interferon in insect cells (11). Subsequent analysis of the AcMNPV polyhedrin gene promoter showed that it was essential to retain the TAAG motif about 50 nucleotides upstream from the ATG of the native coding region and the intervening sequences to achieve maximum gene expression (22,23). A burst sequence associated with very late gene expression was also identified just upstream of the polyhedrin ATG (24). Generally, if polyhedrin gene-based transfer vectors contain the complete 5′ noncoding gene region then, maximum foreign gene expression will be attained when it is introduced into the parental virus. Some plasmid transfer vectors have gone one stage further in retaining part of the polyhedrin gene coding region, albeit with a mutated ATG (17), which is claimed to enhance foreign gene expression further.

All of the early baculovirus transfer vectors required that the inserted foreign gene coding region donated its own ATG codon to ensure translation initiation. Most only had a single restriction site for the insertion of the recombinant DNA sequences. Later versions of these reagents added multiple cloning sites for more convenient ligation of DNA fragments. Early transfer vectors were also quite large, with ~7 kbp of AcMNPV DNA spanning the polyhedrin gene region inserted into a base vector such as one of the pUC series. This could cause some difficulties in inserting larger foreign genes. The size of these vectors is now much reduced with examples such as pBacPAK8/9 at about 5.5 kbp. There is probably still some scope for reducing this size further.

The use of fusion vectors has also become widespread. These may be composed of plasmids with a short sequence encoding a signal peptide coding region to direct recombinant proteins to the endoplasmic reticulum of recombinant virus-infected cells. Several different signal peptides are in use, which include AcMNPV GP67 (25) and honey bee mellitin (26). Further fusions have been made with peptide tags such as histidine residues at the N or C termini of the protein. These are intended to aid protein purification

TABLE 2.1. Commercially Available Transfer Vectors

Type (Gene Locus)	Vector (Size)	Promoter(s)	Insertion Sites/Other Features	Additional Features	Supplier	Parental Virus (Source)
Single promoter (*polyhedrin*)	pFastBac™1 (4.8 kbp)	*Polyhedrin*	*Bam*H I, *Rsr* II, *Bss*H II, *Eco*R I, *Stu* I, *Sal* I, *Sst* I, *Spe* I, *Not* I, *Nsp*V, *Xba* I, *Pst* I, *Xho* I, *Sph* I, *Kpn* I, *Hin*d III	—	Invitrogen	Bac-to-Bac[a]

[a]Supplied in *E.Coli* (17: Invitrogen).
[b]Within S tag.

from virus-infected cells. Such fusions leave some extra amino acids at either end of the recombinant protein, hence, other vectors include appropriately sited protease cleavage sites to facilitate postpurification cleavage from the isolated molecules (27).

Most baculovirus transfer vectors are intended for the insertion and expression of single foreign genes within AcMNPV. If more than one gene is to be expressed then, specialized vectors can be used that allow for the insertion of 2–5 foreign genes at the polyhedrin gene locus. These use multiple copies of the polyhedrin or p10 gene promoters assembled in tandem or reverse orientation. Transcription terminators such as those from Simian virus 40 or beta globin are used to minimize polycistronic mRNAs (28).

Although most baculovirus transfer vectors are based on the polyhedrin gene locus, an alternative for the insertion of foreign genes is the *p10* gene region. This has the disadvantage of lacking a readily selectable marker for screening recombinant viruses, but this was circumvented by inserting the lacZ coding region for blue white selection of recombinant plaques. This coding region also contains a *Bsu*36I restriction enzyme site, hence, it is also possible to linearize virus DNA prior to cotransfection with the transfer vector (21). With the use of available transfer vectors it is feasible to insert up to seven genes within the AcMNPV genome.

2.4.2 Transfer Vectors for the Bac-to-Bac System

Transfer vectors for use with Bac-to-Bac are specific for this system. They are incompatible with either circular or linear DNA methods described in the section titled Circular Virus Genomic DNA or Rescue of Linear Baculovirus DNA. The base vector is pFastBac1. A derivative, pFastBacHT, has a histidine tag coding region with a protease cleavage site. The pFastBacDual has both polyhedrin and *p10* gene promoters for coexpression of two genes. All three vectors have a variety of cloning sites for insertion of coding sequences.

2.4.3 Transfer Vectors for Baculo Direct

Unlike other technologies for making recombinant baculoviruses, the use of BaculoDirect requires a slightly different approach. Gene constructs derived via PCR (polymerase chain reaction) are cloned into a Gateway entry vector. These sequences can then be transferred *in vitro* to any of the other compatible plasmids. The introduction of genes into the baculovirus is also done *in vitro*, with subsequent transfection of insect cells with recombinant DNA to make the infectious stock. Despite the ease of use, the system does not have the flexibility of numerous transfer vectors to achieve expression of foreign genes with different peptide tags or promoters. There are three BaculoDirect constructs available. These facilitate N-terminal tagging of proteins with V5-His tags, C-terminal tagging with V5-His tags and a combination of N-terminal V5-His tagging, and an N-terminal honeybee melittin secretion signal for improved protein secretion.

2.5 MODIFYING THE BACULOVIRUS GENOME TO IMPROVE PROTEIN PRODUCTION

Most parental baculovirus genomes used for foreign gene expression are only modified at the polyhedrin gene locus. The remaining 154 potential ORFs are unchanged in the expression vector subsequent to foreign gene insertion. Although the function of some baculovirus genes has been determined, many are uncharacterized with little idea of how their products might affect recombinant protein production. Essentially, many baculovirus expression vectors are simply wild type polyhedrin-negative genotypes containing a foreign gene that are still able to cause the full pathology associated with baculovirus infection in insects.

The discovery that baculoviruses encode chitinase and cathepsin, which result in liquefaction of the insect larval host, suggested that removal of these genes might improve recombinant protein production. Deletion of the cathepsin gene from *Bombyx mori* NPV demonstrated that recombinant protein degradation in virus-infected insects was reduced (29). Chitinase appears to accumulate in the endoplasmic reticulum of AcMNPV-infected cells. Deletion of the chitinase and cathepsin genes from AcMNPV results in greatly improved secretion and stability of recombinant proteins (15). Commercial expression vectors based on these gene deletions are available as flashBACGOLD from Oxford Expression Technologies Ltd., Oxford, UK.

2.6 INSECT CELL CULTURE

Considerable progress in the use of insect cell lines to host production of recombinant proteins with baculovirus expression vectors has been made in recent years. The first continuous insect cell line was derived from *Trichoplusia ni* (30). Since then, over 50 lepidopteran species have been used to establish more cell lines from embryonic, larval, pupal, and adult sources of tissue. For baculovirus expression, the most commonly used cell lines are from *T. ni* (31) or *Spodoptera frugiperda* (32). Originally, these cell lines were cultured in medium containing serum, but more recently many applications have moved to using defined, serum-free media.

2.6.1 Culturing Cells in Serum-Containing Medium

Cell lines from *T. ni* or *S. frugiperda* are most often propagated using medium such as TC100 (33) supplemented with

foetal bovine serum (FBS). This replaced many early insect media formulations that used insect hemolymph as a growth supplement, which was difficult to obtain in large quantities. While the addition of FBS makes the final medium less defined, it does alleviate problems such as the shear sensitivity of insect cells and affords some masking of proteases that can degrade recombinant proteins.

One of the most commonly used insect cell lines for work with baculoviruses is *S. frugiperda* Sf21, which was derived from ovarian tissue (32). This is generally propagated in TC100 containing 10% FBS, although it will tolerate 5% serum. The cells can be grown in monolayers attached to a plastic or glass surface or in suspension as spinner cultures where densities can reach 2×10^6 cells/mL before viability starts to decline. One of the major advantages of many insect cells is that when grown as monolayers they can be readily harvested by scraping from the surface that has supported their growth. Unlike most mammalian cells they do not need to be detached using trypsin. However, a few cell lines such as those from *Heliothis virescens* do need to be removed from a solid support using trypsinization (34). They can also be propagated in suspension and then returned to monolayers for specific experiments. Originally, most recombinant AcMNPV were produced using Sf21 cells. However, one of the perceived disadvantages of these cells is that they consist of a mixed population from the original source of tissue. A cloned cell line was derived from Sf21 cells and designated Sf9 (35). This has become the cell line of choice in many laboratories for working with recombinant baculoviruses.

Adult *T. ni* ovaries were the source of tissue used to derive TN-368 cells (36), which are also commonly used to propagate AcMNPV. A cell line with enhanced characteristics for recombinant protein production was originally isolated from *T. ni* embryonic tissues as BTI-Tn-5B1-28 (31). A clone derived from this was designated BTI-TN5B1-4. This cell line is generally better for producing secreted glycoproteins. More recently, it was designated for commercial purposes as High-Five™ from Invitrogen Ltd. Although cell lines derived from *T. ni* offer significant advantages over others for recombinant protein production, care must be exercised in using them. Serial propagation of AcMNPV in *T. ni* cells in culture results in the rapid selection of virus mutants with either deletions, insertions, or single nucleotide changes in the *FP-25* gene, which encodes a 25K protein (37–39). Such mutations result in the few polyhedra or FP phenotype since transcription from the polyhedrin gene promoter is reduced. Interestingly, transcription of p10 remains unaffected by such mutations in FP-25 (40).

2.6.2 Culturing Insect Cells in Serum-Free Medium

The use of FBS solved many of the earlier problems associated with formulating efficient insect cell culture media. However, it also added a level of uncertainty in that serum can vary in quality from batch to batch, requiring testing prior to purchasing a large stock. Also, as more users needed to purify protein from insect cell cultures infected with recombinant baculoviruses the presence of animal serum was a complicating factor. Even minor traces of serum components are undesirable if the purified protein is to be used to analyze its function or tested in clinical trials. The fears of contamination of serum with agents such as bovine spongiform encephalopies made the development of defined, animal product-free media a priority. Several serum-free media are now available from various suppliers such as Invitrogen and Sigma. Their development began with the formulation of IPL-41 and its derivatives (40,41). Frequently, these media allow higher cell densities ($>10^7$ cells/mL) to be attained in suspension cultures, hence improving the productivity of the baculovirus expression system (42). One of the few problems associated with their use is that Sf9 cells grown as a monolayer are susceptible to shear damage when scraped from a plastic flask. Instead, cells must be removed from the support by vigorous tapping. This is most successful when the cells are confluent.

2.6.3 Modification of Insect Cell Lines to Improve Recombinant Protein Production

While baculovirus-infected cells are able to perform many of the posttranslational modifications to recombinant proteins to confer biological activity, these products may not be identical to the same proteins made in mammalian cells. Although the very high levels of expression of recombinant proteins using the baculovirus system are one of its strengths, it may be difficult for the host cell to process accurately the mass of protein produced. Host cell gene expression is repressed in baculovirus-infected cells (43,44). Hence there may be a diminishing pool of proteins available to modify recombinant molecules very late in virus replication.

A major difference between insect and mammalian cells concerns the production of *N*-glycosylated proteins. In insect cells the *N*-glycans are usually high-mannose in content with no terminal sialic acid residues (45). They are relatively simple and short structures. However, in mammalian cells the original *N*-glycan is extended by glycosyltransferases. The *N*-glycan may also terminate with a sialic acid residue to confer a negative charge. Terminal sialylation blocks the removal of glycoproteins by carbohydrate-specific receptors in mammalian species (46). Consequently, recombinant glycoproteins produced using the baculovirus system, which lack the N-terminal sialic acid are unlikely to persist for long in mammals (47). This would have serious consequences for therapeutic glycoproteins.

These problems with glycoproteins were addressed by genetically modifying the insect host cell so that it constitutively expressed genes encoding mammalian glycosyltransferases. The Sf9 cell line was transformed with a plasmid-based vector containing β1,4-galactosyltransferase coding region under the control of the AcMNPV *ie-1* gene promoter (48). When this cell line was infected with AcMNPV, the virus glycoprotein GP64 contained β-linked galactose residues. Further modification of this cell line with an α2,6,-sialyltransferase gene resulted in the production of GP64 with a terminal sialic acid (49). The system was extended by introducing a range of mammalian glycosyltransferase genes into Sf9 cells to derive SfSWT-1, which was able to produce complex, biantennary *N*-glycans with sialic acid at the α3 branch and galactose at the α6 branch (50). Clearly, there is considerable scope for adapting insect cells to ensure that they produce recombinant proteins that are more similar to their native mammalian form compared to those produced in unmodified hosts.

2.6.4 Scaling Up Insect Cell Cultures

Insect cell lines, particularly Sf9, can be cultured using a wide variety of formats in monolayer or suspension. Prior to the advent of serum-free media, scale up was an issue because early formulations such as TC100 containing FBS proved unable to support culture volumes greater than 1000 ml in spinner/suspension. Insect cells have a high demand for oxygen and the bubbling of gas through the cultures resulted in foaming and shearing of the insect cells. However, present day serum-free media have solved many of these problems and it is now possible to use large (>10 L) bioreactors for producing recombinant proteins. These instruments have sophisticated monitors for pH, temperature, nutrients, and oxygenation to ensure optimal conditions for growing the cells.

On a smaller scale it is possible to use simple shake cultures to propagate virus-infected cells, which may be particularly attractive to the academic user. It is also feasible to use the Wave Bioreactor™ technology (GE Healthcare), where simple sterile plastic bags containing medium are rocked on a wave platform to ensure adequate agitation of cells and oxygenation during growth (51). These bags may contain 100 mL–500 L working volumes, providing considerable flexibility to the user. The bags are disposable and therefore, may be replaced almost immediately when one is harvested. This avoids the need to clean and sterilize a dedicated glass bioreactor system. They may also contain sophisticated controls to regulate growth conditions as described above.

Thus, the baculovirus insect cell culture system can be operated at a wide variety of scales for production of recombinant proteins. Very simple sterile plastic or glass flasks or large volume agitated bioreactors can be employed. Most laboratories with facilities for bacterial or mammalian cell culture can usually adapt their facilities to grow insect cells.

2.7 BACULOVIRUSES FOR GENE EXPRESSION IN MAMMALIAN CELLS

One of the primary features of baculoviruses as biocontrol agents is that they cannot cause an infection in human cells. However, it has been known for many years that AcMNPV BV can enter these cells, although no cytopathic effect has been observed (52,53). Whether or not this counts as an "infection" is debatable. The requirement for a safe way to transduce mammalian cells for gene expression or therapy led to the development of suitably modified baculovirus vectors containing mammalian gene promoters (54,55). BacMam technology is based on the Bac-to-Bac system in *E. coli* (17). The pFastBac transfer vectors used to create recombinant baculoviruses in bacterial cells are modified so as to contain the cytomegalovirus (CMV) immediate early gene (CMV) promoter which is active in mammalian cells. These are then introduced into the baculovirus genome via the normal transposition method and subsequently used to infect insect cells. The resulting BacMam particles are generally concentrated prior to use to improve the efficiency of introducing them into mammalian cells.

BacMams can transduce a wide range of mammalian cells (56) including the commonly used Human embryonic kidney (HEK) 293, Chinese hamster ovary (CHO), COS-1, Sarcoma osteogenic (Saos) -2, and Human Bone Osteosarcoma epithelial (U2-OS) lines as well as nondividing cells (55). However, transduction efficiencies may vary considerably depending on cell type and can be as high as 95% for Baby hamster kidney (BHK) cells or below 10% for mouse embryonic fibroblast (NIH-3T3), or cells of hematopoietic origin (56,57). Entry of baculovirus to mammalian cells is thought to be similar to that of insect cells, by receptor-mediated adsorptive endocytosis. However, the mechanisms responsible for intracellular trafficking and nuclear entry still remain to be elucidated, and it is likely that these are the stages where efficient transduction and recombinant expression are blocked (58). Various methods have been described in the literature to improve delivery and expression of foreign genes by BacMams: for example, using phosphate-buffered saline (PBS) in place of culture media and longer transduction incubation times at lower temperatures (59,60). Treatment of transduced cells with histone deacetylase inhibitors, such as butyrate, trichostatin A (TSA), or valproic acid has also been used to enhance recombinant expression. The observed increase in expression may be the result of an association between the BacMam DNA and histones or histone-like proteins, which can upregulate transcription, depending on their acetylation status (56,61,62), although cytotoxicity is often associated

with the use of these drugs (61). Promoter choice can also play a role. For example, the hybrid CAG promoter, consisting of the chicken β-actin promoter fused to a CMV immediate early enhancer element, showed increased reporter expression in human epithelial cervical carcinoma (HeLa) cell line and COS-1 cells when compared with a CMV promoter (63). It has been speculated that incorporating additional copies of baculovirus genes, such as the AcMNPV homologous region (*hr1*) (64) could be beneficial in enhancing promoter transcriptional activity (65). Indeed, overexpression of the baculovirus GP64 envelope protein showed increased reporter gene expression in Human hepatocellular liver carcinoma (HepG2) cells (66,67). Pseudotyping baculoviruses by introducing heterologous viral envelope proteins such as the vesicular stomatitis virus G protein (VSV G) and the rabies virus G glycoprotein (RVG) have also improved transduction efficiency, probably by augmenting gp64-mediated endosomal release (58,68). Pseudotyping was also used to overcome complement-mediated inactivation, which has removed the primary barrier to using baculoviruses for gene therapy (69). However, regardless of these improvements to the system, there still remains much to be done to universally improve the efficiency of BacMam transduction and expression.

Despite this bottleneck in efficiency, BacMams still offer many advantages over transient transfection and mammalian viral vector-based assays. These include a better biosafety profile (BacMams are inactivated by human complement and classified as Biosafety Level 1), no environmental risk (the vector is polyhedrin-negative), reduced cost (no transfection reagents are required, large-scale plasmid DNA purification etc.), no reagent cytotoxicity (as is observed with many transfection reagents), and no transient expression that facilitates expression of toxic proteins. BacMams are also easily generated and production can be rapidly scaled up, can simultaneously deliver multiple genes (70) for coexpression, and are highly adaptable to high throughput screening assays. It is also possible to control the expression level of the target gene by varying the virus dose applied to the cells (i.e., for modulating receptor coupling). As such, BacMam technology is being increasingly used for the development of pharmacologically relevant assays for drug discovery, particularly for membrane proteins such as G-protein coupled receptors (GPCRs), ion channels, transporters, nuclear receptors, and viral targets (71).

2.8 CONCLUSION

Baculoviruses have provided a durable and reliable system for the production of recombinant proteins in insect cells for over 25 years. Despite the early problems for the nonexperts in insect virology in selecting recombinant viruses, several user-friendly systems are now available that permit rapid and efficient insertion of foreign genes into the baculovirus genome. Many of these are available commercially in kit form. Accompanying developments in insect cell cultures and media mean that very high cell densities can now be achieved with concomitant yields of recombinant protein. These improved cells and media are also very simple to use and require little specialized equipment. Finally, the use of baculoviruses as biological insecticides was founded on the idea that they are nonpathogenic for higher vertebrates. This feature of their safety has been further exploited in the development of vectors for transduction of human cells, where they show great promise as a vector for gene therapy.

BACULOVIRUS KINETICS, INSECT CULTURE

LESLIE CHAN, STEVE REID, AND LARS KELD NIELSEN
Australian Institute for Bioengineering and Nanotechnology, University of Queensland, Brisbane, Australia

3.1 HISTORY AND CHALLENGE

From the mid-1950s, when the pioneering work of Earle and colleagues (1) enabled routine cell culture, until the emergence of commercial hybridoma and recombinant technologies in the 1980s, cell technology was almost synonymous with viral vaccine production technology. Vaccine production posed a number of unique challenges for research as compared to those faced in microbial fermentation, such as the following:

- the exclusive use of primary cells/tissue and diploid human cell strains rather than cell lines in human vaccine production;
- the predominant use of anchorage-dependent cells;
- the inherent complexity of cell-virus systems;
- the inherent problems of working with human or animal pathogens.

As a result, cell technology research followed a path divergent to microbial fermentation research, which in the same period moved toward bioprocess engineering science, including detailed studies of kinetics. Much work in cell technology was related to "scale-out" technology, that is, ways to handle large numbers of small cultures (e.g. Roux or roller bottles), and the technology surrounding the fermentation process (medium preparation, sterile techniques, downstream processing). Notable exceptions were the development of large-scale BHK (baby hamster kidney) suspension culture for production of Foot-and-Mouth and later, rabies vaccines (2,3) and the development of microcarrier technology for large-scale propagation of anchorage-dependent cells (4).

The 1980s saw the development of large-scale production of polio and rabies vaccines in Vero cell microcarrier cultures and the development of standards for the use of heteroploid cell lines for human vaccine production (5,6). Economy-of-scale, quality control issues, and increasing reticence against the use of animal-derived tissue have resulted in virus production in continuous cell lines becoming the preferred option for new viral-based vaccines, where it was previously limited to animal vaccines. In the past decades, vaccine production has been joined by protein and biopesticide production in insect cells and production gene therapy vectors as bioprocesses relying on virus production.

There is still much to be learned about the kinetics of virus production, even in many of the well-established production systems. This can partly be attributed to a relative lack of academic groups working on the engineering of viral vaccine production and partly due to the inherent complexity of virus processes. Not surprising, most progress has been achieved in the baculovirus/insect cell system, which has several advantages, including the following:

- baculovirus are nonpathogenic in humans and animals;
- insect cells are anchorage-independent and do not produce large amounts of acids, hence quality data can be generated in shaker flasks;
- the infection cycle is extended, which overcomes the problem of overlapping processes in most viral systems.

Mathematical modeling plays a crucial role in building an understanding of the kinetics of virus production. Without models, it is practically impossible to unveil the kinetics underlying the complex, observed dynamics. Consider a

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

typical production process where cells are infected at a low multiplicity of infection (MOI), where initially only a fraction of cells will be infected. In order to describe the behavior of this process, we need the following:

- a model of noninfected growth;
- a model of the physical interaction between virus and cells (attachment and internalization);
- a model of the infection cycle in individual cells to account for changes as cells gradually change from being biomass producers early in the infection cycle to being virus producers late in the cycle;
- a population balance model to take into account the fact that cells may be infected at different point in time and thus at any point in time, the dynamics of the culture is the cumulative effect of the kinetics shown by the cells in various stages of infection;
- a mass-balance model to take into account the physical system, for example describing substrate consumption in a batch culture or the dilution effect in a continuous culture.

In addition, depending on the actual system studied, it may be necessary to include the following:

- a model describing genetic stability of the virus, for example, to account for the accumulation of defective viruses observed in continuous culture;
- a model to describe the effect of multiple infection such as when using multiple virus constructs for multicomponent virus-like particles' production or packaging of gene therapy vectors.

We have previously reviewed three early kinetic models developed for baculovirus infection of insect cells (7) and several models have been proposed more recently (8–14). Several groups, including ours, have developed relatively detailed kinetic models of the baculovirus system. By comparing and contrasting the approaches taken, it is possible to gain insight into what works and what does not. In the remainder of this article, we will describe how to develop kinetic models of virus production using the baculovirus system as the model system. The emphasis is on how to link experiments and model development. The first section provides a brief introduction to baculoviruses. The second section presents the cell yield concept, a highly simplified view of viral processes based on a pseudo mass balance of the process. The cell yield concept provides an objective for process optimization, but does not provide the means for designing the process. For this, we need a kinetic model and this is developed in two stages. First, a model is developed for synchronous infection and this model is then used together with a population balance model and virus attachment kinetics, to formulate a model for asynchronous infection. The usefulness of the developed model is illustrated in the final section, where very low MOI is discussed as a possible production strategy.

3.2 BACULOVIRUS

Baculoviruses and their use as expression vectors have been described in several excellent books and reviews (15–18). Baculoviruses are rod-shaped viruses with ~130 kb of genetic material located on a single double-stranded DNA molecule. Baculoviruses have been isolated from over 500 insect species, mainly of the order Lepidoptera. The biology of *Autographa californica* nuclear polyhedrosis virus (AcNPV) has been studied in great detail and forms the basis of most recombinant expression systems, while *Helicoverpa zea* nuclear polyhedrosis virus (HzNPV) is produced commercially and *Helicoverpa armigera* nuclear polyhedrosis virus (HaNPV) is considered for biopesticide usage.

The individual viruses in NPVs are occluded (embedded) in a paracrystalline matrix composed mainly of a single protein called *polyhedrin*. The occlusion body, called *polyhedron*, protects the enclosed virus particles against the environment. Upon digestion by larvae, the polyhedron will dissolve in the alkaline gut juices and the released viruses will infect the midgut epithelium cells. During the ensuing infection cycle nonoccluded viruses (NOVs) will be formed in addition to the occluded form. NOVs bud through the cell membrane into the hemolymph, where they become responsible for lateral infection (Fig. 3.1).

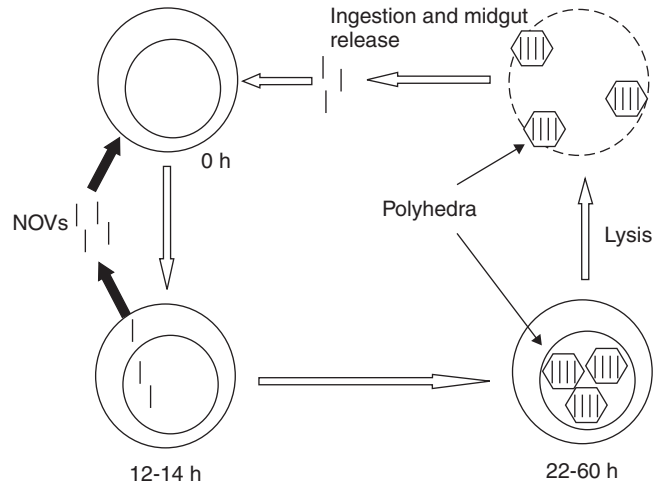

Figure 3.1. Infection cycle of NPV baculoviruses. The open arrows indicate the virus cycle between larvae from ingestion of polyherdra and midgut release of virus to the release by lysis of new polyhedra. The solid arrows indicate lateral infection through nonoccluded viruses (NOVs) released early in the infection cycle.

Several cell lines are available for propagating baculoviruses. AcNPV is typically propagated in suspension cultures of Sf-9 cells, a cell line established from ovarian tissue of *Spodoptera frugiperda* (fall armyworm), while HzNPV can be propagated in cell lines derived from ovarian tissue of *H. zea* (cotton bollworm). Propagation relies on the lateral infection route, that is via NOV infection. This is the basis for the baculovirus expression system, where the highly expressed but nonessential polyhedrin gene is replaced with a gene of interest through homologous recombination. The model system used by many to study recombinant expression in baculovirus is that of β-galactosidase expression. While ideal for gene expression, the fact that polyhedrin is nonessential for *in vitro* culture poses stability problems for biopesticide production, where occlusion bodies are essential for delivery. Typically, baculoviruses will degenerate to low producers in five to ten *in vitro* passages (19), unless a stable isolate has been found (20).

3.3 CELL YIELD CONCEPT

Baculovirus production is greatly affected by a number of process variables, including the design of the fermentation system, cell line (21,22), composition of the medium used for cell growth (23–27), age and condition of the cell population at time of infection (TOI) (28–32), MOI (33–36), and passage number of virus inoculum (37,38). Most of these variables are set early in process development; for example, we have chosen batch fermentation in serum-free medium using the aforementioned cell lines and a low-passage number virus stock.

The two remaining parameters, TOI and MOI, are highly correlated and—combined with the variability of cultures and the relatively inaccurate assays available for virus determination—it proved to be a nontrivial task to resolve their effect empirically. Indeed, prior to the development of kinetic models, descriptions of TOI and MOI effects tended to be inconsistent listings of individual observations. Only through working with a relatively complex model, did we finally develop a conceptual understanding of the system that we termed the *cell yield concept* (39). Like any good concept, it is a simplification with obvious limitations and should only be regarded as a first handle on the system. Importantly, however, it does not rely on baculovirus-specific features and should be applicable to other virus production systems. The cell yield concept is based on an overall pseudo balance for the process:

$$\text{Substrate} \rightarrow \text{cells} + \text{virus/viral products}$$

The process is catalyzed by cells and each cell can support the production of only a limited number of virus particles. The virus yield per cell is highest at low cell density but remains essentially constant up to the point where substrate becomes limiting. Thus, until the point of substrate limitation, the yield of virus will increase nearly proportionally with cell yield (i.e., the total number of cells produced in the process). Once substrate becomes limiting, any further yield in cells comes at the expense of virus and viral product yields.

What is important here is that there is no distinction made based on when the cells were produced: whether they all were produced prior to infection as would be the case at high MOI infection, or whether most were produced in parallel with the infection process as would be the case at very low MOI. In other words, the outcome is ultimately dictated by the total cell yield in the process, not on the combination of TOI and MOI used to achieve this yield. This point is illustrated in Fig. 3.2a for recombinant baculovirus and Fig. 3.2b for HaNPV production. By choosing

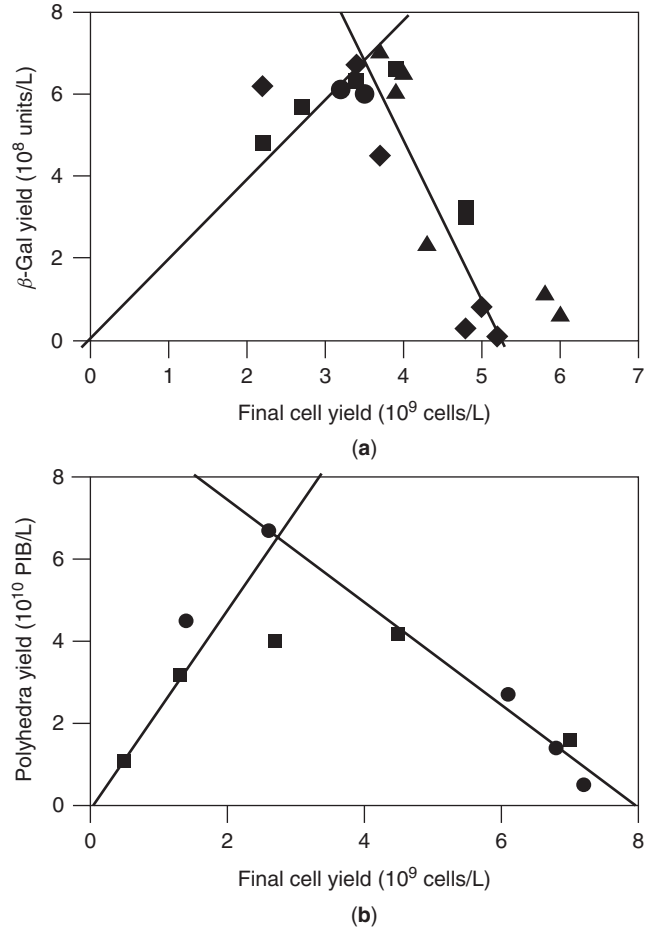

Figure 3.2. The cell yield concept. (a) Total β-galactosidase yield for r β-gal-AcNPV infections of Sf-9 cells in SF(00II medium performed at MOIs of 5 (circle), 0.01 (square), 0.0001 (triangle), and 0.0001 (diamond) in shaker flasks. (b) Polyhedra yield for HaPNV infections of *H. zea* cells in SF-900II + 10% serum medium performed at MOIs of 0.5 (circle) and 1–2 (square) in shaker flasks.

the appropriate TOI it is possible to achieve the optimal cell yield for whatever MOI is chosen.

At high MOI (>5 infective viruses per cell), essentially all cells will be infected immediately and the ensuing infection process will be synchronous. Cell growth halts almost immediately and thus the cell yield is close to the cell density at TOI. Thus, to achieve optimal production, cells should be infected at a cell density close to the optimal cell yield. At lower MOIs, only a fraction of the cells are initially infected (primary infection). It can be assumed that the remainder will continue to grow as noninfected cells. These cells and their progeny will first be infected at some later point (secondary infection) when the cells infected in the primary infection begin to release progeny virus. Hence, the cell yield may be much higher than the cell density at TOI. Thus, to achieve optimal production when using low MOIs, cells should be infected at a cell density lower than the optimal cell yield.

Practically, we obtain the product versus cell yield curve by performing a series of high multiplicity infections at different cell density. For insect cells, we use a bioreactor for cell growth, harvest 100 mL aliquots into shaker flasks at 6–12 h intervals, infect at MOI 5–10, incubate on shaker, and follow the ensuing infection process (Fig. 3.3). Because pH is not a problem in these cultures, the response curve observed in shaker flasks is valid even for controlled bioreactors. In many systems, it may be necessary to perform the infection in bioreactors to match the expected performance in a controlled system.

In suspension insect cell culture, the limiting substrate is a nutrient and the maximum reasonably well-defined. In many virus production systems, cells are anchorage-dependent and the limiting substrate will be surface area. In such systems, the transition could be broader and the decline is not necessarily linear. Even in this case, however, the observed optimum cell yield provides an initial goal to aim for in optimizing the process. It does not, however, indicate how to achieve this cell density if we choose a low MOI. In order to predict this, we need a kinetic model.

3.4 KINETIC MODEL OF VIRAL INFECTION: SYNCHRONOUS INFECTION

All studies of viral kinetics should commence with a study of synchronous infection somewhat below the optimal cell yield. If a batch culture of cells is infected at a high multiplicity (MOI > 5), the ensuing infection process will essentially be synchronous, that is, all cells will go through the infection cycle simultaneously and will—at any given point—be at the same point in the cycle. Under these conditions culture dynamics simply reflect the infection cycle occurring in each cell, amplified by the number of cells.

Synchronous cultures are biphasic in nature. We distinguish between the noninfected (cell-only) phase and the infection phase. During the noninfected phase, time is the independent variable. During the infection phase, we introduce a new independent variable, *infection time*, denoted

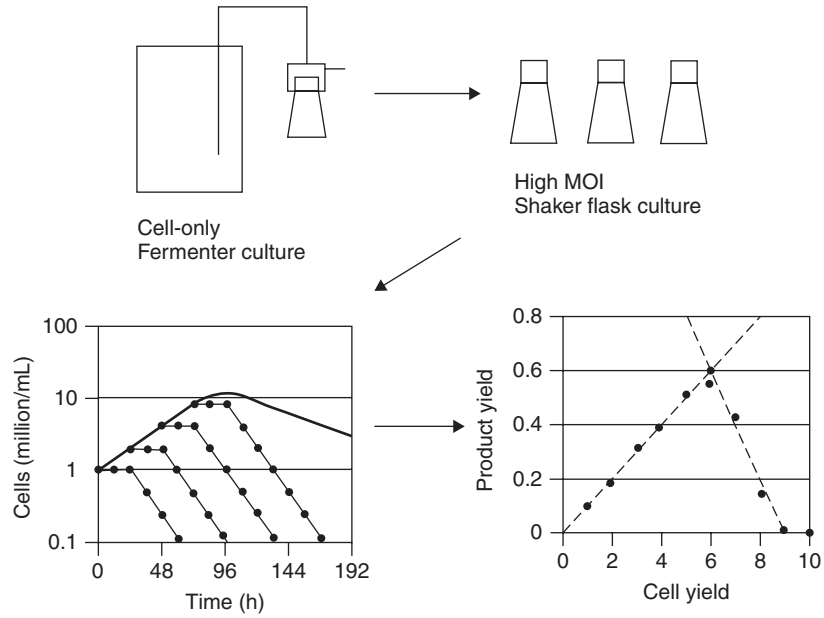

Figure 3.3. Generating the product versus cell yield curve. During a cell-only bioreactor culture, cells are repeatedly harvested straight into shaker flasks and infected at high MOI and the infection ensued. Maximum product and cell yield are used to generate the product versus cell yield curve and the maximum determined by drawing the supporting lines.

as τ and measured in hours postinfection (hpi). This terminology can cause some confusion. Infection time does not automatically follow true time; rather it relates to a reference infection. The reference infection is typically a high MOI infection (e.g. MOI = 10) of cells in the early to mid-exponential phase (i.e. relatively low cell density), and in a given medium. When we say that a cell is at 15 hpi, we are actually not saying that the cell has been infected for 15 h; rather, we are saying that the cell is at the same point of the infection cycle that a cell would be after 15 h in the reference system.

Infection time can be slower or faster than true time. Infection in late exponential phase, for example, often results in slow progression through the infection cycle (discussed later), that is infection time goes slower than real time. For some viral systems, the initial viral load per cell can affect the timing of the infection cycle and in a very high multiplicity infection, infection time may go faster than real time. We define the infection velocity, ν, as

$$\nu = \frac{\mathrm{d}\tau}{\mathrm{d}t} \tag{3.1}$$

and note that for the reference system the infection velocity is one hour of infection time (hpi) per one hour of true time (h).

3.4.1 NonInfected Cell Growth

Any traditional cell growth model could be used to describe cell growth prior to infection. Experience tells us, however, that for most virus production systems, cells must be infected in optimal health, that is in the mid-exponential phase, in order to achieve a reasonable product yield. Thus, all relevant situations can be modeled with a simple exponential growth model

$$\frac{\mathrm{d}N_\mathrm{V}}{\mathrm{d}t} = (\mu_{\max} - k_\mathrm{D})\ N_\mathrm{V} \tag{3.2}$$

where N_V is the concentration of viable cells, $\mu_{\max}$ the maximum specific growth rate, and k_D the specific death rate. The noninfected cell parameters, $\mu_{\max}$ and k_D, can be determined using standard techniques from the number of viable and dead cells during the exponential phase of a noninfected culture.

3.4.2 Infection Cycle: Qualitative Aspects

Typically, the qualitative aspects such as virus attachment mechanism, molecular biology, and general timing of events, are well-established for commercially relevant viruses. This information serves as a sound basis on which mathematical models can be formulated. The starting point may be a graphical representation of the infection cycle as in Fig. 3.4 for recombinant baculovirus (see also Ref. 40) where the first step is virus diffusing to the surface of the cell and (2) attaching to a specific receptor. (3) Baculovirus enter the cytosol via random endosomal activity, (4) followed by pH-regulated fusion with the endosomal membrane. From the cytosol, (5) baculovirus is localized to (6) the nucleus, where the outer protein coat dissolves. All of these processes take place within the first couple of hours of cells being inoculated with the virus. Hereafter follows the "genetic" part of the infection with (7) simultaneous replication of viral DNA, (8) transcription, and (9) translation of viral proteins. The infection cycle is "timed" through sequential protein expression and can be divided into three phases (16):

1. *Early (0–6 h Postinfection).* The viral reproduction apparatus is established and the cellular reproduction apparatus switched off.
2. *Late (8–18 h Postinfection).* Synthesis of nonoccluded virions, which are coated in protein (16) and are capable of budding from the cell surface (17).
3. *Very Late (20–72 h Postinfection).* Polyhedrin or recombinant product is transcribed using a unique, viral-derived RNA polymerase. In wild-type virus, virions are embedded in occlusion bodies composed primarily of polyhedrin.

3.4.3 Infection Cycle: Modeling

There are two approaches that can be taken to describe the infection cycle: an unstructured and a structured, mechanistic approach. In the unstructured approach, the temporal

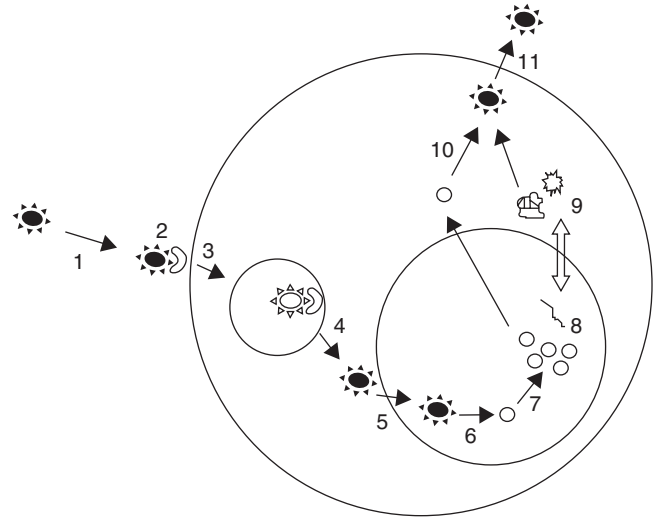

Figure 3.4. The infection cycle in recombinant baculovirus. 1. Diffusion, 2. attachment, 3. internalization, 4. fusion, 5. nuclear location, 6. uncoating, 7. replication, 8. transcription, 9. translation, 10. encapsulation, and 11. budding.

element of the infection cycle is described by a number of time-varying rates. No attempt is made to follow the internal events of the cell. The five existing full models all employ this approach (9,11,36,41,42).

In the structured, mechanistic approach, the infection cycle is described as closely as possible to the true mechanism outlined in Fig. 3.4. For example, separate variables are used to describe viruses at the different locations (free, attached, endosomal, cytosolic, and nuclear) and rate equations are expressed in terms of these variables. Shuler's group has outlined a possible structure for such a model (40) and has developed detailed models up to the point of nuclear location (discussed later). Sanderson *et al*. (14) and Jang *et al*. (12) have developed structured models of batch and fed-batch infections based on Shuler's outline and an animal cell metabolism model (43) which include descriptions of coinfection, metabolic fluxes, and feedback inhibition. Roldao *et al*. (13,44) also developed a structured model, to describe coinfections for the production of three types of Rotavirus-like particles. As a guide to more fundamental research, the mechanistic models obviously excel. Ultimately, they will also prove excellent engineering tools for designing viral production processes. Presently, however, the structured models are too cumbersome and require too much effort to develop, so here we will concentrate on the unstructured models.

The modeling approach described below has three important features:

1. Only directly observable state variables are used.
2. All parameters are graphically verifiable.
3. All parameters are estimated for high MOI.

In order to achieve this simplicity, a number of assumptions have been made. It is assumed that there is no growth after infection. In our experience, the total number of cells does increase on average by 15% postinfection, suggesting that cells may continue to divide through the early phase of infection. Accounting for this growth, however, would involve deciding whether both daughter cells in a division are infected or only one of them. It is possible to determine this based on the MOI for individual cells, but introducing this distinction adds substantially to the numerical effort, and the simplifying assumption of no postinfection growth is made in most models of infection.

Presently, we shall not consider the effects that multiple infection and infection with defective virus particles have on the infection cycle. We will only consider a "standard" infection at relatively high MOI (5–10) producing a single type of infected cell. This corresponds to the approach taken in our 1994 model to describe β-galactosidase production using a recombinant AcNPV to infect Sf-9 cells in suspension culture (42). More advanced models will be described later. For modeling purposes, the time points of interest are those linked with readily observable events, such as

- virus release,
- membrane integrity,
- β-galactosidase production and release.

Extracellular virus is not observed in the culture fluid until around the onset of the very late phase. Electron microscopy observations (unpublished) have confirmed that virus progeny is produced from the beginning of the late phase, τ_E. The newly produced virus progeny were observed on the cell surface and some were observed to readsorb to the cell of origin. Surface presentation of NOV in the late phase could be the means by which lateral infection of proximal cells occurs in the gut cells of insects (15). It is not clear if the release, rather than surface presentation, of virus progeny is linked to the very late phase or is simply a delayed process. Hence, in all three pioneer models of baculovirus kinetics (36,41,42), the commencement of virus release is designated by its own marker, here designated τ_{VRC}. Viruses appear to be released at a relatively constant rate, α_{VR}, and this end after the end of the very late phase at a point designated τ_{VRE}. Thus, the specific rate equation for virus release, r_{VR}, is

$$r_{VR}(\tau) = \begin{cases} 0, & \text{for } \tau \le \tau_{VRC} \\ \alpha_{VR}, & \text{for } \tau_{VRC} < \tau \le \tau_{VRE} \\ 0, & \text{for } \tau \ge \tau_{VRE} \end{cases} \tag{3.3}$$

Since virus binding has finished by the time virus release is observed, the virus titer, V, can be described by

$$\frac{dV}{d\tau} = r_{VR}(\tau)N_V - k_V V \tag{3.4}$$

where the second term accounts for degradation of the virus, which is significant for many viruses. Virus degradation is assumed to follow first order kinetics with the degradation constant, kV. Inserting Equation 3.3 in Equation 3.4 and integrating, we find the solution

$$V^*(\tau) = \begin{cases} 0, & \text{for } \tau \le \tau_{VRC} \\ \dfrac{\alpha_{VR}}{k_V}(1 - e^{-k_V(\tau-\tau_{VRC})}), & \text{for } \tau_{VRC} < \tau \le \tau_{VRE} \\ \dfrac{\alpha_{VR}}{k_V}(1 - e^{-k_V(\tau_{VRE}-\tau_{VRC})})e^{-k_V(\tau-\tau_{VRE})}, & \text{for } \tau \ge \tau_{VRE} \end{cases} \tag{3.5}$$

Membrane integrity can be measured by trypan blue dye exclusion. For noninfected cells, membrane integrity can be used as an indicator of viability. For infected cells, however,

membrane integrity gradually decreases during the late part of the infection rather than spontaneously at the end of infection (36). As viruses and recombinant products are also released gradually, there is no particular need for the model to identify the point of death and lysis. The gradual staining of cells is expressed with an empirically fitted equation giving the fraction of stained cells as a function of τ

$$f_U(\tau) = \begin{cases} 1, & \tau \le \tau_U \\ e^{-\beta_U(\tau-\tau_U)}, & \tau \le \tau_U \end{cases} \tag{3.6}$$

where τ_U is time following infection where staining commences and β_U is the first order rate of staining hereafter. Using a similar approach, de Gooijer *et al*. employed the gradual visual changes in infected cells to follow the progression of infection with wild-type viruses (41).

In the baculovirus expression vector system, the recombinant protein is expressed under the control of the polyhedrin promoter. Thus, recombinant protein expression is directly linked to the expression of the very late genes commencing at τ_L and terminating at τ_{VL}. The production rate is assumed constant, α_{PP}. Both intracellular and extracellular β-galactosidase can be determined experimentally. β-galactosidase is not a secreted product and protein release is assumed to be linked to the leakiness of the membrane as evidenced by trypan blue uptake. Thus, release is assumed to commence at the same time as staining, τ_U. Hereafter, the rate of release is assumed to be proportional to the intracellular concentration (the release constant denoted α_{PR}), that is,

$$r_{PR}(\tau) = k_{PR}(\tau)\, p_i(\tau) \tag{3.7a}$$

where

$$k_{PR}(\tau) = \begin{cases} 0 & \text{for } \tau < \tau_U \\ \alpha_{PR} & \text{for } \tau \ge \tau_U \end{cases} \tag{3.7b}$$

The intracellular concentration, p_i, is given by

$$\frac{dp_i}{d\tau} = r_{PP}(\tau) - r_{PR}(\tau)\, p_i; \quad p_i(0) = 0 \tag{3.8a}$$

where $r_{PP}(\tau)$ is the specific production rate

$$r_{PP}(\tau) = \begin{cases} \alpha_{PP} & \text{for } \tau_L \le \tau \le \tau_{VL} \\ 0 & \text{otherwise} \end{cases} \tag{3.8b}$$

Solving Equation 8, the intracellular concentration can be determined

$$p_i(\tau) = \begin{cases} 0 & \text{for } \tau \le \tau_L \\ \alpha_{PP}(\tau - \tau_L) & \text{for } \tau_L < \tau \le \tau_U \\ \dfrac{\alpha_{PP}}{\alpha_{PR}} + \alpha_{PP}\left(\tau_U - \tau_L - \dfrac{1}{\alpha_{PR}}\right) & \\ \quad e^{-\alpha_{PR}(\tau-\tau_U)} & \text{for } \tau_U < \tau \le \tau_{VL} \\ p_i(\tau_{VL})\, e^{-\alpha_{PR}(\tau-\tau_{VL})} & \text{for } \tau \ge \tau_{VL} \end{cases} \tag{3.9}$$

The extracellular product concentration is given by

$$\frac{dP}{d\tau} = r_{PR}(\tau) N_V - k_P P \tag{3.10}$$

where the second term accounts for decomposition of extracellular product.

The number of parameters in the above model may initially seem large. All parameters, however, can be determined and visually verified using a synchronous infection of cells in the mid-exponential phase and several are determined independently of other parameters. Decomposition parameters, k_V and k_P, are determined from the exponential decay curves observed in cultures in which cells are removed after some viruses and products have been produced. The membrane integrity parameters, τ_U and β_U, are determined by nonlinear regression from synchronous culture cell viability data.

The three viral production parameters—α_{VR}, τ_{VRC}, and τ_{VRE}—are obtained by nonlinear regression on experimental data using Equation 3.4 as illustrated in Fig. 3.5. The timing parameters are visually verifiable, while the production rate is more difficult to confirm due to the effect of degradation. The parameters for product formation are determined in a similar manner.

The protein release model described above is a convenient assumption, especially when moving from synchronous to asynchronous infections. However, it presumes that stained cells (that have lost the ability to

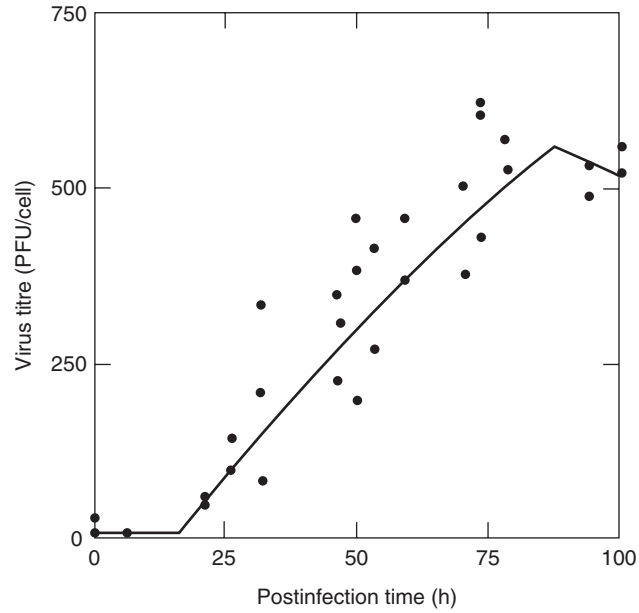

Figure 3.5. Fitting of virus production parameters. Sf-9 cells cultured in serum Sf-900II medium were infected with recombinant baculovirus at a multiplicity of 10 PFU. The datapoints are from three independent experiments and the solid line represents the model fit to data.

exclude trypan blue) are still metabolically active and continue to express protein product, which is unlikely to be true. A more likely scenario is one in which protein product is generated exclusively by unstained (viable) cells while protein leakage occurs only in stained (nonviable) cells. Haas and Nielsen (10) have proposed such a protein release model, by using an empirically fitted normal cumulative probability distribution to describe the change in nonviable cell proportion postinfection, which is paired with a zero-order kinetic model of specific intracellular protein production (by viable cells), to predict the specific extracellular protein level at any point of time postinfection.

3.4.3.1 Substrate Limitation. The simple model outlined above works well when the cell yield is below the optimal cell yield defined earlier. Near the optimal cell yield, however, it is our experience that the infection process slows down and the response is slower than predicted.

In suspension cultures, the limitation appears to be related to the depletion of an essential substrate (31,45). In our 1994 model, we had to overcome several problems in order to describe substrate limitation (42):

1. *Limiting Substrate is Unknown.* The limiting substrate is still to be identified and the model had to assume an arbitrary substrate to be present at 1 unit/L of fresh medium.
2. *Substrate Limitation Causes Complex Changes in Kinetics.* It has been our experience that substrate limitation causes a general slowdown of the growth and infection processes, not only a lowering in production rates as assumed by Licari and Bailey (36). As a simple initial approach, the model was made a simple depletion model, that is, all cellular processes were assumed to occur at maximum rate until depletion of substrate, at which point all cellular processes would stop.
3. *Consumption Pattern Unknown.* The limiting substrate being unknown it was not possible to formulate a consumption profile. Instead the specific consumption rate was assumed constant for noninfected and infected cells. The concept was that substrate consumption remained constant while the end-product would change from cell mass to viral products over the infection.

With these simplifying assumptions the resulting substrate limitation model only required a single parameter to be obtained, namely, the maximum cell density observed in a noninfected culture, Y_S. Mathematically, the model read

$$\frac{dS}{d\tau} = -\frac{\mu}{Y_S N_V}, \tau = 0 : S = 1 - \frac{N_V}{Y_S} \tag{3.11}$$

where S is the substrate concentration and the boundary condition accounts for the amount of nutrients consumed during the cell growth phase.

While this model capture the essence of the cell yield concept (Fig. 3.2), the temporal development remains poorly described around the peak, since the model fails to describe the slowdown in growth and infection when substrate becomes limiting. Moreover, the assumption of constant substrate consumption before and after infection—while fortuitously correct for β-galactosidase production in Sf-9 cells—does not hold for other systems (Table 3.1) (46). This flaw, however, can be corrected by introducing a separate consumption rate after infection $q_S \neq \mu / Y_S$.

One possible solution to address the model's inability to accurately describe substrate limitation is to make the infection velocity, ν, a function of substrate concentration, for example,

$$\nu(S) = \frac{S}{K_S + S} \tag{3.12}$$

Note, that with this definition the "infection time" τ, becomes a marker of the progression through the infection cycle rather than a measure of time. At $S = K_S$, for example, the cell progresses half an "infection hour" for each true hour in culture. If the specific rates of virus 3 and protein production 8b also are multiplied with ν, the result is to stretch out the infection cycle at lower substrate levels without changing the total yields.

If the limiting substrate is the space available, Equation 3.12 can be replaced with a spatial saturation model

$$\nu = \frac{\text{total capacity—capacity taken by noninfected and infected cells}}{\text{total capacity}} \tag{3.13}$$

as was done by Licari and Bailey (36). The approach argued here, however, differs from that used by Licari and Bailey,

TABLE 3.1. Specific consumption rates (mmol per 10^{12} cells per hour) for five amino acids before and after infection[a]

System Phase	Gln	Asn	Leu	Thr	Tyr
Sf9/rAcNPV Uninfected	24	2	8	3	13
Sf9/rAcNPV Infected	18	13	9	4	14
H.zea/HaNPV Uninfected	59	125	16	7	9
H.zea/HaNPV Infected	20	37	2	1	2

The comparison shows that while consumption remains essentially constant after infection in the Sf9/rAcNPV system, there is a significant drop in the *H. zea*/HaNPV system. [a]From Ref. (46).

in that they only took the change in production rate into account, not the prolonging of the infection cycle. The new approach is yet to be tested. The constant K_S will have to be a fitted constant, that is, chosen as the value that gives the best description to a series of high MOI experiments infected at different initial cell density.

3.4.3.2 Multiplicity of Infection. Infected cells continue to bind viruses after the initial infection, yet the proposed model does not take into account possible differences caused by the MOI of individual cells. Conceptually, an increase in multiplicity represents an increase in number of viral templates; hence, at least the early stages of infection should progress faster at high multiplicity. Indeed, increased rate of RNA synthesis was observed during the 2.5 h after infection when BHK cells were infected with an increasing number of Semliki Forrest Virus (47). What remains unclear is to what extent this transient increase affects the overall timing and whether or not total productivity is affected by the multiplicity.

In our experience, the use of an MOI of 10 versus an MOI of 5 in suspension culture does not significantly change the timing of the infection cycle. Furthermore, experiments using two different viruses suggest that any additional viruses compete with the existing viruses within the cell (Table 3.2). When recombinant β-galactosidase AcNPV and VP7 AcNPV viruses were added simultaneously (both at an MOI of 5), virus production for each was ~50% of that observed in the absence of the other virus. When one virus was added earlier, it gained a greater share of the total production at the expense of the other virus, and with 4 h difference the titer of the second virus would only reach about 10% of the normal level. It follows from these two sets of observations, that when a cell is infected with 10 instead of 5 viruses, the productivity *per virus* is essentially halved. Presumably, there is an upper limit on the copy number during the infection cycle and this limit is reached even if a single virus enters the cell.

Although MOI does not appear to affect timing or outcome significantly for baculovirus, there may be other systems where this is an important issue. In particular, timing may be important for viruses with a much shorter cycle than baculovirus, when stochastic aspects may become dominant. Hence, it may be necessary to model the effect of multiplicity. If infection occurs over a short period of time (either due to rapid binding of an available virus or due to deliberate removal of the viral inoculum after a short contact period), the effect of multiplicity can be accounted for by defining separate cell populations, N1, N2, and so on and define separate kinetics for each population. The number of cells in each population can be determined by assuming that viruses get distributed randomly according to the Poisson distribution with MOI as the parameter (9,11,36).

A common error, originating with Licari and Bailey's model (36) but often repeated, is the use of Poisson statistics for continuous models. While infection can be described as a Poisson process, a probability for one or more infections to occur cannot be assigned for the instant. Models employing this approach use the arbitrarily chosen time step used for numerical integration, typically 1 h. As indicated by Table 3.2, there is no evidence that additional infection events cannot occur after 1 h.

If infection occurs over a longer period of time, it becomes necessary to take into account that the first virus bound may have been replicated before later viruses bind. This situation may occur in a system where binding is intrinsically slow or during secondary infection in low MOI infections (discussed later), where the primary infected cells continue to release viruses gradually throughout the secondary infection. This situation can only be dealt with using highly mechanistic models as we would need to know not only the amount of DNA/RNA already present in the infected cell to add the contribution from additional infections, but also the delay between virus attachment and release of DNA/RNA into the cytosolic or nuclear pool.

3.4.3.3 Multiple Virus Infection. The experiment described in Table 3.2 is an example of viral production systems in which cells are infected by several different viruses. Multiple virus infection can be a deliberate process as in packing of replication deficient virus for gene therapy or production of multisubunit proteins (e.g.

TABLE 3.2. The effect of coinfection

	Timing VP7 h	rβgal-AcNPV titer 10^8 pfu/mL (%max)	rVP7-AcNPV titer 10^8 pfu/mL (%max)
Culture 1	−inf	0.00 (0)	0.62 (100)
Culture 2	−4	0.09 (7)	0.55 (89)
Culture 3	−2	0.22 (18)	0.58 (94)
Culture 4	0	0.56 (46)	0.33 (53)
Culture 5	2	0.77 (64)	0.18 (29)
Culture 6	4	0.68 (56)	0.08 (13)
Culture 7	+inf	1.21 (100)	0.00 (0)

Cells were infected with two recombinant AcNPV viruses—one producing β-galactosidase and one producing VP7, a blue tongue virus capsid protein—both at an MOI of 5. The table presents the timing of rVP7-AcNPV virus addition relative to rβgal-AcNPV addition and the resulting virus titers for the two viruses.

virus-like particles (48)). It may, however, also be the inadvertent outcome of defective virus accumulation.

The latter is an important quality control issue in most viral production systems and is frequently termed the *passage effect* (49), because serial passage at high multiplicity leads to defective virus accumulation. For Baculovirus, we can consider two types of viruses: normal infective particles (I-NOVs) and defective interfering particles that lack about 44% of the virus genome (D-NOVs). There is a third type that leads to an abortive infection, but we will ignore this type here for illustration purposes. With the two virus types, three modes of infection can be envisaged (41):

1. Correct infection arising from entry of at least one I-NOV without any D-NOVs. This infection gives rise to I-NOVs and a small number of D-NOVs.
2. Simultaneous infection of a cell by at least one I-NOV and at least one D-NOV. The genetic advantage of the D-NOV results in production of large quantities of D-NOVs and few I-NOVs.
3. The third mode results from infection of a cell with a D-NOV in the absence of an I-NOV. Without the helper effect of the I-NOV, such infections do not produce any virions.

If we assume that infection occurs over a short period of time, we can again consider the statistics of random virus distribution and calculate the probability for each mode of infection. Because of the vast difference in productivity (a single D-NOV will make the cell produce almost exclusively D-NOV progeny), we do not have to consider exactly how many viruses of each type attaches. Infection results in the formation of three populations, N_{I}, $N_{\mathrm{I+D}}$, and N_{D}, and we would define a parameter set for each population.

In general, it would be necessary to subdivide the $N_{\mathrm{I+D}}$ population into many subpopulations to account for differences resulting from different initial amounts of the two viruses. Hu and Bentley (48) developed such a stochastic model for simulating the coinfection of two recombinant baculoviruses encoding four protein products for virus-like particle production. Alternatively, it may again be necessary to consider a structured modeling approach, now with separate pools of DNA and RNA representing each virus. Structured models are also required if the infection process is not instantaneous.

3.5 KINETIC MODEL OF VIRAL INFECTION: ASYNCHRONOUS INFECTION

Asynchronous infection represents a significantly more complex problem than synchronous infection. Firstly, it is necessary at any point in time to keep track of cells at any point of the infection cycle. Secondly, understanding the kinetics of virus attachment and internalization is of paramount importance in asynchronous cultures, whereas in the synchronous culture it is sufficient to assume that all cells were infected simultaneously. The complexity of asynchronous culture dynamics, however, is also the main argument for modeling: it is practically impossible to quantitatively comprehend culture dynamics without the aid of a model. This section outlines how to use the behavior observed at high multiplicity infection—together with a population balance and attachment kinetics—to predict the behavior in low multiplicity infections, where the infection process is asynchronous.

3.5.1 Population Balance for Asynchronous Infection

When cells are infected at an MOI less than 3–5 in a batch culture, the culture will no longer be synchronous. At any point in time, the culture will be composed of noninfected cells and cells at different points in their individual infection cycle. The culture behavior is the cumulative behavior of these individual cells. In a continuous culture, noninfected cells are added continuously and the culture will obviously be asynchronously infected.

In order to keep track of the culture, we introduce the cell density function for infected cells, $n(t, \tau)$, where t is true time and τ is time since infection. Note that $n(t, \tau)\mathrm{d}\tau$ represents the number of cells at true time t, that have been infected for a period between τ and $\tau + \mathrm{d}\tau$ hours. Assuming no postinfection growth (as discussed earlier), the law of conservation for cell numbers reads

$$\begin{pmatrix} \text{change in number} \\ \text{of cells in } [\tau, \tau + \mathrm{d}\tau] \end{pmatrix} = \begin{pmatrix} \text{number of cells} \\ \text{entering } [\tau, \tau + \mathrm{d}\tau] \end{pmatrix} - \begin{pmatrix} \text{number of cells} \\ \text{leaving } [\tau, \tau + \mathrm{d}\tau] \end{pmatrix}$$

$$n(t + \mathrm{d}t, \tau)\mathrm{d}\tau - n(t, \tau)\mathrm{d}\tau = \nu(t, \tau)n(t, \tau)\mathrm{d}t - \nu(t, \tau + \mathrm{d}\tau)n(t, \tau + \mathrm{d}\tau)\mathrm{d}t$$

$$\frac{\partial n}{\partial t} + \nu \frac{\partial n}{\partial \tau} = 0 \tag{3.14}$$

Normally, it will be assumed that $n(0, \tau) = 0$, that is at $t = 0$, no cells are infected. If, furthermore, the infection rate at all times t that is $\mathrm{IR}(t) = \nu n(t, 0)$, is specified, then Equation 3.14 has a unique solution.

3.5.2 Attachment, Internalization, and Infection

The first event of the infection cycle is the attachment of virus to the cell. Wickham *et al*. (50) identified three modes of viral attachment for a number of different animal viruses:

Mode 1: Virus attaches to single receptor and is internalized.

Mode 2: Initial attachment to receptor is followed by reversible attachment to surrounding receptors and the complex is internalized.

Mode 3: Similar to Mode 2, except the number of receptors is so high that spatial saturation of cell surface with virus may occur.

Some insect cells, such as T.ni cells, have sufficient number of binding sites to indicate a possible involvement of spatial saturation, while for others such as *S. frugiperda*, the number of binding sites is too low (38,49). Practically, saturation is likely to be a factor only in low temperature attachment studies, where very high virus titers are used and internalization is minimal (51). Under standard infection conditions, binding is first order with respect to both virus and receptor number and the depletion of extracellular virus (V) due to binding is (52)

$$\frac{dV}{dt} = -k_a N V \tag{3.15}$$

where k_a is the attachment rate constant and N is the total number of cells. Dissociation has been neglected as it is typically slow relative to multivalent bond formation (stabilization) and internalization.

The infection rate, IR(t), differs from the attachment rate in that the former is only concerned with attachment to previously uninfected cells, N_V, rather than all cells. The infection rate is expressed as

$$\mathrm{IR}(t) = -k_a N_V V \frac{\text{cells}}{\text{PFU}} \tag{3.16}$$

where the last part is a unit conversion from viruses to cells.

The interpretation of k_a depends on whether attachment is diffusion- or reaction-limited. The maximum rate of attachment occurs when attachment is diffusion limited and every virus collision with the cell surface results in binding (52). This diffusion limited attachment rate can be calculated from a modified Scoluchowski equation (52)

$$k_{a(\text{diffusion})} = 4\pi r_{\text{cell}} D_v \eta \tag{3.17}$$

where r_{cell} is cell radius, D_v is the diffusion coefficient of the virus, and η is an efficiency factor accounting for the fact that virus can only attach to the cell surface where a receptor is present ($\eta \to 1$ as the number of receptors increases). For binding of AcNPV to *Spodoptera* cell lines (e.g. Sf-9), typical numbers are $r_{\text{cell}} = 9\ \mu\text{m}$, $D_v = 4 \times 10^{-8}\ \text{cm}^2/s$ (at 28°C from Stokes–Einstein equation corrected for rod-shape of virus, 40 nm × 300 nm), and $\eta = 0.5–1$ (50,52). Inserting these values in Equation 3.17, the diffusion limited rate is found to be $k_{a(\text{diffusion})} \sim 1–3 \times 10^{-8}\ \text{cm}^3/\text{cell/min}$.

When attachment is reaction-limited, k_a is equal to $k_f(\alpha N_r)$, where k_f is the intrinsic forward rate constant for binding of a single viral attachment protein to a receptor, α is the number of attachment proteins per virus, and N_r is the average number of receptors per cell.

Equation 3.17 is for cells in suspension (i.e. spheres) and the corresponding equation for cells in a monolayer is $k_{a(\text{diffusion})} = 4r_{\text{cell}} D_v \eta$. Assuming limited spread in the monolayer and assuming that receptors do not localize on the exposed surface, the theoretical ratio of $k_{a(\text{diffusion})}^{\text{suspension}}$ to $k_{a(\text{diffusion})}^{\text{monolayer}}$ is π. For reaction-limited attachment, this ratio is 4, the ratio between exposed surface area in suspension and in monolayer. Hence, $k_{a(\text{diffusion})}^{\text{suspension}} / k_{a(\text{diffusion})}^{\text{monolayer}} \sim 3–4$ can be used as general correlation and a ratio of almost 3 is indeed observed experimentally (52).

The observed attachment rate varies with virus, host, medium, mode of infection, and cell density (or "health" of cells). For Sf-9 cells propagated in serum-free SF900II suspension cultures, we observe attachment rates of $\sim 1.8 \times 10^{-8}\ \text{cm}^3/\text{cell/min}$, that is around the diffusion limit, up to a cell density of $4 \times 10^6\ \text{cells/cm}^3$ (Fig. 3.6), which corresponds to the optimal cell yield for this system (53). The attachment rate for the same virus and cell line in serum containing IPL-41 suspension cultures is only one-fifth, highlighting the sensitivity of attachment to medium composition (54).

Attachment continues after the initial infection. For baculovirus, the attachment rate remains at noninfected level

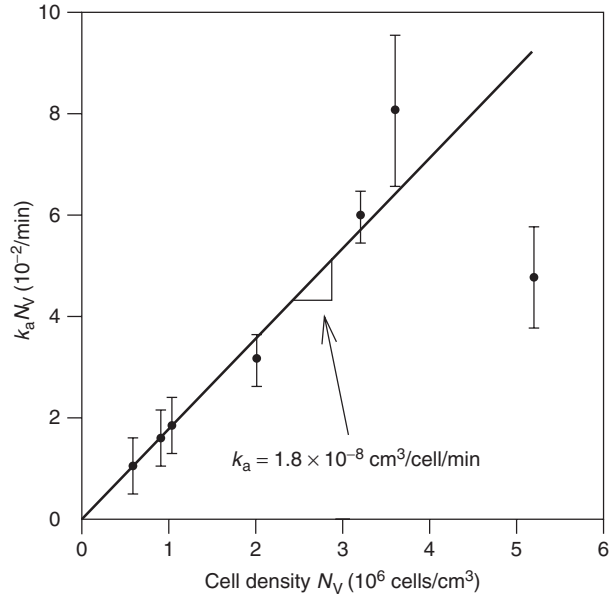

Figure 3.6. Attachment rate of recombinant AcPNV virus to Sf-9 cells in serum-free medium. Suspension cultures were incubated with ~50–100 radioactive labeled virus particles per cell and the attachment determined from the exponential decline in free virus concentration.

for 2–4 h, before falling exponentially until it reaches zero around 15–20 h postinfection (Fig. 3.7) (53). The 2- to 4-h period is consistent with the time it takes for the virus to internalize and commence transcription (52). The exponential decline may be attributed to the effect of natural protein turnover in the absence of new transcription and translation (the virus takes control over RNA and DNA replication, which is ultimately performed by a virus-specific replication apparatus). Mathematically, we can describe the infection rate for infected cells by

$$k_{\mathrm{ai}}(\tau) = \begin{cases} k_{\mathrm{a}}, & \tau \le \tau_{\mathrm{IE}} \\ k_{\mathrm{a}} e^{-\beta_{\mathrm{i}}(\tau - \tau_{\mathrm{IE}})}, & \tau > \tau_{\mathrm{IE}} \end{cases} \tag{3.18}$$

where τ is a measure of how long cells have been infected, k_{a} is the uninfected infection rate, β_{i} is the decline rate, and τ_{IE} is the duration of the immediate early period, that is the postinfection period until cell behavior is affected. The fit of Equation 3.18 to real data is shown in Fig. 3.5.

Internalization follows different routes for different viruses. Baculovirus enters cells through receptor-mediated endocytosis followed by low-pH mediated fusion of the viral and endosomal membrane (52). A similar mechanism is used by orthomyxovirus (e.g. influenza), togavirus (e.g. Semliki Forrest virus, rubella, yellow fever, dengue), and rhabdovirus (e.g. rabies). Internalization is reasonably fast (of the same order or faster than binding) and will not saturate under normal infection conditions (52). Only 50% of AcNPV virus is effectively internalized with the remainder found stuck on the outer membrane (52,53). A similar efficiency has been observed for Semliki Forrest Virus and it appears to reflect the efficiency of endosomal fusion rather than defective virus (51). Indeed, Dee and Shuler have presented evidence that low estimates for infective to total virus particles normally observed for AcNPV (typically 1 in 100–300) is caused by inadequate virus assays rather than truly defective viruses (51). It is possible that all virus particles in a low-passage inoculum are fully functional, but half gets randomly routed from endosomes to the lysosomes and released back to the cell surface following partial degradation.

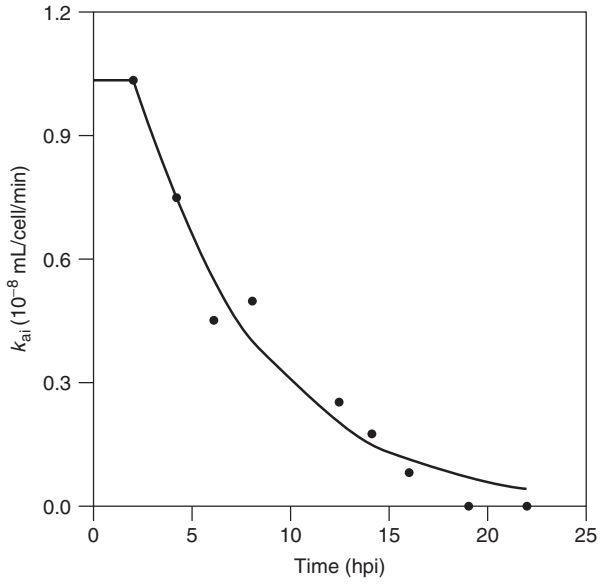

Figure 3.7. Attachment of AcPNV virus to Sf-9 cells in serum-free medium following infection. Cells were infected at 2.3×10^6 cells/mL at an MOI of 5.

Accurate virus titers are crucial to predict the behavior in low multiplicity infections. While it probably matters little for kinetics if cells are infected with 5 or 50 infective viruses (the result is a synchronous infection in both cases), an infection at 0.01 virus per cell will behave very differently from an infection with 0.001 virus per cell. For Equation 3.16 to make any sense, V must represent the true number of infective viruses.

3.5.3 Mass Balances

Mass balances are formed by combining the population balance model with the virus attachment model and infection cycle model. For example, the virus titer in a batch culture is described by the ordinary differential equation

$$\begin{aligned} \frac{\mathrm{d}V}{\mathrm{d}t} = & -k_{\mathrm{a}} N_{\mathrm{V}} V \text{ attachment to non-infected cells} \\ & - \int_{\tau=0}^{\infty} k_{\mathrm{ai}}(\tau) n(t,\tau) \mathrm{d}\tau \text{ attachment to infected cells} \\ & + \int_{\tau=0}^{\infty} r_{\mathrm{VR}}(\tau) n(t,\tau) \mathrm{d}\tau \text{ production} \\ & - k_{\mathrm{V}} V \text{ degradation} \end{aligned} \tag{3.19}$$

where the integrals are used to "sum up" the contributions to binding and production of cells at different stages of infection.

Similarly, for substrate, the mass balance for a batch culture is

$$\begin{aligned} \frac{\mathrm{d}S}{\mathrm{d}t} = & -q_{\mathrm{S}} N_{\mathrm{V}} \text{ consumption by noninfected cells} \\ & - \int_{\tau=0}^{\infty} q_{\mathrm{S}}(\tau) n(t,\tau) \mathrm{d}\tau \text{ consumption by infected cells} \end{aligned} \tag{3.20}$$

3.5.4 Solving the Model

In order to solve the model, the population balance, virus mass balance, and substrate mass balance models must be solved simultaneously. If we use a simple substrate depletion model, the maturation velocity is constant, $\nu = 1$, until

depletion after which, all cellular processes are assumed to cease. Prior to depletion the model is

$$\mathrm{IR}(t) = k_a N_V V \tag{3.21a}$$

$$\frac{dN_V}{dt} = (\mu - k_d)\ N_V - \mathrm{IR}(t) \tag{3.21b}$$

$$\frac{\partial n}{\partial t} + \frac{\partial n}{\partial \tau} = 0 \tag{3.21c}$$

$$\frac{dV}{dt} = -k_a N_V V - \int_{\tau=0}^{\infty} k_{ai}(\tau) n(t,\tau) d\tau + \int_{\tau=0}^{\infty} r_{VR}(\tau) n(t,\tau) d\tau - k_V V \tag{3.21d}$$

$$\frac{dS}{dt} = -q_S N_V - \int_{\tau=0}^{\infty} q_S(\tau) n(t,\tau) d\tau \tag{3.21e}$$

$$N_V(0) = N_0 \quad n(0,\tau) = 0 \quad n(t,0) = \mathrm{IR}(t)$$
$$V(0) = V_0 \quad S(0) = S_0 \tag{3.21f}$$

In this case, Equation 3.21b has the simple solution

$$n(t,\tau) = n(t-\tau, 0) = \mathrm{IR}(t-\tau) \tag{3.22}$$

that is, the number of cells of infection age τ at true time t is exactly the number of cells infected $(-\tau)$ hours earlier. If we introduce the variable, $s = t - \tau$, Equation 3.21c is converted to

$$\frac{dV}{dt} = -k_a N_V V - \int_{s=0}^{t} k_{ai}(t-s)\mathrm{IR}(s) ds + \int_{s=0}^{t} r_{VR}(t-s)\mathrm{IR}(s) ds - k_V V \tag{3.23}$$

The integrals on the right hand side of Equation 3.23 can be calculated at each time point, t, by numerical integration using the infection rates, IR(s), in previous time points as nodes. Thus, the problem can be solved using a standard ordinary differential equation (ODE) solver. We use a variable step-length, improved Euler algorithm, and the trapezoidal rule for integration. It should be stressed that Equation 3.22 holds only when the infection velocity is constant. If we introduce a more accurate description of infection velocity under substrate limitation, such as Equation 3.12, the solution is nontrivial and requires a numerical method for solving the first order partial differential equation and the ODEs simultaneously (e.g. method of lines).

Figure 3.8 illustrates the model's ability to predict the behavior in low MOI experiments. All parameters were obtained from high multiplicity infections in shaker flasks, yet the model adequately predicts the dynamics of a culture infected at a MOI 4 orders of magnitude lower, in which total infection occurs only after tertiary infections.

3.5.5 Using the Model

Having introduced this relatively complex modeling framework, it is important to return to basics such as how does

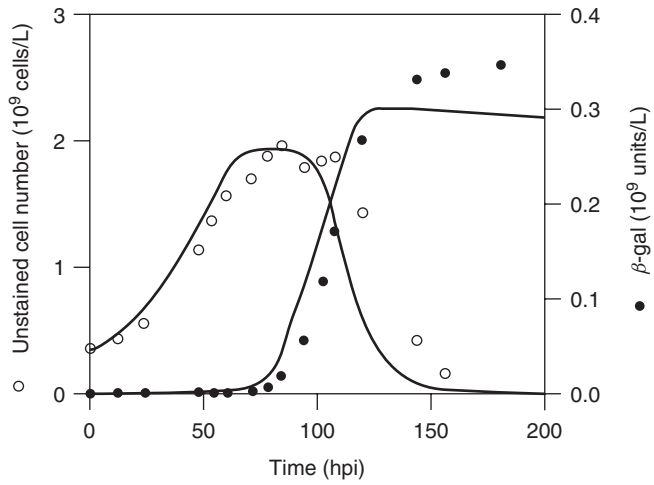

Figure 3.8. Model fit. The model with parameters determined in high MOI shaker flask cultures was used to predict the behaviour in bioreactor cultures, where cells were infected at 0.35×10^6 cells/mL at an MOI of 0.0001.

this help us in developing better viral production processes? This final section will illustrate how we have used the model to develop very low MOI infection processes.

There is substantial commercial incentive to use very low MOIs. The virus titer for a high yielding recombinant baculovirus is $\sim 2 \times 10^{12}$ PFU/L. Thus, to achieve synchronous infection (MOI = 5) in a 10,000-L batch culture infected around the optimal cell yield of 4×10^9 cells/L, we would need 100 L of virus stock. Due to the so-called passage effect (38)—serial passage leading to defective viruses—the virus stock should preferably be derived directly from a well-characterized Master Bank. Assuming that the Master virus stock is stored in 10-mL lots, the 100-L virus inoculum could be produced through 2–3 batch scale-up fermentations. In other words, a process relying on synchronous infection will consist of two parallel scale-up processes: one for cells and one for virus.

A more straightforward strategy is to inoculate the 10,000-L batch reactor directly with the 10-mL virus stock. This would obviously lead to an infection at a very low MOI and total infection would rely on secondary and tertiary infections. According to the cell yield concept, if the right cell density is chosen at TOI, the culture will reach the optimal cell density and yield the optimal product titer. That this actually works was illustrated in Fig. 3.2, where MOIs down to 0.0001 were used. Figure 3.2 does not address two important issues concerning the utility of low multiplicity infection: dispersion and reproducibility.

Intuitively, low MOI infection must lead to dispersion in product release and, hence, an undesirable increased exposure of the product to the culture environment (an important issue with labile viral products). Model simulations, however, revealed that low MOI infections in the baculovirus system do not necessarily result in significant dispersion. The reason for limited dispersion is that only a small fraction of cells are involved in building up the virus titer and that the final surge in virus titer leading to total infection occurs over a short period of time. Interestingly, dispersion does not increase with decreasing MOI. In fact, the highest level of dispersion will occur with an MOI of ~ 0.7 where half the *final* cell number is infected in first round and the other half (after cell growth) in the second round of infection.

These model predictions were confirmed experimentally (Fig. 3.9). Except for a delay in the onset of measurable production, lower MOIs did not alter the β-galactosidase concentration profiles (Fig. 3.9a). For each of the four multiplicities, the production period lasted ~ 36 h, occurred at an identical rate, and yielded approximately the same final β-galactosidase concentration. There is no apparent difference between infecting cells early at a very low MOI or late at a high MOI. This suggests that the final infection in all the experiments infected almost all of the cells and that this infection occurred over a relatively short period. For an MOI of 5, the final infection is also the primary infection and β-galactosidase production commenced at the onset of the very late phase 20–24 hpi. For an MOI of 0.01, only 1% of the cells are infected in the primary infection. The secondary and final infection appears to have occurred around 24 hpi, leaving another 20–24 h until the commencement of the major release period. Similarly, for MOIs of 0.001 and 0.0001 two and three rounds of infections, respectively, seem to have preceded the major final infection. The point is further illustrated by comparing the ratio of intracellular to total β-galactosidase yield for the four MOIs (Fig. 3.9b). In all four cases, the maximum intracellular β-galactosidase level was 50–60% of the total activity obtained at the end of the culture and the time to achieve this level was always 24 h after the onset of production.

The real challenge of performing low MOI infections is to ensure that the final infection reproducibly occurs when the culture has reached the optimal cell yield. In high MOI cultures, we can track the cell density all the

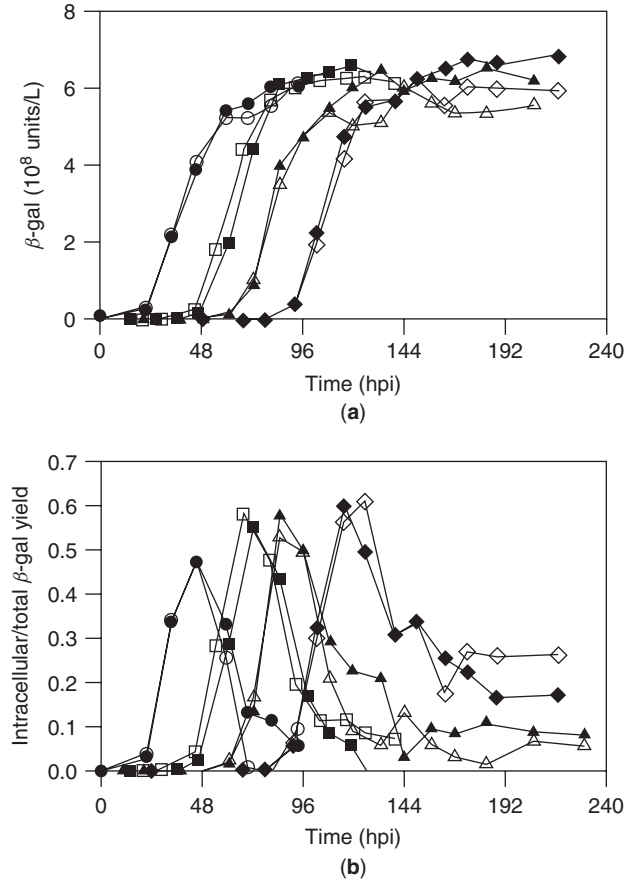

Figure 3.9. β-Gal production profiles for the best infections performed at MOIs of 5 (circle), 0.01 (square), 0.001 (triangle), 0.0001 (diamond) in shaker flasks. The figure shows (a) the total β-gal concentration and (b) the ratio of intracellular on total β-gal concentration.

way and cause infection when the culture reaches the optimal cell density. In contrast, low MOI cultures must be infected long before the optimal cell yield, and we rely on virus production and cell growth to reach the optimal cell density. The optimal cell density at infection, given the MOI, can be predicted using the model as was done in the above experiments and the main issue is to ensure reproducible behavior of the culture. Inherent variability in cell growth and relatively inaccurate assays make these a nontrivial task in the laboratory environment. For example, in our experience the specific growth rate of Sf-9 cells changes over their useful culture lifespan from $\sim$0.026 h^{-1} a month after thawing to 0.032 h^{-1} 3–5 month later, before they rapidly degenerate. In an industrial setting, where cells are taken from a well-characterized Master Bank, this should be less of a problem. Similarly, the low virus inoculum requirement means that the virus is taken directly from a well-characterized Master Bank thereby avoiding variation caused through scale-up processes.

CELL CULTURE, ASEPTIC TECHNIQUES

4.1 INTRODUCTION

4.1.1 Microbial Contamination

We live in a world in which we are constantly surrounded by microbes, in our environment as well as upon and within our own bodies. Yet the successful performance of cell culture demands that we be able to maintain and manipulate our cultures free of all microbial contamination. As we cannot sterilize our cultures after manipulating them, we are completely dependent on *Aseptic Technique* to ensure that, in handling our reagents, cells, and all the associated equipment, we maintain the sterile environment that our cultures require.

Aseptic technique is a combination of many procedures all designed with the single goal of *minimizing the probability* of a microbe gaining access to the cell culture environment. It is important to appreciate this concept of minimizing the probability of contamination, as even the best aseptic technique cannot absolutely guarantee the maintenance of sterility (indeed all sterilizing techniques work on this same principle (1)). Thus, a methodical and fastidious approach is required, with attention to each element of each procedure. Dropping an element or cutting corners may not necessarily result in an actual contamination the first time, but will *increase the probability* of a contamination occurring. Consequently, it is essential that all the elements of an aseptic procedure are carried out consistently every time, making sterility breakdowns rare events.

4.1.2 Cellular Cross-Contamination

Cell culture requires more however, than just the type of aseptic technique used for the exclusion of microbes. Our work becomes at best meaningless, and at most potentially dangerous if we are not culturing the cells we think we are. Thus aseptic technique for cell culture must include procedures to minimize the possibility of contaminating one cell line with another. Evidence that such inadvertent cross-contamination could occur was presented in the 1970s when various cell lines from a number of different laboratories were all shown by isoenzyme analysis and/or karyotyping to be, in fact, HeLa cells; these findings were later extended to include contamination involving cells other than HeLa (2–4). Thus the second aim of all aseptic technique used for cell culture is to minimize the probability of contaminating our pure characterized cultures with microbes or other cells.

4.1.3 Biohazards

So far we have concentrated on the role of aseptic technique in protecting the cells that we are culturing. However, there is another element to almost all aseptic techniques used for cell culture, which is the protection of the operator from hazards posed by the cells or (re)agents used in their culture.

Both human and nonhuman cells may carry viruses pathogenic to humans, and at least one actual fatality has

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

been documented, which was caused by inadequacies in the handling of such cells (5). Thus any new or poorly characterized cell line, or any cell line new to a laboratory *must* be handled as if it harbored a potential pathogen. Indeed, although the risk may be less when handling cell lines that have been extensively screened for microbiological contamination, the assays for such contaminants have limitations both in the level of contamination and the range of organisms they can detect. Furthermore, the continual discovery of previously unidentified human viral pathogens—for example, in the last 30 years we have seen the discovery of human retroviruses, and various "new" human herpes and hepatitis viruses—suggests that however extensive our microbiological screening, we can never be certain that a cell line might not contain a potentially dangerous viral "passenger." Moreover the risk is not limited to viruses as other contaminating microbes (such as mycoplasma) could be hazardous, and it may be that the cells themselves could pose a threat if inoculated into an operator via a puncture wound, for example owing to their oncogenic potential (6).

The commonest cell culture *reagent* that could be biohazardous is animal serum, of which the most widely used is fetal calf serum. This can contain a variety of microorganisms, but mycoplasma and bovine viruses are probably the most important. The agent that causes bovine spongiform encephalopathy (BSE) is also of concern, particularly as it appears to be the cause of variant Creutzfeldt–Jakob disease (vCJD) in humans (7–9). The chances of such agents being present in a batch of serum appears to be low (10) and can be minimized by purchasing only from the most reputable suppliers, who can document the source and health of the animals at slaughter and the standard of abattoir procedures, and who process and test the serum to minimize the chance of such agents appearing in the final product. Sourcing from a country where BSE is not endemic is important (see www.oie.int for the latest information), but as there was (and probably still is) a lot of "fake" Australasian and other sera on the market (much of it originating in countries where blue tongue, foot-and-mouth disease, and other viruses are a problem (11)) purchasing from a reputable supplier is doubly important. Further guidance on this topic has been issued by the World Health Organization (10).

Other reagents that may pose a hazard are those intentionally added to cultures, such as viruses that are being propagated or assayed. (Radioisotopes and other harmful chemicals may also pose a risk, but these hazards cannot be addressed by aseptic technique.)

Because of all the potential hazards outlined above, it is essential to carry out a full risk assessment before starting the culture of any cell line (12). The results of this will have a major impact on the aseptic techniques used, and most importantly on the environment in which they are carried out. Reference must always be made to the relevant local and national regulations governing the handling and containment of biological organisms (13).

4.1.4 Cell Culture Environments

The environments in which cell culture may be carried out vary both in the degree of protection given to the cells against external contamination, and the degree of protection afforded to the operator against potential hazards posed by the culture and its manipulation. In the early days of cell culture, procedures were carried out on the open laboratory bench, an environment which did little to protect the culture and nothing to protect the operator. As laminar flow cabinets or hoods—now more correctly termed *unidirectional airflow cabinets* (UDAFs)—and microbiological safety cabinets (MSCs) became available and our understanding of the possible hidden hazards associated with cell culture increased, so the move has been away from the open bench toward a more protective environment. However, cell culture can still be carried out successfully on the open bench, and under circumstances where the risk assessment indicates a minimal risk to the operator, and where using an appropriate MSC is not possible, doing so may still be justified. The vast majority of the principles and aseptic techniques utilized for culture are the same whether they are to be performed on the open bench or carried out within the environment of an MSC. Thus the general principles of aseptic technique for cell culture will be described first, as applied to working on the open bench. This will be followed by an examination of high efficiency particulate air (HEPA) filtration and the range of sophisticated equipment currently available, which employs HEPA filtration and provides protection to the operator and/or the cell cultures, and the adaptations in aseptic technique required to use this equipment safely and successfully. Finally, cleanrooms for use in cell culture will be examined.

4.2 ASEPTIC TECHNIQUE: GENERAL CONSIDERATIONS

4.2.1 Culture Equipment

All materials that come into direct contact with a cell culture *must* be sterile–aseptic technique only aims to maintain that sterility. As a consequence, all equipment such as flasks, bottles, dishes, pipettes, and so on must be treated by a sterilizing technique that gives a very high probability of sterility and is appropriate for the individual piece of equipment and the materials from which it is manufactured. The conditions of subsequent storage prior to use are also important. All sterile cell culture equipment should be stored in a clean, dry environment away from unnecessary airflow, and protected from possible sources of physical, chemical,

or other damage to itself or any of the packaging that maintains its sterile integrity. The integrity of such packaging (e.g. the bags containing single-use pipettes or the autoclave bags containing autoclaved materials) must be confirmed before the equipment is used: any equipment in damaged or inadequate packaging must be discarded, or repackaged and resterilized before use. Sometimes damaged equipment comes in perfectly good packaging; for example, crushed and cracked cell culture flasks can arrive inside a plastic bag that is still airtight. *Never* be tempted to use equipment over which you have the slightest doubt concerning sterility. It may be expensive to discard or resterilize, but not as expensive as your wasted time and the other materials you will waste working on a contaminated culture.

All equipment to be used directly in, or indirectly associated with, aseptic techniques must be carefully chosen with the three aims of aseptic technique constantly in mind:

- protection of the cells from microbes;
- protection of the cells from cross-contamination with other cells;
- protection of the operator from possible associated hazards.

Illustrations could be given relating to almost any piece of equipment, but two are given below:

1. Pipetting aids must always be used to operate pipettes, thereby protecting both the operator and the cells from each other. There are many designs, and the most comfortable and efficient for you and your type of work should be selected; one that is too awkward to use, or takes too long to pipette the volumes you use, will lead to tiredness, and a tired operator is a sloppy operator with poor aseptic technique.
2. An incubator is an essential piece of equipment, but must be kept clean in order to minimize the growth of microbes within it; so one that is easy to clean and has no inaccessible areas that will harbor microorganisms should be chosen. If humidified, the incubator should also have very good control of the humidity, as condensation forming on flasks and dishes can be a major source of microbial contamination. Indeed, persistent contamination can be a major problem in humidified incubators. This problem can be overcome by using a dry incubator (i.e. nonhumidified) so long as this is consistent with the research being undertaken. In the case of incubators maintaining a CO_2 atmosphere, one must check that the CO_2 sensor will operate satisfactorily under nonhumidified conditions. If a humidified incubator must be used, then it must be thoroughly cleaned and decontaminated at frequent and regular intervals, and a suitable microbial growth inhibitor [e.g. Roccal II (Sterling)] added to the humidifying water, which itself should be changed at weekly intervals. Where the incubator has a heat-sterilization cycle, this should be employed (at the highest temperature possible) for decontamination.

4.2.2 Working Area

Whether working in an MSC or not, a suitable working area must be chosen where the environmental flow of potentially contaminating particles can be minimized. A separate room, which is not a thoroughfare and is designated only for use when employing aseptic techniques, is preferable. This should be kept as clean as reasonably possible, with the minimum amount of equipment necessary, and preferably without shelving (which can harbor dust) above the working area. Air movement should be kept to a minimum commensurate with adequate ventilation and temperature control. If a separate room is not available, find a quiet corner of the laboratory where you can get as near as possible to the above conditions. (Siting of MSCs is dealt with further in the section titled Class II Microbiological Safety Cabinets.)

The work surface *must* be kept clean and tidy. Start with a clear surface, and wash it down with 70% ethanol or other liquid disinfectant (1). Then introduce to this clean area *only* those items required for a particular procedure. If these are many, it is better to break the procedure down into a series of steps and change the items in your clean area at suitable points, rather than work in a clutter. Arrange your equipment so that you have easy access to all items without having to reach across one to get to another, and make sure there is a large open space in the center on which to work. Having too many items in your clean area will inevitably lead, sooner or later, to you touching the sterile surface of (e.g.) a pipette against a nonsterile item. Cultivate a sensitivity to such undesired contacts, and always work within the central range of your vision. The same principle applies here as mentioned above: if you are in any doubt about the sterility of an item, don't use it—it is just not worth it.

Should you spill a liquid, mop it up immediately, and swab the surface down with your liquid disinfectant. Finally, when the work is done, remove all items from the work surface and swab down again.

4.2.3 Personal Hygiene

Before Work. Wash your hands. If you have long hair, tie it back or wear a suitable cap to keep it away from your face and the work. (Hair is a good source of microorganisms, particularly yeast, and when working with a Bunsen flame it is not unknown for individuals with long hair worn loose to set it on fire.)

During Work. Never eat, drink, smoke, chew, or apply cosmetics in the laboratory. This is to avoid bringing the hands (which may have hazardous material on them) into contact with the mouth or other mucous membranes, which offer easy access to the body. Similarly, always cover any cuts or cracks in the skin to avoid the ingress of unwanted material.

At the End of Work. Always wash your hands, irrespective of whether you have been wearing gloves or not.

4.2.4 Clothing

Before starting any aseptic handling make sure you are correctly clothed. A clean laboratory coat with long sleeves and close-fitting cuffs is the minimum requirement. Gloves can be useful (if carefully chosen so that they have the minimum adverse effect on manual dexterity and sensitivity), as they may contain any flakes of skin or loosely adherent microbes that may be present on the hands. Furthermore, if pulled up over the cuffs of the laboratory coat, they may contain any flakes of skin or microbes that might otherwise be expelled from the cuffs by currents of air forced down the sleeves by your movements. Nitrile or latex surgical gloves without a powder coating are the best type to use. Gloves should be sprayed or swabbed regularly during use with a liquid disinfectant (preferably 70% ethanol, as it simply evaporates leaving no residue) but, particularly if you are using a Bunsen, do not forget that 70% ethanol is flammable. Gloves also offer you a degree of protection from your cells. Keep an eye on the condition of your gloves, and if they get holed, discard them immediately and replace them with fresh ones. The use of a face mask is also worth considering, particularly if you have a moustache and/or beard (see comments on hair above).

4.2.5 Swabbing/Spraying

As far as possible, the surface of all nonsterile items should be dried (if necessary), then sprayed or swabbed with a liquid disinfectant before being introduced into your clean working area. This is particularly important for items coming from refrigerators, water baths, or humidified incubators, where microbial growth can be rife. Again, don't forget that 70% ethanol is flammable!

4.2.6 Capping

Deep screw caps are preferable to other types of closures for all bottles used routinely in aseptic techniques. They generally offer a good seal when screwed down, and offer a significant degree of protection to a bottle's contents even when only placed loosely in position, a situation that often occurs during aseptic handling. Bottles with International Organization for Standardization (ISO) threads can be used with a variety of caps of different materials, as well as other fittings designed for liquid handling.

4.2.7 Pouring

Pouring from one sterile container to another should be avoided if at all possible. Pouring generates aerosols, and they can carry cells or infectious biological reagents to other cultures or the operator. However, the most common risk is to sterility maintenance, as a bridge of liquid can be formed between the nonsterile outside and the sterile inside of a vessel and act as a conduit for the introduction of microorganisms. It follows that, if pouring *must* be done, then it must be done as a single delivery in one tip; even then it still carries a significant risk.

4.2.8 Flaming

When working on the open bench, it is common to use the flame of a Bunsen or similar burner to flame the necks of the bottles and screw caps before and after use, and glass pipettes before use only. This practice comes from microbiological technique, and its purported mechanism of action (and indeed its usefulness in cell culture) is open to some discussion. Any sterilizing or fixing effect on microbes is restricted to dry surfaces in direct contact with the flame. Some workers claim that if one works close to the flame, an updraught is created that prevents particles settling onto the work; others claim that the convection currents produced are not unidirectional and cause more problems than they solve. Either way, *flaming is not an essential part of sterile technique* even on the open bench, and should be avoided if at all possible when working in UDAFs or MSCs, as it disturbs the airflow and can be a fire hazard.

4.2.9 Pipetting

Pipettes commonly used in cell culture handle volumes from around 1 to 100 mL. Below 1 mL, Gilson- or Eppendorf-type pipettes (sometimes termed *micropipettes*) would normally be used along with single-use sterile disposable plastic tips (although for unmeasured volumes, glass or plastic Pasteur pipettes are also useful). From 1 mL upward, standard glass or disposable plastic pipettes probably represent the easiest way of manipulating measured volumes of liquids. Syringes can be used and are particularly useful for measuring volumes of highly viscous liquids such as glycerol or methylcellulose solutions. However, the hypodermic needles that fit them are not long enough to reach the bottom of most cell culture vessels, would be virtually impossible to use with viscous liquids, and carry the risk of causing needlestick and associated injuries to operators. Mixing needles—basically

a length of plastic tubing connected to a suitable fitting for a syringe—are a better option, will reach the bottom of all except some of the larger vessels, and are available presterilized (e.g. from Henleys Medical Supplies, Welwyn Garden City, Herts, United Kingdom). However, syringes may still prove unsuitable for manipulating some cells, owing to the high shear forces created when liquid passes through the relatively small aperture where the needle is mounted.

As mentioned before, pipettes must only be used in cell culture applications in association with a pipetting aid that must be suitable for the range of pipettes to be used. All pipettes should be fitted with a cotton (or similar) plug to maintain the sterility of the inside of the pipette when used with the (nonsterile) pipette aid. Suitable pipettes may conveniently be purchased as preplugged sterile single-use plastic items, which are discarded after use. Despite this, many laboratories still use glass pipettes, which appear to be a cheaper option in the long run. However, when the cost of unplugging, cleaning, drying, replugging and resterilization are factored in, any financial advantage claimed for glass pipettes is less evident. In addition, safety can be more of an issue with glass pipettes, as they are more prone to breakage, and consequently to injuring the operator if stressed or chipped during use.

When using a pipette, a number of precautions must be taken. The first is when inserting the pipette (particularly if it is a glass pipette) into the pipette aid. The pipette must be held at a point close to the pipette aid and excessive force must be avoided; it is easy to break a pipette, with the broken end then lacerating the hand or arm of the operator. Then, when sucking up liquid into the pipette, it is important that the cotton plug is not wetted. If it is, the pipette may effectively become blocked, or if it is not blocked then microbes can be introduced into the sterile liquid as it is being expelled from the pipette. Finally, in order to reduce the formation of aerosols, liquid should be expelled from the pipette as gently as possible, commensurate with the technique being employed. For the same reason, bubbles should not be blown through cell culture solutions, and the tip of a pipette should never be held above the lip of a vessel while expelling a liquid.

Pipetting aids can potentially harbor and spread contamination, but a little care can minimize this problem. They should be cleaned every time before use and regular decontamination should also be considered (some are designed to tolerate fumigation or autoclaving). In addition, if fitted with an integral filter, this should be changed regularly.

4.3 ASEPTIC TECHNIQUE: BASIC PROCEDURES

The range of aseptic manipulations that may be employed during cell culture is enormous, therefore the following procedure will be used to illustrate the way in which the principles discussed so far are brought together to form an aseptic procedure.

4.3.1 Manipulation of Cells and Liquid Reagents

This is illustrated by a procedure for supplementing a bottle of medium with fetal calf serum and then passaging a suspension cell line on the open bench. In this example, glass pipettes, presterilized within a metal can, are used for manipulating the solutions.

4.3.1.1 Protocol.

1. Bring medium and serum from the refrigerator or freezer, check the caps are secure, and then warm/thaw them in a water bath set at 37°C.

   The water bath should be sited away from the clean working area, as it can be a source of contamination, particularly bacteria and algae. To minimize this, water baths should be emptied, cleaned, and decontaminated on a frequent and regular basis, and preferably left empty when not in use. A contaminated water bath will contaminate any item placed in it. Indeed, such contamination should be assumed to occur every time a water bath is used, therefore items placed in it must be securely closed, and dried and decontaminated before use (see step 3).
2. Prepare your clean area by removing all unnecessary items and spraying/swabbing the bench with liquid disinfectant and allowing the surface to dry.
3. Bring to your working area only the equipment you need for the first step (supplementing the bottle of medium). The pipette can and pipetting aid should be sprayed down with liquid disinfectant before being placed in an easily accessible position within the clean working area. The Bunsen burner should also be introduced to the area; it should be clean, but should *never* be sprayed with ethanol (in case some has not evaporated by the time it is lit). Finally the medium and serum bottles are removed from the water bath, dried, sprayed with liquid disinfectant, and placed in the clean working area.
4. If ethanol or another flammable disinfectant has been used, wait until it has all evaporated before lighting the Bunsen. Open the pipette can and place the lid out of the way but still within the clean working area (i.e. with its mouth neither facing the ceiling nor in contact with the bench).

   In many cases, the lid can be placed under the open end of the pipette can to tilt the can upward at a convenient angle for removing pipettes. This also ensures that the lid is out of the way during subsequent operations.

5. Slacken the caps of the medium and serum bottles.
6. Remove a pipette carefully from the pipette can, touching the top of the pipette as little as possible with the fingers, and allowing the selected pipette to touch the other pipettes as little as possible, particularly near their tops.

   The aim here is not to touch any part of the pipette that will come into contact with your sterile solutions or equipment on the tops of the other pipettes which may have been touched by nonsterile hands or gloves.
7. Insert the pipette carefully into the pipetting aid, then flame the pipette by pushing it length ways through the Bunsen flame, rotating it through 180° (around the long axis of the pipette), then pulling it back through the flame. This should take no more than 3 s.

   Remember to hold the pipette close to its point of insertion into the pipetting aid and not to use excessive force, in order to avoid the dangers associated with breaking a pipette.
8. Pick up the bottle of serum in your free hand.
9. Grasp the lid of the bottle in the crook formed between the little finger and the palm of the hand holding the pipetting aid and unscrew the bottle from the lid.
10. Flame the neck of the bottle, by rotating it briefly in the Bunsen flame, then holding the pipette and bottle at an angle such that the pipetting aid and hand never get positioned vertically above the open mouth of the bottle, insert the pipette into the bottle.

    On the open bench, particles may fall downward from nonsterile items such as hands or pipetting aids onto whatever is underneath. Thus, the open necks of sterile bottles or flasks should never be below such nonsterile items, and this is the reason for working at an angle. This is also the case when working in a hood or cabinet with a vertical (top to bottom) airflow, such as a Class II MSC (see later section).
11. Draw up the required amount of serum into the pipette, then withdraw it from the bottle.
12. Flame the neck of the serum bottle, then bring it to its lid, and place the lid securely on the bottle. Pick up the bottle of medium and repeat steps 9 and 10.
13. Expel the contents of the pipette into the medium, withdraw the pipette, reflame the neck of the bottle, and replace the lid. Finally, discard the pipette into a container of disinfectant.

    To continue the process and use the freshly prepared medium to passage a suspension cell line.
14. Remove the bottle that contained the serum from the clean working area, as it is no longer required.

    This is to keep the working area as uncluttered as possible.
15. Take a new, sterile, plastic cell culture flask out of its sterile wrapping, ensure that it is not damaged and that its cap is secure, and place it in the clean working area.

    When first removed from its wrapping, the flask should be sterile both inside and out, and thus should not need spraying with disinfectant.
16. Pipette an appropriate amount of the freshly prepared medium into the flask using the technique detailed in steps 5–13, but here of course the liquid is withdrawn from the bottle of medium and expelled into the culture flask. It is recommended that the neck of the culture flask is *not* flamed, as the plastic could easily melt or catch fire.
17. Remove from the incubator the flask containing the cells to be passaged, and make sure its cap is secure. If there is any wetness on the outside of the flask, dry it immediately as such moisture is an excellent source of microbes. Spray or swab the outside of the flask with liquid disinfectant if this will not affect the culture (i.e., if the flask is sealed and there is no chance of the disinfectant reaching the cells). Once the flask has dried, introduce the flask to the clean working area.
18. Resuspend the cells and pipette an appropriate volume from the cell-containing flask into the flask containing fresh medium, again using the technique described in steps 5–13, and *not* flaming the necks of the plastic flasks. When expelling the cell suspension into the fresh medium, place the tip of the pipette either against the vessel wall or below the surface of the medium, and once the cells are expelled do not blow bubbles through the medium. Both these precautions are to avoid the formation of aerosols, as described earlier.
19. Place the new flask of cells in the incubator and discard the old flask of cells (to be destroyed by incineration or autoclaving). If the work is now finished, turn off the Bunsen, replace and/or secure any closures (lids on pipette cans, caps on bottles, etc.), remove all items from the clean working area, and spray and wipe down with liquid disinfectant.

4.3.1.2 General Note. Ethanol, including 70% ethanol solution, poses a real fire hazard when used with techniques that employ a Bunsen burner. It is recommended that in this situation a nonflammable disinfectant is used if at all possible.

As far as possible, only one cell line should be handled at a time, and each cell line must have a bottle(s) of medium dedicated for use only with that cell line and clearly labeled to this effect. All cultures and bottles of medium for one cell line must be removed from the working area,

the Bunsen turned off, and the area sprayed/swabbed down with disinfectant before introducing another cell line to the area. This should only be done after a gap of at least 5 min, to allow any possible cell-containing aerosols to dissipate. These precautions are to avoid cellular cross-contamination. Remember that working on the bench offers no protection to the operator from any biohazards present in the cell culture, and should only be undertaken if the risk assessment permits.

4.3.1.3 Working without a Bunsen. When working without a Bunsen, one must be even more fastidious with regard to maintaining the initial sterility of one's equipment. The advantage is that the fire hazard is eliminated, but one loses the comfort that if the outside of a pipette (for example) were to be nonsterile, then passing it through the Bunsen flame *might* sterilize it. Thus, for example, it may be worth using individually wrapped single-use pipettes rather than reusable ones, in order to avoid the potential for contamination when removing the pipette from the pipette can. Individually wrapped pipettes should be opened at the end furthest from the tip, and the open end of the wrapper turned inside out over the wrapping still in place, such that when the pipette is withdrawn it can only touch the inner surface of the wrapping, which should still be sterile. Similar precautions should be taken when removing other sorts of wrapping from sterile equipment.

Provided the maximum precautions are taken to maintain the initial sterility of all equipment, aseptic technique performed without a Bunsen can give at least as good results in terms of sterility maintenance as when using a Bunsen. Indeed, the decreased time of exposure to the environment caused by not having to flame the equipment may be positively advantageous in this respect.

4.3.2 Aseptic Manipulation of Equipment

The above handling guidelines should be sufficient to cover most cell culture operations carried out at the small scale. However, as the scale of operation increases, it may be necessary to aseptically assemble sterile pieces of equipment, for example, connect segments of tubing, or connect tubing to culture or media vessels. This is best achieved by completely covering the equipment to be sterilized in a wrapping that microbes cannot penetrate. Then, once sterilized, the equipment remains sterile until it is unwrapped immediately prior to aseptic assembly. In many cases it may be worth covering the actual assembly points separately to help maintain sterility. Assembly is then simply achieved after discarding the final wrapping on all assembly points. As with the aseptic techniques already described, manipulations are best performed wearing (sterile) gloves, and in an environment that will protect the equipment from airborne contaminants. In this case, that might be a Class II MSC, but could also be a vertical or horizontal *UDAF*, as sterile equipment poses no microbiological risk to the operator.

However, although the actual points of connection must always be sterile, it is not always possible for the whole of each piece of equipment to be sterile. An example of this might be when replacing an empty media vessel with a full one on a pilot-scale culture system, or when sampling from such a system via a septum. Maintenance of sterility during such manipulations may be facilitated by the use of a surface sterilizing reagent such as beta-iodine or 0.2% chlorhexidine gluconate ("Hibitane") in 70% ethanol. As an example, when disconnecting one piece of tubing connected to another by a Luer or similar fitting, and replacing it with a new one, one would proceed as follows:

1. Douse both halves of the existing connection, and both the new connector-half and its cover, plug or sheath, with the liquid surface sterilizing agent. This can be done conveniently by squirting the liquid disinfectant over the area from a squeeze bottle.
2. Using swabs made of segments of sterile butter muslin (or a similar absorbent and autoclavable cloth) soaked in the surface sterilizing agent, wrap the four half-connectors separately. This should be done such that the swab on each half-connector butts up against, but does not overlap, that on the other half. In order that any stray strands from the cut edges of the muslin do not get trapped in the new connection when it is made, these swabs should first be folded in half then placed on the half-connectors such that the folded edges butt together. Leave the swabs in place for at least 3 min to sterilize the covered surface.
3. Rapidly remove the cover, plug, or sheath from the new connector, break the old connection and make the new connection. This is done with the swabs still in place, and they are only discarded after the connection has been completed.

Wearing (sterile) gloves is strongly recommended. Also, note that if any of the tubes already contain liquid then they must be clamped before attempting this procedure.

It should be noted that the swabs soaked in surface sterilizing agent can fulfill two purposes. The first is to sterilize the area surrounding a connection. Thus, if there is any slight inaccuracy in making a connection, then the surrounding area that might be touched will be sterile and not compromise the sterility of the system. The second role is to act as a barrier between one's gloves (which may not be sterile) and the sterile surfaces.

Sampling from a septum is achieved in a similar way, but only the surface of the septum is sterilized using a

soaked swab, and in this case the swab is discarded before penetrating the septum with a sterile needle. (By the term *septum*, here we mean a small unit often marketed as a sterile injection site, not the large industrial type fitted to fermentors and similar equipment.)

As with all aseptic techniques, the surface sterilizing agent/swab technique gives no total assurance of sterility, and the relatively short exposure times and nature of the chemicals involved mean that some organisms may not be inactivated. However, in practice it appears to be an effective technique when used against those organisms commonly found in laboratories. We have run cell cultures in bioreactors using antibiotic-free medium for over 6 months in an ordinary laboratory, with hundreds of aseptic manipulations carried out as described. The cultures tested negative for bacteria, fungi, yeast, and mycoplasma at the end of this period.

4.4 HEPA FILTRATION

4.4.1 Introduction

Although performing aseptic techniques on the open bench can be successful, it offers no protection to the operator from any hazards posed by the work, and the high particulate load in the air of the average laboratory means that the chances of contamination of the work are always significant. These problems can be greatly reduced by performing the work in a suitable environment that incorporates a controlled flow of air from which the vast majority of both inert particles and associated viable contamination has been removed. This is achieved by the use of HEPA filtration.

HEPA filters are defined by their particle removal efficiency and their flow rate. They have a removal efficiency of at least 99.97% and they attain this efficiency when the air velocity through the filter is ~2 cm/s (4 ft/min). Although higher-grade filters have been developed recently [e.g. ultra low penetration air (ULPA) filters], these are intended for the microelectronics industry where contamination of the electronic components with very small particles can be a significant problem. This level of filtration is not normally required for pharmaceutical and biological (including cell culture) applications. Indeed, providing a level of filtration greater than that required can have significant cost penalties, and the associated working practices may make the work unnecessarily difficult and time consuming.

4.4.2 Mechanisms of Filtration

Filtration of a gaseous medium is not a simple process of sieve retention but rather the sum effect of several different mechanisms. The relative contributions of these various mechanisms can vary considerably depending on the size of the particles and the air velocity passing through the filter.

Sieve retention is the simplest mechanism of particle retention and occurs when the particle is larger than the spaces between the fibers of the filter medium. This sieving effect is only of significance for relatively large particle (>2 μm) and these would normally be captured by the coarser and less expensive prefilter placed upstream of a HEPA filter. It would not be cost effective to use HEPA filters to remove large particles.

The three most important particle removal mechanisms of HEPA filters are inertial impaction, diffusive retention, and interception (Fig. 4.1).

4.4.2.1 Inertial Impaction. As the air flows around the fibers of the filter medium (see the section titled Construction of HEPA Filters) the larger particles, because of their inertia, do not follow the airflow but continue in their original direction and become embedded in the fibers. This mechanism is a major factor for particles of >1 μm. As the air velocity through the filter increases, this mechanism becomes more effective.

4.4.2.2 Diffusive Retention. Small particles (<0.1 μm) are retained primarily by impaction resulting from Brownian motion (i.e., randomized movement caused by the particles in question being hit by other small particles or the molecules of the gas in which they are suspended) which causes them to deviate from the direction of the airflow. This random motion results in the impaction of the particles on the fibers of the filter.

4.4.2.3 Interception. Particles of an intermediate size (ca. 0.1–0.5 μm) have less inertia than the larger particles and tend to follow the flow of air around the fibers. If a particle strikes a fiber as it passes it, that is tangentially, or if it approaches one closer than half its diameter it will be captured and retained by it, this mechanism being interception.

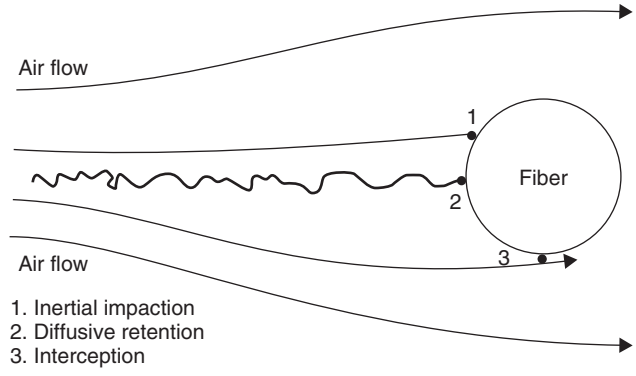

Figure 4.1. Schematic representation of mechanisms of filtration.

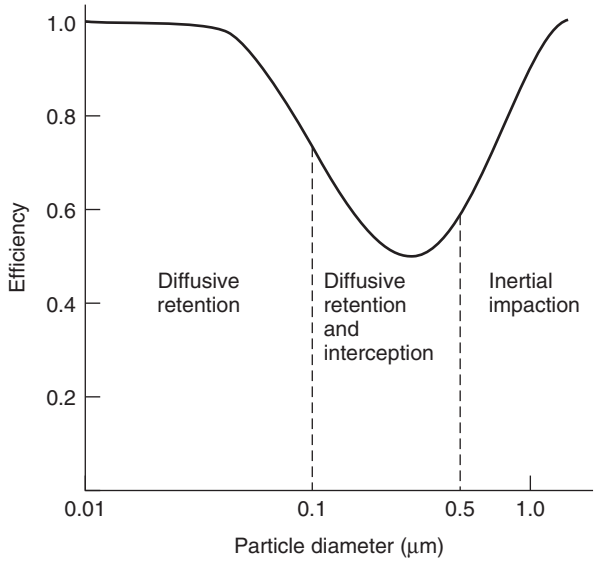

Figure 4.2. Classical efficiency curve for a HEPA filter.

Once a particle has come into contact with the fiber of the filter it is held by surface/surface interactions, such as electrostatic forces, and will become difficult to dislodge. It is the combination of these mechanisms that explains the efficacy of HEPA filters.

4.4.3 Filter Efficiency

Figure 4.2 shows the classical efficiency curve of a HEPA filter, the minimum efficiency being for a particle of about 0.2–0.3 μm, particles both larger and smaller being removed more efficiently. However, the actual minimum efficiency is variable and will depend on the following factors (14):

- the density of the individual particles;
- the velocity and mean free path of the particles;
- the thickness of the medium;
- the velocity, pressure and temperature of the air;
- the sizing and distribution of the fibers within the filter medium.

As penetration is a function of so many variables, the actual shape of the curve and the minimum efficiency will vary. Rather than considering a single most penetrating particle size it has been suggested that it would be better to think in terms of the most penetrating particle range, for example, 0.1–1.0 μm (14).

Filter efficiency decreases with increasing flow rate, conversely the lower the flow rate the more efficiently a filter will retain particles. Airflow velocities of around 90 ft/min, as frequently found in cleanroom situations, should not result in problems due to particle penetration of intact HEPA filters as any upstream particles are likely to be either too small or too large to penetrate to any significant degree. The large surface area of HEPA filters is designed to provide an adequate volume of filtered air at the flow rate required to maintain suitable conditions within the cleanroom or device (e.g. UDAF). It is possible, by increasing the amount of filter medium in a filter, not only to decrease the pressure drop across it but also to increase its efficiency. If the air velocity were reduced sufficiently it could be possible to achieve 99.97% removal of particles in the range 0.1–1.0 μm with a relatively coarse filter. However, the dynamics of filtration is but one factor necessary to achieve suitable air quality in any particular situation. The filtered airflow volume needs to be sufficient to allow adequate flushing of the critical area in order to cope with the particulate and microbiological contamination that may be introduced from the process equipment or the personnel.

4.4.4 Construction of HEPA Filters

The filter medium is a paper formed from fine glass fibrils, the higher the efficiency of the filter the higher the proportion of smaller fibers. The filters can be constructed in a number of ways depending on the nature of the system/room/cabinet and the predefined standards it must meet. Each method is intended to produce a relatively large surface area of filter medium, which is sealed within a rigid frame and with a suitable gasket to prevent the leakage of unfiltered air into the working environment. The filter medium is mounted in the frame, normally in one of the following ways (15):

4.4.4.1 Standard Filters. The sheets of filter medium are folded in parallel pleats, the pleats being separated by corrugated aluminum or Kraft paper separators. The filter medium and separators are assembled and bonded to the frame with a resin. The frame may be constructed of metal, wood/chipboard, or plastic.

For most biological or pharmaceutical applications filters with wooden/chipboard frames would not be considered suitable because these materials can themselves shed particles and because of the potential for microbiological growth on the frame, particularly if they became damp. However in some applications, for example when used in certain chemical or biological processes, the use of wooden frames may be indicated in order to facilitate incineration after use.

4.4.4.2 Mini-Pleat Filters. This format is a modification of the standard filter but without the use of separators; the filter medium is folded in tighter pleats (~2–3 pleats/cm compared to ~1 pleat/cm for standard filters). To allow the air to flow satisfactorily the paper has in-built nylon

cords or molded media that protrude slightly from the paper folds in order to hold them apart. These filters can provide greater volume flow capacity and more uniform face velocities compared to standard filters but they are more expensive. However, as they hold approximately twice the surface area of filter medium when compared to the same size of standard filter unit, they may have advantages where space constraints are a problem or where extended use between filter changes is required.

4.4.4.3 Flanders Filters. This type of filter is constructed from crenellated corrugated filter paper, the surface "texture" acting in lieu of separators to keep the pleats apart. The crenellated surface and the absence of separators result in ~40% more available filtration area compared to standard filters. These filters, however, only fit patented frames. The filter-holding frames have a slot filled with thixotropic gel, which accepts a tongue on the filter edge, achieving an air tight seal without using a compressed gasket [the gaskets on both standard and mini-pleat filters use compressible gaskets made from closed-cell neoprene, polytetrafluoroethylene (PTFE), or molded polyurethane].

4.4.5 Testing of HEPA Filters

Filters are tested by the manufacturers to assign or confirm their particle removal efficiency. In addition, on-site testing after delivery and installation needs to be carried out to verify that no damage has occurred during storage, transportation, or installation. At times confusion has arisen regarding the purpose and intention of this on-site testing.

The tests carried out by the filter manufacturers use relatively sophisticated equipment to control challenge aerosol particle size, airflow rates and so on, and would normally consist of one of the following:

4.4.5.1 Hot DOP (Dioctylphthalate) Test. Thermally generated particles of dioctylphthalate (DOP), of an essentially monodisperse aerosol with a mean diameter of ~0.3 μm, is generated upstream of the filter and the percentage penetration determined by comparing the downstream concentration of particles to the upstream (100%) concentration.

4.4.5.2 Sodium Flame Test. An aerosol of particles of sodium chloride, mainly within the range of 0.02–2.0 μm with a median of 0.6 μm, is generated by atomizing a sodium chloride solution and evaporating the water. By comparing the upstream and downstream concentrations photometrically, the percentage penetration can be determined. The hot DOP and sodium flame tests produce substantially similar size distribution aerosols and the tests give comparable results.

4.4.5.3 Oil Mist Test. This is the basis of the German (DIN 24184) test. The principle of the test is the same as the DOP and sodium flame tests, but the test aerosol is an oil mist with a particle size between 0.3 and 0.5 μm.

The test normally carried out on-site is a cold version of the DOP test or a variant of it using, for instance, a different challenge aerosol such as mineral oil. An aerosol of polydisperse particles in the range 0.1–3.0 μm is generated, usually at ambient temperature, and introduced upstream of the filter, while the downstream filter face is scanned with a photometer to detect any leaks, again by comparing the upstream and downstream concentrations of the aerosol. It is normally accepted that a photometer reading of >0.01% is indicative of an unacceptable leak. There are a number of fundamental differences between this test and the more sophisticated tests used by the filter manufacturers to verify the particle removal efficiency (e.g., particle size distribution, concentration of the aerosol challenge, temperature control, airflow velocity control, etc.). This *in situ* test is intended to be a check of the integrity of the complete filter installation, and is not suitable to verify the particle removal efficiency of the filters.

4.5 HOODS AND CABINETS EMPLOYING HEPA FILTRATION

These can be divided into two categories: UDAFs, where a flow of HEPA-filtered air is used to protect the work from contamination by particulates, but which offer little or no protection to the operator from hazards posed by the work; and MSCs, all of which offer protection to the operator but which may or may not offer protection to the work.

4.5.1 Unidirectional Airflow Cabinets

4.5.2 Horizontal Flow

In these hoods, the flow of HEPA-filtered air is directed from the back of the hood across the work surface toward the operator. Thus these hoods should only be used for the manipulation of clean, preferably sterile, nonhazardous equipment and solutions, and never for cell culture (Fig. 4.3).

4.5.2.1 Vertical Flow. In these hoods the airflow is from top to bottom. Thus, air is not blown directly from the work at the operator as in a horizontal flow hood, but the absence of a front screen and of filtration of the exhaust air means that there is still no significant protection offered to the operator. Thus it is recommended that these hoods are also not used for cell culture (Fig. 4.4).

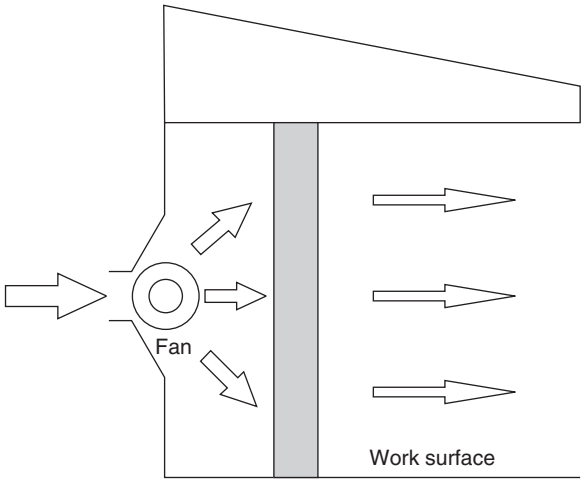

Figure 4.3. Schematic cross-section of a horizontal unidirectional airflow cabinet (arrows indicate airflow; hatched area = HEPA filter).

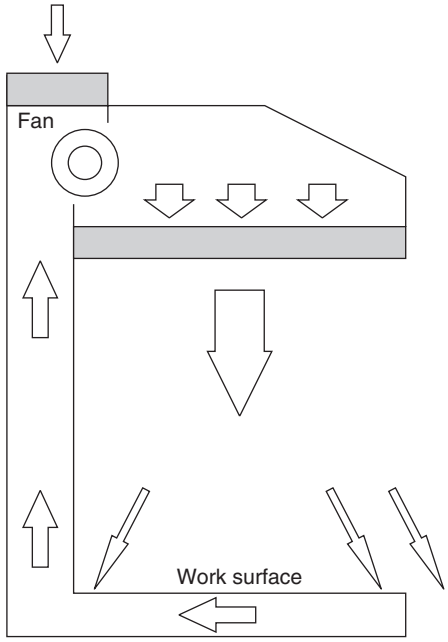

Figure 4.4. Schematic cross-section of a vertical unidirectional airflow cabinet (arrows indicate airflow; hatched areas = HEPA filters).

4.5.3 Microbiological Safety Cabinets

An MSC can be defined as a cabinet intended to offer protection to the user and environment from the aerosol hazards of handling infected and other hazardous biological material, but excluding radioactive, toxic, and corrosive substances, with air discharged to the atmosphere being filtered (16). Some, *but not all* of these cabinets will also offer protection to the work from environmental contaminants.

4.5.3.1 Class I MSCs. These cabinets operate by pulling in a constant stream of air from the room through the working aperture, and passing it through a HEPA filter to exhaust. The inward airflow through the working aperture protects the operator from particulates generated within the cabinet, and these particulates are prevented from escaping to the environment by the HEPA filtration of the exhaust. However, this type of cabinet offers no protection to the work from particles generated outside the cabinet. Class I MSCs are generally used for the handling of viruses and other biological agents that pose a moderate risk to the operator (Fig. 4.5).

4.5.3.2 Class II MSCs. These are the cabinets most commonly used for cell culture, as they are easy to use but offer protection both to the operator from particulates generated inside the cabinet, and to the work from particulates generated outside the cabinet (Fig. 4.6).

The work is protected by the vertical flow of HEPA-filtered air from the top of the cabinet, and by the fact that air entering the front of the cabinet is drawn directly away beneath the work surface without passing over the work. The operator is protected by the inflow of air at the working aperture, which prevents the outflow

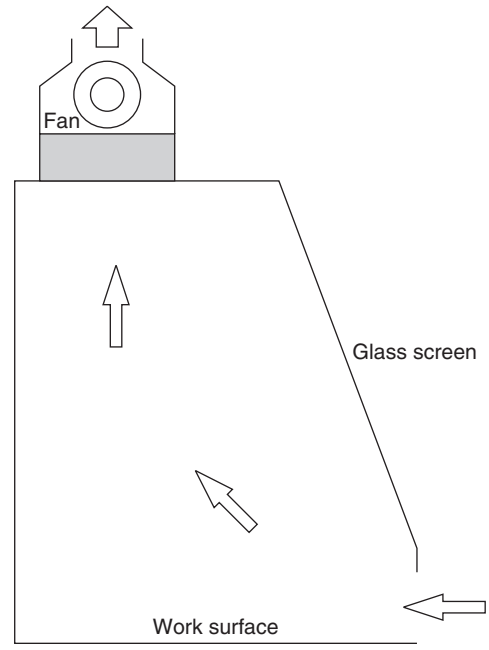

Figure 4.5. Schematic cross-section of a Class I microbiological safety cabinet (arrows indicate airflow; hatched area = HEPA filter).

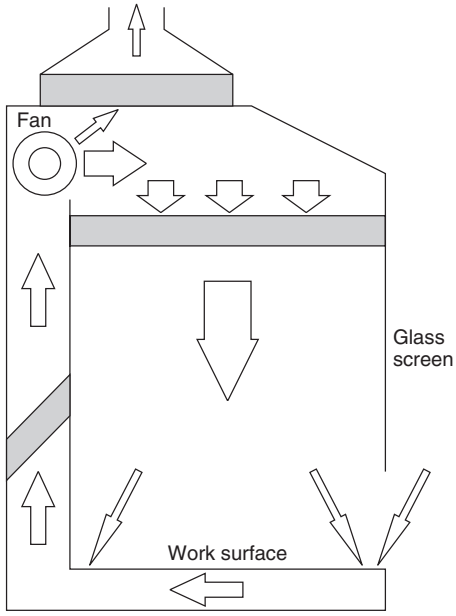

Figure 4.6. Schematic cross-section of a Class II microbiological safety cabinet (arrows indicate airflow; hatched areas = HEPA filters).

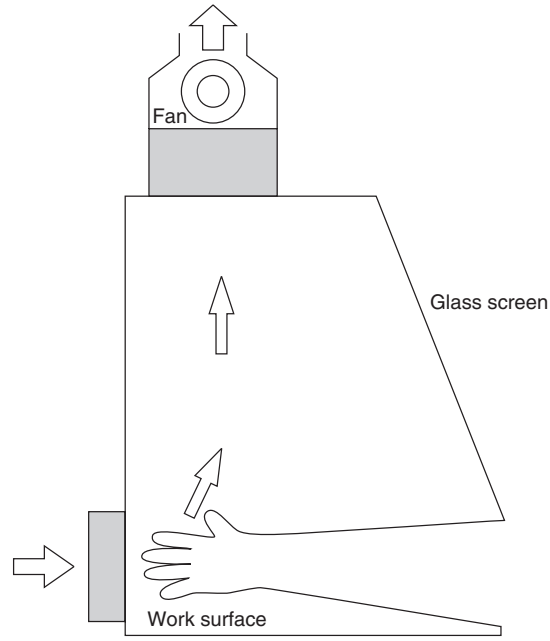

Figure 4.7. Schematic cross-section of a Class III microbiological safety cabinet (arrows indicate airflow; hatched areas = HEPA filters).

of particles from inside the cabinet, and by the fact that all the exhaust air is HEPA filtered before being released to the environment. Only a percentage of the total airfow within the cabinet is sent to exhaust, the amount required being that needed to compensate for the air constantly flowing into the cabinet at the front aperture; the balance of the air is recycled within the cabinet.

4.5.3.3 Class III MSCs. These cabinets offer maximum protection, both to the work and to the operator and environment, but are extremely cumbersome to use and are only normally employed when manipulating dangerous [Hazard Group 3 or 4 (13)] pathogens. In these cabinets, the operator is separated from the work by gloves mechanically attached to the cabinet, and both the inlet and exhaust air have airborne particulates removed by HEPA filtration systems (Fig. 4.7).

4.6 WORKING WITHIN UNIDIRECTIONAL AIRFLOW CABINETS AND MICROBIOLOGICAL SAFETY CABINETS

4.6.1 General

Before use, all cabinets/hoods should be switched on and allowed to run for at least 15 min before use, to establish the correct airflow and clear any airborne particles. When using cabinets that employ a blanking plate for the front aperture (Class I and II MSCs) the blanking plate should be removed immediately before starting the fan and placed on a *clean* surface (not the floor!). It is replaced once the fan has been stopped after use (although many cabinets are designed to run continuously). In all hoods/cabinets, the use of Bunsen and similar burners should be avoided if at all possible as they disturb the airflow pattern and may be a fire hazard. All hoods/cabinets must be kept as clean as possible, and the working surface should be cleaned with a suitable disinfectant before and after every use. Spills should be mopped up immediately and the working surface wiped with disinfectant. If anything should be spilt down the perforations in the working surface of a vertical UDAF or Class II MSC, then the working surface must be removed and the underlying area cleaned and treated with a suitable disinfectant. This should in any case be done at least weekly even if no known spills have occurred.

In order to operate efficiently, the hood/cabinet must be tested regularly (at intervals of not more than 1 year) for HEPA filter integrity, airflow direction and rates, and particulate containment and elimination of external contamination if appropriate (see the section titled Testing of Class I and Class II Microbiological Safety Cabinets). If used for handling level 3 pathogens, testing must be performed more frequently (i.e. at least every 6 months). All hoods/cabinets must be fully tested when first installed and whenever they are relocated within or between laboratories (see the section titled Class II Microbiological Safety Cabinets). Some cabinets may have integral airflow meters that continuously monitor performance, and cabinets should not be used if the meter

indicates that parameters are outside the range required for safe operation. Where such a meter is not incorporated into the cabinet's design, simple and regular (e.g. monthly) in-house testing using an anemometer can help to show consistency of performance, and indicate if, for example, a prefilter needs changing. However, this does not remove the necessity to check the cabinet's operation fully every 6–12 months, and after being installed or moved.

4.6.2 Unidirectional Airflow Cabinets

4.6.2.1 Horizontal Unidirectional Airflow Cabinets. Because the airflow is directed at the operator, these hoods must *never* be used for cell culture or when manipulating any other potentially hazardous material.

The type of aseptic technique described in the section titled Manipulation of Cells and Liquid Reagents should be adopted when working in such hoods. However, it must be modified such that any item that may not be sterile (e.g. hands and pipetting aids) should, instead of not being directly above any sterile openings (e.g. open bottles), not be directly *behind* them.

4.6.2.2 Vertical Unidirectional Airflow Cabinets. General aseptic technique is carried out as described for use on the open bench, without a Bunsen burner.

4.6.3 Microbiological Safety Cabinets

4.6.3.1 Class I Microbiological Safety Cabinets. As stated above, these cabinets are designed to protect the operator from the material being handled, and offer no protection to that material or the work being performed with it. Thus, such a cabinet must be positioned where the incoming air is as clean as possible. In addition, in order not to compromise the containment of particulates within the cabinet, it must be sited where there is minimum air turbulence outside the cabinet—see the next section (on Class II cabinets) for further details. The lack of protection offered to the work means that the amount of work carried out in a Class I cabinet should be kept to a minimum. For example, if performing a virus assay by plaque formation on a cell monolayer, the handling of the (uninfected) cells when preparing the monolayer should be carried out in a Class II cabinet. Only the preparation, dilution, and addition of the virus should be performed in the Class I cabinet.

Performing manipulations within the Class I cabinet is rather different from that described for all the other types of hood or cabinet, as the only way to protect the work from the incoming unfiltered air is to position equipment such that the airflow is directed away from any sterile area, for example open bottles or culture dishes. Thus, when removing material from a bottle, for example, the base of the bottle should be pointed into the airflow with the neck pointing toward the extract filter. In cases where equipment (e.g. Petri dishes or multiwell plates) must remain horizontal when opened, they should be positioned well to the rear of the cabinet away from the front aperture. The length of time that vessels are left open must in all cases be kept to a minimum. In other respects, aseptic technique used in Class I cabinets is the same as that described for use on the open bench in the section titled Manipulation of Cells and Liquid Reagents.

4.6.3.2 Class II Microbiological Safety Cabinets. Protection of both the work and the operator is dependent on the integrity of the inward airflow at the working aperture and its efficient and immediate removal through the perforations/slits in the front of the working surface. Eddies caused by (i) turbulent air outside the cabinet, or (ii) around the arms of the worker, can cause nonsterile incoming air to be directed across the top of the work surface, or air from within the cabinet to escape, unfiltered, to the environment. Two ways to avoid this are as follows:

1. Steps must be taken to reduce to a minimum the turbulence of the air in the vicinity of the front of the cabinet. This means that very careful consideration must be given to the siting of the cabinet in terms of its proximity to building/room structures (walls, columns, and doors), work benches, other cabinets, and routes of movement by other worker (Figs 4.8 and 4.9). Furthermore, in the vicinity of the cabinet the velocity of the air due to the room's ventilation system must be kept to a minimum. It is particularly important that air entering the room via grilles, diffusers, and so on should not discharge directly across or toward the aperture of the cabinet, and every attempt should be made to keep all air velocities in the room below 0.3 m/s. Clearly, when designing a new laboratory the siting of the MSCs must be decided early and incorporated into the design process. Positioning of cabinets in an existing laboratory similarly requires the most careful consideration, and all cabinets must be performance tested once in their new position, even if they have only been moved a short distance within the same room. These requirements apply equally to Class II and Class I cabinets.
2. The operator should avoid rapid movement of his/her arms in the working aperture, and should avoid coughing, sneezing, singing, whistling or, as far as possible, talking or being otherwise disturbed while working. It should always be remembered that the front perforations/slits are a nonsterile area, and thus all work should be performed at least 5 cm away from them. Similarly the perforations/slots at the rear of the working surface should be kept clear so as not to impede the downward flow of air in the cabinet.

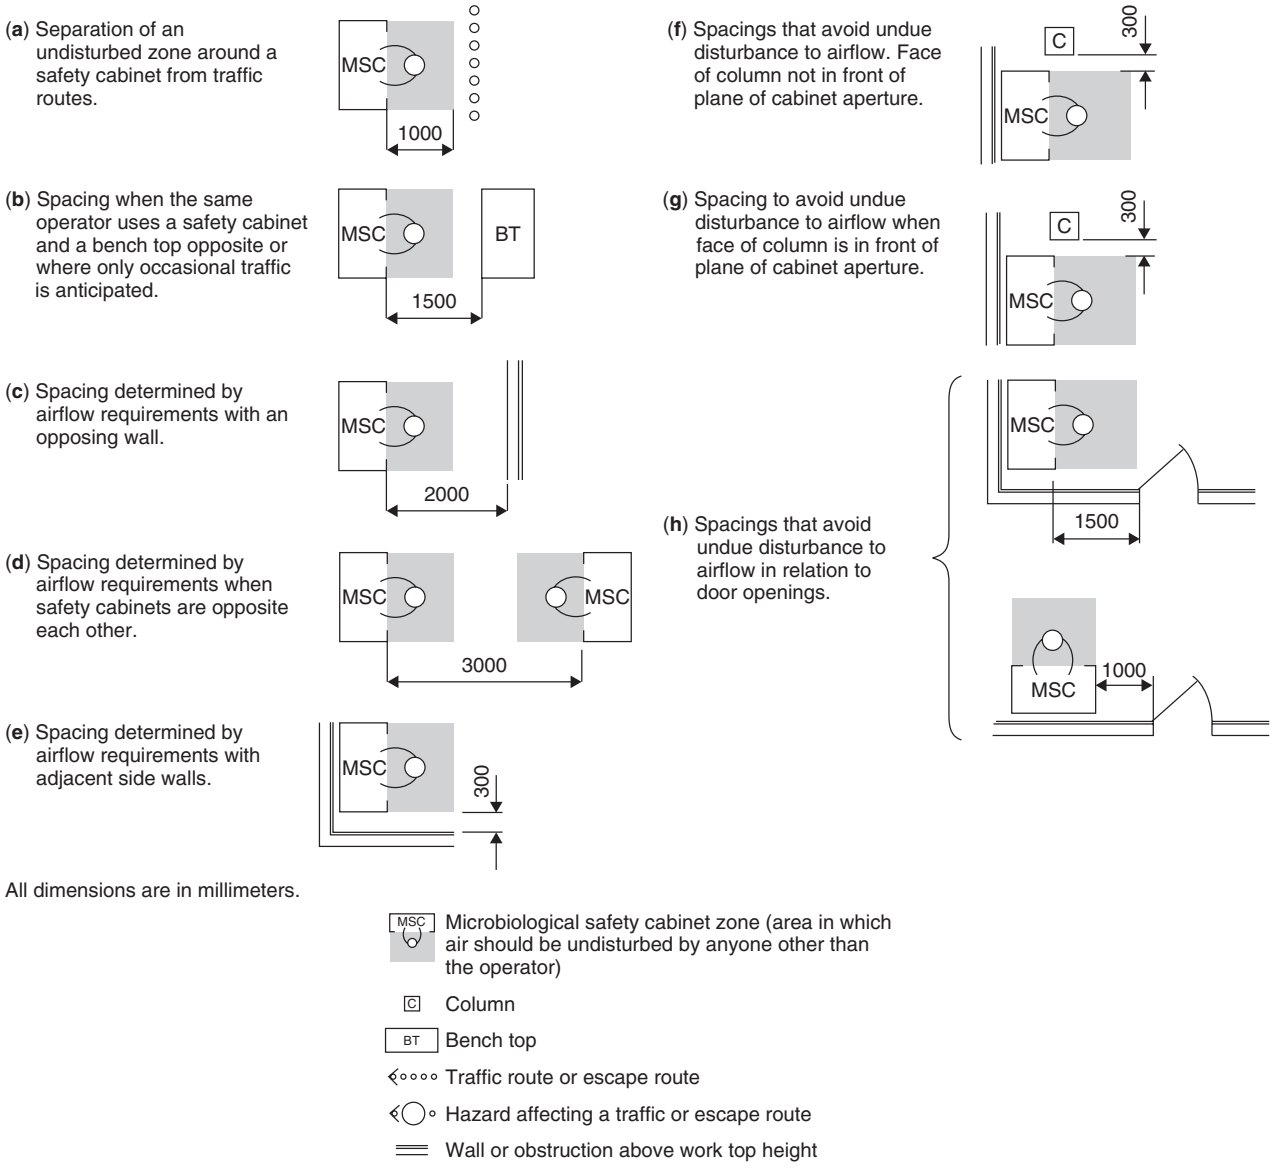

Figure 4.8. Siting of microbiological safety cabinets: recommendations for minimum distances for avoiding disturbance to the safety cabinet and its operator. [Reproduced with permission from BS 5726:2005.]

In all other respects, aseptic technique for use in a Class II MSC is the same as for work on the open bench without a Bunsen. Care must be taken, however, not to place any piece of apparatus in a position where it will obstruct the airflow within the cabinet (e.g. over a grille) or to inadvertently allow a piece of sterile apparatus to come into the nonsterile airflow at the front of the cabinet, for example when removing a pipette from a pipette can.

4.6.3.3 Class III Microbiological Safety Cabinets. These are such specialized pieces of equipment, and used to handle such hazardous materials, that no advice will be offered here. They must only be used after the most thorough and rigorous training.

4.7 TESTING OF CLASS I AND CLASS II MICROBIOLOGICAL SAFETY CABINETS

Class I and Class II MSCs require some common basic tests of function to demonstrate satisfactory performance, but a Class II cabinet also needs additional testing due to its design and method of operation.

The full details of the tests to be carried out and detailed test methods should be obtained from the relevant official

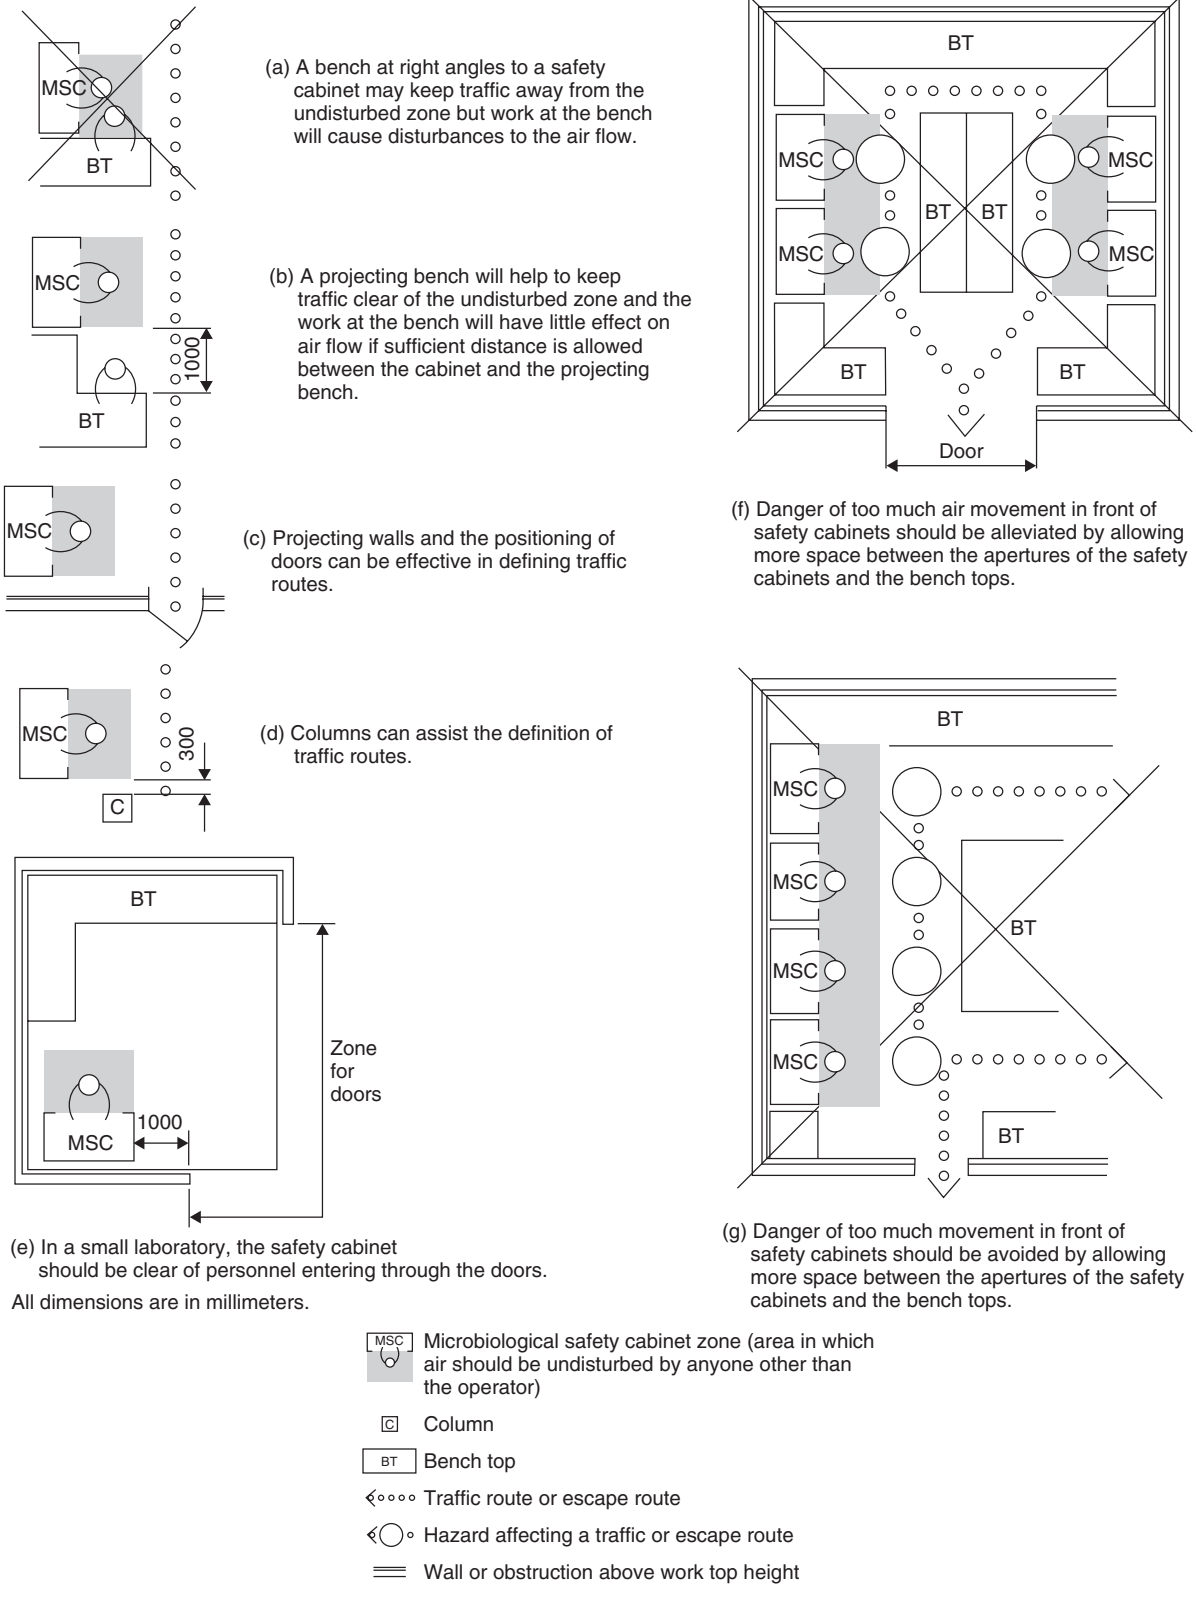

Figure 4.9. Siting of microbiological safety cabinets: Avoiding disturbance due to other personnel. Note: Siting arrangements which should be avoided are overlaid with a cross. [Reproduced with permission from BS 5726:2005.]

standards. However, the following is an overview of the testing requirements for these two types of safety cabinet together with an indication of their relevance.

4.7.1 Performance Tests

Table 4.1 provides a quick reference to the performance tests needed for Class I and Class II cabinets.

4.7.1.1 Operator Protection Tests. Ideally there should be no escape of aerosols from the inside of the cabinet to the external environment. However, with open-fronted cabinets some escape will be inevitable, but this should be within "acceptable" limits in order to minimize any risk to the operator.

This test is intended to quantify the degree of protection offered by the cabinet, and is defined as the ratio of exposure to airborne contamination generated on the open bench to the exposure resulting from the same dispersal of airborne contamination generated within the cabinet (16).

The test basically consists of generating a detectable aerosol within the cabinet and determining the proportion of the aerosol that escapes to the outside of the cabinet through the front aperture. During the test, the airflow entering the cabinet is disturbed in order to simulate the effect of an operator's arm, by introducing a cylinder through the front aperture. A number of different aerosols have been described, some of which have been incorporated into official standards.

4.7.1.1.1 Biological Method. This utilizes a bacterial spore suspension (e.g. *Bacillus subtilis* var. *globigii*) which is generated inside the cabinet using a nebulizer, and determining the number of spores escaping by using microbiological air samplers situated outside the cabinet but close to the open aperture. The protection factor is calculated by comparing the numbers generated inside to those detected outside.

Spraying spore suspensions can be potentially problematical because of the risk of inhalation by the operators, in addition to the problem of contaminating a cabinet that is intended to be used for cell culture work where bacteria-free conditions are needed. Another potential problem that is sometimes overlooked is that the precision of microbiological enumeration methods is not particularly good and can vary according to the type of air sampler used. Any variability in the counting method may well have an effect on the accuracy of the calculated protection factor. Another disadvantage to this method is that the agar plates exposed in the air samplers need to be incubated to allow the bacteria to grow and the result will not, therefore, be available until several days after testing.

4.7.1.1.2 The Potassium Iodide (KI Discus) Test. The arrangement of aerosol generator, cylinder, and samplers is similar to that used in the Biological Test, but in this case the challenge aerosol is produced by dropping a solution of potassium iodide under controlled conditions onto a rapidly rotating disc (17). The aerosol dries rapidly and produces particles in the size range of 3–10 μm. The particles are collected in membrane filter-based air samplers. The filters are then placed in a solution of palladium chloride enabling the particles to be seen and counted under a low-magnification microscope. The biological and potassium iodide methods give comparable results.

Other aerosol materials, such as polystyrene microspheres, have been used with the same kind of nebulizer utilized for spores, and seem to be suitable alternatives to the Biological and KI Discus tests. In addition, in order to enhance the level of particle detection, optical brighteners can be added to the membranes that are used to capture the aerosol (18,19).

The requirement for this test is that no individual protection factor obtained should be less than 1.0×10^5. This means that an operator working in a safety cabinet should be exposed to less than 1/100,000 the level of airborne contamination within the cabinet. Similarly, it means that the operator is exposed to less than 1/100,000 the level of airborne contamination compared to working on an open bench (assuming the same level of aerosol generation).

4.7.1.2 External Contamination Test. This is intended to demonstrate whether the curtain of air descending at the front of a Class II cabinet prevents contamination from

TABLE 4.1. Performance Tests for Class I and Class II MSCs

Test	Class I	Class II
Operator protection test	Yes	Yes
External contamination test	No	Yes
Cross-contamination test (where applicable)	No	Yes
Airflow checks	Yes	Yes
Temperature checks	No	Yes
Tests for leakage	Yes	Yes
Lighting level checks	Yes	Yes
Noise level checks	Yes	Yes

the room entering the working area of the cabinet where it might compromise the work being carried out. A spore suspension and nebulizer, as used in the Biological Operator Protection Method, is used to generate a large aerosol of spores outside the cabinet but close to the open aperture for a period of not less than 4 min, and the number of spores entering the cabinet during this period and for a further 5 min afterward is detected using exposed agar plates that are distributed over the working surface. The challenge aerosol should contain at least 3×10^6 spores.

Both the British and US National Sanitation Foundation standards permit no more than five colonies per test (in total, not per agar plate) and a control test, where the test is repeated but with the cabinet switched off, should have more than 300 colonies present on the agar plates.

This test carries similar problems of potential contamination with bacterial spores as mentioned in the previous section, but the Potassium Iodide Test could be used as a quicker and safer alternative. Another alternative would be to use an electronic particle counter to compare the particle counts both inside and outside the cabinet. However, unless a sufficiently large room particle count is obtained then test sensitivity may be a problem, in which case a particulate aerosol would need to be generated. A disadvantage of employing an alternative method to that specified in the relevant standard is the problem of setting acceptable limits for the test method employed.

4.7.1.3 Cross-Contamination Test. This test is intended to demonstrate whether aerosols generated on one side of the cabinet will contaminate materials at the other side. There are differences in the test methods described in the US and British standards, although the principle is the same. A nebulizer is used to generate a spore aerosol on one side of the cabinet and agar plates are used to detect the degree of contamination on the other side of the cabinet. The problems of bacterial contamination mentioned earlier, that is those of deliberately contaminating a cabinet intended for cell culture work, are equally applicable with this test. However, the relevance of the test needs to be considered carefully as it may not be applicable for most safety cabinet applications. It was originally introduced to test relatively large cabinet installations where more than one operator was working within a single cabinet and to provide some evidence that cross-contamination did not occur between one operation and the other. Where a single operator is working within a cabinet, this type of test is probably not necessary.

4.7.1.4 Airflow Checks. In order to function properly, air must enter Class I and Class II cabinets with a velocity sufficient to retain within the working area any aerosols or particles that may be generated. However, this flow rate should not be so high that turbulence is created within the cabinet; otherwise, there is an increased risk that air will spill out of the open aperture. Air movements into the cabinet can also be influenced by air currents from within the room (e.g. from the ventilation system, other equipment operating in the vicinity, opening and closing of doors, movement of people, etc.). The control of the inward flow of air in Class II cabinets is further complicated by the gain in energy (in the form of heat) of the recirculating air, which can disturb the balance between room air and cabinet air at their interface (20).

For Class I and Class II cabinets it is necessary to measure the inflow, and for Class II cabinets also the downward flow inside the cabinet. The expected airflows should be within the limits given below (Table 4.2).

In addition to velocity measurements, air visualization tests can be useful for checking that air flows inward over the whole of the working aperture. This can be particularly useful for demonstrating any effects caused by air currents within the room under different operating conditions. This can be done relatively simply using commercially available smoke pencils or cotton wool swabs soaked in titanium tetrachloride.

While this test is simple to perform and can provide evidence of satisfactory air movement, it is not particularly sensitive as smoke streams are transient and sometimes difficult to see (21). The use of schlieren photography has been

TABLE 4.2. Airflow Rates for Class I and Class II MSCs

Cabinet Type	Inward Velocity (m/s)	Downward Velocity
Class I	0.7–1.0[a]	N/A
Class II	≥0.4[b]	0.25–0.5[a]

[a] No individual measurement to differ from the mean by more than 20%.

[b] With Class II cabinets the downward flow of air within the cabinet cannot be so easily measured, as the inward flow of air at the open aperture varies in the vertical plane, normally having a higher velocity at the bottom. This also makes it difficult to make meaningful measurements of the inward airflow using anemometer readings at the aperture (or to set limits for a range of readings across this open face). To overcome this problem it is customary to measure the air velocity in the exhaust duct and then calculate the volume of air being extracted; this volume equates to that being drawn in through the front opening. The mean inward velocity can then be calculated by dividing the volume of discharge air by the cross-sectional area of the front aperture (20).

used successfully to visualize airflow patterns and provide more meaningful data on air movements in safety cabinets (22). However, although this is an elegant technique it is a method not available to most testing facilities.

4.7.1.5 Temperature Checks. This is a particular requirement for Class II cabinets because of the potential heat gain referred to earlier. After 4 h of continuous running with the fan(s) and lights on, the air temperature inside the cabinet measured 100 mm above the center of the working space should not rise by more than 8°C above the ambient laboratory temperature (16).

4.7.1.6 Test for Leakage. This test is to demonstrate the absence of any significant leaks through filters, seals, and construction joints. The same principle is used as that described earlier for the *in situ* testing of HEPA filters, using cold DOP or a suitable mineral oil. A test aerosol is generated on the dirty side of the filter, seals, and joints, the clean sides being scanned with a photometer probe.

Again it should be recognized that this test is not suitable for confirming the efficiency rating of the installed HEPA filters, but is only intended to detect leaks that may affect the integrity of the cabinet.

4.7.2 Testing Program

The following is not meant to be a comprehensive list of all the checks and tests to be carried out but is given as broad guidance:

4.7.2.1 Testing after Installation. After a cabinet has been delivered or moved, a number of tests will need to be carried out. Checks should be performed on the integrity of filters, gaskets, and construction joints in order to confirm that no damage or movement, that might affect performance, has occurred during transportation or installation. Performance tests for airflow, operator protection, and, ideally, external contamination should be performed. The test for cross-contamination may be appropriate in some cases. Also, if the cabinet was dismantled for transportation and then reassembled, checks must be made to detect any leakage of the cabinet carcass.

4.7.2.2 Periodic Testing. A suitable regular testing program will have to be put in place but the level and frequency of testing will be a matter of judgment, depending not only on the particular application and the type of work being carried out, but also on the need to satisfy health and safety requirements and whether full compliance to the relevant published standard is required.

In order to confirm continual satisfactory operation, the checks performed ought to include airflow measurements (and possibly air visualization checks), tests of filter and seal integrity, and operator protection tests. As a minimum these tests should be carried out annually, but more frequent testing will be required if high-risk pathogens are handled.

4.8 CLEANROOMS FOR CELL CULTURE USE

Modern cleanroom technology was originally developed for the military and space industries and was quickly utilized in the electronics industry. This technology was then embraced by the pharmaceutical and biological industries for aseptic operations. The basic design, construction, and operation of cleanrooms for different industries and different applications followed similar principles. A significant advance was the development of HEPA filters (23). Following the introduction of the conventional turbulent flow facilities using HEPA-filtered air, the laminar flow room concept developed, although this probably had greater application in the microelectronics industry and generally it was not seen as cost effective or directly applicable for many pharmaceutical cleanroom operations. This basic cleanroom technology was undoubtedly the best available at the time but for pharmaceutical and similar aseptic operations its limitations have become apparent. The direct involvement of people within the cleanrooms introduces a potentially significant particulate and microbiological bioburden to the process (24,25). The problems associated with the control of the personnel activities is becoming increasingly realized and we are now seeing reference to clean zones and the introduction of isolator systems for critical activities, for example filling or the loading of freeze driers. These can give a greater level of protection to the process and can also provide added protection to the staff where the materials they are handling may be toxic or a potential source of infection.

4.8.1 Cleanroom Standards

4.8.1.1 Design and Operation of Cleanrooms. Following the advent of cleanrooms, the need for suitable formal standards against which they could be designed, built and tested became apparent. Over the years, a number of different standards have been produced, but the scope and basis of the classification methods differed and this resulted in considerable confusion.

The standard that became well established and that greatly influenced other cleanroom standards was the US Federal Standard 209 (FS 209). Subsequently, other national standards were produced, but the basis of the particulate classification system adopted for each of them was modeled on FS 209. Some of these standards introduced different terminology, a different basis for classification, differing levels of requirements and so on. The use of these various standards sometimes created

difficulties when companies were operating or trading in different countries and where compliance with different standards was required. These differences undoubtedly combined to create confusion and uncertainty, and this was exacerbated when later versions of FS 209 changed from counts per cubic foot to counts per cubic meter. Thus 100 counts per cubic foot became 3520 counts per cubic meter. On top of this, the FS 209 nomenclature was changed at the same time, to become M followed by the logarithm to the base 10 of the maximum number of particles per cubic meter. Thus the "old" Class 100 became M 3.5, and similarly the "old" Class 10,000 became M 5.5.

As a consequence of the confusion and difficulties in trying to cope with so many different cleanroom standards, a concerted effort was made to harmonize these various standards and this resulted in the publication of ISO 14644—Cleanrooms and Controlled Environments. This was published under the auspices of the ISO and has superseded many of the separate national standards.

ISO 14644 encompasses a range of cleanroom issues such as classification, testing methods to prove compliance, design and construction, operation, requirements for separative enclosures, and so on and comprises the following parts:

Part1: *Classification of air cleanliness*

Part 2: *Specifications for testing and monitoring to prove continued compliance with ISO 14644-1*

Part 3: *Metrology and test methods*

Part 4: *Design, construction and start-up*

Part 5: *Operations*

Part 6: *Terms and definitions*

Part 7: *Separative enclosures (clean air hoods, glove boxes, isolators, and minienvironments)*

Part 8: *Molecular contamination*.

The ISO classification of air cleanliness is based on the following equation:

$$\mathrm{Cn} = 10^{N} \times (0.1/D)^{2.08}$$

where Cn is the maximum permitted concentration (in particles/m^3 of air) of airborne particles that are equal to, or larger, than the considered particle size; N is the ISO classification number; and D is the considered particle size, in micrometers.

In this standard the reference particle size is 0.1 μm. (This particle size was chosen largely for the benefit of the electronics industry, and marks another change from FS 209, which used 0.5 μm. However, the above equation permits interconversion on the basis of the particle size measured.)

Table 4.3 is based on the equation above, and shows the maximum limits for the various particle sizes specified for the different classes in ISO 14644-1.

Table 4.4 shows a comparison between some of the equivalent classes of ISO 14644-1 and the "old" and "newer" versions of FS 209.

The ISO standard has the provision for testing in any of three occupancy states. The "as-built" state refers to the empty cleanroom before the installation of production equipment and with no people present. In this state there

TABLE 4.3. Particle Concentration Limits as Specified in ISO 14644-1

ISO Classification Number	Maximum Concentration Limits (Particles/m^3 of Air) for Particles Equal to and Larger than the Considered Sizes Shown Below					
	0.1 μm	0.2 μm	0.3 μm	0.5 μm	1.0 μm	5.0 μm
Class 1	10	2	—	—	—	—
Class 2	100	24	10	4	—	—
Class 3	1,000	237	102	35	8	—
Class 4	10,000	2,370	1,020	352	83	—
Class 5	100,000	23,700	10,200	3,520	832	29
Class 6	1,000,000	237,000	102,000	35,200	8,320	293
Class 7	—	—	—	352,000	83,200	2,930
Class 8	—	—	—	3,520,000	832,000	29,300
Class 9	—	—	—	35,200,000	8,320,000	293,000

TABLE 4.4. ISO 14644-1 Classes and Corresponding FS 209 Classes

Standard	Class					
ISO 14644-1	3	4	5	6	7	8
"Old" FS 209	1	10	100	1,000	10,000	100,000
"Newer" FS 209	M 1.5	M 2.5	M 3.5	M 4.5	M 5.5	M 6.5

should be a low level of particles that will reflect the quality of air supplied and the operational efficiency of the cleanroom. The "at-rest" state refers to the cleanroom after equipment installation and operation but with no people present. Under these conditions, there will be a higher level of particles. The "operational" state refers to the cleanroom under normal operating conditions. Under these conditions, there will inevitably be an even higher level of particles owing to the presence of people and to the activities being undertaken.

The ISO standard also includes methods for using particle sizes outside the normal size range. The use of "ultrafine" particles (<0.1 μm) in the analysis is intended primarily for the microelectronics industry where smaller particles are a concern. The use of "macroparticles" (>5.0 μm) is intended for use in, for instance, some parts of the medical device industry where smaller particles are not important.

It should be recognized that the particle size distributions defined in cleanroom standards are for classification purposes, and will not necessarily represent the actual size distributions found in any particular cleanroom situation. The source, type, and amount of particulate matter will vary considerably from one facility to another and within an individual facility when different activities take place. Simple idealized particle size distributions with straight line relationships will not always occur in practice, a factor not always recognized by users of cleanrooms or by regulatory authorities.

4.8.1.1.1 Control of Airborne Contamination. The control of airborne contamination in a cleanroom is accomplished by the following means:

1. *Preventing Entry*. This is achieved by filtering the air entering the cleanroom and preventing the ingress of external air by the use of a positive air pressure relative to the external environment.
2. *Purging*. The air handling system changes the air in the room at a sufficient rate to remove or dilute particulate matter generated within the room, from either the process or the personnel.
3. *Minimizing the Generation of Particulate Matter*. Room appointments (floors, walls, equipment, etc.) are chosen for their resistance to particle generation. The number of people admitted to the cleanroom is kept to the minimum that is consistent with the work that must be performed, and cleanroom clothing is made of nonlinting material and designed to minimize the release into the room of particles shed by the personnel (e.g., skin flakes, hair, etc.).
4. Providing localized protection for the product or process from the settling of particulate matter, from product-to-product contamination and for the protection of staff from potential hazards.
5. Providing designated areas for personnel entry, for the entry of equipment, parts, and so on, and for the cleaning of equipment and parts.
6. Controlling the flow of materials through the process steps and controlling the personnel activities.

4.8.1.1.2 Critical Design Parameters. A number of critical parameters need to be addressed in any cleanroom facility; these can be summarized as follows:

- total particulate cleanliness;
- microbiological cleanliness (where necessary);
- HEPA filtration specification;
- room pressurization;
- temperature and humidity;
- air change rates;
- hazards from products and processes;
- disinfection and cleaning procedures.

4.8.1.1.2.1 Total Particulate Cleanliness. This will be dictated by the nature of the work to be carried out. Conventional aseptic filling operations will require an ISO Class 5 (FS 209 Class 100/M 3.5) room, but in most instances cell culture work will probably only require an ISO Class 7 (FS 209 Class 10,000/M5.5) room.

Overspecifying a room needs to be avoided to prevent unnecessary construction and maintenance costs.

4.8.1.1.2.2 Microbiological Cleanliness. Again this will depend on the nature of the work and the need to control this parameter. For aseptic filling operations, a comprehensive microbiological monitoring program would be needed to demonstrate compliance with appropriate standards. The nature of cell culture work probably makes this requirement unnecessary in most cases.

4.8.1.1.2.3 HEPA Filtration Specification. This aspect is dealt with separately earlier in the chapter. However, it should be recognized that the type of grille or diffuser on the filtered air inlet will influence air movement in a conventionally ventilated room (26). Careful consideration will need to be given to the siting of safety cabinets to avoid the disruption of air movement into the cabinet (see the section titled Class II Microbiological Safety Cabinets).

4.8.1.1.2.4 Room Pressurization. The establishment of pressure levels is an important requirement to prevent the ingress of external, unfiltered air into the cleanroom or clean zone. Depending on the size and complexity of the facility, it may be necessary to provide a cascade of differential pressures across rooms or zones within the cleanroom. Room

pressures can also be an indicator of a number of performance characteristics such as air balance stability, HEPA filter blockage, control and fan faults, and so on. It is normal to provide a pressure differential of at least 15 Pa between adjacent areas (the highest pressure being in the most critical area) although some reduction in this figure may have to be accommodated in relatively complex facilities with multiple pressure differentials in order to avoid excessive overpressure relative to the outside (27).

4.8.1.1.2.5 Temperature and Humidity. These parameters need to be controlled to create comfortable conditions for the staff and avoid excessive generation of particles (bearing in mind that under normal conditions the personnel are usually the major source of particulate contamination in cleanrooms). As a general guide the temperature should be around 20°C and the humidity levels not more than 50% RH although there may at times be differences to cater for specific requirements (e.g. low RH for moisture sensitive materials).

4.8.1.1.2.6 Air Change Rates. This determines the quantity of air moving through the classified clean space. It is needed to provide an adequate degree of flushing of the room or zone in order to avoid the buildup of particulate matter. In trying to determine the required air change rate, due allowance will also have to be given to compensate for internal heat gain, process exhaust (e.g. loss of air through safety cabinets), an allowance for loss due to leakage (e.g. through doors), and the air volume required to pressurize the room. Minimum air change rates of 20 room volumes per hour are often quoted but rates of 30–35/h are not uncommon to compensate for the parameters mentioned above.

4.8.1.1.2.7 Hazards from Products and Processes. Many of the potential hazards that may be encountered during cell culture have been dealt with in the sections titled Biohazards and Aseptic Technique: General Considerations. Additional hazards may be posed by large-scale operations or specialized techniques, particularly those capable of producing aerosols. It is essential that a full risk assessment is carried out, and that, where appropriate, measures are put in place in the cleanroom to deal with identified hazards.

4.8.1.1.2.8 Disinfection and Cleaning Procedures. There are many factors that influence the efficacy of disinfectant procedures. The choice of cleaning agents and disinfectants, how they are prepared and used, and the environment in which they are used can have a bearing on their efficacy. There is no compound which has all the characteristics of an ideal disinfectant and the choice of which to use in any particular situation will need to be made carefully, taking into account Health and Safety considerations, the risk of corrosion of treated surfaces and the potential for residues as well as the factors which influence efficacy (1). The choice of which disinfectants to use must be made specifically for each working environment.

Periodic rotation of disinfectants has been advocated by some workers in order to change the selective pressures on microorganisms and avoid the emergence of strains that are less susceptible to the disinfectants. Although regulatory authorities sometimes require some form of rotation, there are arguments for and against this practice. This is a controversial subject and the principle of disinfectant rotation is not universally accepted.

4.8.1.1.3 Process and Personnel Influence. Although the design and maintenance of a cleanroom are undoubtedly important, probably even more important are the activities of the personnel working within it. The cleanroom only provides a suitable environment within which the processes can be operated. The design and control of the processes and the personnel activities need to given very careful consideration. Poor practices within a well-designed and -maintained cleanroom will inevitably result in contamination problems. Good techniques are crucially important; otherwise, all the effort and cost expended in providing the cleanroom facility and associated equipment will be wasted. We have attempted, in some of the earlier sections, to describe some aspects of good technique as applicable to cell culture, and further details can be found elsewhere (28,29).

CELL CYCLE IN BIOPROCESSES

Mariam Naciri and Mohamed Al-rubeai
University College Dublin, Belfield, Dublin, Ireland

5.1 INTRODUCTION

The cell cycle model (G_1-event model) currently accepted by authors of the major cell and molecular biology books (2–5) describes the cell cycle as discrete phases controlled by cell cycle proteins interacting with each other and directing cellular events including DNA synthesis and cell division. However, the validity of this model and the interpretation of many experiments that underpin the current established view of the cell cycle and its regulation have been questioned (6,7). The proposed alternative, the continuum model, suggests that the cell cycle does not exist as currently recognized but takes the form of a continuum from one cell division to the next, rather than discrete phases with discrete groups of regulatory proteins. A hypothetical initiator of DNA replication is synthesized by the cell during all phases of the cell cycle, and its concentration reaches a critical level that initiates DNA synthesis. Thus the cell can control its rate of division by regulating the amount of initiator. Nevertheless, until discussion of these competing models is concluded, with perhaps more work to determine the correctness and applicability of the continuum model, it is only reasonable to accept the weight of evidence for the established view of the cell cycle and its regulation. Thus the established model is summarized here and is the basis for the process biotechnology applications that are described.

The pathways of cell cycle regulation are, unsurprisingly perhaps, shared with another important cell process: apoptosis, or "programmed cell death," which is, in effect, the opposite of the cell proliferation cycle. Because the cell cycle and apoptosis share some common pathways, regulatory imbalance can lead to cancer in multicellular organisms (8). Regulation of the cell cycle is also crucial in embryology and ontogeny, where features such as limb formation, tissue differentiation, and growth are a function of the balance between proliferation and apoptosis. Therefore, much of the cell cycle (and apoptosis) literature is from the field of biomedical science, particularly cancer and anticancer chemotherapy research. General texts, as well as much of what is written here, provide a consensus of information describing a hypothetical typical cell and thus, by implication at least, describe what is true of all eukaryotic cells.

5.2 THE CELL CYCLE

5.2.1 Overview

The cell cycle and its control mechanisms are highly conserved, so most of what is described in general terms for a "typical mammalian cell" is also true for other animals (such as insects) and plant cells, although there is the obvious exception of the cell wall and its effect on cell division. The cell cycle and its control in yeast are essentially similar to but much simpler than the analogous mechanisms in higher eukaryotes; where one protein pair exerts a particular control function in a yeast, several may be required for the same function in an animal cell. As a result of this less complex system and the fortuitous discovery of cell cycle control mutants (*cdc* mutants) in which the cell cycle is inhibited at specific stages, many early discoveries about cell cycle control were made using the budding yeast *Sacharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe*. Subsequent research

has shown homology between cell cycle control proteins in yeast and those in mammalian cells.

However, the bacterial cell cycle is markedly different from the eukaryotic cell cycle, and its control mechanisms are (to date) less well understood than the analogous processes in eukaryotes. Given a hypothetical typical bacterial cell, its structure and thus the function of its cell cycle are very different from those of a eukaryotic cell. Bacteria, like all cells, are enclosed in a cytoplasmic membrane, but in addition, they have a cell wall outside the cytoplasmic membrane. Within the cell there are no organelles, only free ribosomes and the nucleus which is actually an area that contains DNA but is not segregated from the cytoplasm by a membrane. The entire genome is contained in a single, circular, double-stranded DNA chromosome; one strand is a closed circle and the other is open. There are no histone or similar DNA-associated proteins; instead there is a relatively high proportion of small, basic polyamines whose function may be to counteract the acidity of the DNA. The "joint" in the closed DNA strand, the origin of replication, is attached to a mesosome, an invagination of the cytoplasmic membrane. When DNA replication starts, the 5′ end of the open strand attaches to the cytoplasmic membrane and starts to form a second mesosome; meanwhile, the DNA unwinds in one direction from the origin of replication and splits into two single strands to form a replication fork. As the replication fork progresses along the chromosome, complementary strands of DNA are synthesized until two daughter chromosomes of double-stranded DNA are formed, each with an origin of replication attached to its mesosome. While the chromosome replicates, the cytoplasmic membrane and cell wall are synthesized in the region between the two mesosomes, enlarging the cell. After chromosome replication, a septum forms across the middle of this region, finally separating the two daughter cells. However, it takes about 40 min to duplicate the single chromosome; hence, to allow doubling times as low as 20 min, each daughter chromosome must start to replicate in exactly the same way before the parent has finished replication. Thus, instead of one there will be three origins of replication operating at once. In addition, when the doubling time of a culture is less than about 40 min, DNA synthesis is continuous, so it may be that DNA replication and cell division cycles are independent in bacteria (9). However, despite the essentially continuous DNA synthesis and cell division shown in the fast-growing cultures likely to be used in process biotechnology, it has recently been shown (10) that slow-growing *Escherichia coli* cells (doubling time up to 5 h) display cell cycle phases analogous to eukaryotic G_1, S, and G_2 phases, *vide infra*, followed by cell division. Furthermore it was shown that initiation of DNA replication was related to cell mass. Two genes, *seqA* and *dnaA*, were shown to be involved in the regulation of replication initiation; gene mutants exhibited decreased and increased mass, respectively, at initiation of replication. Recent work with *Caulobacter* (11) described a protein, CtrA, that has sequence homology with response regulatory proteins in other bacteria including *E. coli* and is involved in cell cycle control including cell division and cell cycle–specific transcription. It was proposed that CtrA is part of a phosphorelay signal transduction system responsible for transcriptional-level control of bacterial cell cycle events.

The mammalian cell cycle is best described by illustration (Fig. 5.1a). Starting from a recently divided daughter cell, untransformed, or "normal," cells may enter gap phase 0, or G_0 (12,13). This is an offshoot from the cell cycle in which cells may remain viable and nondividing but retain the potential to divide given the appropriate stimulus (14,15). A cell, depending upon its type, can remain

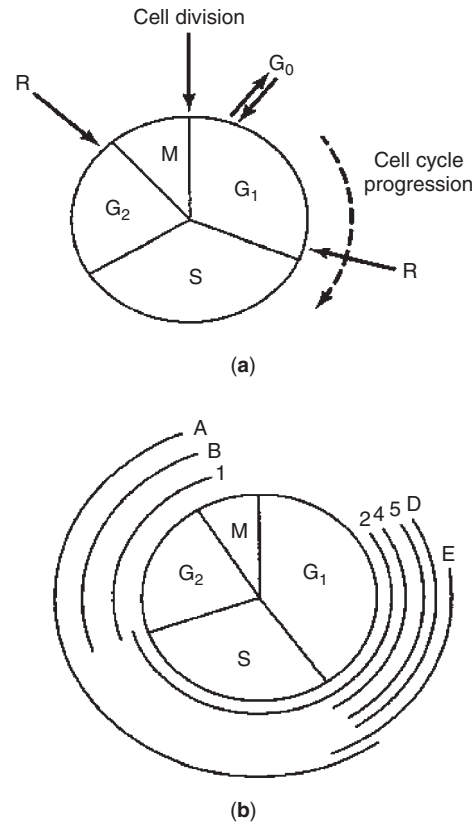

Figure 5.1. (a) A simple diagrammatic representation of the cell cycle. G_0, gap phase 0; G_1, gap phase 1; S, synthesis phase, in which the DNA and cell cytoplasmic components are duplicated; G_2, gap phase 2; M, cell division by mitosis (or meiosis); R, restriction point (check point). (b) A simple diagrammatic representation of cyclin and cyclin-dependent kinase activation during cell cycle traverse. A, cyclin A; B, cyclin B; D, cyclin D; E, cyclin E; 1, cyclin-dependent kinase 1 (homologous to cdc2); 2, cyclin-dependent kinase 2; 4, cyclin-dependent kinase 4; 5, cyclin-dependent kinase 5.

out of the cell cycle, in G_0, for extended periods but can return to gap phase 1, or G_1, due to cell maturation after a certain time has elapsed, after a critical mass or size is reached, or as a response to an external stimulus (16–19). In contrast, cells from continuous (sometimes called *established* or *immortal*) cell lines and transformed cells (which includes most animal cells used in biotechnology) do not enter G_0 after division but restart their cell cycle after mitosis by progressing directly to G_1. During G_1, cells prepare to duplicate themselves. When a cell enters the synthesis, or S phase, it starts to precisely and accurately duplicate its genome by synthesizing DNA and the associated nuclear protein components, so that daughter cells carry a genome identical to each other and to the parent. During this time, ribosomes, mitochondria, endoplasmic reticulum, and all the other subcellular organelles are also replicated in preparation for cell division. Thus by the end of S phase, a normally diploid ($2n$) cell will be tetraploid ($4n$), containing enough DNA (and cellular components) for two cells. After S phase, the cycling cell enters the second gap, or G_2, phase. During G_2 the cell synthesizes the proteins required to direct chromosome segregation and cell division in the following mitosis, or M phase. After mitotic division the daughter cells return to G_1 at the beginning of a new cell cycle or exit the cycle to G_0. In a typical cell cycle of 24-h duration, G_1 would last 10 h, S phase 9 h, G_2 4 h, and mitosis 1 h. However, the duration of the cell cycle varies both between cell lines and between individual cells within the same culture. Variation in cycle time is usually due either to cells exiting the cycle and arresting in G_0 or to a variation in the duration of G_1. It has been suggested that the intercellular variability of the postmitotic early G_1 period is smaller than that seen with initiation of DNA replication (presynthetic late G_1) (20). It is also postulated, by the same author, that cells that make the "yes or no" decision in the postmitotic early G_1 period about whether to proceed through the cell cycle, also have the capacity to decide in the presynthetic late G_1 period, when the cell will enter S phase. Heterogeneity in the duration of G_1 is the main reason why a synchronized culture loses synchrony with time to the extent that the culture is completely asynchronous within three or four cell cycles.

This apparently simple cell cycle is subject to complex control mechanisms. Some of the molecular pathways have been understood only in recent years and there may be others that have not yet been described. Mammalian cells periodically transcribe cell cycle genes that encode proteins directly involved in cell cycle regulation. These include the cyclins and the cyclin-dependent kinase (Cdk) families. The Cdks are phosphorylating enzymes that are inactive when not associated with an appropriate cyclin; it is the associated cyclin that determines the substrate specificity of the complex. The activity of this heterodimeric complex is then regulated by phosphorylation or dephosphorylation of specific activation and/or inhibition sites, as well as by further binding with inhibitory proteins. Many of the cyclins, Cdks, and related regulatory proteins are expressed or form active complexes only during particular cell cycle phases. Cdk4–cyclin D1 drives cells through mid G_1, Cdk2–cyclin E drives late G_1, Cdk2–cyclin A controls entry into S phase, and Cdk1–cyclin B drives the G_2–M transition; their phase-related activities are summarized in Fig. 5.1b and Table 5.1. Others, including Cdk4 (21,22) are expressed throughout the cell cycle. The noncyclic proteins exert their cell cycle-;controlling effects by association with phase-specific cyclins or Cdks, association with Cdk-cyclin inhibitors, and specific amino acid phosphorylation or dephosphorylation to form active complexes in specific phases. A family of genes encoding proteins related to the retinoblastoma susceptibility gene, *RB*, and genes for transcription factors including *BYMB, E2F1*, and *JUN* are all induced in late G_1 or early S phase and have been shown to interact with cell cycle regulatory complexes. In addition, there are restriction points in the cell cycle that, once passed, commit the cell to continuing the division cycle. There are also check points where in effect, the cell ensures that the previous phase has been completed properly before proceeding or that there has been no DNA damage. To continue to mitosis before the genome is properly duplicated, for example, would be catastrophic for the cell; one if not both daughters would not be viable. It has been suggested that induction of the *p53* tumor suppressor gene and its transcriptional activation of the Cdk inhibitor *p21WAF1/CIP1* with subsequent cell cycle arrest, following DNA damage, allows time for DNA repair before entering S phase (23). Activation of *p53* in cells with unrepaired DNA damage may lead to apoptotic cell death.

5.2.2 Gap Phase 1 or G_1

G_1 was originally thought to be a gap in the cell cycle—a resting phase while the cell recovered from division before starting a new cell cycle by synthesizing more DNA—although this is now known to not be so. Rather, complex control processes are preparing the cell to synthesize the cellular machinery required for DNA synthesis in the S phase. There is also a "point of no return" near the end of G_1 called the *restriction point* (R), which is analogous to START in yeast. Once cells pass this point they are committed to the next stages of the cell cycle. Signals for passing this point include adequate cell size and a favorable environment, including the presence of growth factors. The transition at the R point from growth-factor dependence to growth-factor independence in normal cells, as opposed to cancer or transformed cells, is likely to reflect a stringent growth regulatory mechanism that is defective in the latter cell

TABLE 5.1. Cyclin–Cdk Complexes, Stability, and Associated Proteins[a]

Cyclin	Associated Cdk	Cell Cycle Activity	Associated Proteins	Stability	Degradation
A	Cdk2 and cdc2 (Cdk1)	S and G2 → M	p107, E2F, p21, PCNA	Unstable in mitosis	Ubiquitin
B1	cdc2 (Cdk1)	G2 → M	(p21), (PCNA)	Unstable in mitosis	Ubiquitin
B2	—	G2 → M	(p21), (PCNA)	Unstable in mitosis	Ubiquitin
C-type	Cdk X	?	ND	ND	PEST
D1	Cdk4(2, 5, 6)	G1	pRb, p21, p27, PCNA, p16, p15	Rapid turnover	PEST
D2	Cdk4(2, 5, 6)	G1	pRb, p21, p27, PCNA, p16, p15	Rapid turnover	PEST
D3	Cdk4(2, 5, 6)	G1	pRb, p21, p27, PCNA, p16, p15	Rapid turnover	PEST
E	Cdk2	G1 and G1 → S	p107, E2F, p21, PCNA and p27 after TGFβ treatment	Rapid turnover	—
F	—	—	ND	ND	—
G	—	—	ND	ND	—
H	Cdk7	All phases	ND	ND	ND

Note: ND, not determined; PCNA, proliferating cell nuclear antigen; TGFβ, transforming growth factor β; PEST, proteins that contains sequences rich in praline (P), glutamate (E), serine (S), and threonine (T).

[a]From Ref. 24: Hunter and J. Pines, *Cell* **79**, 573-582 (1994), Copyright Cell Press, used with permission.

types. Coordination between cell cycle commitment, START (or R), and cell size, involving the G_1 cyclins, has been suggested as a regulatory mechanism for cell growth in yeast. During early G_1, immediately after G_0, cells are stimulated to reenter the cell cycle; a critical step occurs involving the induction of cell cycle–specific genes including *myc, cyclin D, and fos*, and *Cdk* genes. It is now apparent that Cdk 2, Cdk 4, and Cdk 5, despite constitutive expression of Cdk4 thoughout the cell cycle, start to complex with cyclins D1, D2, and D3 and become active in early to mid G_1 (possibly at a point when or soon after noncycling cells return from G_0). The level of activation of the G_1 Cdk–cyclin complexes peaks at about R; so it is possible that, by reaching a threshold activity, it is these complexes that allow cells to pass R. Cdk2 also forms active complexes with cyclin E starting from mid G_1 and peaking later than the Cdk–cyclin D complexes, in other words, between R and the G_1–S phase transition.

The primary substrate of the cyclin D complexes is the retinoblastoma tumor suppressor gene product pRB. Active, unphosphorylated pRB complexes with and inhibits the transcription factor E2F. When pRB is phosphorylated and inactivated, the complex dissociates, releasing active E2F; the cell cycle is not stopped at the G_1 checkpoint, and cells are allowed to proceed to S phase (25). E2F was originally characterized as an activator of the adenovirus early region 2 transcription unit (25). It is now recognized that E2F promotes the transcription of enzymes associated with DNA synthesis (26,27). It has been proposed that the cyclin E complex also phosphorylates pRB, with similar effects (28).

5.2.3 Synthesis Phase or S

The transition from G_1 to S phase is marked by the transcription (as already described) and activation of the many synthetic enzymes required for cellular duplication including DNA polymerase α, thymidine kinase, and dihydrofolate reductase (DHFR) (29). This is followed by the exact duplication of the genetic material and replication of organelles and structural proteins. At the same time, there is a marked change in the regulatory proteins activated. At the onset of S phase, the activation of the G_1-phase Cdk–cyclin complexes decreases in the same temporal order as it increased and the complexes dissociate. As Cdk2 disssociates from cyclins D and E, it complexes with cyclin A which starts to be synthesized at about the G_1–S transition. The Cdk2–cyclin A complex retains its activity until the end of S phase. Disruption of cyclin A function inhibits DNA synthesis, suggesting that a threshold activity of the Cdk2–cyclin A complex is essential for the maintenance of S phase.

5.2.4 Gap Phase 2 or G_2

As with G_1, G_2 was originally thought to be a gap in the cell cycle, as a resting phase while the cell recovered from DNA synthesis before dividing. This has now been shown to not be so although G_2 remains analogous to G_1 in that once the appropriate control signals are received, genes encoding for the proteins responsible for cell division are transcribed and ready for cell division. At the end of S phase the activity of the Cdk2–cyclin A complex decreases as the components dissociate. Cyclin A and cyclin B then form complexes with Cdk1 (also often referred to as cdc2 because of its homology with the product of *S. pombe* cell division cycle gene 2). It is these complexes, increasing in activity throughout G_2 and continuing into mitosis, that mediate activation of the cell division machinery. At the transition point between G_2 and M is a second check point that, in effect, ensures that the cells are big enough, the environment is favorable, and DNA synthesis has been fully and accurately completed before the cell continues into mitosis and division.

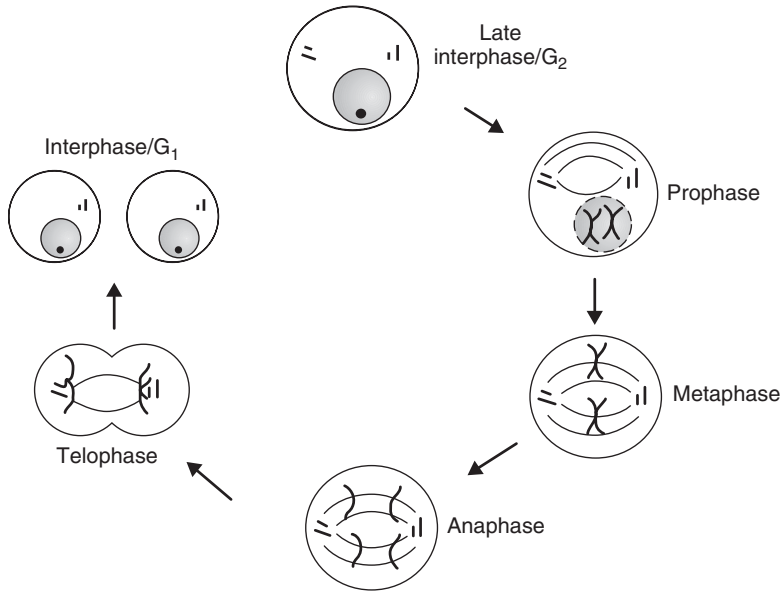

Figure 5.2. A simple diagrammatic representation of mitosis.

5.2.5 Mitosis or M: Cell Division

Mitosis is the division of one normally diploid, or $2n$, somatic cell into two genetically identical (both to each other and the parent) cells. Mitosis, like the cell cycle itself, displays distinct phases that are best represented diagrammatically (Fig. 5.2). When the cell leaves interphase at the end of G_2, it enters prophase. The nucleolus disappears (disperses), and nuclear DNA condenses into chromosomes. Following DNA synthesis in S phase, a normally diploid ($2n$) cell is now tetraploid ($4n$) and contains an identical pair of each chromosome, which is in turn organized as a pair of identical chromatids joined to each other at the centromere. During late prophase, the nuclear envelope is broken down. At the same time, the centrioles divide; one pair migrates to each cell pole with spindle fibers, which are microtubular structures, linking each pair. The transition from prophase to metaphase is marked by alignment of all the chromosome pairs on an equatorial plane, the metaphase plane, with their centromeres connected to each polar centriole pair by spindle fibers. The cell progresses into anaphase when the chromosomes separate and one chromatid from each homologous chromosome pair migrates along the spindle fibers toward each centriole. In the next phase, telophase, when the chromatids (one from each homologous chromosome pair) arrange at each pole, the spindle fibers depolymerize, and cytokinesis (division of cytoplasm) begins as a cytoplasmic cleavage furrow begins to form. Further changes follow: the cytoplasm cleaves completely, chromosomes uncoil, the nuclear envelope re-forms around each nucleus, and the nucleoli reappear to give two genetically identical daughter cells in interphase. The final telophase changes, in which the cytoplasm divides and the cells separate, are markedly different in plant cells and in animal cells due to the constraints of the rigid cellulose cell wall. As with other cell cycle phases, Cdk–cyclin complexes perform a major regulatory function in mitosis. The activity of Cdk1–cyclin A and Cdk1–cyclin B, which started in G_2, continues to increase until the middle of mitosis at the metaphase–anaphase boundary. At this point the activity of both complexes declines abruptly to zero, allowing the cell to complete mitosis. It is also thought that the rapid decrease in G_2 cyclin–Cdk complexes is necessary for cells to start a new cell cycle at G_1.

5.2.5.1 Meiosis. Although unlikely to be encountered in process biotechnology, it is useful to point out that germ cells may undergo an alternative form of division to form zygotes, which may also be considered to be a form of terminal differentiation, called *meiosis*. Assuming a normally diploid ($2n$) cell, initial cell division occurs exactly as in mitosis until the end of anaphase, or in this case the first meiotic anaphase. At telophase the cell may divide or partially divide and enter a brief meiotic interphase comprising two identical diploid ($2n$) daughter nuclei (if not cells). Otherwise the cell progresses directly to the second meiotic prophase. Now there is only a single copy of each chromosome, still comprising two chromatids. During the second meiotic anaphase, the chromatids separate again to each of four poles. The cell then progresses to (the second meiotic) telophase and on to interphase to give four haploid (n) daughter cells instead of the two diploid ($2n$) cells produced by mitosis.

5.2.6 Gap Phase 0 or G_0

The term G_0 was first used in the early 1960s when three types of cells were recognized: static cells, incapable of further division (e.g. a terminally differentiated adult neuron); renewing, constantly dividing cells (e.g. bone marrow cells); and conditionally renewing cells which do not normally divide but can respond to an appropriate extraordinary stimulus (e.g. liver cells starting to proliferate after partial hepatectomy). G_0 is used to describe this last category of cells, which have "opted out" of the cell cycle after a mitosis because of, for example, growth-factor depletion. In this circumstance, in contrast, transformed or tumor cells do not enter G_0 but continue through the cell cycle until they die from nutrient exhaustion, often by apoptosis. It has been argued that G_0 should not be used to describe cells, for example, in the stationary phase of a hybridoma or CHO (Chinese hamster ovary) batch cultures, which are in a pseudo-steady state of growth and death due to nutrient depletion and/or accumulation of toxic metabolites. Unlike normal cells, they have not down-regulated themselves; they have been closed down by their environment. Cells that lose their ability to respond to growth-factor depletion or do not exit the cell cycle to G_0 may have a defective G_1 program which is different from the cyclin-Cdk4-pRB phosphorylation mechanism involved in R regulation in normal cells. However, G_0 is commonly used today, some claim inappropriately, to describe any cell (containing a G_1 amount of DNA) that is not expected to proceed to S phase for any reason, including the result of any means of artificial interference with the cell cycle. Markers of G_0 include reduced RNA, reduced ribosome content, and an absence of cyclins D and E (30).

5.2.7 External (Environmental) Influence on the Cell Cycle

Extrinsic cell cycle regulation may be considered at two levels. At the more basic level is the effect of the physical environment and nutrient availability; the more complex level of extrinsic cell cycle control is through growth factors. The physical environment has a great effect on the cell cycle. When temperature is reduced from the optimum, the length of the cell cycle increases, and growth rates slow down. When temperature exceeds the optimum even by a few degrees, profound changes in cell behavior occur including the expression of heat shock proteins, and cells eventually die. Alternatively, if appropriate nutrients such as amino acids and glucose are not available in the medium, cell cycle duration and even progression will be influenced due to lack of energy and the precursors for protein and DNA synthesis.

Serum starvation, in the presence of appropriate nutrients and physical conditions, may also affect the cell cycle but this is more likely to be caused by the absence of the specific growth factors that serum provides. Most, if not all, cell lines were originally grown in medium containing animal serum, usually newborn or fetal bovine serum. The main contribution to the cell cycle and hence, growth of a culture from these undefined and heterogeneous supplements, is the supply of growth factors that promote or enhance the cell cycle. Thus, because G_0 cells reenter the cell cycle as a result of serum addition, serum is regarded as a source of positive regulatory growth factors. The presence of growth factors in the environment, their binding to specific transmembrane receptor proteins, and subsequent signal transduction, effects changes in cellular processes including the cell cycle. Expression of cyclin D, important in progression through G_1, is induced by growth factors (31). These effects are cell-type dependent because cells do not all express the same growth-factor receptors. Furthermore, different cell types or lines may not only require different individual growth factors but may require a specific cocktail for optimal proliferation. Fibroblast growth, for example, requires growth factors including fibroblast growth factor (FGF), epidermal growth factor (EGF), and platelet-derived growth factor (PDGF). Other growth factors that promote cell division include insulin-like growth factor (IGF) I and II, macrophage–granulocyte colony stimulating factor (G-CSF), and endothelial cell growth factor. Each growth factor stimulates a specific receptor on the plasma membrane, which in turn activates protein kinases, many of which phosphorylate tyrosine residues on their substrates, so they are generically called *tyrosine kinases*. Subsequent signal transduction by phosphorylation or dephosphorylation cascades can lead to an increased rate of protein synthesis, influence the activity of DNA topoisomerase or modify the glucose transport system, all with the similar effect of promoting cell division. Transformed cells are known to have a reduced (or no) requirement for external growth factors when compared with normal cells. However, through adaptation of cell lines and extensive development of medium formulation, many cells can now be grown in a protein-free medium, indicating that it is possible to bring about cell proliferation and support long-term culture in media free of (extrinsic) growth factors, hormones, and other contaminating proteins. This absence of extraneous protein is particularly important in large-scale process biotechnology for facilitating downstream processing and product recovery. However, in addition to the positive growth-promoting (cell cycle-promoting) factors, there are also negative, growth-inhibiting factors, although these may be the same growth factors displaying opposite effects under different conditions. Transforming growth factor $\beta 1$ (TGF-$\beta 1$), in addition to its strong positive stimulatory effect, has been shown to produce a density-independent negative response that prolongs G_1 in the NIH-3T3 mouse embryo cell cycle and has a similar effect on mortal human fibroblasts (32).

It is commonly accepted that the depletion of glucose and amino acids as well as the accumulation of toxic metabolites (ammonia and lactate, e.g.) inhibits culture proliferation.

5.3 METHODS FOR DESCRIBING THE CELL CYCLE

5.3.1 Mitotic Index

There are three main approaches to describing the cell cycle. The first and most historically established approach is to determine the percentage of cells in mitotic cell division. This method, called the *mitotic index*, is simple and can be applied to attached cells grown on a microscope slide or any other appropriate substratum, as well as cells in suspension. There are many fixation and staining methods described in any textbook of cytology, from which a protocol appropriate to animal cell biotechnology can be selected. A generic protocol is as follows. Take cells grown on a glass microscope slide (or coverslip) or prepare a smear of suspended cells on a microscope slide, using an attachment agent such as polylysine if necessary. Fix the cells with a fixative appropriate to the proposed staining method. Stain the cells with either a standard cytological or histological stain that differentiates DNA such as Feulgen staining, or alternatively, stain with a fluorescent DNA stain such as ethidium bromide (EB), Hoechst 33258, or DAPI. Examine stained slides by conventional or fluorescence microscopy, as appropriate. Count the number of nuclei in mitosis and express the result as a percentage of the total. A recent publication investigating mitosis in a hydrodynamically stressed environment, described the use of the fluorescent DNA-intercalating stain propidium iodide (PI) with cells fixed with 3:1 ethanol to glacial acetic acid, followed by fluorescence microscopy (33). A major disadvantage to measuring the mitotic index is that although it gives information about cell division in M phase, it can give no information about the other cell cycle phases or their associated processes. Measuring the mitotic index also exhibits disadvantages common to all manual microscopic methods including sampling error, because a small proportion of the total population is examined and interobserver variation results from subjective discrimination between mitotic and interphase cells. Furthermore, this slow and labor-intensive method is not appropriate for on-line automation or use in integrated process control.

5.3.2 Labeled Nucleotide Uptake in S Phase

An alternative approach for describing the cell cycle is to document the incorporation of labeled nucleotides into nuclear DNA during S phase. This method relies on [^{3}H]thymidine incorporation followed by autoradiography and can be used in one of two ways: continuous labeling, in which the cells are exposed to the label for a fixed time period, usually 24 or 48 h followed by analysis at that time; or pulse-chase labeling, in which the cells are exposed to the label for a short pulse (0.5–1 h) and then analyzed at regular intervals for 24–48 h. Continuous labeling gives information about the growth fraction of a culture, which is the percentage of cells that are in the cell cycle during the labeling period. However, this information is not likely to be of great use to the process biotechnologist because most cells under optimum conditions, when viability is close to 100%, will also have a growth fraction close to 100%. A simple generic protocol for continuous labeling is as follows: [^{3}H]thymidine is added to the culture medium, and the culture continues for a specified period; cells are fixed and subjected to autoradiography; when the autoradiograph has developed, the number of radiolabeled nuclei is counted and expressed as a percentage of the total.

In contrast, pulse-chase labeling is used to determine the average duration of each cell cycle phase. A generic protocol for [^{3}H]thymidine pulse-chase labeling is as follows: [^{3}H]thymidine is added to the culture; after a short period (1–2 h), cells are removed to a fresh medium without [^{3}H]thymidine; the culture is sampled regularly at times greater than the length of one cell cycle (24–48 h); each sample is subjected to autoradiography; and the number of labeled mitoses is counted as a percentage of the total. The average duration of G_2, S, M, and the total cell cycle is measured from the plot of labeled mitoses against time, then G_1 is calculated. Details of using [^{3}H]thymidine incorporation for determining growth fraction and cell cycle phase duration are summarized elsewhere (34). As with the mitotic index, any autoradiographic technique exhibits inherent disadvantages including sampling error because a small proportion of the total cell population is examined; the technique is slow, labor intensive, and not appropriate for on-line automation or use in integrated process control; and the use of radioisotopes requires additional containment and waste disposal facilities.

In recent years the thymidine analogue bromodeoxyuridine (BrdU) has been used as a safer, nonisotopic alternative to [^{3}H]thymidine for DNA labeling. BrdU can be used in exactly the same way as [^{3}H]thymidine, as either a continuous or pulse-chase label. The only difference in the protocol is that BrdU incorporation is detected by immunostaining with fluorescent anti-BrdU antibodies followed by fluorescence microscopy instead of autoradiography, so the method still suffers the disadvantages of any manual microscopic method. Alternatively, BrdU incorporation can be measured by flow cytometry, *vide infra*.

5.3.3 Measuring DNA Content

The third and probably easiest approach to adopt for cell cycle analysis is to measure the DNA content of each cell in a population by flow cytometry and thus determine the proportion of cells in G_0 or G_1, S, and G_2 or M at the time of sampling. A major and obvious advantage to this approach is that heterogeneous nonsynchronized cultures can be analyzed easily and rapidly, with the useful bonus that sub-G_1 apoptotic populations can also be identified. Other advantages include minimizing sample error by analyzing a large number of cells, and minimal interobserver variation because of the objective discrimination between G_1, G_2, and S cells. Furthermore, the method is appropriate for near on-line automation and use in integrated process monitoring or control. Although this approach is not able to resolve G_0/G_1 or G_2/M because DNA content is the same, this is of little concern in most process biotechnology applications because the (transformed) cells commonly used do not enter G_0. Furthermore the G_2 or M cell subpopulation can be resolved, if necessary, by measuring the mitotic index of the population (as already described) to determine the proportion of cells in M phase.

5.3.4 Flow Cytometry for Cell Cycle Analysis

Flow cytometric cell cycle analysis by measuring DNA content may follow any one of many protocols. A generic protocol is as follows: fix or permeabilize the cells; stain with a fluorescent DNA stain; measure stained DNA content by flow cytometry; and analyze data by simple gating or using dedicated cell cycle analysis software. Variations include pretreatment of cells; altered fixation or permeabilization protocols; postfixation treatment of cells; different stains, although stains such as PI or EB which intercalate into double-stranded nucleic acid are commonly used; and methods for data analysis. A typical flow cytometric measurement of PI-stained DNA in ethanol-fixed recombinant CHO cells and the subsequent cell cycle analysis using software based on a polynomial S-phase algorithm with an iterative nonlinear least squares fit, is shown in Fig. 5.3. By fitting the G_1 and G_2 peaks as Gaussian distributions and the S-phase distribution as a Gaussian broadened distribution, the cell cycle phase distribution can be deconvoluted.

Flow cytometry can also be used with BrdU incorporation to measure the growth fraction or to determine average cell cycle phase times. For flow cytometric analysis, BrdU incorporation can be detected by either fluorescent immunostaining or its quenching effect on Hoechst DNA stains. Thus BrdU incorporation can be analyzed simultaneously with DNA content. The advantage of this method is that it can recognize arrested but non-DNA-synthesizing cells during S phase. Cell size and/or protein content can also be analyzed simultaneously to give further related information. Again, there are many variations on a theme,

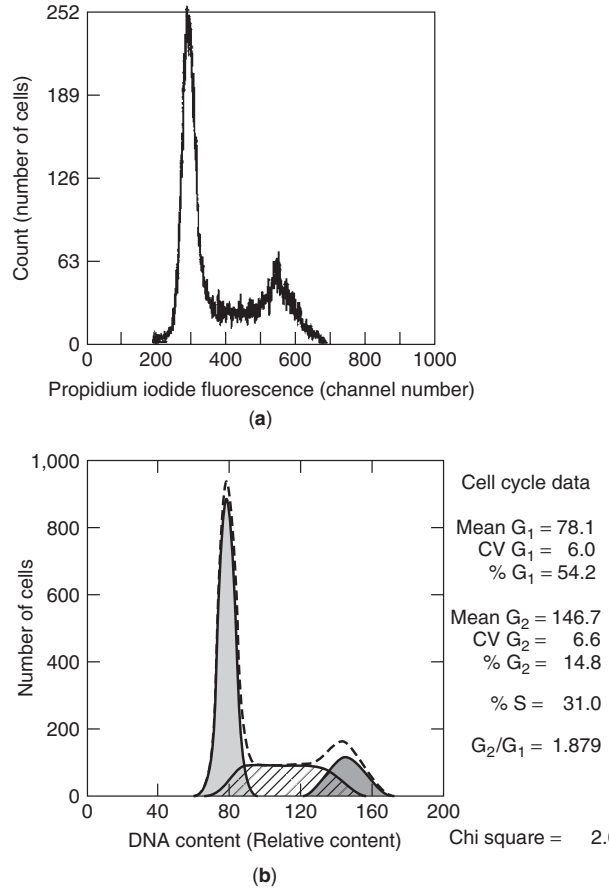

Figure 5.3. (a) Typical flow cytometric measurement of fluorescent (propidium iodide–stained) DNA content in recombinant CHO cells. (b) Resolution of cell cycle fractions from the fluorescent DNA content of recombinant CHO cells, using dedicated cell cycle analysis software (Multicycle®, Phoenix Flow Systems).

details of which and other flow cytometric methods for cell cycle analysis have been summarized elsewhere (35). Flow cytometry is also very useful for analyzing specific cell cycle–related proteins, following appropriate fluorescent immunostaining. For example, the absence of cyclin D or E in G_0 cells, shown by flow cytometry, has been used to distinguish G_0 from G_1 cells (22), and flow cytometric measurement of the Ki67 nuclear antigen has been shown to correlate with [^{3}H]thymidine and BrdU incorporation (36). Multiparameter flow cytometric analysis of G_1 and G_2 cyclin expression and DNA content has also been shown to be a useful tool in cell cycle analysis (37) because G_1 cells can be differentiated from G_0 cells, and cells with unusual karyotypes (e.g. G_1 tetraploid) can be distinguished from G_2 diploid cells. Flow cytometry can also be applied to investigating the relationship between the cell cycle and recombinant protein expression in economically important cell lines as a means of optimizing medium and environmental conditions for successful commercial operation.

5.4 IMPORTANCE OF THE CELL CYCLE IN PROCESS BIOTECHNOLOGY

5.4.1 Culture Proliferation and Growth

The cell cycle is the means by which a culture proliferates. Cell division and cell death, both active programmed cell death (apoptosis) and passive necrosis, are responsible for the change in the number of cells present. In addition to the cell cycle control genes, the transcription of genes coding for proteins involved in nucleotide and DNA synthesis is also cyclic. However, the progress of the cell cycle is costly in nutrient utilization and energy expenditure, particularly during S phase when the nucleic acid content of the cell is duplicated, and also during other phases because regulatory proteins are continuously synthesized and degraded. In theory it should be possible to arrest cells, in other words, stop them from cycling, thus preventing the "wastage" of energy and nutrients that could otherwise be directed into product synthesis. The maintenance energy model (38) states that energy (as adenosine triphosphate or ATP) consumption is divided into that which is needed for cell growth (cell cycle progression, as determined by increase in cell number) and that which is needed for cell maintenance. Based on this model it has been determined that the maintenance energy requirement of a hybridoma is $14.4/10^9$ mmol ATP/cell day, at a specific growth rate (μ) of 0.66 per day (31) corresponding to 62% of the energy (ATP) consumed. These values were confirmed by work that showed that the maintenance energy requirement of the same cells under slightly different nutrient and specific growth rate conditions was $11.4/10^9$ and $12/10^9$ mmol ATP/cell day, again, corresponding to $\sim$60% of the estimated ATP consumption rate (39). These observations agree with the value of 65% which was determined as the proportion of energy consumption used for maintenance by mouse LS cells grown at $\mu = 0.60$ per day (40). Thus it is apparent that about two-third of the energy used by a culture is for its own maintenance, and this proportion is not likely to be readily altered. Consequently, it appears that if the growth (cell cycle progression) requirement was removed, all of the remaining resources could be directed toward product elaboration, or alternatively, cultures would require up to one-third less energy and nutrient resources for the same product yield. However, we have shown recently that the increase in specific productivity of NS0 arrested culture over the proliferated culture cannot only be met by energy diversion alone (unpublished data). The increase in specific recombinant productivity is the result of an overall increase in cell growth (protein synthesis, cellular energy). In addition, the more active mitochondria in the arrested culture mean that the cell now needs more energy, rather than diverting energy.

Three main approaches have been used to prevent cells from cycling. The first is chemical blockade. For example, the addition of thymidine, hydroxyurea, TGF-β or adriamycin to culture medium causes cells to arrest at the G_1-S phase boundary, so cells accumulate in G_1 and specific productivity increases (41,42) . Other cell cycle inhibitors used to enhance productivity include protein synthesis inhibitors [potassium acetate, cycloheximide, aphidicolin, rapamycin, doxorubicin, staurosporine, mimosine, and nocodazole) (43–45)] and RNA synthesis inhibitor (Actinomycin D) (42). However, this production advantage is short-lived because the imbalanced growth state leads to culture death (usually by apoptosis) within a few days of the onset of the chemical blockade. The second approach is not to arrest the cell cycle but to substantially reduce its progression by reducing the culture growth rate. Using a custom-built total cell recycle bioreactor system, where the growth rate of a mouse hybridoma was substantially reduced ($\mu < 0.05$ μ max), Flickinger et al. (46) showed that specific monoclonal antibody secretion remained constant as the specific growth rate decreased. This demonstrated that production could be uncoupled from growth (cell cycle progression), although there was no evidence that the energy saved by substantial (>95%) reduction of growth was diverted into production. However, using this method for production-scale processes may have the advantage of less medium (energy or nutrient) expenditure per unit product, although the total product yield per unit of production (from each bioreactor) would not be increased. Furthermore, questions of product fidelity, especially with respect to glycosylation, are raised when growth is limited by the stress of nutrient deprivation or limitation.

The third approach is to use cell engineering to genetically control proliferation. Cytostatic genes, p21, p27, and IRF-1 have been used to control proliferation in a bioprocessing environment. The induction of p21 and p27 leads to the accumulation of most of the cells in the G_1 phase of the cell cycle while IRF-1 showed aphasic cell cycle arrest (46). In our laboratory NS0 and CHO cell lines have been constructed to inducibly express the $p21^{CIP1}$ cyclin-dependent kinase inhibitor, using the Lacswitch system (47,48). In these studies, arrested cells causing the overexpression of p21 have been shown to increase cell productivity. Long-term perfusion culture of p21 inducible NS0 cells showed that the antibody product could be increased 4-fold upon growth arrest (48). Bi *et al*. (49) found that arrested cells have higher mitochondrial mass, dehydrogenase activity, and ribosomal protein S6, as well as larger cell size indicating the uncoupling of cell growth, energy metabolism, and protein synthesis from cell cycle progression. At a later study (unpublished results; S H G Khoo, PhD thesis), the increased antibody productivity seen in the arrested cells is shown to be directly correlated with the increase in biomass (dry cell weight) and total intracellular protein. The results from various physiological and cellular organization levels have

demonstrated relatively good consistency. The cells are able to shift to a high productivity state by transcriptional and mRNA stability changes to the heavy and light chains, as well as cope with high productivity by a simultaneous increase in the post-translational capacity of the cell, including N-glycan biosynthesis and secretory functions. Energy metabolism remains a critical issue during high antibody productivity. These changes are controlled at the gene transcription level, demonstrating that the cellular objective is altered toward a high productivity state.

Besides having high productivities, it was believed that a decrease in the number of cell divisions reduces the possibility of genetic drift, which is of great importance when using genetically engineered cells for the production of biologics (43). Furthermore, once a high cell density is achieved, cessation of cell growth reduces the accumulation of toxic products, cell lysis and potentially reduces product contamination with cellular debris and product deterioration due to glycosidases and proteases (50).

Recent work tested the use of extracellular nucleotides, nucleosides, and bases as arresting agents. Carvalhal and coworkers (51) have used NADH, NAD, ATP, ADP, AMP, and adenosine to arrest the cell cycle and enhance productivity. AMP has been demonstrated to be the most promising for increasing specific productivity in CHO cells, resulting in cell arrest in the S phase. The authors suggested that a considered use of such natural compounds is required due to the presence of nucleotides and nucleosides in certain media (51). Other interesting approaches to increase productivity via inhibition of cell cycle progression include high osmolarity and low temperature (52,53). Both techniques have been shown to increase specific productivity where in many cases, the latter has been shown to be proportional to proliferation inhibition, but the role of the cell cycle in regulating or determining their effects is still not clear.

5.4.2 Production in Relation to Cell Cycle Phase

It is important not to confuse the relationship between cell cycle phase and productivity, with the relationship between cell cycle arrest and productivity. The substantial increases in productivity from the metabolically engineered transfects just described are most likely to exist because the arrested cells do not need to devote resources to biomass production (54). This section addresses the situation in "simple" recombinant cells that may be grown in standard industrial processes such as batch, continuous, or draw-and-fill semicontinuous culture modes. Determining the relationship between cell cycle phase and productivity is important for developing automated on-line (or near on-line) process control strategies. These strategies will be based on models that, in addition to the basic parameters of pH, dissolved oxygen (dO_2), cell density, and so forth, must incorporate information concerning cell state, including cell cycle phase and its effect on productivity.

It has been shown that specific monoclonal antibody production by a synchronized mouse–mouse hybridoma culture is maximal during G_1; furthermore, the specific activity increases when the cell cycle is arrested and cells are maintained in late G_1 (55). However, apparent specific productivity also increases when the culture declines (viability decreases); this is the result of substantial passive release of intracellular product into the culture medium from dead and dying cells. Phase dependence was also found in recombinant CHO cells transfected with an expression vector containing *dhfr* and *lacZ* genes; the former was controlled by an SV40 (simian virus 40) promoter, and the latter was controlled by the constitutive human cytomegalovirus (hCMV) promoter (56). In this study, the nonsecreted product, β-galactosidase, was produced almost exclusively during the S phase. Furthermore, cell cycle arrest in S phase, by specific inhibition of DNA polymerase, did not inhibit transcription or translation and thus had no effect on β-galactosidase expression.

However, the literature on the relationship between cell cycle and protein expression summarized in Table 5.2, is inconsistent. Different researchers have shown that product expression (or the maximum rate of expression) is related to different cell cycle phases. In addition, others have shown that product expression is aphasic. These observations do not necessarily contradict each other and may be a true reflection of the systems used, because a variety of cells, products, and constructs were studied. Cell cycle–dependent product expression may not be universal and could vary with cell type or cell line, the construction of the expression vector, the nature of the recombinant gene expressed, or the promoter or enhancer used to drive product expression. Other variables may include post-transcriptional regulation (mRNA level), product gene copy number, and even the culture mode (e.g. whether the cells are attached to a substrate or are free in suspension), may be relevant. However, there are two potential flaws in studying cell cycle–related productivity: synchronizing cells using chemical means, such as thymidine block or nutrient starvation, and comparing cells of different phases that are from the same culture but separated in time. The two problems often go together, for example, following a culture for a day after release from the thymidine block. The difficulty with the former is that the chemical stress used (whatever its nature) may, in addition to its desired effect on cell synchrony, directly cause perturbations in productivity that could wrongfully be ascribed to the cell cycle. The difficulty with the latter is simply that if two cell populations from a culture are separated in time, they are also separated in environmental conditions; recent work (57) has shown that the effect of medium condition is dominant to any cell cycle effect on productivity. The effect of temporal separation is made more uncertain following stress synchronization; an early population may have only partially recovered from the stress, whereas a later population may have fully recovered.

TABLE 5.2. Variation in Phase Expression of Different Products with Cell Line and Promoter

Cell Line	Promoter	Product	Phase Expression	References
Mouse leukemia	Endogenous	DHFR	Aphasic	58
CHO	Endogenous	DHFR	Aphasic	59
Human osteosarcoma	Endogenous	DHFR	Aphasic	59
Mouse embryo fibroblast	Endogenous	DHFR	Aphasic	59
Human prostrate epithelium	Endogenous	PSAP	All except early G_1	60
Hybridoma	Endogenous	MAb	G_1/G_0 (mainly)	61
CHO	AMLP	DHFR	G_1 (mainly)	62
Hybridoma	Endogenous	MAb	G_1/S	63
Mouse plasacytoma	Endogenous	Immunoglobulin	Late G_1/early S	64
Human lymphoid cell	Endogenous	Immunoglobulin	Late G_1/S	65
CHO	Endogenous	DHFR	G_1/S	30
Mouse leukemia	Endogenous	TMPS	S	58
CHO	CMV	β-Gal (*lac*Z)	S	57

NS0	CMV	MAb	G_1	58
NS0	CMV	MAb	G_1	64
CHO	GS	MAb	G_1/S and G_2/M	70

Note: DHFR, dihydrofolate reductase; CHO, Chinese hamster ovary; TMPS, thymidine monophosphate synthetase; MAb, monoclonal antibody; PSAP, prostrate-specific acid phosphatase; AMLP, adenovirus major late promoter; CMV, cytomegalovirus; β-Gal (*lacZ*), β-galactosidase (product of the *Escherichia coli lacZ* gene); SV40, simian virus 40; MMTV, mouse mammary tumor virus; NS0, mouse myeloma; GS, glutamine synthetase; tPA, tissue-like plasminogen activator; IFN-γ, interferon-γ; UPA, urokinase-like plasminogen activator; PA, plasminogen activator.

5.4.3 Cell Cycle Analysis as a Proliferation Predictor

Cells may be arrested in G_1 before the restriction point, but once past that point, they are committed to continuing their cycle and dividing unless prevented from doing so by a catastrophe or artificial intervention. Therefore, one can presume that once a cell enters S phase, under normal growth conditions, one single cell will in due course become two cells. This phenomenon can be used to predict culture growth. The growth-enhancing effect of peptone supplementation on hybridoma culture was predicted by cell cycle analysis 5 h after supplementation, although the effect on cell density was not apparent until 16 h later, 21 h after supplementation (71). A similar use of cell cycle analysis was made with CHO cells: the percentage of S-phase cells correlated with the specific growth rate 10.5 h later and the time difference was the average duration of S phase remaining plus the duration of G_2 and M for that population (72). Thus, the proportion of cells in S phase can be used to predict the subsequent proliferation rate of that culture.

5.4.4 Cell Cycle-Related Susceptibility to Hydrodynamic Damage

The effect of hydrodynamic stress as found in stirred and sparged bioreactors, is at least in part related to cell cycle phase, and there may be a role for hydrodynamic cell damage in the induction of apoptosis (73). It has been reported that DNA synthesis (74) and the proportion of the cell population in S phase (75) were increased under conditions of hydrodynamic stress (high sparging and agitation rates). However, the cell number remained low even though the S-phase population correlated with an increase in cell number. The observed reduction in growth rate was shown to be a consequence of a decline in the proportion of G2- and M-phase cells with a corresponding decrease in the cell size of the population, suggesting that the larger G2 cells were particularly susceptible to hydrodynamic damage (73). Subsequently it was shown that mitotic cells, while also being susceptible to hydrodynamic damage due to their size, were even more sensitive to hydrodynamic damage than G2 cells perhaps due to cytoskeletal rearrangements, alteration of plasma membrane fluidity, or morphological changes during mitosis (33).

5.4.5 Cell Cycle and Apoptosis

Apoptosis (active or programmed cell death) is the means by which intrinsic or extrinsic stimuli activate a series of molecular cascades, triggering events that culminate in a particular morphologically, ultrastructurally, and biochemically defined process of cell death that is, in effect, the opposite of the cell cycle. Entry of a cell into apoptosis can be restricted to a particular cell cycle phase (57,66–78) although this cell cycle dependence does not appear to be universal (79). Cell cycle checkpoints appear to link the

cell cycle to apoptosis. Deregulation of the cell cycle components has been shown to induce mitotic catastrophe and to trigger apoptosis (80).

Cell cycle progression and apoptosis are not only opposite in effect, they may also be alternate outcomes from a single cell control mechanism; they are inextricably linked by common components in the signal transduction pathways for both processes. In addition, circumstantial evidence from the induction of apoptosis by DNA damage or cell cycle disruption and the existence of many oncogenes that both promote the cell cycle and induce apoptosis implies that there is an equilibrium between these two antagonistic processes in all eukaryotic cells. It has been demonstrated by several investigators that apoptosis can occur at any stage of the cell cycle (41,81). For an excellent review of the link between apoptosis and cell proliferation, see Ref. 82.

CELL GROWTH AND PROTEIN EXPRESSION KINETICS

DHINAKAR S. KOMPALA
Chemical and Biological Engineering Department, University of Colorado, Boulder, Colorado

6.1 INTRODUCTION

In this article, the experimental observations and mathematical descriptions of mammalian cell growth kinetics, as well as protein expression kinetics, in batch, fed-batch, continuous, and perfusion cultures are summarized. Focusing primarily on the experimental data from freely suspended single-cell cultures, which are being used increasingly in the biotechnology industry because of their simplicity and easy scalability (1), this article discusses the development and utility of mathematical models of mammalian cell growth kinetics in operating and controlling bioreactors. Further, it addresses the different observed patterns of protein expression kinetics as they relate to cell growth kinetics for hybridoma versus recombinant mammalian cells, and discuss the different bioreactor operating strategies necessary to maximize the production of desired proteins from any production pattern.

Mathematical models of animal cell growth kinetics may be classified along the lines of microbial growth models, which are either structured or unstructured and segregated or unsegregated (2). The unstructured cell growth models consider cell mass as a single entity, compositionally uniform and unchanging even at different growth conditions, whereas the structured growth models include some details on the varying composition of intracellular components (ribosomes, proteins, metabolites, etc.). The unsegregated cell models consider all cells identical, whereas the segregated cell growth models allow for cellular variations or different cell types (such as high and low producers, cells at different cell cycle phases, or cells with different target gene copy numbers). Therefore, the unstructured, unsegregated models are simpler in their kinetic expressions and numeric simulations, but can become unrealistic when dealing with complicated growth phenomena. When the models include more details on the intracellular composition of the average cell (structured growth models) or allow for the different cellular types (segregated growth models), the mathematical descriptions become more realistic, but at the same time more difficult for estimating model parameters, independent model verifications, and numerical computations. Therefore, we will focus in this article primarily on the simpler types of mathematical models for simulating or predicting the different cell growth and protein expression kinetics and provide some references to the more complicated mathematical models developed for mammalian cells.

6.2 BATCH CULTURE KINETICS

6.2.1 Experimental Data

Typical batch culture data for cell growth and product expression kinetics of a murine hybridoma cell line grown in homogeneous suspension cultures (3) are shown in Fig. 6.1. The salient features in the cell growth curve include an early exponential cell growth period, a gradual slowdown in cell growth as the viable cell concentration reaches its maximum value because a key nutrient component is depleted or a toxic metabolite has accumulated, and a subsequent cell death period.

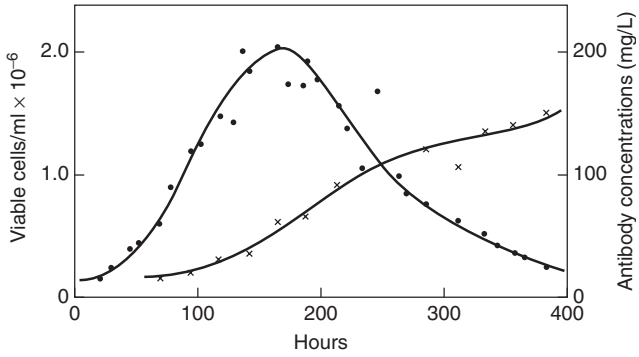

Figure 6.1. Batch culture kinetics of a mouse hybridoma cell line in a 1000-L fermenter, showing viable cell (•) and monoclonal antibody (×) concentrations. [Reproduced from Ref. 3 with permission.]

The product (monoclonal antibody) accumulation curve shows more subtle features, which are harder to interpret. One common observation is that the antibody production rate (the *slope* of the curve marked ×) is maximum when the viable cell concentration is at its maximum, and the production rate is noticeably slower when the viable cell concentration is lower. A second common observation made from these data is that the antibody production rate increases again as more cells die.

The first observation on the antibody production curve suggests that the antibody production rate is proportional to the viable cell concentration, which can be expressed mathematically as

$$\frac{\mathrm{d[MAb]}V}{\mathrm{d}t} = q_{\mathrm{MAb}} X_{\mathrm{v}} V \tag{6.1}$$

where [MAb] is the antibody concentration (mg/mL), t is time (day), V is culture volume (mL), q_{MAb} is the specific (per cell) antibody production rate (mg/cell/day), and X_{v} is the viable cell concentration (cells per milliliter). Assuming constant culture volume (for batch cultures) and a constant specific production rate (as a first guess), this equation can be simplified to give

$$[\mathrm{MAb}] = q_{\mathrm{MAb}} \int X_{\mathrm{v}} \mathrm{d}t \tag{6.2}$$

This equation has been used by different investigators to define the viability index (4), which is also known as the *integral of viable cells* (IVC) (5) and correlates strongly with product titer. This simple relationship immediately suggests some strategies for increasing antibody titers in batch cultures, such as prolonging the viability of the cells, increasing the viable cell concentration, or a combination of the two. These strategies have been implemented easily by strengthening or increasing the concentrations of some medium components to achieve higher viable cell concentrations, and by feeding in concentrated medium intermittently or continuously after about 5 days into batch culture to delay the depletion of key nutrient components in the so-called fed-batch culture operation (6,7).

The second observation on the slight increase in product accumulation during the late culture period, when most cells are dying, has prompted a number of experimental studies to characterize this phenomenon. However, this increase in product accumulation caused by the release of stored products from dying cells is a small fraction of the total product accumulated in the batch or fed-batch cultures (5,8).

6.2.2 Unstructured Kinetic Models

Factors that limit the maximum viable cell concentration and the prolonged viability of these cells were investigated by several investigators (7,9,10). It is commonly found that the growth-limiting substrates are glutamine and glucose and that the toxic metabolic by-products are ammonia and, to a lesser extent, lactic acid. On the basis of these observations, extended Monod saturation kinetic expressions for multiple substrates and inhibitors were proposed (11–13) to describe the specific growth rate μ of hybridoma cells as a function of the concentrations of the limiting nutrients and toxic by-products. A typical expression (12) for μ is

$$\mu = \mu_{\max} \left(\frac{G}{K_G + G}\right)\left(\frac{Gn}{K_{Gn} + Gn}\right) \left(\frac{K_A}{K_A + A}\right)\left(\frac{K_L}{K_L + L}\right) \tag{6.3}$$

where μ is the specific growth rate of hybridoma cells; $\mu_{\max}$ is the maximum specific growth rate; and G, Gn, A, and L are the concentrations of glucose, glutamine, ammonia, and lactate, respectively. The different Ks represent the saturation constants for growth or inhibition by each of these chemicals. A similar multiple saturation kinetic expression has been proposed (11) for the experimentally observed death of these cells in the presence of the two metabolic by-products and in the absence of growth-limiting nutrient:

$$k_{\mathrm{d}} = k_{\mathrm{d,\,max}} \left(\frac{A}{K_{A\mathrm{d}} + A}\right)\left(\frac{L}{K_{L\mathrm{d}} + L}\right)\left(\frac{K_{Gn,\mathrm{d}}}{K_{Gn,\mathrm{d}} + Gn}\right) \tag{6.4}$$

where k_{d} and $k_{\mathrm{d,max}}$ represent the specific death rate and its maximum death rate constant, respectively and the different K_{d}s represent the saturation constants for ammonia, lactate, and glutamine, respectively.

The cell growth and death rate expressions (Eqs 6.3 and 6.4) can be coupled with material balance equations for glucose, glutamine, ammonia, and lactate through the use of yield coefficients Ys and maintenance coefficient m (14)

to describe the dynamic variations of all these chemical and cell concentrations in batch or continuous cultures. Bree *et al*. (11) simulated the dynamics of cell growth and death, consumption of the limiting nutrients, accumulation of by-products, as well as the product antibody concentration in a glutamine-limited serum-supplemented batch culture. The rate expression for intracellular antibody production was proposed as

$$\frac{\mathrm{d[MAb]}}{\mathrm{d}t} = k_{\mathrm{p}} X_{\mathrm{v}} \left(\frac{K_{\mathrm{p}}}{K_{\mathrm{p}} + Gn} \right) \left(\frac{X_{\mathrm{T}}}{K_{\mathrm{XI}} + X_{\mathrm{T}}} \right) \qquad (6.5)$$

where k_{p} is the maximum specific antibody production rate constant, K_{P} is an inhibition constant for glutamine, X_{T} is the total cell concentration, and K_{XI} is an inhibition constant for total cell number. This proposed expression suggests that the specific monoclonal antibody production rate constant q_{MAb} used in Equations 6.1 and 6.2 is not a constant and has to be modified to reduce the specific production rate at high glutamine concentration and at low total cell concentrations. Many of the parameter values, particularly the yield coefficients, saturation coefficients, and the rate constants, were determined from experimental data, and remaining six parameters were adjusted to fit the experimental data. Although the model development and consequently the simulations miss a slight reutilization of lactate in late batch culture period, it is remarkable that this unstructured kinetic model can describe the experimentally measured consumption of glucose and glutamine relatively closely. Model simulations ignore the early batch data, recognizing the well-known difficulty of fitting the initial lag phase with the Monod saturation kinetic expressions. The complexities of animal cell culture, such as the complex media requirements, are manifested in the formulation of multiple saturation or inhibition kinetic expressions and difficulties in determining model parameters.

Dalili *et al*. (15) subsequently developed simpler kinetic expressions for these three rates (cell growth, cell death, and product expression) in glutamine-limited serum-supplemented batch cultures. These model simplifications recognize that glucose is typically in excess and therefore not rate limiting (as recognized by Bree *et al*. as well). Further, ammonia and lactate saturation terms are also eliminated in both growth- and death-rate expressions because these toxic metabolites do not build up to growth-limiting or toxic levels in their batch cultures, but the death rate expression has an additional low constant death rate. A significant difference from the previous model by Bree *et al*. is proposed in the antibody production rate expression. On the basis of their experimental observations of a relatively constant specific antibody production rate for a given initial serum concentration and a reduced production rate as glutamine is depleted, they propose the following rate expression for specific antibody production:

$$q_{\mathrm{MAb}} = m(S_{\mathrm{i}}) \frac{Gn}{K_{\mathrm{MAb}} + Gn} \qquad (6.6)$$

where $m(S_{\mathrm{i}})$ is a production rate constant, which is a function of the initial serum concentration, and K_{MAb} is a saturation constant for antibody production. Most of the simplified model parameters were estimated from a single batch culture experiment, and the glutamine degradation-rate constant was estimated from available literature. With these rate expressions and associated material balance equations, they simulated the dynamic variations in the cell number, glutamine, and monoclonal antibody concentrations in batch cultures with the same initial serum concentration. The model simulations agree reasonably with the set of batch culture data in which glutamine is the limiting nutrient.

Following these early modeling attempts, many other unstructured models (16–21) were proposed with many small differences in their rate equations. Portner and Schafer (22) analyzed about 10 different unstructured kinetic models for hybridoma cell growth and metabolism published in the literature that vary significantly in each of the rate expressions, and compared some model simulations with different sets of experimental data. Though these models were developed on the basis of different sets of experimental data from different hybridoma cell lines growing on different medium formulations and varying serum content, their quantitative comparisons provide some useful general conclusions.

6.2.3 Comparison of Model Simulations with Experimental Data

Despite the use of different rate expressions, many of these models agree well for specific growth rates with experimental data from continuous cultures at different dilution rates. However, significant differences are found between the model simulations and experimental data in the trends of specific death rate, glucose and glutamine consumption rates at low growth rates, and lactate yield from glucose and monoclonal antibody production rate plotted against the specific cell growth rate.

A comparison of the model prediction with experimental data for a specific death rate indicates the adequacy of each proposed rate expression within a limited range of specific growth rates, but shows diverging trends outside that range. These large differences strongly indicate that the proposed expressions for cell death (typically saturation terms with ammonia and lactate and an inhibition term for glutamine) are not quite representative of apoptosis, which is the prevalent mode of gradual cell death due to the buildup of toxic metabolites or depletion of nutrients during the long batch and fed-batch culture times. Necrosis, or sudden traumatic

death more common during excessive sparging or stirring, is not addressed by these proposed rate expressions. Even with these barely adequate specific death rate expressions, these unstructured kinetic model simulations were applied to develop or optimize fed-batch culture strategies (23,24) to increase hybridoma cell densities, prolong their viabilities, and thus increase antibody titers.

Nutrient consumption rate expressions have been typically based on the successful models of microbial growth kinetics. For the simpler microbial growth on a single rate-limiting carbon and energy substrate, the substrate consumption rate in batch cultures is typically modeled as proportional to the cell growth rate, and the proportionality coefficient is usually called the *yield coefficient Y* (grams of cell mass dry weight generated per gram of substrate consumed). In continuous cultures, an additional maintenance coefficient m is necessary (14) to account for the lower observed yield coefficients at low growth rates. For mammalian cell cultures, however, each of the two major required nutrients glucose and glutamine can provide the carbon and energy requirements to different degrees, depending on the availability of the other substrate, as summarized in Fig. 6.2.

The model simulations with the standard method of using a yield coefficient and a maintenance term in each

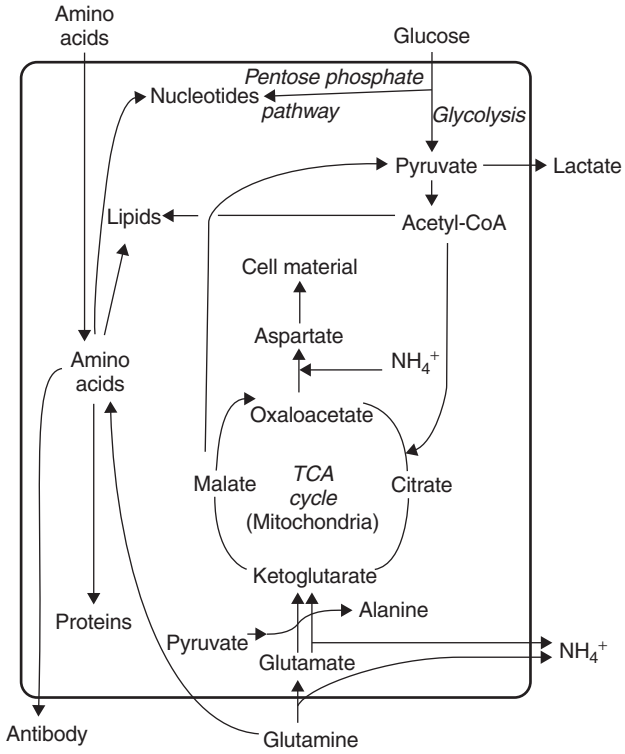

Figure 6.2. Summary representation of metabolic pathways for the utilization of glucose and glutamine in mammalian cells. [Reprinted from Ref. 19] with permission.]

nutrient consumption equation agree with the chemostat data on nutrient consumption rates over a limited range of dilution rates (20). Glucose consumption rates exhibit a saturation-type dependence on residual glucose concentration, even at a constant cell growth rate μ. Therefore, some modelers proposed saturation-type kinetics for nutrient consumption rates as a function of the residual nutrient concentration (18,21,25). However, these different modifications to nutrient consumption rates describe a set of observed data and do not represent the intrinsic flexibility of intracellular metabolism summarized in Fig. 6.2. Observations of multiple steady states through controlled nutrient feeding procedures in fed-batch cultures (26) highlight the feasibility of exploiting metabolic flexibility to minimize the toxic metabolite buildup, and to increase the cellular yield. Such strategies are developed only with a more detailed analysis of intracellular metabolism summarized in Fig. 6.2, and cannot be predicted with any of the simpler unstructured kinetic models discussed before.

Similarly, the two different rate expressions (Eqs 6.5 and 6.6) proposed before for antibody production kinetics in batch cultures represent simplified descriptions of more complex intracellular mechanisms governing synthesis and secretion of monoclonal antibody. Because these expressions do not directly represent the details of intracellular mechanisms, they are expected to be valid mainly in the cases for which they are developed and tested. Subsequent modelers (16–18,22) have used the classical Leudeking–Piret equation for product expression kinetics, typically consisting of a constant (nongrowth-associated) q_{MAb} plus in some cases a growth-associated term, which is proportional to the specific growth rate μ.

6.3 CONTINUOUS CULTURE KINETICS

6.3.1 Experimental Data

In batch cultures, all of the culture conditions such as cell number, nutrient concentrations, and product concentrations change throughout the culture period. Consequently, it becomes difficult to evaluate whether the key metabolic parameters, such as the cell-specific antibody production rate q_{MAb} and the different yield coefficients, remain constant or change systematically with time or nutrient concentrations. This uncertainty contributes significantly to the diversity of rate expressions proposed by different researchers using only batch culture data. More accurate experimental data are obtained from the steady-state conditions obtained over longer periods of continuous cultures. A constant nutrient flow rate F is fed into a bioreactor and the spent medium from the bioreactor is removed along with the cells to the same flow rate to maintain a constant bioreactor culture volume

V. At a constant dilution rate D $(= F/V)$, the continuous culture bioreactor gradually reaches a steady state and hence known as the *chemostat*, wherein the concentrations of chemicals (nutrients, metabolite products) as well as the cells remain constant, even as the cells are actively growing, consuming nutrients, and secreting products. At each steady state, the specific cell growth rate can be easily estimated from the material balances using the measured values of D, X_v, and X_T as

$$\mu = D\frac{X_T}{X_v} \tag{6.7}$$

Similarly, the specific nutrient consumption rates, as well as the antibody production rates, can be estimated through material balance equations and measured concentrations of nutrient and antibody, respectively. Using this method with their steady-state data from continuous cultures of hybridoma cells, Miller *et al*. (12) calculated many metabolic quotients or specific nutrient consumption and product formation rates over a range of cell growth rates or dilution rates.

An interesting highlight from Miller *et al*.'s (12) continuous culture data is that growth rate does not immediately adjust to a change in dilution rate, but changes gradually to reach a new steady state. Consequently, the cell number and nutrient concentrations can go through maxima or minima as cells adapt slowly to the newly imposed dilution rate. Similar dynamic phenomena have been observed repeatedly in microbial cultures as well. The unstructured Monod models are commonly found to be incapable of predicting these dynamics accurately.

6.3.1.1 Inverse-Growth-Associated Production Kinetics. The most surprising result from Miller *et al*.'s (12) steady-state experimental measurements of hybridoma cell metabolism in continuous cultures is that the specific antibody production rate q_{MAb} does not appear to be related to the specific cell growth rate μ according to standard models of growth-associated or nongrowth-associated production kinetics. Instead, the specific antibody production rate appears to follow a new inverse-growth-associated pattern; that is, the specific (per cell) antibody production rate is about two- to threefold higher at lower cell growth rates, as shown in Fig. 6.3.

This inverse-growth-associated production pattern obtained from steady-state data in continuous cultures of murine hybridoma cells has been corroborated by other continuous culture experimental results (17,27,28) and other growth-limiting batch culture conditions (29–31) such as high osmolarity and suboptimal pH and addition of specific growth inhibitors. Although a few experimental studies (20) have observed nongrowth-associated or growth-associated production kinetics, the predominant observation on *monoclonal antibody* production kinetics from *hybridoma* cell cultures has been inverse-growth associated, as shown in Fig. 6.3.

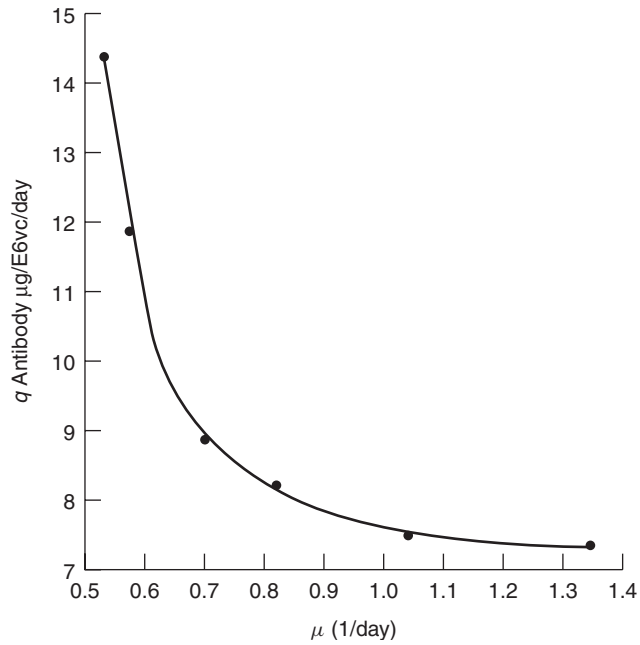

Figure 6.3. Commonly observed inverse-growth-associated production of monoclonal antibody production by murine hybridoma cells. [Reprinted with permission from Ref. 12.]

6.3.1.2 Growth-Associated Production Kinetics. Among the well-characterized exceptions to the commonly observed inverse-growth-associated production kinetics, the production kinetics of humanized chimeric antibodies in transfected myeloma cells have been found to be growth associated in steady-state continuous cultures (32), as shown in Fig. 6.4. These growth-associated production kinetics are commonly observed in the production of recombinant therapeutic proteins, such as γ-interferon and human growth hormone, in batch and continuous cultures of transfected mammalian cells (33,34). An interesting switch in the production pattern has been reported (35) in batch cultures of baby hamster kidney (BHK) cells: although the specific production rates of a secreted recombinant antibody and a secreted reported protein (alkaline phosphatase) are growth associated in suspension cultures, inverse-growth-associated production kinetics are reported for the same cell lines when they are grown attached to microcarriers. However, in the light of the difficulties in getting accurate kinetic results from batch cultures and the added difficulty in estimating the growth rate from attached growth on microcarriers, it is not certain whether this reported switch in the production kinetics on changing the culture environment is reproducible or an experimental artifact.

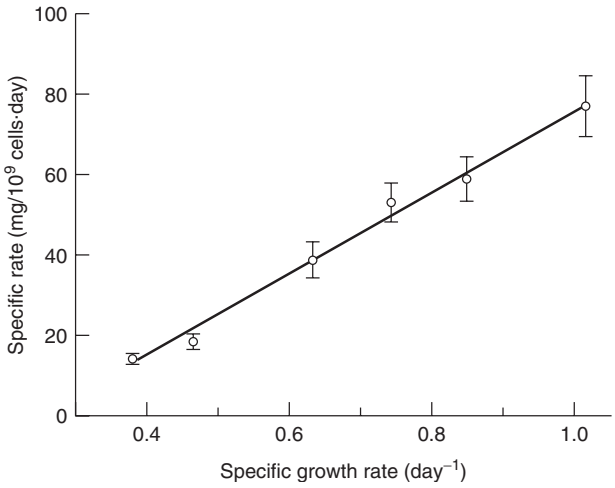

Figure 6.4. Growth-associated production of chimeric antibody by transfected myeloma cells. [Reprinted with permission from Ref. 32.]

In summary, it is well established through continuous suspension culture steady-state results that transfected mammalian cells exhibit growth-associated production kinetics for the synthesis of different recombinant proteins, as shown in Fig. 6.4, whereas the production kinetics for the synthesis of monoclonal antibody from hybridoma cell cultures follows an inverse-growth-associated pattern, as shown earlier in Fig. 6.3.

6.3.2 Structured Kinetic Models

In contrast to the unstructured kinetic models that consider the cells as uniform in composition, the structured kinetic models consider the dynamic variations of some key intracellular metabolic components, such as DNA, RNA, nucleotides, proteins, amino acids, membranes, and lipids. Batt and Kompala (36) developed a structured kinetic modeling framework for simulating the dynamics of cell growth in batch and continuous cultures of mammalian cells. To simplify their structured kinetic model, Batt and Kompala lumped these components into four separate pools and developed different rate expressions in the form of Equation 6.3 for the synthesis of each pool. Then the cell growth rate is simply calculated as the sum of the rate equations of all intracellular pools. With this framework, the model calculates the dynamics of cell growth rate even in the unbalanced growth conditions, such as in the initial lag phase of batch cultures and when the dilution rates are shifted up or down in continuous cultures. The structured growth model has been shown capable of simulating the maxima and minima observed in cell number and nutrient concentrations during the shift-up or shift-down experiments. Therefore, this structured model can be useful for simulating simple batch culture dynamics and steady-state data in continous cultures and also for simulating the dynamics of these cultures due to intermittent additions of nutrients, as well as the fed-batch cultures discussed in a later section.

However, as the single growth rate expression (Eq. 6.3) is now replaced with a rate expression for each of the four intracellular pools, the number of model parameters increases significantly. Although some of these parameter values of lymphocyte metabolism are determined from the literature, many other parameter values were estimated from the same experimental results of Miller *et al*. (12). For the antibody synthesis rate, this structured kinetic model uses a descriptive rate expression based on the experimental data shown in Fig. 6.3 in the absence of an exact mechanistic understanding of this pattern. With a more detailed understanding of the mechanisms involved in determining the inverse-growth-associated production kinetics, it is possible to alter the rate expression within the same structured kinetic modeling framework to enhance the utility of model simulations.

DiMasi and Swartz (37) developed a so-called energetically structured model, focusing on energy metabolism of hybridoma cells, represented by four pseudometabolite pools, such as glycolytic intermediates, metabolites derived from glutamine, energy charge (38) of the cell (ratio of ATP, ADP, and AMP), and the redox state of the cell or the ratio of NADH/NAD. Then the specific nutrient uptake rates and waste product synthesis rates are expressed as combinations of saturation and inhibition terms based on these pseudometabolites. The cell growth rate expression is formulated as a product of multiple exponential saturation terms each based on a single pseudometabolite. Although this approach recognizes the possible variations in the different intracellular metabolites, as in the previous structured kinetic model, the growth rate expression multiplies different saturation terms, as in the unstructured models represented by Equation 6.3. This energetically structured model satisfactorily describes the steady-state data for different nutrients and metabolites from Miller *et al*.'s (12) continuous culture experiments. It is not known if the simulations of the model are equally successful in simulating the dynamic variations in shift-up or shift-down experiments. As in the previous structured kinetic model, incorporating mechanistic detail into the model comes at the cost of additional model parameters, which need to be estimated through independent experiments to test any predictive capabilities.

Because of the increasing availability of detailed mechanistic knowledge, it is becoming possible to develop kinetic models for different metabolic pathways, for example, monoclonal antibody assembly and secretion (39), and regulatory subsystems, for example, intraorganelle pH regulation (40). Because the speed and ease of numerical computations have increased rapidly along with our detailed mechanistic

knowledge, it may indeed be possible to develop a more complete structured kinetic model to describe the complex dynamics of animal cell cultures. Barford and coworkers (41,42) used a modular approach to construct a complex structured kinetic model with three major compartments of cell culture medium, cytoplasm, and mitochondria. However, as the number of parameters increases dramatically to more than a hundred with such detailed mechanistic models describing over 40 model variables, it is increasingly difficult to estimate the parameter values to simulate the cell metabolism on a computer. Therefore, these researchers (43) had to use artificial intelligence methods, such as a hybrid neural network model (44), in conjunction with the metabolic model to optimize the estimation of parameter values so that model simulations agree better with experimental data on the dynamics of metabolite concentrations in batch cultures.

6.3.3 Cell Cycle Models

Suzuki and Ollis (45) proposed a cell cycle model for antibody synthesis by hybridoma cells to explain the repeated observations of inverse-growth-associated production kinetics of monoclonal antibody in continuous cultures of murine hybridoma cells, as shown in Fig. 6.3. On the basis of prior literature on cell cycle-dependent synthesis of antibodies by myeloma or lymphoid cells, they proposed that hybridoma cells secrete monoclonal antibodies primarily in the late G1 and early S phase of the cells. According to the well-established cell cycle models, cells spend more time in the G1 phase during low growth rates in continuous cultures, as well as in growth-limited batch or fed-batch cultures. Consequently, the higher antibody synthesis in the late G1 phase results in a higher specific (per cell) antibody synthesis rate at lower growth rates. At higher growth rates, the cells spend less time in the productive G1 phase, resulting in a reduced specific antibody production rate. This cell cycle model for antibody synthesis by hybridoma cells was investigated experimentally by a number of investigators (46–48) providing significant support for this central hypothesis.

Following Suzuki and Ollis's successful prediction of the inverse-growth-associated antibody production kinetics by hybridoma cells with the cell cycle model, Linardos *et al*. (49) proposed a cell cycle model for apoptotic cell death, which is observed strongly at low cell growth rates. They proposed that apoptotic cell death occurs primarily in cells arrested in the G1 phase of the cell cycle and that the death rate is proportional to the fraction of cells arrested in the G1 phase. This cell cycle model satisfactorily describes the higher cell death rates at low dilution rates in continuous cultures of hybridoma cells.

With these two successful descriptions of antibody productivity and cell death by simpler cell cycle models, Martens *et al*. (50) developed a combined cell cycle and unstructured kinetic model for simulating Miller *et al*.'s (12) continuous culture steady-state data. The cell growth rate expression is similar to Equation 6.3 and the substrate consumption rate equations are based on the yield coefficient and maintenance energy terms described earlier. Although the model simulations follow the trends qualitatively in the steady-state data, the average model parameter values chosen do not fit the experimental data closely enough. Further, the predictions of this unstructured kinetic model for dynamic variations in batch, fed-batch, or continuous culture shift-up or shift-down experiments are expected to be more divergent, as discussed earlier.

The dramatic switch in protein expression kinetics from the inverse-growth-associated production of antibodies by hybridoma cells (Fig. 6.3) to a growth-associated production of recombinant proteins by transfected mammalian cells (Fig. 6.4) has been addressed with a cell cycle model (51). Gu *et al*. (51) assumed that although hybridoma cells produce antibodies primarily in the G1 phase, transfected mammalian cells produce their recombinant proteins primarily in the S phase. Gu *et al*.'s (51) cell cycle model predictions for an intracellular reporter protein accumulation, shown in Fig. 6.5, have an inverse-growth-associated production pattern for the G1-phase-synthesis assumption and a growth-associated or nongrowth-associated production pattern for the S-phase synthesis assumption. The S-phase synthesis assumption is supported by flow cytometric investigations on recombinant protein synthesis in transfected Chinese hamster ovary (CHO) cells (52,53). On the basis of the different cell cycle phase-specific characteristics of recombinant protein expression from different promoters, Kompala and coworkers (54,55) developed different CHO cell lines

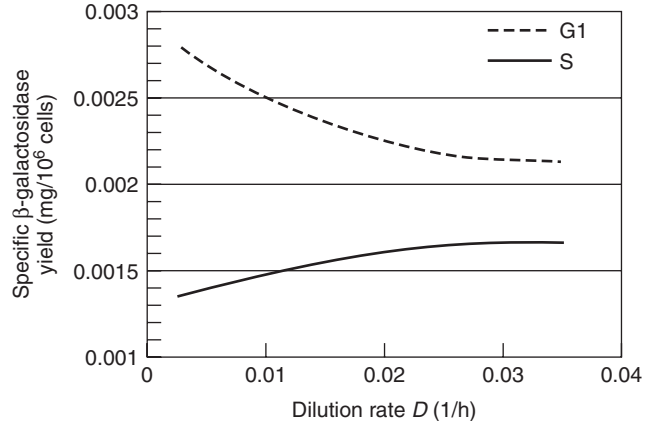

Figure 6.5. Predictions of the previous two production patterns with different assumptions on the cell cycle phase-specific expression for intracellular protein accumulation. [Reprinted with permission from Ref. 51.]

transfected with different expression vectors that contain the same reporter gene (*lac Z*). In continuous cultures of stably transfected CHO cells, the S-phase-specific SV40 promoter-driven expression of β-galactosidase was growth associated (54), whereas the G1-phase-specific adenovirus major late (AML) promoter-driven expression of the intracellular reporter protein was inverse-growth associated (55). If these results yielding the dramatic switch between growth-associated and inverse-growth-associated production kinetics are reproducible with secreted reporter proteins, this phenomenon will have a significant impact on maximizing culture productivities, as discussed in the section on fed-batch cultures.

6.3.4 Segregated Models

Long-term cultures of some hybridoma cell lines have shown a gradual decrease in antibody productivity due to the appearance of faster growing nonproducer hybridoma cells (16). The loss of culture productivity can be modeled only by explicitly recognizing the growth and production kinetics of these two distinct cell lines, producer and nonproducer, in a segregated modeling approach (56). On the basis of a similar approach used successfully to analyze instabilities in recombinant bacterial cultures, new insights have been developed on the rate of conversion from producers to nonproducers and the growth rate difference between two cell types required to generate this culture instability (57). More general segregated models develop single-cell models, along the lines of pH regulation model of CHO cells (40), and integrate them among the whole cell population to develop population balance models (58). The desirability of population balance models for analyzing mammalian cell cultures as well as the difficulties associated with the detailed modeling analysis are discussed in a recent review on modeling of mammalian cells (59). With numerous theoretical and computational difficulties added on top of the difficulties in developing detailed mechanistic models for single cells, the population balance modeling approach is not yet widely used in understanding the kinetics of mammalian cell growth and protein expression.

6.4 FED-BATCH AND PERFUSION CULTURES

6.4.1 Optimization of Monoclonal Antibody Production

Successful exploitation of cell growth and protein expression kinetics has led to systematic development of fed-batch cultures for maximizing monoclonal antibody productivity from hybridoma cells (60). Maximizing the hybridoma cell concentration and maintaining the viability of these cells by careful feeding of medium concentrates, as suggested by Equation 6.2, are the key ingredients in this optimization process. An equally important ingredient in achieving high product titers has been the *inverse-growth-associated* production kinetics, as shown in Fig. 6.3. During the early batch culture period, cells grow at a high rate with a low specific production rate. After high cell densities have been achieved, controlled nutrient feeding reduces the cell growth rate and maintains the cells' viability as long as possible. During this low growth fed-batch culture period, the specific (per cell) antibody production rate is significantly increased, as shown in Fig. 6.3, resulting in a large production of monoclonal antibodies in fed-batch cultures. Similarly, in high cell density perfusion cultures, after high cell densities are achieved through the early batch culture period, the cells are maintained in a lower growth mode once perfusion culture begins. During such a high cell density perfusion operation, the specific production rate increases (61), resulting again in larger antibody titers than in continuous cultures.

6.4.2 Model Simulations for Fed-Batch Cultures

The preceding development of optimal fed-batch and high cell density perfusion cultures to maximize culture productivity has taken place without any significant direct input from model simulations. The unstructured models, based on extended Monod Kinetics, are ill suited for dynamic simulations, even though they have been applied for this purpose in fed-batch (23,24) as well as perfusion (62) cultures. Emborg and coworkers (63) simulated the structured kinetic model of Batt and Kompala (36) in batch and fed-batch culture modes and indeed found the fed-batch cultures better suited for maximizing culture productivity, as confirmed by many experimental studies. Ryszczuk and Emborg (64) subsequently compared the fed-batch simulations of the same structured model (36) with an unstructured model to conclude that the structured model simulations are more responsive to the different fed-batch culture strategies and predict a more significant improvement in antibody production in fed-batch cultures.

6.4.3 Suboptimal Growth-Associated Production Kinetics

Although high cell density fed-batch and perfusion cultures have been successful in maximizing monoclonal antibody production from hybridoma cells, a necessary requirement for this optimization has been *inverse-growth-associated* production kinetics, as shown in Fig. 6.3. However, recombinant protein synthesis kinetics from transfected mammalian cells are typically growth associated, as shown in Fig. 6.4. Some experimental researchers have already

recognized the suboptimal nature of fed-batch cultures for these mammalian cell lines and have used repeated batch cultures (65) to maximize protein synthesis. Unfortunately, these repeated batch cultures are significantly inferior from the perspective of process optimization. During exponential batch cultures where the growth and specific (per cell) production rates are high, the cell concentrations are typically low. After cell numbers reach a high enough value and the cell growth rate slows down, the specific productivity drops enormously, if the cells exhibit growth-associated production kinetics. If the successful paradigms of high cell density fed-batch and perfusion cultures for maximizing the monoclonal antibody synthesis from hybridoma cells are to be applied to recombinant mammalian cell cultures, then it will be necessary to reengineer them to obtain the same inverse-growth-associated production kinetics. The reengineering of CHO cells to achieve inverse-growth-associated production kinetics has so far been demonstrated only for an intracellular reporter protein (54,55).

6.5 CONCLUSIONS

This article highlights the importance of characterizing cell growth and protein synthesis kinetics to maximize culture productivity. Unstructured kinetic models, based on extensions of classical Monod kinetics, yield and maintenance coefficients, and Leudeking–Piret production kinetics, provide the simplest choice for describing the dynamics of cell growth, nutrient consumption, and product expression. Structured kinetic models address more details of cellular metabolism and consequently can describe more accurately cell growth and product expression dynamics in batch, fed-batch, and continuous cultures. With increasing knowledge of animal cell metabolism, it may soon be more feasible to develop more detailed structured kinetic models to enhance our understanding and optimization of mammalian cell cultures.

Protein expression kinetics follow two different patterns, namely, growth-associated and inverse-growth-associated production kinetics. Inverse-growth-associated production kinetics more commonly found for the monoclonal antibody synthesis by hybridoma cells have been successfully exploited to maximize productivity in high cell density fed-batch and perfusion cultures. Growth-associated production kinetics, observed increasingly in the production of therapeutic proteins by recombinant mammalian cells, are more difficult to optimize because repeated batch cultures and continuous cultures are necessary to maintain the high cell growth and specific production rates. It may be possible to employ the successful paradigms of high cell density fed-batch and perfusion cultures to maximize antibody productivities, if recombinant mammalian cells can be engineered to yield inverse-growth-associated production kinetics.

Acknowledgments

The author's research on mammalian cell culture kinetics has been funded by grants BES-9504840, BES-9817249, and BES-0541119 from the National Science Foundation.

NOMENCLATURE

A	ammonia concentration (g/L)
D	dilution rate (day^{-1})
F	nutrient flow rate (mL/day)
G	glucose concentration (g/L)
Gn	glutamine concentration (g/L)
K_d	saturation constant in death rate (g/L)
K_{MAb}	Monod saturation constant for antibody production (g/L glutamine)
K_P	inhibition constant for glutamine (g/L)
K_{XI}	inhibition constant for total cell number (cells/mL)
K_d, $K_{d,max}$	specific death rate and maximum death rate constant (day^{-1})
k_p	maximum specific production rate constant (μg/106 cells/day)
L	lactate concentration (g/L)
[MAb]	antibody concentration (g/L)
m	maintenance coefficient ((g or mM)/day/cells)
$m(S_i)$	specific antibody synthesis rate constant, which is a function of initial serum concentration (μg/106 cells/day)
q_{MAb}	specific (per cell) antibody production rate (μg/106 cells/day)
t	time (day)
V	culture volume (L)
X_T	total cell concentration (cells/mL)
X_v	viable cell concentration (cells/mL)
Y	yield coefficients (cells or g or mM)/(g or mM)
μ, μ_{max}	specific growth rate and its maximum value (day^{-1})

CELL VIABILITY MEASUREMENT

NING WEI AND BENJAMIN SOMMER
Faculty of Technology, Fermentation Engineering, University of Bielefeld, Bielefeld, Germany

7.1 INTRODUCTION

Cell viability is a fundamental physiological characteristic of a cell, and has been one of the general interests in biology and biotechnology since the microscopic discovery of cells, because it is the basis of various kinds of cell-based biological research and applications. Cell viability has a direct impact upon the productivity and quality of biological production, as well as the performance of biological systems. Diverse assays have been invented for assessing viability. The major categories of these methods include permeability assays, functional assays, flow cytometry, and physical methods. The assumption that only viable cells possess an intact cytoplasmic membrane that prevents normally impermeable matters from passing through the membrane is made for all kinds of permeability assays. In functional assays, the activity of intracellular enzymes, ATP level, RNA level etc., are investigated. Flow cytometry can be described as automated microscopy, in which a single file of cells are formed in a sheath flow and presented in front of a focused light beam. Multiple optical characteristics of the cells are investigated simultaneously. Methods based on various physical properties of cells have also been developed for the determination of cell viability.

7.2 PERMEABILITY ASSAYS

Since long it has been known that cells are surrounded by a barrier labeled as the cell membrane. Therefore, since the beginning of the twentieth century various cell viability assays have been developed on the basis of the test of the permeability, or integrity of the cytoplasmic membrane. Permeability assays can be classified into three different groups: exclusion, inclusion, and release.

7.2.1 Exclusion

It is evident that upon cell damage, bulky, charged molecules that are normally excluded by a cell are able to access the cytoplasm through the compromised membrane. If the molecules added have special light-absorbing or fluorescent properties, the damaged cells can be readily identified. These molecules are named *stains.* For mammalian cells the classical stain is trypan blue (1,2). Under bright field microscopy, damaged or dead cells appear purple-violet, whereas live cells are not stained. Methylene Blue is widely used for the determination of yeast viability (3). Nevertheless, this stain is notoriously inaccurate when the yeast viability is below 95%. Therefore, an alternative stain, Methylene Violet is recommended (4). The applicable stains can also have special fluorescent characteristics. For instance, Propidium Iodide (PI) is a common fluorescent stain that binds to nucleic acids. In dead cells, the intensity of the red fluorescence from PI is much higher than that in live cells. For identifying the bacterial viability, a dual stain composed of two fluorescent dyes, SYTO 9 and PI, is used. SYTO 9 penetrates all bacterial membranes and stains the cells green, while PI only penetrates cells with damaged membranes, and the combination of the two stains produces red fluorescing cells (5). Besides, the use of Acridine Orange (AO), Alcian Blue (6), Congo Red (7), Ethidium Bromide (EB) (8), and SYTOX Green (9) for assessment of viability is based on the same principle.

7.2.2 Inclusion

The converse of dye exclusion is dye inclusion. The nonfluorescent esterase substrate fluorescein diacetate (FDA) is used commonly in assessing viability of mammalian cells and yeasts (10,11). FDA diffuses into cells, where it is cleaved by cellular esterase to yield a fluorescent product, fluorescein. Fluorescein is an impermeable, charged molecule, thus, will be retained in viable cells, and stain the cells green. However, FDA will leak from cells with damaged membranes, therefore, damaged or dead cells fluoresce only weakly. FDA is not an ideal fluorescent substrate for bacteria, as they retain fluorescein poorly, resulting in low S/N (signal to noise) ratio (12). Leakage of probe to the external environment may be reduced by using FDA derivatives with additional functional groups. For instance, carboxyfluorescein diacetate (CFDA) (13), chloromethylfluorescein diacetate (CMFDA) (14), Calcein-AM (15), and 7′-bis-(carboxyethyl)-5 (6)-carboxyfluorescein-pentaacetoxymethylester (BCECF-AM) (16).

7.2.3 Release

The release of specific molecules or intracellular enzymes can also be used to measure cell viability. Typical assays in this aspect include the assessment of the release of ^{51}Chromium (17) and lactate dehydrogenase (LDH) for mammalian cells (2,18–20), magnesium, phosphate, and potassium for microbial cells (21–23). In addition, iododeoxyuridine (^{125}I-UDR) (24,25), [^{3}H]praline (26), [^{75}Se]selenomethionine, and [^{3}H]uridine (27) have been used to assess cell viability by measuring the incorporation of these compounds into DNA (^{125}I-UDR), RNA ([^{3}H]uridine), and proteins ([^{3}H]praline and [^{75}Se]selenomethionine) of the cells.

^{51}Cr is a γ-emitting radioisotope. It is known to bind tightly to intracellular proteins. The disadvantage of using ^{51}Cr as an indication of cell viability is a high spontaneous release rate of the ^{51}Cr-labeled proteins. In comparison, use of ^{125}I-UDR, [^{3}H]praline, [^{75}Se]selenomethionine, and [^{3}H]uridine is less problematic, since they are directly incorporated into the DNA, RNA, and proteins of the cells. Nevertheless, the above radioactive compounds may be toxic to the cells, and thus limit the sensitivity of the assay.

7.3 FUNCTIONAL ASSAYS

7.3.1 Bioluminescence Assay

Bioluminescence occurs in biological systems when a biochemical reaction produces an electronically excited unit, which emits a photon so as to return to the ground state. The basis of the assay is the measurement of intracellular ATP, a universal energy unit in all living cells. When a cell dies, the intracellular ATP is rapidly degraded by ATPases and the ATP levels decline quickly. ATP-dependent oxidation of the substrate luciferin in the presence of luciferase produces oxyluciferin, carbon dioxide, adenosine monophosphate (AMP), inorganic phosphate, and light. One photon is produced per molecule of hydrolyzed ATP. The amount of light emitted is directly correlated with the amount of ATP present (2,28–30).

7.3.2 Tetrazolium Assay

Instead of direct measurement of ATP content, activity of enzymes involved in the production of ATP can also be examined for assessment of cell viability. Tetrazolium dyes are most widely used to measure activity of mitochondrial reductases. Tetrazolium dyes act as electron acceptors and are reduced to formazan products. These have special optical properties, hence, they are readily identified. The most frequently used tetrazolium dyes are 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (2,31) and 5-cyano-2,3-ditolyl tetrazolium chloride (CTC) (32).

MTT is widely used in assessment of viability of mammalian cells. In viable cells, MTT is reduced to a formazan product, which strongly absorbs light at a typical wavelength of about 560 nm. Usually a solution, for example, dimethyl sulfoxide, is used to dissolve the purple insoluble formazan product, and the absorbance of this colored solution can be quantified by a spectrophotometer. CTC is widely used in assessing viability of microbial cells. CTC has an advantage that the formazan product is fluorescent, which enormously enhances the sensitivity of the assay.

7.3.3 FISH Methods

Fluorescent *in situ* hybridization (FISH) is a cytogenetic technique. It uses oligonucleotides that bind to intracellular DNA, RNA, or chromosome. The binding sites are located where they show a high degree of sequence similarity. These oligonucleotides are usually designed for specific target and must be tagged with fluorophores, so that FISH can be observed and analyzed with either fluorescence microscopy or flow cytometry. If a selective oligonucleotide probe binds specifically to intracellular rRNA's, the intensity of fluorescence can then be correlated to viability (33,34). By contrast, antibody-labeling methods often fail in viability assessment. The reason therefore, may be the short half-life of rRNA within nonviable cells.

7.3.4 Membrane Potential Assay

In microorganisms a potential is present across the cytoplasmic membrane of viable cells, whereas absent from nonviable cells. This potential is principally generated by

the extrusion of H^+ ions by H^+ ATPase or the electron transfer chain. Some stains for assessing viability are based on this fact. Cells that have a membrane potential (generally negative inside) accumulate positively charged dyes, such as rhodamine 123 (35), whereas negatively charged dyes, such as those from the oxonol group (36,37), are excluded. As a result, rhodamine 123 stains viable cells, while oxonol will stain nonviable cells. These dyes can be excited by a laser with a central wavelength of about 490 nm and emit green fluorescence. They have been used successfully for bacteria and yeasts. In eukaryotic cells, rhodamine 123 accumulates preferentially in the mitochondria, which possess a high membrane potential. This may result in toxicity to the cells.

7.3.5 RT-PCR Methods

Methods based on polymerase chain reaction (PCR) have been developed for detecting the presence of specific nucleic acids as indicators of cell viability. DNA is highly stable even in dead cells and may still be detected after a long term by PCR. Thus, it is hardly suitable for the detection of viable cells. RNA, in contrast, is prone to chemical degradation due to the susceptibility to hydrolysis of the ribose 2′-hydroxyl group, as well as the rapid nucleolysis by cellular ribonucleases. Therefore, RNA was found to be unstable in dead cells and favorable for viability assessment in comparison to DNA (38).

Various attempts to prove the suitability of RNA detection by RT-PCR (reverse transcriptase PCR) methods for an estimation of cell viability have been made so far (39–43). It was found that during incubation at room temperature subsequent to cell killing, RNA could only be detected for a certain time by RT-PCR, indicating its degradation *postmortem* and its eligibility as a target substance for the detection of viable cells (43). However, the time passing until the RNA target may no longer be detected from a population of dead cells only, needs to be determined prior to analyses of unknown samples. Moreover, the incubation time required until the target is completely abolished depends on the RNA type investigated (43,44). mRNA is supposed to be the least stable among the RNA species and therefore the ideal target substance.

Moreover, the choice of the RNA target molecule, particularly its stability, as well as the sequence and length of the PCR amplicon must be considered carefully to prove its suitability as an indicator of live cells prior to analysis of unknown samples (43,45).

Since common RT-PCR is generally not quantitative, this method does not yield the absolute amount of viable cells in an analyzed specimen (46). Therefore, a quantitative estimation of RNA molecules by real-time RT-PCR (quantitative RT-PCR, qRT-PCR) was found to allow a more precise determination of the viable cell quantity because of a direct correlation between the PCR signal (RNA copy-number) and the viable cell concentration (38,47).

The CT (number of cycles at which fluorescence reaches the threshold) values of a qRT-PCR assay were observed to strongly correlate with the amount of viable cells (as determined by reproductive methods) employed to the reaction (38), as shown in Fig. 7.1.

As stated above, a positive RT-PCR signal does not necessarily report a viable cell; it may also result from a cell that has died only recently, with the target RNA not being degraded in time. Thus, the qRT-PCR CT values solely allow statements about the maximum number of putative viable cells in a sample, rather than the actual live cell titre.

7.3.6 FUN-1 Assay

A new fluorescent probe has been recently developed exclusively for assessing the viability of yeasts (48). This

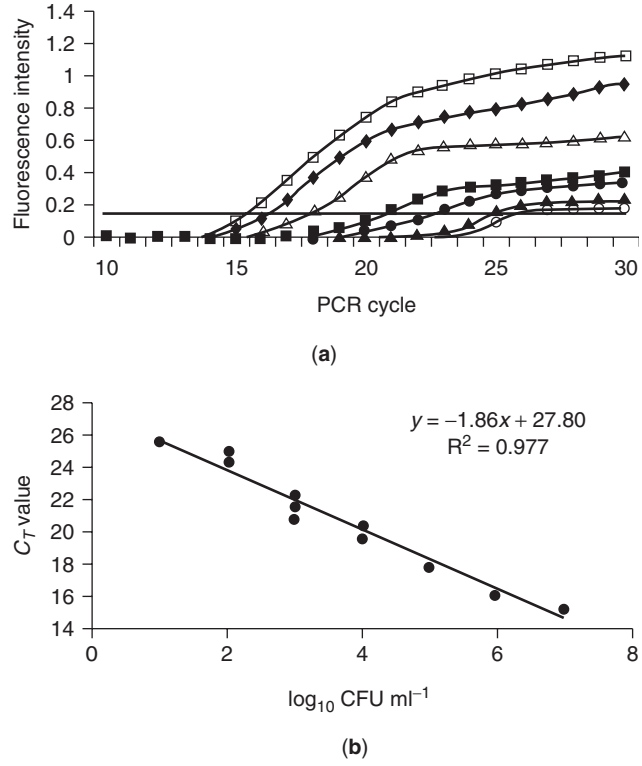

Figure 7.1. Correlation qPCR (Ct)<-> viable cells (CFU). Real-time RT-PCR assays of serial dilutions of mixed cultures of yeasts and molds. (**a**) Increase in fluoresence intensity with the number of PCR cycles. Fungal contaminations were present at 7( ), 6( ), 5( ), 4( ), 3( ), 2( ), and 1(◦) $\log_{10}$ CFU mL^{-1}. The straight horizontal line indicates the threshold value. (**b**) C_T values plotted against the $\log_{10}$ CFU mL^{-1} derived from, the plate count; three repetitions for each dilution are indicated. [Source: Fig. 3 of Ref. 38.]

membrane-permeant and nucleic acid-binding dye is named *FUN-1*. It has been found to give rise to cylindrical intravacuolar structures (CIVS) in *Saccharomyces cerevisiae*. Biochemical processing of the dye by active yeasts yields CIVS that are markedly red-shifted in fluorescence emission and therefore, spectrally distinct from the nucleic acid-bound form of the dye. Generally, in presence of FUN-1, live cells are marked clearly with orange fluorescent CIVS, whereas dead cells exhibit extremely bright, diffuse, green-yellow fluorescence.

7.3.7 DNA Gel Electrophoresis for Apoptosis Analysis

There are in general, two distinct sorts of cell death: necrosis and apoptosis. While necrosis is a passive form in which cell die from acute cellular injury, and apoptosis is rather a *programmed* intracellular process which involves a series of biochemical events leading to a characteristic cell morphology and death.

During apoptosis DNA is cleaved at the internucleosomal sections to produce low molecular DNA fragments of 180–200 pb. Therefore, DNA Gel Electrophoresis (DGE) can be performed to detect a characteristic "laddering" pattern of these smaller DNA fragments on agarose gels after electrophoresis (49) if the cells have undergone an apoptosis.

7.4 FLOW CYTOMETRY

Flow cytometry is a technique, by which the measurements of physical and/or chemical characteristics of single cells or other particles are made when they pass through a measuring apparatus, flow cytometer, in a fluid stream. Measurements of optical properties of single cells (or other particles) are by far the most common in flow cytometry, although other properties, for example, electrical and acoustic properties, can be also measured. When a flow cytometer is equipped with an electrical and/or mechanical mechanism diverting cells (or other particles) according to the range of values of their measured characteristics, it becomes a cell sorter (50,51).

Flow cytometry can be described as automated microscopy, in which cells are injected into a fast flowing fluid stream termed as *sheath flow*. The slow moving cells are hydrodynamically focused at the central line of the sheath flow, creating a single file of cells that move into the measuring apparatus termed as *cytometer*. In the cytometer, optical characteristics of cells are measured as they are presented in front of a focused light beam. Usually, a fluorescent stain is applied upon the cells, and the emitted fluorescence is detected for cell analysis. Besides, forward and side scatter is also measured. In modern instruments the fluorescent emission is measured normally by multiple detectors at different spectral regions, for instance, three detectors for red, orange, and green fluorescence, respectively. In data processing, multivariate analysis methods are generally applied. The most frequently used is a binary plot, by means of which, two selective optical characteristics of the cells are depicted as visually separable data clouds.

In the past decade, flow cytometry has been employed extensively in the field of biotechnology (52–58). Some typical applications are determination of cell parameters (e.g. measuring viability, apoptosis, proliferative activity, and DNA content), functional screening of genetic libraries for drug target discovery, screening of combinatorial protein libraries, vaccine analysis, isolation of human chromosomes, etc. In most of the applications, fluorescent reagents are required to label the cells.

Flow cytometry is also commonly used for determination of viability. Because of the variety of cell types in biotechnology it may need different reagents for specific assays of cell viability. For instance, viability of mammalian cells can be determined through the exclusion of PI or EB by the intact membrane of viable cells. However, this approach is less useful with bacteria (59,60). In flow cytometry, for bacteria viability measurements, it has been found that rhodamine 123 is an effective reagent (61,62). Alternative approaches are based on the facts that lipophilic cations are accumulated by microbial cells and nonfluorescent substrates are converted to fluorescent products by the metabolic activities of viable cells (63). In the research of Caron *et al*. (64), bacteria were classified into different groups according to their specific interactions with fluorescent dyes EB, bis-oxonol (BOX), and PI. Cells that performed exclusion of EB are classified as metabolically active cells; uptake of EB but exclusion of bis-oxonol (BOX) is related to de-energized cells with a polarized cell membrane, and uptake of both dyes related to depolarized cells. Permeabilized cells were identified by PI.

In recent years, ready-made reagent "kits" are also commercially available from specific suppliers. These kits enable rapid development of protocols. For instance, the measurement of bacteria viability can be accomplished using the LIVE/DEAD BacLight bacterial viability kit from Molecular Probes. The FUN-1 kit from the same company will favor the determination of yeast viability.

In Ref. 49, several methods based on flow cytometry have been introduced to investigate apoptosis in commercial cell culture processes. For instance, using high-affinity DNA binding fluorochromes, like PI, apoptosis can be probed with the occurrence of a sub-G1 region of the cell cycle distribution. Another method is on the basis of dual staining with annexin V-FITC and PI. The fundamental hereby is the externalization of phosphatidylserine (PS), which is normally present on the inner surface of an intact membrane, to the outer layer of the surface of an apoptotic

cell, which loses its membrane phospholipids asymmetry. Since necrotic cells in the absence of membrane integrity will also stain positive with annexin V-FITC, dual staining with PI enables the appropriate distinguishment. Moreover, techniques based on TUNEL (TdT-mediated dUTP Nick End Labeling), Rhodamine-123 and detection of Caspase-3 Activation, respectively, have also been introduced in this work.

7.5 PHYSICAL METHODS

7.5.1 *In situ* Microscopy

Characterization of cell populations is normally performed by *ex situ* means, namely, cells are extracted and taken away from the original place (e.g. a bioreactor) and measured in a separate apparatus. However, techniques, which can measure the cells at the original site, have also been developed. One of them is *in situ* microscopy (ISM). Through a microscope, which is directly mounted at one port of the bioreactor, the cell parameters can be determined, and hence, the growth of the cell population can be monitored.

One of the earliest realizations of ISM was accomplished by Bittner (65). In this work a sterilizable sensor with a miniaturized and automated mechanical sampling mechanism is made for monitoring cell concentration and size distribution. Suhr *et al*. constructed their sensor on the basis of fluorescence of intracellular NADP(H) (66). It realized an epifluorescence microscope with a pulsed nitrogen laser as stimulating light source. Because of unknown fluctuations of the camera sensitivity quantitative evaluation of the emitted fluorescence was not enabled. For this reason no information about cell viability was obtained, but only cell concentration can be monitored with this sensor.

In order to realize on-line monitoring of cell viability Wei *et al*. (67,68) developed an ISM probe based on dark field microscopy. With this probe enhanced image contrast and quality were obtained, thus, morphological information of fine intracellular structures could be used in conjunction with advanced machine learning technique. The computer learned from the images of cell populations containing only live or dead cells, and understood the morphological characteristics of live and dead cells, respectively. In this way it was trained and used for evaluation of any given cell images, and gave the determination of the viability. In their work *in situ* measurement of both density and viability of yeast *S. cerevisiae* was realized.

7.5.2 Dielectrophoresis

In electrophoresis, particles or molecules are separated by their net intrinsic charge upon exposure to a uniform direct current (DC) electric field. Separation is achieved by distinct mobility, either caused by nonuniform mass/charge ratios or, if the mass/charge ratios are equal for different specimen, by migration through porous substances that function as particle sieves.

In dielectrophoresis (DEP), particle separation results from the application of nonuniform, alternating current (AC) electric fields. This technique makes use of differences in the polarizability of dissimilar substances and works even if the net charge of a substance is zero. In a DC field, equal and opposite charges ($+q$ and $-q$) are induced at the boundary of the particles, which yields a macroscopic dipole (69).

Equation 7.1 describes the net translational dielectrophoretic force a particle or cell experiences in an electric field E, where α is the effective polarizability of the cell that depends on the cell conductivity and permittivity with respect to the surrounding medium (70). Besides the conductivity of the medium, a furthermore depends on the frequency supplied to a DEP chamber.

$$F_{\mathrm{DEP}} = \alpha \cdot \nabla E^2 \tag{7.1}$$

If α is positive the induced dipole moment is aligned with the applied field and the cell moves toward the strong field region (positive DEP). A negative α results in a dipole moment aligned opposite to the field, and causes a motion toward the weak field region (negative DEP) (69).

The field factor E^2 accounts for the field gradient between the electrodes, the voltage applied, and the distance of the cell from the electrodes.

Since cell death coincides with a break-down of membrane integrity, it permits a free diffusive exchange of intra- and extracellular compounds. The conductivity of dead cells is therefore significantly higher compared to viable cells with an increase by a factor of 10^4 (69). Accordingly, by choosing an appropriate frequency, α may obtain values that allow a separation of viable from nonviable cells by means of positive and negative DEP.

For a gentle separation of live and dead cells, the electrode design is of particular importance. Upon reduction of the electrode distance, a proportionally lower voltage is required to generate an equal dielectrophoretic force. Electrical heating and electrochemical effects are, hence, directly proportional to the electrode scale. Microelectrodes of castellated interdigitated shape are frequently used to spatially segregate viable and nonviable cells (71).

Such electrodes may be loaded with a cell suspension and, provided that an appropriate frequency is applied, allow selective retention of either dead or live cells at the electrode edges. By convective flushing, the nonretained cell type is eluted from the electrode chamber and may be quantified using turbidity measurement, plate counting or staining procedures. This method has been successfully established for different cell types, especially, yeast (71).

Moreover, repeated reversing of the flow direction in phase with activation and inactivation of the applied voltage, renders a possibility for continuous cell sorting (72).

7.5.3 Impedance Measurement

Impedance is a physical characteristic of matters that can be used for studying biological materials. As depicted in the theory of electrical engineering, impedance is complex, consisting of a reactive and a resistive part, which correspond to conductance and capacitance, respectively. Impedance alteration in a medium containing cells can reflect the change of metabolic activity of the cells, hence, measurements of impedance have been used to quantify viable microorganisms (73,74).

7.5.4 Image Analysis

Viability determination based solely on image analysis has recently come into the sight of biotechnologists. Long *et al*. developed a method employing fluorescence microscopy in conjunction with machine learning techniques (75). They used iterative training procedures to choose the most representative samples for determining the correct decision boundary for distinguishing dead cells from live ones.

Wei *et al*., in contrast, developed a machine vision system based on dark field microscopy in conjugation with supervised machine learning and wavelet feature selection (76). This automates the cell viability assessment, and yields comparable results to commonly accepted methods. The eligibility lies in the fact that, according to the research, live cells exhibit morphologically more details and are intracellularly more organized than dead ones, which display more homogeneous and diffuse gray values throughout the cells.

CONTAMINATION DETECTION IN ANIMAL CELL CULTURE

Carol Mclean

Colin Harbour
University of Sydney, NSW, Australia

8.1 INTRODUCTION

This chapter describes the detection of contamination in cell culture by a range of infectious agents, including bacteria, fungi, mycoplasmas, viruses, and prions. The presence of any form of microbial contamination renders the results of scientific studies with that cell culture invalid. In manufacturing processes designed to produce therapeutic biologics from cell culture systems, it is imperative that all possible steps be taken to ensure that the product is free from any infectious agents. This chapter provides a historical perspective to demonstrate how contamination and its detection have affected the development of cell culture as a technology and then describes the current regulatory requirements expected of cell-culture-derived biologics. The regulatory framework is described, in part, to draw attention to the current gulf in cell culture practices with regard to contamination detection required by manufacturers compared to that performed by cell culture workers in institutions devoted to research such as universities. The issues of good manufacturing practice (GMP) and good laboratory practice (GLP), which largely determine the procedures adopted by the former group, are usually ignored by the latter. This is an unacceptable situation and it is our hope that this chapter will indicate what can happen if the detection of contamination is not performed as an essential part of cell culture practice. In addition, the chapter describes appropriate strategies for detecting contamination and thus avoiding the generation of erroneous results in cell culture research and providing the safest possible biologics.

8.2 HISTORICAL PERSPECTIVES

Following the cultivation of nerve cell tissue using the hanging drop technique by Harrison in 1907, the historical development of cell and tissue culture was inhibited by the problem of microbial contamination. Microbes grow rapidly in the enriched media required for cell and tissue growth leading almost inevitably to the destruction of such cultures. Although some practitioners were successful, such as Alexis Carrel who had shown in 1923 that it was possible to culture cells *in vitro* for long periods by employing rigorous aseptic techniques, the problem of microbial contamination was never controlled sufficiently until the introduction of antibiotics in the 1940s. Since then, the introduction of work stations such as laminar air flow cabinets for cell culture manipulations in clean, filtered air, has also contributed enormously to reducing the levels of microbial contamination. Nevertheless, contamination does occur from time to time, and regular screening for the presence of bacteria, fungi, and mycoplasmas should be mandatory practice in all cell culture facilities. This is even more important today when the routine use of antibiotics for cell culture is discouraged because it may make low level contamination difficult to detect, lead to the emergence of

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

resistant micro organisms, and in the production situation, could result in side effects in patients, who receive cell-culture-derived biologics contaminated with trace amounts of antibiotics. The procedures for detecting these microbes are relatively straightforward, and the appropriate protocols are provided in this chapter. By contrast, the detection of viral contamination is more complex, and thus this chapter devotes more attention to this problem.

As stated earlier, the introduction of antibiotics in the 1940s led to rapid advances in cell culture, such as the work of Enders and co-workers who published the first report of growing polio virus in nonneural cells in culture (1). This seminal work, recognized with the award of a Nobel prize, showed that it was feasible to produce viruses and hence viral vaccines in cell culture systems and thus provided the stimulus for the development of cell culture as a technology. Rapid advances were then made resulting in the production of the Salk polio vaccine derived from monkey kidney cells, which was first licensed in 1954, followed by the Sabin polio vaccine (a live vaccine) which was first licensed in 1955 (2,3). Unfortunately, it was recognized then that these early polio vaccines were contaminated with a virus, simian virus 40 (SV40), present in the monkey kidney cells. This finding had a salutary effect on the cell culture "industry" and demonstrated clearly that any material of biological origin can be contaminated with an infectious agent (4,5). Since that discovery, various strategies have been introduced to address the issue of viral contamination, including a wide range of different types of viral assays which are described in this chapter. The problem of viral contamination was also a major driving force in developing more sophisticated cell culture techniques, including the introduction of normal diploid cell lines for producing viral vaccines (6,7). These cells provide the opportunity to establish frozen cell banks and thus the time to perform comprehensive investigations designed to detect microbial contamination. Thus, as a result of these screening procedures, normal diploid cell lines are inherently safer than primary cells in their potential to transmit infectious diseases, but because absolute safety can never be guaranteed, all cell lines must be regularly, monitored. Further advances in cell culture technology and molecular biology have led to the introduction and acceptance of transformed or continuous cell lines for producing a range of biologics for therapeutic use such as interferon (8), monoclonal antibodies, and various recombinant proteins, for example, tissue plasminogen activator (9). Many of these cells are known to express endogenous retroviruses (10–12) which have oncogenic potential, and this issue has been addressed by the introduction of a comprehensive range of screening assays which are described in detail in this chapter.

After summarizing the historical development of cell culture so as to emphasize the move away from the use of primary cells to improve safety regarding transmitting infectious agents, it is somewhat ironic to note that the most recent developments in this field, broadly categorized as cell and/or gene therapy and tissue transplantation involve, in many cases, a return to the use of primary cells with all, of their inherent safety risks (13,14). These primary cells, which may be autologous, allogenic, or xenogenic cells chemically stimulated *in vitro* in some way or even genetically modified, must be administered to a patient as rapidly as possible after treatment because the cells have a limited life span and the patient is more than likely gravely ill. Therefore, it is a necessary to perform all quality control screening procedures as rapidly as possible. For example, by the end of the 14-day period required for a routine sterility test, the patient may have died or become so sick that the treatment would no longer be effective. The sample sizes required for the recommended screening procedures may constitute an unacceptably large proportion of single-patient treatments, and reducing the sample size so as to preserve the treatment dose will obviously lead to a reduced likelihood of detecting infectious agents. These are important issues created by new developments in cell culture technology, and the ways by which they are being addressed are discussed later, as is the prion problem (15). At this time, the latter has become a major challenge for all those involved in manufacturing biologics and is discussed in more detail later in this chapter. The prion, or proteinaceous infectious particle, appears to have crossed the species barrier from cows suffering from bovine spongiform encephalopathies (BSE) and resulted in a new variant of Creutzfeldt–Jakob disease (vCJD) in humans. The prion is the latest discovery of an infectious agent that can infect humans and underlines the continuing need and importance of the screening procedures described in this chapter (16). In the next section the detection of contamination is described in the context of the current regulatory framework which has developed to ensure that cell-culture-derived biologics are as safe as possible.

8.3 REGULATORY ISSUES

Biopharmaceuticals are manufactured from three main sources comprising human tissues or plasma, animal tissues or plasma, and mammalian cell lines. Production of biologics in mammalian cell lines offers the advantage over the other systems that the products can be readily manufactured in large amounts and, compared to biologics prepared from human tissues or plasma, are less likely to be contaminated with human pathogens. Mammalian cell culture systems, however, carry the risk that the cell line or raw materials used in cell cultivation can introduce a viral contaminant of animal origin capable of zoonoses or other microbial contaminants pathogenic

to humans such as *Mycoplasmas*. For example, some cell lines harbor viral sequences integrated into the genomic DNA that are passed vertically from generation to generation such as endogenous retrovirus sequences which are found in cell lines of many species. Integrated viral sequences alternatively originate from virus that was deliberately introduced during establishment of the cell line such as Epstein–Barr virus (EBV) used to immortalize human B cell lines for establishing human hybridomas and human–murine heterohybridoma. Raw materials or ingredients of animal origin used during cell line cultivation or product purification that may introduce adventitious agents include reagents, such as bovine serum used in cultivation of cell lines, and monoclonal antibodies produced in ascites or cell culture used for affinity purification of the product. Manipulation of cell lines, product intermediates, and materials by human operators during manufacturing provides a further source of adventitious agent contamination, for example, via aerosols or by direct contact.

"Notes for guidance" and "points for consideration" have been issued by various national and international agencies, including the CBER (Center for Biologics Evoluation Research) a branch of the Food & Drug Administration of the USA in the United States, the Committee for Proprietary Medicinal Products (CPMP) in the European Commission, and Japanese regulatory authorities, that outline the testing strategy recommendations and requirements for safety evaluation of biological products made in cell line systems (17–21). The strategies recommended vary slightly from one agency to another; therefore integration has been done by the International Committee for Harmonisation (ICH) (18). These guidelines are initially published in draft form and issued to interested parties for comment before being issued as a final version. The final versions of these regulatory documents are not issued simultaneously; therefore when testing cell lines used to produce biologics, the most recent final versions of the relevant regulatory documents, as well as the most recent version of the ICH guidelines, should be consulted.

The regulatory documents mentioned recommend the following strategies as evidence of product safety with respect to viral contamination:

1. Testing cell lines and raw materials for viruses that may be infectious for humans.
2. Testing the product/intermediates at appropriate stages during the production process for viral contaminants.
3. Validation of the production process for its capacity to remove and/or inactivate viral contaminants.

The approach adopted by manufacturers will depend on several factors such as the nature of the particular product, the results obtained during testing (points 1 and 2 above), and will generally be a combination of the three. Some biopharmaceutical products undergo little or no downstream processing and therefore rely on virological testing and characterization of the producer cell line and the final product, for example, replication-incompetent gene therapy vectors (22,23).

When physical and/or chemical purification steps are involved in the manufacture of the final product, validation of the ability of the process to remove or inactivate viral contaminants is performed by process validation studies (also called *virus clearance studies*) (point 3 above) (18,24). These contaminants may be known to exist in the manufacturing process, such as murine endogenous retroviruses in cell lines of murine myeloma lineage used in the manufacture of therapeutic monoclonal antibodies (19,20), or they may be contaminants for which there is a risk in the manufacturing process but for which testing for low levels of such contamination in process samples and raw materials is limited by the sample size.

Process validation studies are done by first establishing a representative downscale version of a specific step in the manufacturer's process that has been identified as known or likely to be effective in removing or inactivating viral contaminants. The downscale version must represent as faithfully as possible the conditions of the manufacturing process with respect to physical and chemical aspects such as flow rate, pH, protein concentration, etc. The downscale process is then spiked with a range of viruses with varying degrees of resistance to physical and chemical methods of inactivation to evaluate the ability of the process to remove and/or inactivate known and/or unknown viral contaminants. The viruses used in process validation studies can be "relevant" or "model" for example, human immunodeficiency virus (HIV) (relevant) and bovine viral diarrhoea virus (BVDV) (a model for Hepatitis C virus), in products manufactured from human plasma. By assaying the viral load in the spiked starting material and processed material, an estimate of the ability of a particular step in the manufacturing process to remove and/or inactivate the virus can be made and consequently provide further assurance of product safety.

When manufacturing a product from a cell line, a seed lot cell bank system must be established, where each bank is comprised of ampoules of cells with uniform composition derived from a cell seed. The master cell bank (MCB) is generally propagated from a selected cell clone under defined conditions, then aliquoted into multiple containers, and stored under appropriate conditions (frozen at or below -100°C). The working cell bank (WCB) is manufactured from one vial of the MCB. Then cells from the WCB (or occasionally the MCB) are propagated to the production cells. A cell bank at the limit of *in vitro* cell age used for production (usually called a *postproduction cell bank (PPCB)* or *extended cell bank (ECB)* is also laid down from

a WCB vial expanded under pilot plant or commercial scale conditions. The number of vials in any MCB and WCB will vary from process to process but is often in the order of 100 per bank, thus enabling long-term supply of material for any one process. The current strategy recommended by the ICH for safety testing cell lines of human or animal origin used to produce biologics (with the exception of inactivated and live vaccines, and genetically engineered live vectors) is outlined in Table 8.1 (18,20). Extensive qualification of the MCB (or WCB) for adventitious agents and identity testing is required, and because the WCB has a low population doubling level beyond the MCB, testing of the WCB is minimal. Testing of the PPCB should be performed at least once to provide assurance that the conditions used during production are unlikely to introduce adventitious agents or activate viral contaminants that may be suppressed at the MCB stage. Therefore testing of the PPCB is repeated if there are changes in the scale or cultivation conditions during production. In-process testing of bulk harvests in the form of cells and fluid harvested from fermenters is also required because, like PPCB testing, this, provides assurance that the conditions used during production do not introduce and/or activate contaminants (18,20).

The use of raw materials from animal origin for the propagation of MCB, WCB, and in production should be avoided if possible. In doing so, characterization of the MCB (or WCB) will provide assurance of the cell bank safety. However, because of the growth characteristics and requirements of cell lines, the use of raw materials such as serum, insulin, transferrin, and trypsin, cannot always be avoided. In such circumstances, raw material must be sourced from suppliers that can provide traceability of their origins, and batches must be sampled and tested for freedom from adventitious agents before their use in manufacturing.

8.4 MANUFACTURING AND SAFETY TESTING STANDARDS

The manufacture of pharmaceutical products must be done in environments that assure the safety, uniformity, efficacy, and quality of the products. A system of principles that lay down the procedures required for production and quality control, including documentation, personnel, environment, equipment, materials, auditing, sampling, and safety, are stipulated by cGMP (25). Testing of biopharmaceuticals for adventitious agents should be performed by laboratories with experience in virological assays and Good Laboratory Practice (GLP) accreditation. International GLP principles have been laid down by the OECD (Organisation for Economic Cooperation Development) (26). These guidelines exist so that safety studies are planned, performed, monitored, recorded, reported, and archived in an organized and controlled manner following approved procedures in a facility with adequate resources so that the quality and validity of the testing are assured.

8.5 EXAMPLES OF VIRAL CONTAMINANTS

Many animal cell lines currently used in producing biologics contain endogenous viruses. For example, cell lines of murine origin can harbor endogenous Type B or Type C retroviruses (oncoviruses), and cell lines of hamster origin express defective Type C and Type R retrovirus particles (27). Table 8.2 lists examples of endogenous retroviruses associated with cell lines commonly used for producing biologics. Exogenous viral infections may be present in cell lines that were acquired by the animal from which the cell line was established, for example, SV40 infection

TABLE 8.1. Testing Strategy for Cell Lines used to Produce Biologics[a]

Test	MCB	WCB	PPCB
Infectious (endogenous viruses)	+	−	+
Electron microscopy	+	−	+
Reverse transcriptase[b]	+	−	+
In vitro assay[c]	+	−	+
In vivo assay[c]	+	−	+
Antibody production assays[d]	+	−	−
Other virus specific tests[e]	As appropriate	−	As appropriate
Mycoplasma	+	+	+
Sterility	+	+	+

[a] Refs. 18 and 20.

[b] Reverse transcriptase assay is not necessary if the cell line is positive for infectious retrovirus.

[c] These assays should be performed on the cells at the limit of *in vitro* cell age generated from the first WCB; for subsequent WCBs a single test can be done either on the WCB or on the cells at the limit of *in vitro* cell age.

[d] These include mouse antibody production assays (MAP), hamster antibody production assays (HAP), and rat antibody production assays (RAP) and are usually applicable only to cell lines of rodent origin.

[e] This includes assays performed on, for example, human cell lines such as PCR assays for the human viruses HBV, HCV, HIV-1, HIV-2, HHV-6, HTLV I and II, EBV, and CMV.

TABLE 8.2. Endogenous Retroviruses Found in Cell Lines Commonly used to Produce Biologics

Cell Line	Retrovirus Particle Type	Infectious
Mouse myeloma/ hybridoma	A, C	Ecotropic and xenotropic
Chinese hamster ovary	C	Noninfectious
Baby hamster kidney	R	Noninfectious
Human/ murine heterohybridoma	A, C	Xenotropic
Human	None	No
Monkey	None	No
Insect	None	No

of Vero cells (4). Alternatively, cell lines may become accidentally infected with an exogenous virus during their establishment and/or development in research laboratories from, for example, another cell line or a laboratory operator. Expression of exogenous or endogenous retroviral infection can in some instances be low or undetectable in normal culturing conditions and can be chemically induced by agents such as 5-bromodeoxyuridine, 5-iododeoxyuridine, sodium butyrate, or 5-azacytidine (28–32).

Current use of replication-deficient virus-based vectors for gene therapy introduces the additional risk of viral contamination by replication-competent viruses which may be generated by recombination between sequences in the viral vector and the packaging cell line. The viruses from which gene therapy viral vectors are constructed are infectious for human cells. Therefore generation of a replication-competent virus may result in disease.

At some point in their histories most if not all cell culture systems have been exposed to raw materials of animal origin such as bovine serum or porcine trypsin, which constitute further potential sources of viral or mycoplasmal contamination. The most common contaminants of bovine serum are BVDV—also called *mucosal disease virus (MDV)*—and bovine polyomavirus (BPyV) (33–36). BVDV is distributed worldwide affecting ~60% of cattle in the United Kingdom and Australia, and is infectious to several even-toed ungulates in addition to cattle, including pigs, sheep, and goats (37). It is therefore probable that a large proportion of bovine products used in cell culture systems is contaminated with either infectious or defective BVDV. The BVDV or BPyV status of bovine raw materials is often not provided, and commonly used filtration techniques used in the manufacture of bovine serum do not efficiently remove these viruses. Some suppliers, however, perform viral inactivation steps such as UV-C or gamma irradiation of serum to provide assurance of product safety (38,39).

Contamination of cell cultures with bovine viruses is of major concern when manufacturing products for use in ruminants because BVDV infection can result in abortion or growth retardation in offspring that are persistently infected (37). Several instances of BVDV contamination have been reported (40–45) which, in cases where the product is a ruminant vaccine, have resulted in livestock growth retardation and death (41,42). Pestivirus RNA has been detected in biopharmaceutical products for human use, although no confirmed symptomatic infections in humans have occurred (45). Bovine serum has also been implicated as the source of epizootic hemorrhagic disease virus (EHDV) in a Chinese hamster ovary (CHO) cell line (46), and the parvovirus, minute virus of mice (MVM), in a baby hamster kidney (BHK) cell line (47). Two similar MVM contamination incidents have been reported in hamster cultures (48,49), one of which was detected in fermenter cultures of CHO cells and the second during production of foot-and-mouth disease vaccine. The source of the contamination in these instances was not identified but in the former case was believed to be from mouse excretions contaminating media or their components during storage.

The main virus of concern in raw materials of porcine origin is porcine parvovirus (PPV) which has widespread distribution, that is, 40% infection has been reported (50), and it has been isolated from commercial trypsin (51). Testing of porcine trypsin for PPV is required by a number of regulatory bodies including the US. Department of Agriculture (9CFR) (52) and the European Pharmacopoeia (53). Examples of exogenous viral contaminants of biopharmaceutical systems are listed in Table 8.3 (54).

8.6 DETECTION OF VIRAL CONTAMINANTS IN CELL LINES

Viral contamination of cell lines can be detected by direct analysis, such as fixation of the cells and examination by electron microscopy, or by polymerase chain reaction (PCR) of nucleic acid extracted from the cell line. Alternatively, viral contaminants can be detected indirectly by examining the effect that the cell line has on a test system, for example, inoculation of a cell extract into a detector cell line or into an animal susceptible to the virus of concern. The effect of a viral contaminant on a cell line or animal test system may be general, producing a cytopathic effect (cpe) in the form of cell or animal death

TABLE 8.3. Examples of Exogenous Viral Contamination in Intermediate and Final Products Manufactured in Cell Culture Systems

Product/Intermediate	Contaminant	Contamination Source	Reference
Polio vaccine	SV40	Infected cell line	4
Vet vaccine	BVDV	Unknown	40
Swine fever vaccine	BVDV or Border Disease virus	Bovine serum or lamb cell culture?	41
Rota-corona vaccine	BVDV	Unknown	42
Final product (IFNα, IFNβ)	BVDV	Bovine serum?	43
Live vet vaccines	BVDV	Bovine serum?	44
Human vaccines (MMR, MR)	BVDV	Bovine serum?	45
CHO cell line	EHDV	Bovine serum?	46
Unprocessed bulk (CHO cell line)	MVM	Medium component?	48
Foot-and-mouth disease vaccine	MVM?	Unknown	49
Vet vaccine	CPV	Unknown	54

or cell morphological change, or may be specific such as in the production of antibodies to a specific virus in mice following inoculation of virally contaminated material. The testing strategies required by the ICH for cell lines used to produce biologics are outlined in Table 8.1. These primarily consist of *in vitro* and *in vivo* testing of the MCB and PPCB for infectious virus and testing using molecular biology techniques and electron microscopy for viruses that may be infectious or defective.

8.6.1 Detection of Retroviruses

Retroviruses are single-stranded RNA viruses, surrounded by a lipid envelope. When examined under thin-section electron microscopy, they are 100–140 nm in diameter and frequently exhibit glycoprotein surface projections. Cell lines of several species, including human, porcine, and murine, contain endogenous retroviral sequences. Murine cell lines of epithelial and myeloma lineages all contain endogenous retrovirus sequences and in many cases express infectious murine leukemia virus (MLV). MLV isolates can show varying tropisms, including ecotropic MLV (E-MLV) which is infectious for cell lines of murine origin or closely related species, and xenotropic MLV (X-MLV) which is infectious for cell lines of species other than of murine origin (37). Xenotropic endogenous retroviruses capable of infecting human cells have been described for murine and porcine cell lines (10,13,55). However the efficiency of murine retroviral infection apparently differs in the few reported incidents. In one study, supernatant was harvested form 17 mouse hybridoma cell lines and inoculated onto the human embryonic lung fibroblast cell line, 7605L. Eight of the 17 supernatants contained type-C retrovirus infectious for the human cells (10). In another study, 18 mouse cell lines of myeloma lineage were assayed for retrovirus by cocultivation with a human cell line, but none were positive (56).

Retroviral vectors used for gene therapy often contain envelope sequences originating from amphotropic MLV (A-MLV), feline leukemia virus (FeLV), or gibbon ape leukaemia virus (GaLV), which have been chosen because they are infectious for human cells (57). Therefore the generation of replication-competent retrovirus (RCR) with human tropism is of concern in such systems. Cell lines of human and simian origin have been used to produce biologics, for example, human–murine heterohybridoma cell lines used to produce monoclonal antibodies. These have the potential to be infected with exogenous human and simian retroviruses such as HTLV, simian retrovirus types 1 and 2, HIV, and simian and human foamy viruses (58–60). Following are details of a number of standard methods for detecting retroviruses which may be encountered in cell lines commonly used in producing biologics. Most of the cell lines and positive control viruses used in these methods are available from the ATCC.

8.6.1.1 Cell Culture Techniques for Retroviral Detection

8.6.1.1.1 Assays for Infectious MLV. Tests for infectious MLV should be performed on cell lines of murine origin on the MCB (or WCB) and again on the PPCB to determine whether there has been any change in the dynamics or tropism of MLV expression. It is also advisable to test samples from at least one fermenter run to monitor the dynamics of infectious retrovirus production during the manufacturing process. Similarly, testing regimes for RCR in retroviral gene therapy systems should include testing the producer cell line (1% or 10^8 of the cells, whichever is least, and 5% of the vector supernatant) (22,23). The following methods outline the procedures for detecting MLV using cell-free supernatant harvested from the cell line under test or fermenter sample. The methods described are so-called direct assay which are quantitative and therefore provide the titer

of virus per unit volume of sample tested. The sensitivity of the direct assay may be increased by serial passage of the inoculated detector cell line and consequently amplification of the retrovirus (61). So-called extended assays are qualitative and can increase assay sensitivity by approximately one log (62). When sampling for retroviral infectivity assays, it is important to harvest supernatant from test cell lines that are actively growing because this is the period during which the retrovirus is normally most highly expressed (63).

8.6.1.1.2 Assays for Ecotropic MLV

8.6.1.1.2.1 XC Assays (64). The XC assays utilize the cell line SC-1 which can be infected with E-MLV without inducing cpe. The virus can subsequently infect cells of the Wilistar rat tumour (XC cell line) in which a prominent syncytial effect is evident. E-MLV cannot infect XC cells directly. The assay should be set up as follows utilizing negative control cultures and positive control cultures infected with a suitable E-MLV for example, Moloney.

1. Plate the SC-1 cells at a density of 10^5 cells per 10 cm^2 plate in Dulbecco's Modified Eagle's Medium (DMEM) containing 10% fetal bovine serum (FBS)(v/v), and incubate at 37°C with 5% CO_2.
2. Examine the cells the following day, and if suitably subconfluent (~20–30%), inoculate with cell-free test material in the presence of polybrene at an effective concentration of 10 μg/mL.
3. Feed the cultures with 4–5 mL of DMEM containing 10% FBS (v/v) following an adsorption period of ~1–2 h at 37°C with 5% CO_2.
4. Maintain the cultures at 37°C with 5% CO_2 until confluent (normally 4–5 days). Then remove the culture medium, and irradiate the cells under UV light for ~1 min to kill the SC-1 cells.
5. Overlay the monolayers with XC cells at a high cell density (~10^6) per plate in DMEM containing 10% FBS, and reincubate the monolayer cultures at 37°C with 5% CO_2.
6. Stain the monolayers, when confluent, with crystal violet. Wash the excess stain from the cells with water, and allow them to dry. Examine the monolayers for infectious centers, identified as holes (plaques) in the XC monolayer. Evidence that the plaques are due to infection by E-MLV is provided by association of the plaque with one or more syncytial cell.

8.6.1.1.2.2 FG10 Assay. The FG10 cell line (also called *D56*) is a 3T3 cell line transformed with murine sarcoma virus (MSV) but does not produce infectious MSV (65). As such the cell line is termed sarcoma positive, leukemia negative (S^+L^-) and can be infected with leukemia virus with the result that the MSV genome is rescued and cell transformation occurs which is manifested as a "focus" at the site of infection. Foci appear as regions of rounded cells in association with a lytic area on the cell monolayer. The murine origin of this cell line permits an assay system for E-MLV. The assay should be set up as follows utilizing negative control cultures and positive control cultures infected with a suitable E-MLV, for example, Moloney.

1. Plate the FG10 cells at a density of 10^5 cells per 10 cm^2 plate in RPMI 1640 medium containing 10% FBS, and incubate overnight at 37°C with 5% CO_2.
2. Examine the cells the following day, and if suitably subconfluent (~20–30%), inoculate with cell-free test material in the presence of polybrene at an effective concentration of 10 μg/mL.
3. Feed the cells with 4–5 mL of RPMI 1640 medium containing 10% FBS (v/v) following an adsorption period of ~1–2 h at 37°C with 5% CO_2.
4. Maintain the cultures at 37°C with 5% CO_2 until confluent (normally 4–5 days). Then examine for foci formation which appear as described before. It is important to maintain the cultures until fully confluent because foci are not easily recognizable in a subconfluent monolayer in which there are many mitotic (rounded) cells and gaps in the monolayer which are similar in morphology to foci.

8.6.1.1.2.3 Mink S^+L^- Assay. The mink lung ($MiCl_1$) cell line is S^+L^- and as such can be infected with leukemia virus resulting in rescue of the MSV genome and cell transformation manifested as a "focus" at the site of infection (66). Confluent monolayers of the $MiCl_1$ cell have a flat morphology, and foci can easily be identified as regions of rounded cells raised above the contact inhibition layer of the monolayer. Focus formation on this cell line from material of origin other than mink indicates the presence of a xenotropic leukemia retrovirus, and thus is an assay system for X-MLV, Fe-LV, and Ga-LV. The assay should be set up as follows utilizing negative control cultures and positive control cultures infected with a suitable xenotropic leukemia virus, for example, X-MLV.

1. Plate the $MiCl_1$ cells at a density of 2.5×10^5 cells per 10 cm^2 plate in RPMI 1640 medium containing 10% FBS (v/v) and incubate overnight at 37°C with 5% CO_2.
2. Examine the cells the following day, and if suitably subconfluent (~20–30%), inoculate with cell-free

test material in the presence of polybrene at an effective concentration of 10 μg/mL.

3. Feed the cultures with 4–5 mL of RPMI 1640 medium containing 10% FBS (v/v) following an adsorption period of ~1–2 h at 37°C with 5% CO_2.
4. Maintain the cultures at 37°C with 5% CO_2 until confluent (normally 8–10 days). Then examine for foci formation which appear as described before. Again, it is important to maintain the cultures until fully confluent because foci are not easily recognizable in a subconfluent monolayer.

8.6.1.1.2.4 PG4 S^+L^- Assay. The PG4 cell line is a feline S^+L^- cell (67) which when infected with leukemia virus, like other S^+L^- cell lines, results in cell transformation manifested as a "focus" at the site of infection. This cell line is susceptible to infection by xenotropic and amphotropic MLV and Ga-LV. Therefore it is useful for detecting RCR in producer cell lines used in gene therapy vector production or in vector supernatant. Foci can be identified on PG4 monolayers as regions of rounded transformed cells adjacent to a lytic region in the cell monolayer. The assay should be set up as follows utilizing negative control cultures and positive control cultures infected with a suitable leukemia virus, for example, A-MLV.

1. Plate the PG4 cells at a density of 2×10^5 cells per 10 cm^2 plate in McCoy's medium containing 10% FBS (v/v), and incubate overnight at 37°C with 5% CO_2.
2. Examine the cells the following day, and if suitably subconfluent (~20–30%), inoculate with cell-free test material in the presence of polybrene at an effective concentration of 10 μg/mL.
3. Feed the cultures with 4–5 mL of McCoy's medium containing 10% FBS following an adsorption period of ~1–2 h at 37°C with 5% CO_2.
4. Maintain the cultures at 37°C with 5% CO_2 until confluent (normally 5–7 days). Then examine for foci formation which appear as described before. It is important to examine the cultures daily because the PG4 monolayer can deteriorate with the formation of holes in the monolayer which makes foci identification difficult.

8.6.1.1.2.5 Mus dunni Assay. The *Mus dunni* tail fibroblast cell line (68) is sensitive to A-MLV, X-MLV, and E-MLV (with the exception of the Moloney strain), and also mink cellfocus-forming viruses. However, acute infection does not result in an obvious cpe (69). This cell line is recommended by regulatory authorities for detecting infectious MLV in production systems using cell lines of murine origin (17,19) and in gene therapy vector systems based on MLV (22,23). Because of the absence of cpe in infected *Mus dunni* cultures, quantitative infection assays ("direct" assay) utilize an immunofluorescence end point. Qualitative assessment of the MLV status of a cell line can be done by inoculating the test material onto *Mus dunni* cells followed by amplification of any infectious MLV present by serial passage of the cells and assay of the *Mus dunni* supernatant for infectious MLV by an appropriate assay such as direct PG4 or direct mink S^+L^- assay described before. The direct and extended *Mus dunni* assays are performed as follows, using negative control cultures and positive control cultures infected with an appropriate virus such as A-MLV.

Direct Assay

1. Seed multichamber slides (slides are commercially available with each well ~4 cm^2) with *Mus dunni* cells at a concentration of 2×10^4 cells/well in DMEM containing 10% FBS (v/v), and incubate the slides overnight at 37°C with 5% CO_2.
2. Examine the cells the following day, and if suitably subconfluent (~50%), inoculate with cell-free test material in the presence of polybrene at an effective concentration of 10 μg/mL.
3. Feed each well with an appropriate volume of DMEM containing 10% FBS (v/v) following an adsorption period of ~1–2 h at 37°C with 5% CO_2.
4. Maintain the cultures at 37°C with 5% CO_2 until confluent (normally 2–4 days). Then fix in cold acetone for 10–15 min.
5. Perform indirect immunofluorescence by placing a suitable volume of anti-MLV antibody into each well (several monoclonal antibodies to MLV are available, e.g. 34, R187, or 548) (70). Place the slide in a humidified chamber at 37°C for a suitable period of time, for examples, 30 min.
6. Wash the slides with phosphate-buffered saline (PBS) to remove the primary antibody. Air dry the slides. Then add antispecies FITC antibody at a suitable dilution to the slides, and allow the antibody to adsorb as before
7. Wash the slides in PBS to remove the secondary antibody, and air dry as before.
8. Examine the slides for fluorescent foci under a suitable fluorescent microscope, and count the foci to give the titer of MLV per unit volume in the test sample.

Extended Assay

1. Seed the *Mus dunni* cells at a density of ~5×10^5 per 25 cm^2 tissue culture flasks in DMEM containing 10% FBS (v/v), and incubate the cultures overnight at 37°C with 5% CO_2.

2. Examine the cells the next day for confluency, and if subconfluent (~50%), inoculate the cells with the test sample in polybrene at an effective concentration of 10 μg/mL. Allow the sample to adsorb for 1–2 h. Then feed the cells with DMEM containing 10% FBS (v/v) and reincubate at 37°C with 5% CO_2.
3. Maintain the cells at 37°C with 5% CO_2, and passage the cultures several times on reaching confluency (normally three to five times is sufficient).
4. MLV can be assayed in the *Mus dunni* cells at this point by several means such as immunofluorescence in which the cells are subcultured into slides and tested as described before for the direct assay. Alternatively, cell-free supernatant can be harvested from the cultures and tested for MLV by the direct infectivity assays described before, or by reverse transcriptase assay.

Little has been published regarding the relative sensitivities of the previously mentioned cell lines for leukemia viruses. However, one study that examined the titers of X-MLV detected in fermenter harvests from a murine plasmacytoma cell indicated that for this particular X-MLV, the *Mus dunni* cell line was the most sensitive, followed by mink S^+L^--cells and PG4 cells were least sensitive (56).

If a cell line used to produce a biologic for human use is positive for a xenotropic retrovirus, it is necessary to determine whether the virus is infectious in human cell lines (19). An alternative approach to assaying cell-free supernatant for infectious retrovirus is by cocultivation of the cell line under test with a detector cell line for a given period of time (e.g. two or three passages) followed by removal of the test cell line and further passage of the detector cell line to amplify any infectious retrovirus present and to dilute any noninfectious retrovirus carried over from the test cell line culture medium. Then the detector cell line can be assayed for the presence of retrovirus by reverse transcriptase assay of the culture supernatant, electron microscopy, or one of the infectivity assays described before. If the cell line under test is nonadherent and the detector cell line is adherent, the test cell lines can be decanted. When both detector and test cell line are adherent, they can be cocultivated in a dish that separates the two cell lines by a transwell membrane which has pores large enough to allow passage of virus but not cells (commercially available transwell dishes normally have membranes with a pore size of 0.4 μm). Human cell lines that have been reported to be susceptible to xenotropic retroviruses include the embryonic lung fibroblast 7605L, the rhabdosarcoma cell line RD, the embryo fibroblast cell line MRC-5, the embryo kidney cell line 293, and the osteosarcoma cell line HOS (10,13,57,62,71).

8.6.1.2 Detection of Retrovirus by Reverse Transcriptase Assay. The presence of the reverse transcriptase enzyme within retroviral particles facilitated the assay for virus (infectious or noninfectious) in supernatant harvested from growing cultures. The reverse transcriptase enzyme synthesizes DNA using an RNA template and therefore can be assayed by including radiolabeled nucleotides in the reaction mixture. The optimum stage for reverse transcriptase detection in cell culture supernatant will depend on the cell line in question. However, in cell lines that produce retrovirus at levels detectable by reverse transcriptase, enzyme activity is normally readily detectable in supernatants harvested from cells that are exponentially growing or have recently stopped growing. The method described here comprises six separate reactions that assay polymerase activity under conditions with an RNA template (poly (rA)), a DNA template (oligo (dT)) or no template, and in the presence of either the magnesium or manganese cation (62). These six conditions control the following: (i) RNA dependent DNA polymerase activity that may arise from contaminating cellular DNA polymerase (higher levels of radiolabeled nucleotide incorporation when the template is DNA indicate that incorporation in the RNA template is likely to be from contaminating DNA polymerase); (ii) failure to separate unincorporated from incorporated radionucleotides (no template control); and (c) distinction between reverse transcriptase enzymes that have a preference for either the magnesium or manganese cation (63,72).

1. Clarify cell-free supernatant (10–20 mL) to remove cell debris by centrifugation at 11,000*g* for 10 min.
2. Pellet the retrovirus in the sample by centrifuging the resultant supernatant at 100,000*g* for 1 h. Then discard the supernatant, and allow the tubes to drain.
3. Disrupt the retroviral particles in buffer (~200 μL) comprising 40 m*M* Tris pH 8.1, 50 m*M* KCl, 20 m*M* DTT, 0.2% NP40.
4. Divide the sample into six 25 μL aliquots, and add an equal volume of one of each of the following six reaction mixtures:
   - 40 m*M* Tris pH 8.1, 50 m*M* KCl, 25 μCi [methyl ^{3}H] TTP, 2 m*M* MnCl, poly r(A) [0.05 A_{260} units].
   - 40 m*M* Tris pH 8.1, 50 m*M* KCl, 25 μCi [methyl ^{3}H] TTP, 2 m*M* $MnCl_2$, oligo (dT) [0.05 A_{260} units].
   - 40 m*M* Tris pH 8.1, 50 m*M* KCl, 25 μCi [methyl ^{3}H] TTP, 2 m*M* $MnCl_2$, 2 m*M* Tris pH 8.1, 30 m*M* NaCl.
   - 40 m*M* Tris pH 8.1, 50 m*M* KCl, 25 μCi [methyl ^{3}H] TTP, 20 m*M* $MgCl_2$, poly r(A) [0.1 A_{260} units].
   - 40 m*M* Tris pH 8.1, 50 m*M* KCl, 25 μCi [methyl ^{3}H] TTP, 20 m*M* $MgCl_2$, oligo (dT)) [0.1 A_{260} units].

– 40 m*M* Tris pH 8.1, 50 m*M* KCl, 25 μCi [methyl ^{3}H] TTP, 20 m*M* $MgCl_2$, 4 m*M* Tris pH 8.1, 60 m*M* NaCl.

5. Incubate the reaction mixtures at 37°C for 1 h to allow RNA-dependent and DNA-dependent DNA polymerase enzyme reactions to occur.
6. Precipitate the DNA or RNA templates onto GF/C filters using 10% trichloroacetic acid (TCA), 1% sodium pyrophosphate.
7. The precipitated nucleic acids with incorporated radiolabeled nucleotides are then measured in scintillation fluid in a scintillation counter.

The background levels of radioactivity obtained by this method are generally of the order of 100–2000 disintegrations per minute (dpm). Levels higher than this in those reactions with a template indicate polymerase activity. However, one can assume RNA-dependent DNA polymerase activity from reverse transcriptase only when the level of incorporation into the DNA template is relatively low, for example, at least half the dpm incorporation into the RNA template. The level of dpm in the reaction mixtures without template should be lower still, for example, half the dpm of the DNA template reaction. Suitable controls for use with this reaction include MLV for reactions that include the manganese cation and maedi-visna virus for reactions that include the manganese cation.

8.6.1.3 Electron Microscopy. Electron microscopy is a direct method of detecting viral contaminants and as such can provide evidence of viral contamination in the absence of any cytopathological effect. It is therefore a useful method for detecting endogenous and exogenous retroviral particles. Cell lines themselves can be examined directly for viral contaminants by thin-section transmission electron microscopy (TEM). Alternatively, the amount of retrovirus in culture fluids sampled from fermenters can be enumerated to determine the retroviral load. Although electron microscopy provides a useful means of detecting and classifying viral contaminants, it is not suitable as a diagnostic method for low levels of contamination because the technique allows examination only of a thin section of a the cell preparation or a small volume of culture supernatant. Quantitation of retroviral particles is required by regulatory authorities for cell lines used to produce monoclonal antibodies (19). The quantity of retrovirus present should be shown to be consistent between lots, and it should be demonstrated in process validation studies that the values obtained are removed or inactivated during product purification.

The retroviral burden in culture or fermenter supernatants can be estimated by negatively staining a virus preparation followed by TEM. However this method can be problematic because retroviruses are fragile and the method may cause structural artifacts that make identification difficult. Following is an outline of a suitable method for quantitating retroviral particles in cell culture or fermenter fluid samples. However, because electron microscopy is a highly specialized technique, the reader is advised to consult more specialized literature before embarking on such methods (71–78).

1. Clarify the culture supernatant by centrifugation at 11,000*g* for 10 min.
2. Pellet the retrovirus from the resultant supernatant by ultracentrifugation at 100,000*g* for 90 min (the conditions required for other virus types will differ).
3. Dilute commercially available latex particles to a concentration of $\sim 10^8$/mL, and mix the concentrated virus preparation with an equal volume of latex particles.
4. Apply the virus/latex particle mix to an EM carbon-coated grid.
5. Wash the EM grid gently with distilled water.
6. Apply a drop of negative stain to the grid (negative stains commonly used include 1–3% phosphotungstic acid (pH 5–8) and 1–2% uranyl acetate (pH 4.4).
7. Following a suitable staining time, remove excess stain from the grid using filter paper.
8. Allow the grid to air dry. Then examine by TEM.
9. The virus concentration in the initial culture supernatant can be determined by the following equation:

$$\text{Concentration of virus} = \frac{\text{Concentration of latex particles} \times 2 \times \text{virus count}}{\text{Latex particle count} \times \text{centrifugation concentration factor}}$$

Culture supernatant preparations from fermenter harvests may have large quantities of cellular debris. This is particularly so for batch fermentation samples. Further purification of the culture supernatant, for example, by sucrose density gradient centrifugation (78) may be necessary to reduce background material that may obscure virus identification.

Direct examination of cell lines by TEM using fixation of a cell pellet and thin-section preparation can be performed as outlined below (75). For detection of retrovirus, the culture should be actively growing.

1. Pellet the cells from a medium-sized culture flask ($\sim 5 \times 10^6$ cells should be harvested) by gentle centrifugation (500*g* for 5 min).
2. Carefully break up the cell pellet into small pieces of about 1 mm^3.

3. Fix the cells in 2.5% glutaraldehyde in phosphate buffer (pH 7.2) for 60 min.
4. Wash the cells three times in PBS (10 min per wash). Then postfix in 1% osmium tetroxide in PBS for 1 h.
5. Wash the cells three times in dH_2O, 10 min per wash. Then dehydrate the cells in a graded ethanol series of 50%, 75%, 95%, and 100% twice (15 min per step).
6. Embed the cells by first placing them in propylene oxide for 10 min: then in a 1 : 1 mix of resin to propylene oxide for 1 h, followed by three 1-h treatments in neat resin.
7. Place the samples in fresh resin, and polymerize the blocks by heating to 60°C for 24 h.
8. One-micrometer sections are then cut from the block using an ultramicrotome; then placed on EM grids and stained in 1% uranyl acetate, then lead citrate, and examined under TEM.

The retrovirus family comprises the oncoviruses, lentiviruses, and spumaviruses. The oncoviruses can be further divided into four groups comprising Type A, Type B, Type C, and Type D. Classification of retroviruses is based on their morphological features and morphogenesis as determined by electron microscopy.

Figure 8.1 illustrates some of the features (micrographs provided by Q-One Biotech Ltd., Glasgow, UK).

8.6.2 *In Vitro* Assays

So-called *in vitro* tests (Table 8.1) are recommended by regulatory authorities for identifying nonendogenous or adventitious viruses in cell banks which may be noncytopathic contaminants of the cell line or were introduced via a raw material or a breach in GMP procedures. The cell lines recommended for such *in vitro* assays by CBER are a human diploid cell line, a monkey kidney cell line, and a cell line of the same species and tissue type as used in production (17). Therefore, cell lines generally employed are the human embryo fibroblast cell line, MRC-5, and the monkey kidney cell line, Vero. The cell line of the same species and tissue type as used in production is as appropriate. CPMP regulations for cell lines producing monoclonal antibodies suggest, in addition, the use of cells capable of detecting a range of human, murine, and bovine contaminants (if relevant) (20). The rationale for the choice of cell lines is to provide a general screening assay that detects a broad range of viral contaminants that may be present in the cell line or in fermenters and may be pathogenic to humans. The assay is performed by examining inoculated detector cell lines for cpe and hemadsorbing agents and therefore has the limitation that it will detect only cytopathic and hemadsorbing viral contaminants that can replicate in the chosen detector cell lines. The specific format of the assay is unspecified by the regulatory guidelines. However, it is stipulated that the assay be examined for cytopathic and hemadsorbing viruses (17,20) and be maintained for a minimum of 14 days with passage of the human diploid cell line for a further 14 days with hemadsorption performed at the end of the cultivation period if the test system can support growth of human cytomegalovirus (17). The nature of the inoculum is specified by ICH as "a lysate of cells and their culture medium" (18). A possible format for such *in vitro* assays would therefore be the following (negative control and suitable positive controls for cpe on each detector cell line used should be tested in parallel):

1. Prepare six-well tissue culture dishes each of MRC-5, Vero, the cell line of the same species and tissue type as used in production (and other cell lines as appropriate) by inoculating 3 mL of cells at $1–2 \times 10^5$ cells/mL in an appropriate growth medium containing 10% FBS (v/v). Incubate the cultures overnight at 37°C with 5% CO_2.
2. Prepare the test sample lysate by harvesting cells and supernatant from a healthy confluent culture grown in a medium-sized flask ($\sim$80 cm^2) (adherent cells can be harvested by first scraping the cells into the spent culture medium with a sterile cell scraper). Clarify the preparation by centrifugation at 500*g* for 5 min. Transfer 70–80% of the supernatant to a fresh container, and place on ice (supernatant 1). Then resuspend the cell pellet in the remaining supernatant, and lyse the cells by freeze/thawing three times. Clarify the resultant lysate by centrifugation as before, and pool this the supernatant (supernatant 2) with supernatant 1 to constitute the sample for inoculation. Preparation of lysate by this method ensures that viruses sensitive to repeated freeze/thawing are represented by inclusion of "supernatant 1," viruses that may be trapped intracellularly are released and present in "supernatant 2," and the presence of intact cells that escaped disruption by freeze/thawing and could potentially interfere with observations for cpe is minimized by clarification of both supernatants 1 and 2. Cell lysates can also be prepared as before for samples taken from fermenters.
3. Inoculate a suitable volume, for example, 1 mL of lysate, into each well of each cell type, and allow the sample to adsorb for 1 h at 37°C with 5% CO_2.
4. Feed the cultures with 3–4 mL of maintenance medium (containing 1% v/v FBS) and incubate at 37°C with 5% CO_2.
5. Examine the cultures every 2–3 days for signs of abnormalities such as cells rounding, syncytia, or cell lysis.
6. Feed the cells as required (after seven days is normally adequate) with an appropriate maintenance

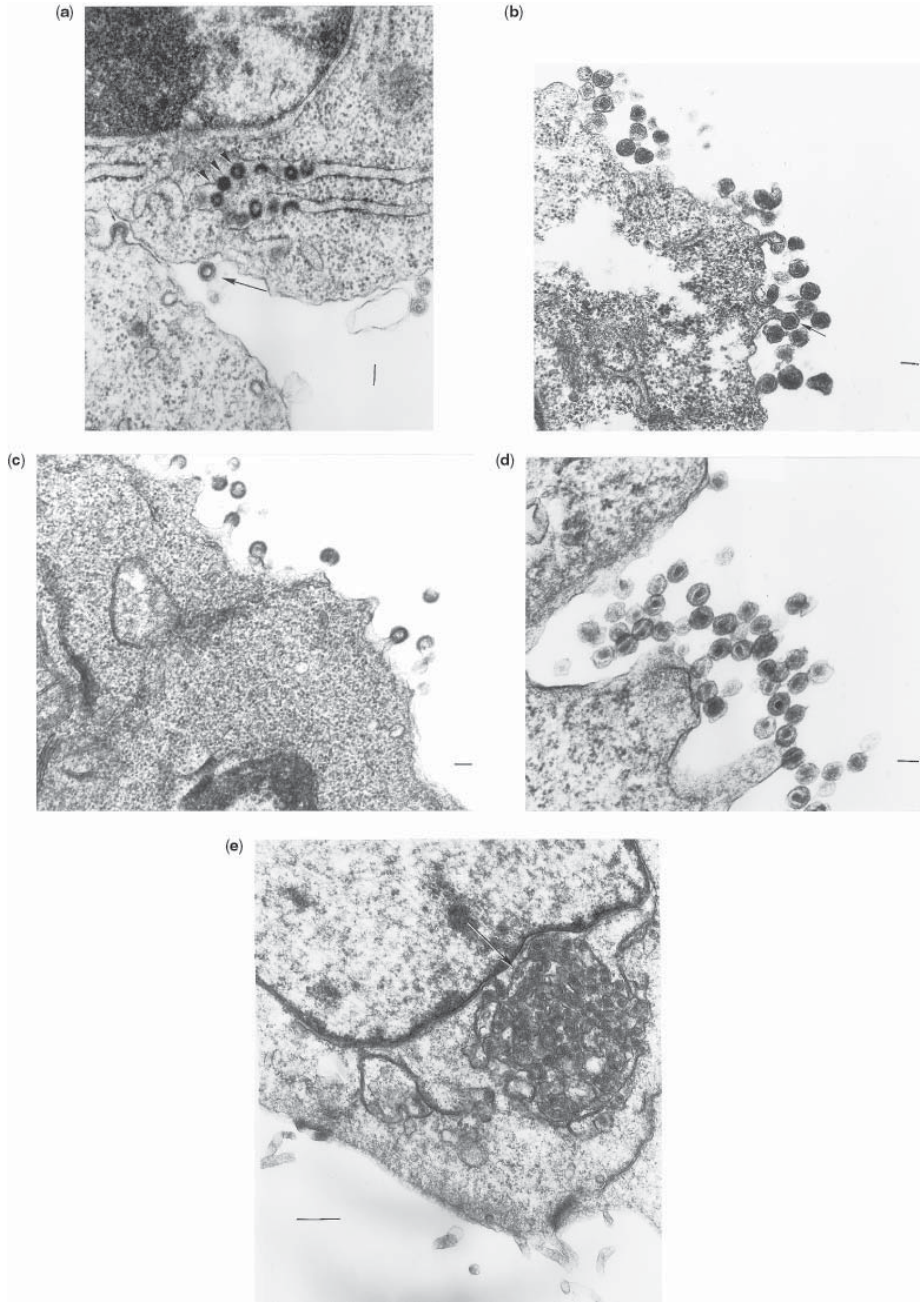

Figure 8.1. TEM micrographs of cells infected with retrovirus. (a) A murine myeloma cell line with an endogenous oncovirus. The large arrow heads indicate Type A particles within the endoplasmic reticulum (ER) characterized by two electron-dense concentric shells surrounding a central area of low electron density. The small arrowheads indicate Type A particles budding into the ER. An immature Type C particle with centrally located core is indicated by the large arrow (in mature Type C particles the core is electron-dense). The small arrow indicates a Type C particle budding from the cell membrane into the intracellular space. Note that the core of Type C particles is formed during budding. The scale bar is 100 nm. (b) Raji cells infected with the Type D oncovirus, squirrel monkey retrovirus (SMRV). Several extracellular Type D particles with electron-dense cores, sometimes tubular in shape, are evident. A budding Type D particle with characteristic preformed core is indicated (arrow). The scale bar is 100 nm. (c) Cells infected with the lentivirus HIV. Several budding particles can be seen characterized, as in Type C particle budding, by simultaneous core assembly. The scale bar is 100 nm. (d) A cell infected with HIV displaying numerous extracellular particles. This micrograph illustrates the characteristic tubularly shaped core of mature lentivirus particles. The scale bar is 100 nm. (e) A monkey kidney cell infected with the spumavirus, simian foamy virus (SFoV). A large group of spumavirus can be seen within the ER of the cell (arrow). The particles are characterized by an electron-dense ring-shaped core with a translucent center surrounded by an envelope with prominent surface projections. The scale bar is 500 nm. All micrographs were provided by Q-One Biotech Ltd., Glasgow, United Kingdom.

medium (Vero and MRC-5 cell lines can normally be maintained in culture in DMEM containing 1% FBS (v/v) without passaging for 14 days. However, if the cell type being used deteriorates during this period, as shown by a negative control culture condition, or assay for hemadsorbing agents on the human diploid cell line (MRC-5) is required at 28 days postinoculation, the cells should be subcultured to prevent this.

7. At 14 days postinoculation (or 28 days for MRC-5 detector cells when the test sample is capable of supporting human CMV growth), perform hemadsorption using guinea pig, human, and chicken red blood cells (rbc's) as follows:
   - Prepare the rbc's by centrifuging at 2000*g* for 10 min. Then wash the pelleted rbc's twice in PBS in tubes with volume markings. Following the second wash, measure the volume of packed rbc's. Then add sufficient fresh PBS to the pelleted cells for a 0.5% preparation of rbc's.
   - Remove the culture medium from the cells, and carefully wash the monolayers with PBS.
   - Overlay duplicate wells of each cell type with 2–3 mL of each of the three rbc species, and incubate the plates at ~4°C for 30–60 min.
   - Remove the rbc's by gentle agitation. Then pipette off. Wash the monolayer gently with PBS two or three times until all the nonadsobed rbc cells are removed.
   - Hemadsorption is indicated by adhesion of the rbc's to the detector cells. A suitable positive control for hemadsorption is parainfluenza type 3 (PI3) which is infectious for both MRC-5 and Vero cell lines.

8.6.3 *In Vivo* Assays

Assays in animals are part of the general safety tests recommended by regulatory authorities for manufacturers of biologics and involve the so-called *in vivo* assay and the antibody production assay (MAP, HAP, or RAP) (Table 8.1). "*In vivo*" assays normally utilize suckling mice, adult mice, guinea pigs, and embryonated eggs. Mice are inoculated intracerebrally, intramuscularly, and intraperitoneally, guinea pigs are inoculated intramuscularly, and embryonated eggs by the yolk sac, allantoic cavity, and amniotic cavity (20,76). The inoculum is normally a small volume of lysate prepared from the cell line under test, and the animals are observed for 3–4 weeks and the eggs for a shorter period of time (refer to refs 20 and 79 for specific durations) for morbidity and mortality. Hemagglutination is performed on fluids harvested from the eggs inoculated vial the allantoic route. The *in vivo* assay is designed to detect a wide range of viral contaminants. Suckling mice are susceptible to many arthropod-borne viruses, Herpes simplex virus, rabies, some arenaviruses, and picornaviruses, including poliovirus, coxsackievirus, echovirus, and encephalomyocarditis virus (adult mice are susceptible to some of these viruses) (77,78); guinea pigs are susceptible to paramyxoviruses, reoviruses, and filoviruses (37), and embryonated eggs are susceptible to poxviruses, paramyxo-, orthomyxoviruses, and Herpes simplex virus (79). Antibody production assays are performed on cell lines of mouse (MAP), rat (RAP) and hamster (HAP) origin to assay for viruses introduced by the source species. These assays are therefore normally performed only on the MCB because a negative result indicates that the cell bank system is free of viruses of the species of origin. In addition, MAP assays are performed on monoclonal antibody preparations made in ascites. The viruses assayed in these tests include hantaan virus, lymphocytic choriomeningitis virus (LCMV), reovirus type 3, and Sendai virus all of which are known to infect humans or primates (20). In these assays, adult mice, rats, or hamsters are inoculated with test cell lysate and held for 4 weeks, then bled, and the serum is tested for antibody to viruses of concern using antibody specific assays such as enzyme-linked immunosorbent assay (ELISA) and indirect immunofluorescence (IF).

8.6.4 Polymerase Chain Reaction (PCR)

PCR is a highly sensitive technique for detecting specific DNA sequences and therefore is important for detecting viral and mycoplasmal contaminants whose genomic sequence is known fully or partially. The reaction involves amplification using repeated thermal cycles of DNA denaturation, primer annealing, and DNA polymerization by *Taq* polymerase of a specific region of DNA defined by the primers. The reaction mass balance alters as the cycles progress resulting in an increase in product (and consequently available template), a decrease of nucleotides and primer (although these two components are greatly in excess in the reaction), and a decrease in the ratio of *Taq* polymerase molecules to available template copies. The reaction therefore reaches a point after 30 cycles or so when production of product is no longer exponential due to limiting *Taq* polymerase and self-annealing of product. The specific conditions employed for any PCR assay depend upon the sequences being amplified, the primers used, the number of initial copies of template in the sample, and the size of the region being amplified. In addition, viruses with RNA genomes must be reverse transcribed before PCR amplification.

PCR is important as a tool for virus adventitious agent detection when a culture system is not available, as is

the case with hepatitis C virus detection, or when detection of infectious virus is limited by the sample size, as is the case with detection of replication-competent virus during monitoring of patients treated with gene therapy constructs. It should be noted, however, that PCR detects infectious, as well as defective virus. Therefore in circumstances where virus is likely to be present but has been inactivated by processing, PCR is less useful, for example, PPV in γ-irradiated trypsin. The specific protocols for viral diagnosis by PCR are beyond the scope of this chapter, and readers interested in the details are advised to consult more relevant literature (80).

8.7 TESTING RAW MATERIALS

8.7.1 Tests for Bovine Viral Contaminants

The most common viral contaminant in raw materials of bovine origin is the pestivirus BVDV because of its prevalence, the large numbers of animals from which a serum batch is prepared, and partial resistance of the virus to standard procedures used to heat inactivate bovine serum for use in tissue culture medium preparations (56°C for 30 min) (81). Some manufacturers of bovine serum reduce the risk of infectious BVDV in bovine serum by irradiation with UV-C (wavelength of 254 nm) or γ- irradiation (38,39). Both techniques are effective inactivators of BVDV and other viruses. However, in the absence of effective virus inactivation treatment of bovine raw material, it is advisable to test for BVDV. The majority of BVDV strains are noncytopathic. Therefore detection of infectious BVDV is most easily done, as outlined in the following protocol, by end-point immunofluorescence using an antibody that recognizes BVDV antigen following inoculation of a susceptible cell line such as the bovine turbinate (BT), bovine trachea (EBTr) cell lines, or the Madin Darby bovine kidney cell line (MDBK). Negative and positive control cultures are tested in parallel. The negative control cultures are cells assayed in parallel and cultured in a medium containing BVDV-free serum. The positive control cultures can either be cells infected with a noncytopathic strain of BVDV (e.g. New York-1) at the same time as the test sample is inoculated, or a subculture of the negative control culture can be infected with a cytopathic strain of BVDV (e.g. NADL) toward the end of the assay.

1. Seed BVDV-free cultures of one of the above cell types into tissue culture flasks to obtain cultures ~70% confluent on the following day.
2. Remove the growth medium the next day, and replace with a culture medium containing 10–15% (v/v) of the test serum as the FBS component (all three cell lines mentioned above grow in DMEM). Alternatively, if the bovine raw material under test is not serum, dissolve the test material in a small volume of BVDV-free medium. Then inoculate this onto the monolayer, and allow it to absorb for 1 h. Feed the cultures with BVDV-free growth medium.
3. Incubate the cultures at 37°C with 5% CO_2, and passage when confluent, (approximately every 3–4 days) for five passages. During subculturing, use a medium containing 10–15% (v/v) of the bovine serum under test.
4. At passage five, prepare the cells for immunofluorescence by subculturing 1×10^5 cells/mL (2 mL per well) onto two chambered tissue culture slides. Reincubate the slides at 37°C with 5% CO_2 until confluent.
5. When confluent, remove the culture medium, and fix the cells by submerging the slides in cold acetone for 10–15 min. At this point, the slides can be stored frozen or tested by immunofluorescence.
6. Perform indirect immunofluorescence using commercially available antibodies to BVDV and commercially available antispecies FITC (fluorescin isothiocyanate) conjugated antibody.
7. Dilute the anti-BVDV antibody to a predetermined working dilution in PBS. Then allow the antibody to adsorb onto the cells by incubation in a humidified chamber at 37°C for a suitable period of time (30 min is normally sufficient).
8. Remove the primary antibody by washing the slides in PBS. Add the secondary antibody (commercially available antispecies FITC conjugated antibody) to each well, and allow this to adsorb as above.
9. Following a suitable adsorption period, wash the slides in PBS to remove the secondary antibody.
10. Examine the slides under a suitable fluorescent microscope. Samples that are positive for BVDV may show varying proportions of positive cells, depending on the strain of BVDV and the number of passages in culture. Figure 8.2 illustrates the pattern of BVDV fluorescence which is predominantly cytoplasmic.

The US Code of Federal Regulations (9CFR) (52) stipulates requirements for testing animal-derived products used as ingredients in producing biologics. In the case of bovine-derived ingredients, specific procedures for viral detection using Vero cells (African green monkey kidney) and a cell line of bovine origin are provided. The method involves cultivating these two cell lines in a medium containing at least 3.75 mL or 15% of the ingredient for 21 days or more with at least two passages during this period. At the final passage, monolayers are set up of specified surface area and assayed 7 days later for viral contaminants by cytological staining, hemadsorption, and IF. Viruses assayed by IF on detector cells of bovine origin are BVDV,

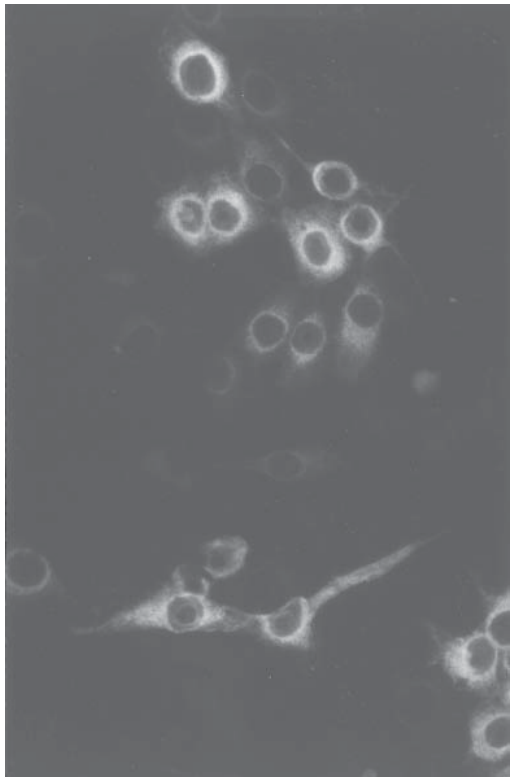

Figure 8.2. BT cells infected with BVDV and assayed for infectivity by indirect immunofluorescence, as described in the text. Cells infected with BVDV display green cytoplasmic fluorescence. Photograph provided by Q-One Biotech Ltd., Glasgow, United Kingdom.

bovine adenoviruses (BAV), bovine parvovirus (BPV), bluetongue virus (BTV), bovine respiratory syncytial virus (BRSV), reovirus, and rabies virus. Vero cells are tested by IF for BVDV, reovirus, and rabies virus.

8.7.2 Tests for Porcine Viral Contaminants

Trypsin is a raw material of porcine origin widely used in cell cultures for dissociating anchorage-dependent cells. The virus of concern in trypsin preparations, as discussed previously, is PPV. As with raw materials of bovine origin, the US Code of Federal Regulations (9CFR) (52) stipulates the method for testing for PPV in trypsin preparations which have not undergone appropriate treatment to inactivate this virus. The following method complies with 9CFR recommendations:

1. Seed duplicate medium-sized tissue culture flasks (75–80 cm^2) of primary porcine kidney cell lines at a density such that at inoculation (the following day) the monolayer is 30–50% confluent. (It is important to inoculate PPV onto mitotically active cells because parvoviruses require the cellular functions available during the S and G phases of the cell cycle for DNA replication (82).
2. The following day, ultracentrifuge the trypsin preparation at 80,000*g* for 1 h to pellet the virus and separate it from trypsin so that monolayer detachment can be avoided (9CFR requires testing 5 g of trypsin is tested and resuspending the resultant pellet in water).
3. Inoculate the resuspended pelleted material into one of the two flasks of primary porcine kidney cells, and incubate for 1 h at 37°C with 5% CO_2 to allow any virus to adsorb. Inoculate the remaining flask with culture medium as a negative control, and incubate as above.
4. Feed the flasks with an appropriate growth medium, and reincubate the culture at 37°C with 5% CO_2.
5. Examine the cultures every 2–3 days for confluency of growth and viral cpe.
6. Maintain the culture for 14 days or more postinoculation, with at least one subculture during this period. It is important to ensure that all subculturing of the primary porcine cells is performed using trypsin that is negative for PPV.
7. At the last subculture (this should fall on or after day seven postinoculation), set up monolayers for immunofluorescence. 9CFR stipulates that these monolayers must be a minimum of 6 cm^2 (commercially available glass or plastic chamber slides are suitable for this purpose). Three sets of 6 cm^2 monolayers are required from the "test material" culture such that two are the "test material" monolayer, and the remaining one is inoculated with PPV as a positive control. Set up one 6 cm^2 monolayer from the negative control culture.
8. One day after subculture, remove the medium from one of the "test material" slides, and inoculate with PPV (100–300 fluorescent units). Allow the virus to adsorb at 37°C with 5% CO_2 for 1 h. Then feed the culture with an appropriate volume (2–3 mL) of fresh medium. Return the slide to a 37°C incubator with 5% CO_2.
9. Examine the cultures every 2–3 days for viral cpe. If cpe is evident on the positive control culture, it can be fixed in cold acetone for 10–15 min. However, a "test material" monolayer must be fixed at the same time. Maintain the negative control and remaining "test material" cultures until at least 7 days post-subculture (i.e. day 14 or later). Then fix with cold acetone as above.
10. Perform indirect immunofluorescence for PPV, as described before for BVDV. Specific fluorescence to PPV is evident from nuclear fluorescence.

PPV cytopathology is often difficult to recognize and requires serial passage before it becomes evident. Therefore, specific end-point assay such as immunofluorescence described before provides conclusive evidence of PPV contamination.

8.8 DETECTION OF MYCOPLASMAS

Mycoplasmas are bacteria that lack the rigid cell wall structure composed of peptidoglycan that is normally associated with bacteria. Thus mycoplasmas have properties that distinguish them from other bacteria. Testing for mycoplasmal contamination requires a different set of assays independent of sterility testing for normal bacteria, and these are described following. The term mycoplasma denotes organisms that belong to the class designated Mollicutes which includes other generic groups referred to as acholeplasma, ureaplasma, and spiroplasma. Many distinct organisms (158 recognized species) are grouped in the class Mollicutes because they lack cell walls due to the absence of the genes for peptidoglycan synthesis (83). Mycoplasmas also differ from other bacteria by incorporating cholesterol and other sterols into their plasma membranes which makes the membranes of mycoplasmas more pliable and more resistant to physiochemical properties than would be predicted (84). This pliability combined with their small size, average diameter of 0.3–0.8 μm, allows them to pass through filtration systems designed to remove bacteria. The most likely source of mycoplasmal contamination in a cell culture facility is a contaminated cell culture, thus emphasizing the need for thorough screening of all new cell lines and appropriate quarantine and storage protocols for all incoming cell cultures. After establishing an infection in a particular cell line, mycoplasma and other microbes are spread by aerosol droplet dispersion via a variety of normal cell culture procedures including pipetting and dispensing of media liquids. The inappropriate use of a common medium bottle or common pipettes between cell cultures and cell lines can lead to contamination of many cell lines in the facility with the same species of mycoplasma (85). Human isolates represent the majority of mycoplasmal contaminants in cell culture. *Mycoplasma orale*, *M. fermentans*, and *M. salivarium* are the most frequently isolated, and *M. buccale*, *M. faucium*, *M. genitalium*, *M. hominis*, *M. pirum*, and *M. fermentans* less frequently. Many species of mycoplasma are known to cross host ranges, and thus isolates from contaminated bovine serum such as *Acholeplasma laidlawii*, *M. arginini* and *My. hyorhinis* represent further cause for concern in cell culture. The consequences of mycoplasmal contamination are too numerous to describe in this chapter. Those interested in a more comprehensive description of the subject are referred to the recent review of mycoplasmal contamination by Lincoln and Gabridge (86). A major problem is that despite heavy microbial contamination, for example, 10^9 colony-forming units per milliliter of culture, the cell cultures often appear to be normal by both macroscopic and microscopic inspection. Thus, due to an undetected mycoplasmal contamination, research results could be distorted and hence erroneous and in a production facility infection could reduce yields of products such as monoclonal antibodies and enzymes.

As a strategy to prevent and control bacterial and mycoplasmal contamination the use of antibiotics in routine cell culture should be avoided wherever possible because they may mask mistakes in aseptic technique and quality control and may also result in the emergence of antibiotic-resistant strains of microorganisms. In any case there is not a single antibiotic which is effective against all bacteria. For example, the inhibitors of peptidoglycan synthesis such as the penicillins and cephalosporins, are clearly ineffective against mycoplasmas, and many antibiotics simply retard or inhibit bacterial growth, that is, they are bacteriostatic agents and do not destroy bacteria. The absence of antibiotics is also a requirement for effective mycoplasmal detection in cell culture. Thus, to summarize this brief background survey of mycoplasmas, it is necessary to perform routine screening for mycoplasmal contamination because mycoplasmas may not cause readily apparent changes in cell culture.

Several direct and indirect procedures are currently used to detect mycoplasmas, but unfortunately, there is not a single, foolproof test that will detect all species. One major problem that has to be addressed in the screening program is the fact that some mycoplasmas will not grow in artificial media and thus must be detected using a cell culture system. The lengthy time required to complete these assays has focused attention on some of the indirect assays, and it is possible that PCR reactions may gain acceptance for these situations, for example, the screening of cells used for *ex vivo* therapies mentioned previously, where a rapid assay is critical. Direct culture methods are the most sensitive but are also the most time-consuming and take up to 28 days for incubation.

Alternative methods for detecting mycoplasmal contamination include PCR reactions, indirect culture methods using DNA fluorochrome stains as described later, DNA probes, ELISAs, biochemical assays, and electron microscopy (87–89). These methods are more rapid than direct assays but less sensitive and vary in their capacities to detect a wide range of species. A thorough review is beyond the scope of this chapter, but readers are referred to a recent publication that details molecular and diagnostic procedures in mycoplasmology, for example, detection by

PCR (90). In points to consider in the characterization of cell lines used to produce biologicals issued by CBER (17), tests for the presence of both cultivable and noncultivable mycoplasmas are recommended. Biological products made in insect cells should be tested for both mycoplasmal and spiroplasmal contamination. If storage is required for samples before assay, then it should be at between 2 and 8°C for 24 h or less and at −60°C or lower for 24 h or more. As specified by CBER (17), mycoplasmal contamination testing must be performed by both the agar and broth media procedures and the indicator cell culture procedure or by a procedure demonstrated to be comparable using the protocols described here.

8.8.1 Cultivation Methods

8.8.1.1 Agar and Broth Procedures

1. Each lot of agar and broth medium should be free of antibiotics, although penicillin G can be present, and each lot of medium should be checked for its mycoplasmal growth-promoting properties. This requires the use of positive cultures that are described below.
2. Inoculate at least 0.2 mL of the sample over the surfaces, of two or more agar plates of one medium formulation. In addition inoculate at least 10 mL of the sample into a flask containing 50 mL of broth medium which is then incubated at 36 ± 1°C.
3. Test 0.2 mL of the broth culture on the third, seventh, and fourteenth days of incubation by subculture onto two or more agar plates of the same medium as that used before.
4. Incubate two of the initial isolation plates and two each of the three subculture plates in 5–10% CO_2 in a nitrogen atmosphere containing no less than 0.5% oxygen during the incubation period. Some laboratories incubate the cultures both aerobically and anaerobically.
5. Incubate all culture agar plates for at least 14 days at 36 ± 1°C, and observe microscopically at 100× magnification for growth of mycoplasma colonies.
6. As positive controls, at least two known mycoplasma species or strains should be used, one of which is a dextrose fermenter, that is, *M. pneumoniae* strain FH or equivalent, and the other an arginine hydrolyzer, that is *M. orale* strain CH 192999 or equivalent species or strains. These positive strains should not be more than fifteen passages from isolation and should be used in a standard inoculum of 100 colony-forming units (CFU) or less. Sterile mycoplasma broth is used as the negative control.

8.8.1.2 Indicator Cell Culture Procedure.

This procedure uses a Vero cell culture known to support the growth of appropriate mycoplasmas. Figure 8.3 illustrates the typical fluorescent pattern observed with normal and mycoplasma-contaminated cultures.

1. Inoculate at least 1 mL of the sample onto two or more indicator cell cultures grown on cover slips, in dishes, or equivalent containers.
2. Incubate the cell cultures for 3–5 days at 36 ± 1°C in 5% CO_2, and then examine by epifluorescence microscopy following staining with a DNA-binding fluorochrome.
3. As positive controls, *M. hyorhinis* strain DBS1050 and *M. orale* strain CH 19299 are recommended using an inoculum of 100 CFU or less.

8.8.1.3 Enhanced Cell Culture Procedure.

Some laboratories employ an enhanced procedure when a test sample interferes with the performance of the direct Vero cell culture assay. Test samples, negative control, and a positive control, that is, *M. hyorhinis*, are inoculated into cultures of Vero cells. T25 flask cultures are appropriate, and the flasks are incubated for 3–5 days. The cells are then removed, and 0.2 mL of each of the cultures is inoculated into each of six wells of Vero cells and then incubated and examined as described in the direct cell culture assay. In evaluating these assays, a sample is considered to meet the requirements of the test for the presence of mycoplasma if mycoplasma, growth does not appear in the sample of inoculated media. In addition all positive cultures must demonstrate appropriate growth, and in all negative cultures growth must not be detected.

8.8.2 Indirect Detection of Mycoplasmas

The direct assays described before are probably beyond the scope of most small cell culture facilities although large production facilities may perform these assays in-house. In contrast some of the indirect assays now available can be performed by any operator because they are available in kit form. An outline of just one of these methods is included here, but a range of indirect methods including PCR reactions is being developed and evaluated.

8.8.2.1 Mycoplasmal Detection using the Gen-Probe System.

This system uses a ^{3}H-labeled DNA probe homologous to mycoplasmal, acholeplasmal and spiroplasmal rRNA. The manufacturers (Gen-Probe Inc.) claim that all species that commonly infect cell cultures can be detected with this probe, which targets the rRNA of the organisms to form a stable RNA to DNA labeled hybrid. The latter

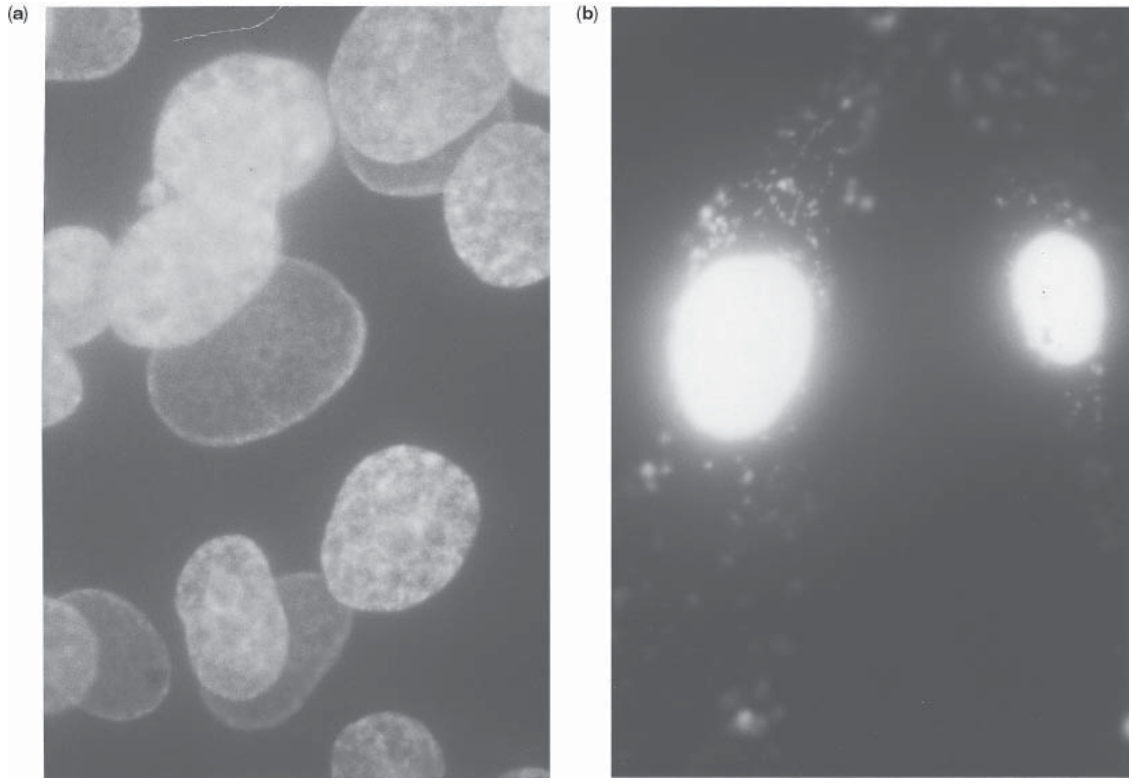

Figure 8.3. Detection of mycoplasmal infection by DNA fluorochrome staining. (a) Cells free of mycoplasmal contamination display only nuclear fluorescence. (b) Cells contaminated with mycoplasma display both nuclear and extranuclear fluorescence.

is separated from a nonhybridized DNA probe using hydroxyapatite, and then the amount present is measured in a scintillation counter. Following is the recommended test procedure:

1. Prepare a background count [in counts per minute (cpm)] on 5 mL of the scintillation fluid used in the scintillation counter programmed to an appropriate parameter to measure ^{3}H activity.
2. Perform a total count determination, that is, the activity of the labeled probe solution, by pelleting a 5 mL suspension of the separation mixture at 500*g* for 1 min (hydroxyapatite in a buffered solution provided in the kit) in a screw-capped scintillation vial. The supernatant is discarded, the pellet is vortexed in 50 μL of the probe solution, and the cpm is determined.
3. Microfuge the test samples, for example, 1.5 mL aliquots of antibiotic-free cell culture medium (in which the test cultures have been grown for a minimum of 3 days), at 12,000*g* for 10 min to pellet any mycoplasmas present.
4. Discard the supernatants, and resuspend the pellets in 200 μL of the probe solution. In addition, prepare positive and negative controls by vortexing 50 μL each of the control solutions provided in the Gen-Probe kit with 200 μL of probe solution.
5. Incubate the preparations overnight at 72°C. Aliquot 5 mL of resuspended suspension into the required number of scintillation vials, and then transfer 200 μL aliquots of incubated sample plus probe solution to the scintillation vials containing the 5 mL of separation solution. Thoroughly mix the solutions by vortexing, and incubate at 72°C for 5 min.
6. Briefly vortex the vials, centrifuge for 1 min at 500*g*, and remove and discard the supernatants. Wash the pellets, reincubate, wash again, centrifuge for 1 min at 500*g*, and remove the supernatant. Rewash the pellets.
7. Add 5 mL of scintillation fluid to each vial, and resuspend the pellets by vortexing. Stand the vials at room temperature for 5 min to minimize background phosphorescence, and then measure ^{3}H activity as described before.

8. The percentage of hybridization of the sample to the probe DNA is

$$\%\text{hybridization} = \frac{\text{Sample cpm} - \text{background cpm}}{\text{Total count cpm}} \times 100\%$$

Controls:

- % hybridization of positive should be >30%;
- % hybridization of negative should be <0.2%.

Providing that the controls are within acceptable limits, a hybridization result of >0.4 is considered positive. This method provides a rapid assessment of mycoplasmal contamination and appears to correlate well with direct culture results which should be used as the gold standard for these indirect assays. The Gen-Probe® system has been used successfully by researchers in the Sydney laboratory, as reported by Thompson (91).

8.9 BACTERIA AND FUNGI

The effects of bacterial and/or fungal contamination on cell culture systems have been long recognized and are well documented in numerous other publications. The risks of such contamination can be reduced by employing rigorous aseptic techniques and using appropriate and regularly maintained and validated equipment, for example, regularly monitoring the performance of all HEPA laminar flow cabinets. Contamination does occur, however, despite the precautions, and thus the kind of protocols for sterility testing recommended by the USA 21 Code of Federal Regulations (92) should be performed regularly on appropriate specimens. The protocol described is applicable to single, bulk, or final product with the recommendation that bulk material should be tested separately from final material and material from each final container should be tested in individual test vessels as follows:

1. Samples are cultured in a fluid thioglycollate medium (THIO) and a soybean-casein digest medium (TSB). Some manufacturers of biologics adopt a more comprehensive approach to sterility testing and also include other media, such as peptone yeast glucose broth and Saboraud dextrose agar slants.
2. The amount of sample tested depends on the nature of the test material. As a guideline, samples from bulk material should be representative of the bulk and be not less than 10 mL. For sterility testing of final containers, it is recommended that samples from at least 20 final containers be taken for each medium used. The volume tested is the entire contents of the final container if it is less than 1 mL and, if 1 mL or greater, then the volume tested should be the largest single dose recommended by the manufacturer or 1 mL, whichever is larger, but not more than 10 mL.
3. Incubate tests using THIO at 30–35°C for no less than 14 days, and examine visually for evidence of growth on the third, fourth, or fifth day, on the seventh or eighth day, and on the last day of the test period. Incubate tests using TSB at 20–25°C, and inspect as described for THIO. If the medium is rendered turbid by the inoculum, thus interfering with visual inspection for microbial growth, then at least 1 mL of the test medium is transferred to additional containers of the medium. It is standard practice to test replicate sets of two tubes of each medium.
4. Positive control strains, for example, *Bacillus subtilis* (ATCC 6633) and *Bacteroides valgatus* (ATCC 8482) for THIO and *Candida albicans* (ATCC 10231) for TSB are used at inoculum levels of less than 100 CFU/inoculum. The viability and purity of these organisms should be verified regularly. A negative control of uninoculated medium serves as the negative control. USP 23 (93) provides more detailed information regarding the nature of the control cultures that should be used in sterility tests, including description of alternative tests, for example, membrane filtration, for samples not readily water soluble.

8.10 OXYGEN UPTAKE RATE

In large-scale cultivation of cells, several parameters can be used to monitor cell growth and metabolism, including oxygen uptake rate (OUR), Eh, pH, glucose uptake, lactate production, glutamine uptake, NH_3 accumulation, and levels of intracellular nucleotide pools. The major limitation is the type of test available to detect the chosen parameter. Recent developments have led to the availability of more on-line detectors, for example, glucose biosensors, which provide a rapid check on the culture condition, and these now augment oxygen and pH probes which have been the major indicators of cell viability and growth to date. For example, in vaccine manufacture the viral infection of some cell types can be monitored by following OUR, which correlates with viral infection (94) because cells have an increasing or constant OUR, during the growth and production phases whereas the OUR drops after viral infection. In a cell culture system contaminated by an aerobic organism, the OUR can increase significantly, whereas the oxygen levels monitored by the oxygen probe often fall to undetectable levels. Thus microbial contamination can often be quickly detected by reference to oxygen levels in the culture, providing that the probes have been calibrated properly. In

addition, pH levels usually fall significantly as a result of lactate production by the microbes, and this can be detected by the pH probe or the rapid change of color of the pH monitoring dye if present in the medium.

8.11 ENDOTOXIN DETECTION

Although endotoxins are not infectious agents, they are derived from the lipopolysaccharide cell wall component of Gram-negative bacteria and could be present even in the absence of viable bacteria. If endotoxin, is present in a therapeutic product administered parenterally, it can induce fever and possibly shock in the recipient. Thus endotoxin testing is incorporated as part of the safety testing protocol of final products. The testing procedure involves either monitoring the rectal temperature of rabbits following injection of a standard amount of product per kilogram of rabbit or using an *in vitro* test known as the *LAL test* in which the lymph material of the horseshoe crab is gelled in the presence of endotoxin. It has been our experience that if endotoxin is present in the cell culture media, it can affect the growth and viability of cell cultures and should always be borne in mind if cells are not growing as expected. This problem can be avoided by using water suitable for injection, which has been pretested for endotoxin, to prepare media if in doubt about the useful water supply.

8.12 STATISTICAL ANALYSIS

In the context of this chapter, statistical analysis of viral contamination in a sample can be at two extremes. First, when assaying raw material or a cell line, the contaminant, if present, is in low amounts and therefore may not be detected. Second, when performing process validations, high titers of virus are spiked into a downscale version of the process, and samples are collected at the start, during, and after processing, and then are assayed for virus titer. Therefore samples generated from process validations can contain high levels of virus or have virus titers close to or below the detection level of the assay. Calculation of virus titers at low concentrations (e.g. in the range of 10–1000 infectious particles per liter) can be made by estimating the minimum detectable level (mdl), whereas estimation of virus titers in samples containing high titer loads can be made by the $TCID_{50}$ assay.

8.12.1 Minimum Detectable Level

There is a discrete probability that a sample that contains a low concentration of virus will produce a negative result when assayed in tissue culture because of random distribution of virus particles and the fact that the sample tested is usually much smaller than the volume available, for example, only a few milliliter sample from 100 to 200 L fermenters is assayed for viral contaminants by *in vitro* assays. The probability P that a sample is negative for viral contamination can be calculated using the following formula:

$$P = \left[\frac{(V - v)}{V}\right]^n$$

where P is the probability that the sample contains no infectious virus, V is the total volume of the material, v is the sample volume, and n is the absolute number of virus particles statistically distributed in V.

When V is much greater than v, the formula can be approximated by the Poisson distribution as

$$P = e^{-cv}$$

where c is the virus titer per unit volume and v is the sample volume.

This equation becomes the following by natural logarithmic (In) conversion:

$$\ln P = -cv$$

or

$$c = \frac{-\ln P}{v}$$

The probability P that the sample is free of virus is normally set at 0.05 or 0.02, that is, in 5% and 2% of cases, respectively, a false-negative result will be obtained; in other words there are 95% or 98% confidence limits, respectively, that the detection limit calculated is correct. Thus, in a sample where virus has not been detected, a minimum detectable limit (mdl) with a set confidence level can be calculated. The following example illustrates the formula

In a solvent detergent process validation study, 450 mL of material was spiked with 50 mL of enveloped virus. One milliliter of the resultant material was assayed for virus, but virus was not detected. By using the above formula and applying a confidence level of virus detection of 98%, the following can be calculated:

$$c = \frac{-\ln P}{v}$$

$$\Rightarrow \quad c = \frac{-\ln 0.02}{1 \text{ mL}}$$

$$\Rightarrow \quad c = 3.9 \text{ virus particles/mL}$$

The mdl of virus in the sample, therefore, is 3.9 virus particles/mL.

The mdl of virus in the process sample, therefore, is

$$\begin{aligned} &3.9 \times \text{total sample volume} \\ \Rightarrow\ &3.9 \times 500\,\text{mL} \\ \Rightarrow\ &1950 \text{ virus particles.} \end{aligned}$$

8.12.2 Quantitation of Virus by $TCID_{50}$

The $TCID_{50}$ (tissue culture infectious dose, 50) is a standard method for infectious virus quantitation defined as the dilution of sample at which 50% of the replicate cell cultures inoculated with the sample become infected. The assay involves serial dilution of a sample and inoculation of equivalent volumes of each dilution onto replicate monolayers of tissue culture cells sensitive to the virus being assayed. At the assay end point, the inoculated cultures are scored as positive or negative for viral infection. In practice, this method involves serial dilution of the sample through an appropriate medium, for example, maintenance medium or PBS, at a dilution factor of normally 3, 5, or 10, and inoculation of a given volume (e.g. 100 μL) into replicate wells of a multiwell plate (e.g. 96-or 24-well plate with eight wells inoculated per dilution). The accuracy of this method can be increased by increasing the numbers of replicate wells inoculated at each dilution and by decreasing the dilution factor. Several formulas may be used to estimate the virus titer in samples assayed by this method, but the method most commonly used is that of Karber expressed by the following equation (95):

$$-m = \log_{10}\text{starting dilution} - \left[\sum p - 0.5\right] \times d$$

where m is the $\log_{10}TCID_{50}$ (per unit volume inoculated per replicate culture), d is the $\log_{10}$ dilution factor, and p is the proportion of wells positive for viral infection.

Thus, in the data shown in Table 8.4, using a fivefold dilution factor, eight replicate wells, and an inoculum volume of 0.1 mL per well, the $TCID_{50}$ can be calculated as follows:

$$\begin{aligned} -m &= -0.7 - (4.875 - 0.5) \times 0.7 \\ -m &= -3.76 \\ TCID_{50} &= 10^{3.76}/0.1\,\text{mL} \end{aligned}$$

Because the value calculated by the Karber formula is a statistical estimate of the titer, the standard deviation s of the $TCID_{50}$ can be calculated using the following equation:

$$s = \sqrt{d}^2 \sum \left[\frac{p1(1-p1)}{(n_1 - 1)}\right]$$

where d is the $\log_{10}$ dilution factor, $p1$ is the observed rate of the reaction, and n_1 is the number of test cultures per dilution.

Therefore, for the example given in Table 8.4, s can be calculated as

$$\begin{aligned} s &= \sqrt{0.49} \times 0.422/7 \\ s &= 0.17 \end{aligned}$$

Using this value for the standard deviation s, the 95% confidence limits can be approximated as $2 \times s$, that is, 0.34.

Calculation of virus titers by these methods is recommended by regulatory authorities for evaluating process validation studies (24). By quantitating virus titers in spiked starting material and processed material by $TCID_{50}$ assay (or mdl calculations for those processes sample with no detectable virus), an estimate of the ability of the process to remove and/or inactivate viruses can be made by the following equation:

$$R = \log_{10}\frac{V_1 \times T_1}{V_2 \times T_2}$$

where R is the reduction factor, V_1 is the volume of starting material, T_1 is the concentration of virus in the starting material, V_2 is the volume of processed material, and T_2 is the concentration of virus in the processes.

TABLE 8.4. Data Used to Calculate $TCID_{50}$ by the Karber Formula

Log Dilution	No. of Positive Wells	Proportion of Wells Positive	Rate of Reaction $[p1(1-p1)]$
−0.7	8	1	0
−1.4	8	1	0
−2.1	8	1	0
−2.8	8	1	0
−3.5	5	0.625	0.234
−4.2	2	0.25	0.188
−4.9	0	0	0
−5.6	0	0	0
		$\sum p = 4.875$	$\sum p1(1-p1) = 0.422$

The 95% confidence limit of the reduction factor can be calculated by the following equation:

$$\pm\sqrt{(s^2 + a^2)}$$

where s is the 95% confidence limit for the titer of virus in the stating material and a is the 95% confidence limit for the titer of virus in the processed material.

8.13 DETECTION OF PRIONS

In recent decades a previously unknown mechanism of disease has been described in humans and animals. Several fatal neurodegenerative diseases, including scrapie in sheep, BSE in cattle, and CJD in humans, are now thought to be caused by the accumulation of a post-translationally modified cellular protein (15,16). CJD may present as a sporadic, genetic, or infectious illness. In the theory proposed by Prusiner, prions are described as transmissible particles that are devoid of nucleic acid and are composed exclusively of a modified protein (PrP^{Sc}). The normal, cellular prion protein (PrP^{c}) is converted to PrP^{Sc} through a post-translational process involving a conformational change whereby the α-helical content decreases while the β-sheet content increases, leading to significant changes in properties. For example, PrP^{c} is soluble in nondenaturing detergents, whereas PrP^{Sc} is not, and PrP^{c} is easily degraded by proteases, whereas PrP^{Sc} is partially resistant. Stanley Prusiner recently received a Nobel prize for his prion studies, and investigations earlier by Carlton Gadjusek led also to the award of a Nobel prize for demonstrating that the neurodegenerative disease known as Kuru found in the Fore people of New Guinea was transmitted from person to person by ritualistic cannibalism and is now recognized as a prion disease (96). Cases of horizontal transmission of CJD were reported in 1974 by Duffy *et al*. (97) who were the first to draw attention to the iatrogenic transmission of CJD following the development of CJD in the recipient of a corneal transplant from a donor who had died from rapidly progressive dementia. Since then, other mechanisms of iatrogenic transmission have been recognized, including contaminated neurosurgical equipment, dura mater homografts, and therapy with human cadaveric pituitary hormones. It is now thought that ~100 deaths worldwide have been caused by growth hormone derived from contaminated pituitary glands (98), and four deaths are associated with the use of pituitary gonadotrophins which appears to be unique to Australia (99). The pituitary hormone program was ended in the mid-eighties following the first reports of deaths, but cases continue to occur after longer and longer incubation periods following exposures that occurred mainly in the 1970s. Another mechanism of CJD transmission was proposed in 1996 by Will *et al*. (100) who reported the deaths of patients who were unusually young for classical CJD and had clinical and neuropathological features different from sporadic CJD; they suggested that it is caused by a novel variant of CJD derived from BSE.

Further cases since then appear to confirm that human disease can be caused as a result of bovine prions passing from BSE or "mad" cows to humans through the consumption of contaminated beef products. This prion disease has been named *new variant* or *variant CJD* (nvCJD or vCJD). This finding, if true, has serious implications for human health in general, particularly in the United Kingdom where "mad cow" disease has had its greatest effect, but it also has enormous ramifications for cell culture practices because bovine-derived products such as serum, transferrin and insulin have long been used to cultivate cells. It is now recognized that strategies designed to reduce the risk of prion transmission via cell culture technology will need to be developed and hence this summary of the prion issue in this chapter.

The prion problem has already impacted on the biologics industry in the United Kingdom where in early 1998 the Government announced that it would impose a ban on the use of all UK-derived human plasma for producing plasma-derived biologics such as albumin, immunoglobulins, and coagulation factors. Although plasma is seen as a very low risk material for transmitting prions because there has not been a case reported to date of CJD transmission via either blood transfusion or blood products, an extremely cautious approach has been taken until more is known about the infectivity of the vCJD agent. It is thought that because the agent has passed from sheep to cows by feeding cows with meat and bone meal derived from scrapie-infected sheep, and then passed to humans, it may have increased virulence if transmitted via biologics derived from humans compared to classical CJD, or perhaps a different distribution within the body leads to a higher level of variant prions in the blood and hence plasma. Until a highly sensitive and reasonably rapid test becomes available for detecting prions, the only strategy available to ensure that biologics are as safe as possible is to avoid using, wherever possible, material likely to be contaminated with bovine, vCJD, and CJD prions. For example, process materials derived from bovine sources, such as Tween 80 used for inactivation of enveloped viruses in the processing of some plasma products, should be replaced by material from nonanimal sources. In addition, excipients, such as albumin, which are often added to stabilize labile biologicals in final products should not be used if there is a risk that they may be contaminated with prions.

The implications for cell culture technology arising from BSE are clearly serious and an international meeting in 1998 under the auspices of the Council of Europe was largely devoted discussing of the prion issue (101). In

summary, the majority opinion from the meeting was to avoid bovine-derived materials for use in cell culture, wherever possible, and in those situations where serum or protein-free culture was not possible, for example, the use of normal cell lines for vaccine production, to use bovine serum from BSE-free areas such as New Zealand, Australia, and the United States and to ensure that the respective government agencies employ a rigorous program to guarantee that particular herds of cattle are disease-free and that pooling or mixing of different serum batches is not allowed. In addition to avoiding the use of contaminated raw materials, it is also necessary to introduce, if possible, measures designed to remove prions from biologics because inactivation is not an option because prions are extremely resistant to physicochemical processes and require sequential treatment of at least 1 h in the presence of 1 M NaOH followed by autoclaving at 121°C to inactivate them (102,103) and an appropriate assay. This brief background to the prion issue has hopefully justified the need for a section on prion assays and demonstrated why this is currently an area of intense investigation.

8.13.1 Prion Assays

8.13.1.1 In Vivo Assays. Prions can be detected *in vivo* by bioassays in susceptible laboratory animals. The practical use of bioassays is restricted due to the existence of a species barrier and long incubation times (several years) for most prion isolate/host combinations. Until recently, it was only possible to work with scrapie prions derived from sheep because this is the only prion material available in plentiful supply. Thus purification processes used to manufacture biologics could be assessed for their capacity to remove scrapie prions following spiking of starting material with large doses of scrapie in scale-down models of the large-scale process. The levels of scrapie prions remaining at different stages of the process are assessed by inoculating specimens into either mice or hamsters. Mouse adapted strains, either ME7, with a 200– to 400-day incubation period, or 22A, with a 300–500 day incubation period, and hamster adapted scrapie, 263 K with a 90– to 200-day incubation period, are the agents which have been used to date for spiking studies. There are clearly disadvantages with assays which generally take >200 days to complete even though they are highly sensitive. The hamster assay is faster than the mouse, assay but housing costs are higher for hamsters with the outcome that the costs for both assays are similar but high. Another major problem is that these studies must assume that the scrapie prion will have properties similar to vCJD and CJD prions, and this is unknown at present. Alternative systems are becoming available, including a mouse-adapted BSE strain for validations and transgenic mice with high levels of expression of human, bovine, or chimeric prion protein (PrP) genes which have an abrogated species barrier and significantly shorter incubation times for prions, compared with natural wild hosts. Thus it is now just becoming possible to quantify prions accurately in the brain and other organs of patients with CJD and cattle with BSE.

8.13.1.2 In Vitro Assays. Because of the high cost and durations of *in vivo* tests they are not appropriate for use in routine screening assays although they will serve as the gold standard by which all *in vitro* tests are assessed for sensitivity and specificity. At present PrP^{Sc} is the only known disease-specific diagnostic marker, and immunoassays have been developed to detect this marker using monoclonal antibodies. This is an area of intense research at present and without doubt rapid advances will occur over the next few years. Currently, Western blotting is the most common method of assay usually involving the following steps:

1. Ultracentrifuge the sample to concentrate the specimen.
2. Perform a protease *K* digest using a method in which the concentration of protease kinase has been optimized to reduce background staining.
3. Denature the preparation, dilute to the end point, and analyze all dilutions by Western blotting.

This assay relies on detecting the protease resistant form of PrP^{Sc} which has been shown to correlate with infectivity. The maximum sensitivity of the assay is $\sim 10^2 - 10^3$ IU, which is less sensitive than the bioassay, but the assay is rapid and cost-effective. At present, immunoassays are limited by the lack of monoclonal antibodies that are effectively specific for the PrP^{Sc} protein and the lack of reagents that can detect the presence of PrP^{Sc} in very low levels in the presence of normal prion PrP. A new assay, DELFIA (a dissociation enhanced lanthanide fluoroimmunoassay), appears to be the most sensitive assay developed to date because it claims that it detects a single infectious unit. At present protease digestion is still required, but it is anticipated that the introduction of reagents that can distinguish between PrP^{c} and PrP^{Sc} will obviate the need for this procedure.

8.14 SUMMARY

This chapter demonstrates that, in some situations at least, the lessons of history can be learned and thus influence current thinking and practices. The problems of virus contamination associated with the initial polio vaccines derived from primary monkey kidney cells described briefly in the historical introduction to this chapter were a major driving force in establishing the comprehensive range of

screening procedures outlined in other sections. These measures have made a major contribution to the excellent safety record for the therapeutic use of biologics derived from mammalian cell culture technology. One cannot be complacent, however, because, as also described in this chapter, new infectious agents continue to be discovered, such as prions, that are considered responsible for BSE and nvCJD and porcine endogenous viruses (PERV). The rapid scientific response to the PERV problem, as measured by the research papers published since 1997 describing highly specific and sensitive assays for detecting these agents (104,105), is reassuring in that it provides evidence that this area of infectious diseases is recognized as important and that the capacity exists for appropriate action in terms of technologies and personnel. These developments augur well for the continued successful screening of cell culture contamination although vigilance is still essential because a new challenge, according to historical precedent, is bound to emerge. The rapid developments in *ex vivo* cell therapies and xenotransplantation involving the use of organs, tissues, or primary cells are a real challenge with regard to the transmission of infectious agents and will clearly need close scrutiny, using protocols described in this chapter, as clinical use of these procedures increases.

CULTURE COLLECTIONS AND BIOLOGICAL RESOURCE CENTERS (BRCs)

DAVID SMITH
CAB International Europe United Kingdom, Egham, United Kingdom

9.1 INTRODUCTION

Culture collections are centers that provide authentic examples of organisms that can be grown or maintained in the laboratory; they normally have a public service role and can provide associated information and services. They can be small and limited in coverage, collected and maintained by single researchers and range through institutional entities to large public service collections covering a broad range of organisms from many sources. They can focus on organism type, for example, fungi or human-derived material and, in some instances, specific genera, on use, for example, industrial enzymes or antimicrobials, on host crops, and they may be linked to a particular sector such as the environment, healthcare, education, or agriculture. Many culture collections have now developed into Biological Resource Centres (BRCs), which give access to high quality biological materials, validated information, and expert services.

9.1.1 Transition toward Biological Resource Centres

The Organisation for Economic Cooperation and Development (OECD) Biological Resource Centre Initiative now defines a Biological Resource Centre (1) as follows:

> Biological Resource Centres are an essential part of the infrastructure underpinning biotechnology. They consist of service providers and repositories of the living cells, genomes of organisms, and information relating to heredity and the functions of biological systems. BRCs contain collections of culturable organisms (e.g. microorganisms, plant, animal, and human cells), replicable parts of these (e.g. genomes, plasmids, viruses, cDNAs), viable but not yet culturable organisms cells and tissues, as well as data bases containing molecular, physiological, and structural information relevant to these collections and related bioinformatics. BRCs should meet the high standards of quality and expertise demanded by the international community of scientists and industry for the delivery of biological information and materials. They should provide access to biological resources on which R&D in the life sciences and the advancement of biotechnology depends.

The OECD BRC initiative to establish the virtual infrastructure Global Biological Resource Centre Network (GBRCN) encourages collections to meet the high quality operational standards required today. In 2007, the results of this seven-year activity were published, *OECD Best Practice Guidelines for Biological Resource Centres* (2). The document delivers the basic rules and best practice as guidance for culture collections. It is intended that BRCs adopt these practices to ensure that users get legitimate and safe access to high quality biological materials and associated information. This best practice brings together the product of decades of research and development. No one single collection can provide the needs of the life sciences and biotechnology. A collaborative approach is necessary with common practices and procedures that allow reproducibility between centers. A global network is under development to improve efficiency by coordinating and driving activities

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

to meet user needs. The BRC has been defined, a global network envisaged, and a capacity building program identified to ensure the functionality of the network and the transition of traditional culture collections to BRCs.

Public service culture collections are charged with several tasks; they are custodians of *ex situ* genetic resources and have a key role to play in their conservation (3). Biologists who collect organisms for their research and publish information on them should deposit key strains in BRCs. This makes them available for confirmation of results and future use in the long term; indeed many scientific journals now require this as a prerequisite to publication. This will aid collections in their major roles of the following:

- the *ex situ* conservation of organisms;
- custodians of national resources;
- provision of living resources to underpin the science base;
- reception of deposits subject to publication;
- safe, confidential, and patent deposit services.

The BRC can support countries establish a means to release the potential of their microbial resources to provide solutions to national economic, environmental, food, and health-care problems and consequently contribute to achieving the Millennium Development Goals. This ambitious agenda for reducing poverty and improving lives can be partially delivered by better management and utilization of biological resources:

- improve livelihoods (Millennium Goal–MG 1);
- provide new sources of food, reduce agricultural losses (MG 2);
- lead to discovery of new drugs and treatments of disease to reduce child mortality and improve maternal health (MG 4, 5, and 6);
- understand and contribute to environmental stability (MG 7);
- develop a global partnership in the conservation and utilization of microbial resources for development (MG 8); and
- resources created from the above can be mobilized to promote gender equality and empower women (MG 3) and achieve universal primary education.

Biotechnology continues to offer a future beyond depletion of our natural resources and can provide a basis for a bioeconomy. More and more natural resource alternatives are being found to provide biofuels, drugs, and neutraceuticals food and beverages. BRCs are knowledge bases necessary to underpin the development of biological based-industries leading to economic development. Research is underpinned by BRCs, an infrastructure that secures the *ex situ* conservation of biodiversity while working in a legal and policy framework to enable access and equitable benefit sharing of biological resources. Collections develop isolation programs, carry out or support organism characterization and screening leading to natural product discovery and added value. Biotechnology is "a global powerhouse with over $60 billion in revenues and hundreds of marketed products, Pharma makes a $6bn spend on candidate compounds with 12% growth each year and Agbio spends $0.6bn" (4). Microorganisms provide an improved route to solutions to several agricultural, environmental, food, forestry, and public health problems, for example, several agents isolated mainly from *Streptomyces* species are in preclinical or clinical development for the treatment of cancer: Rebeccamycin analog (lymphomas and neuroblastoma.); COL-3 (a tetracycline analog) for advanced solid tumors; Bizelesin (a CC1065 analog); UCN-01 (a staurosporine analog); KRN5500 (a spicamycin analog); 17-AAG (17 Allylamino-17-desmethoxy-geldanamycin); and FR 901228 (a bicyclic depsipeptide) (5).

In the field of microbiology and cell culture, there are currently over 520 collections registered with the World Data Centre for Microorganisms (WDCM) and there are countless other collections associated with bioindustry, microbiology laboratories, and research and higher educational establishments (6). A little over 20 WDCM registered collections have some form of independent third-party certification or accreditation to demonstrate the provision of quality services. In other fields, there are similar numbers of collections maintaining other types of biological materials. The OECD Best Practice can be used as a benchmark for culture collections worldwide, and mechanisms to ensure that collections adopt these standards to deliver high quality should be put in place (2). The traditional collection activities are losing pace with technology and user needs, and they require a major shift in their operations and delivery. Advances in molecular biology take authenticity by taxonomy to another level, analytical tools to characterize strain properties are often beyond the reach of the small specialist collections. Access to such expertise and technology might be through partnerships. To achieve access to and utilize the world's biodiversity requires sharing of tasks, and a global network of collections is needed with close links to the user community.

To deliver their services, BRCs preserve their holdings using long-term storage techniques such as cryopreservation and lyophilization depending upon the organism type. Quite often, these techniques require optimization to enable not only survival but also retention of properties. On receipt, a collection should request the depositor to assure that the materials have been collected legitimately and that they are allowed to deposit them. A collection must also have

the expertise and facilities to handle them. There is extensive legislation that impacts upon access to, the safe handling, distribution, and use of biological resources (7–9). A number of culture collection organizations exist to help collections keep up to date in a constantly changing legal framework, notably biosecurity, shipping regulations, and ethical access and use. These include the World Federation for Culture Collections (WFCC) at the global level (10), European Culture Collection Organisation (ECCO) at a regional level (11), and there are several national federations or affiliations.

9.1.2 Sustainability of BRCs

BRCs demonstrate a wide variety of structures and scope, and, consequently, there are differing financial models supporting each. The BRC includes a range of activities directly related to quality control, collection development, and operation that may include opportunities for cost recovery activities. There are the traditional lines of income such as culture supply, identification, and characterization of cultures and private, confidential or patent deposits. Among several potential sources of revenue is the generation of genomics and proteomics data that complement and add value to biological materials themselves. The degree to which such activities may actually provide support sufficient to ensure financial sustainability of a BRC is unproven. However, it is generally expected that most BRCs, whether single larger national centers or smaller distributed or specialized centers, require some degree of core funding by their respective national governments. Other kinds of funding sources include support from industry, grants from agencies that support research, cost recovery through fees-for-service, development of databases, and other tools that compliment the core role of BRCs, and even funding from charitable sources, especially those associated with public health or sustainable development.

As the needs and capacities of individual countries vary, governments should identify collections and centers already capable of or near to being designated as BRCs, and build upon and improve these before starting up new BRCs, especially where resources are limited (1). Similarly, partnerships must be developed among BRCs and appropriate existing agencies, identifying their capacities and interests in terms of support for BRCs. The OECD initiatives ultimate goal is the long-term sustainability of BRCs (1). The OECD task force concluded the following:

- BRCs should be encouraged to coordinate their activities to best serve their essential functions in response to the needs of sectors that depend on their biological resources.
- Governments must be encouraged to provide a baseline of long-term core funding to centers that provide a public service to high standards, to promote their research and development.
- Various foundations and philanthropic or charitable organizations should be asked to extend the level of support.
- Marketable products and services may be developed, including those aimed at meeting regulatory demands and for sale to specialized customers, as long as they do not divert capacity from core activities.
- Industry should be persuaded to take a long-term view of its interests and to offer core support, either through funding or through direct participation in their functioning, provided the latter maintain their independence.

The financial models provided by existing "culture collections" of various types are well recognized and include the following:

- The "General Collection"—often a national/regional facility
  - "popular items" for distribution can guarantee income
  - archive function requires subsidy
- The "specialist collection"—usually more localized
  - the "Institutional Collection"—can provide internal institutional service or wider external community/network service.
  - the "research collection"—provides a service relevant to one or more research interests.

These models vary considerably in the proportion of income derived from the various sources defined below. It must be emphasized, however, that the larger the archiving function carried out for strategic reasons rather than supply, the greater is the need for public and private subsidy.

The OECD Biological Resource Centres Task Force recognized two types of income streams. "Existing" income streams are those that support existing models of culture collections. "Anticipated" income streams represent activities in which BRCs will or may participate and that may generate recoverable income from stakeholders.

9.1.3 Existing Income Streams

- Government support;
- Private industrial support for participation in the functioning of BRCs;
- Private industrial support for internal restricted BRC activities;
- Public and private foundation support;

- Public fundraising;
- Fees for supply of biological resources and technical materials;
- Provision of specialist services and technical consulting expertise;
- Research income (grants and contracts);
- Fees for repository service (safe deposits and patent strain maintenance);
- Provision of technical courses;
- Exploitation of and adding value to genetic resources.

9.1.4 Anticipated Income Streams

- cDNA libraries, genomic libraries, filter sets, clones, plates, PCR products;
- Microarrays and reagents;
- RNAi resources;
- Accreditation/standardization—added value products and services;
- Data storage and retrieval;
- Software development/collaborations—data mining tools;
- Technology development/collaborations—LIMS/robotics;
- Sequence database annotation/phenotypic analysis;
- Linking genomics databases to proteomics;
- MLST (multilocus sequence typing)—population studies.

9.2 CULTURE COLLECTION FUNDING

The World Data Centre for Microorganisms (6) provides key elements of information regarding culture collections, and statistics are summarized annually on the World Federation for Culture Collections (WFCC) website (10). This data demonstrates that governments support 147 of the 525 culture collections registered, which is 20 fewer than 4 years ago, a further 30 (reduced from 33) are semigovernmental, 131 (reduced from 141) are supported by university, 6 are supported by industry, and 18 are private (6, four years ago); over all, the total number of collections have increased by 44 since 2003. It is a fact that availability of governmental funds is reducing, and it is more appropriate that collections should not simply receive core funding but must justify funding by providing services under contract. Collections help meet obligations of governments to the Convention on Biological Diversity and making available biological resources to underpin science, education, and the economy. Collections protect public funding investments in research by preserving the biological materials generated. Government funding is usually balanced against the income received for the various services and products offered by the collection. This leaves very little for investment, to enable the collections to improve their coverage and incorporate new and advancing technologies. Collections need sound and innovative business plans to allow them to keep pace with the ever increasing demands of their users.

The traditional business of collections must be extended by the provision of new products to meet the needs of today's users. Additional products may include DNA, enzymes, metabolites, and other derivatives from authenticated strains. Collections can move beyond this by developing commercial products through the provision of biotechnological solutions through the discovery of active compounds and funding it through public/private investment. The sale of products and services and the delivery of consultancies can be supplemented by research program funding for projects designed to meet donor requirements. The deposit function of collections should also be supplemented by engaging each program funders to protect their investments by paying for deposits in collections and supply of reference strains.

Not only do collections need to find novel ways of funding but they also need to keep abreast and harness new technologies to produce information on the strains, also adding value with the aim to provide today's users with the information they need. Bioinformatics is of increasing importance to the operation of collections and new ways of collecting, storing, analyzing, presenting, and interrogating information are required to make best use of biodiversity information. It is essential, if collections are to survive, that they keep pace with new technologies and user needs, and it is essential that

- BRCs need to function as a strategic, national repository for key academic and industrial research resources, which will in turn provide an income stream.
- Governments and their funding agencies must ensure that products derived from publicly funded research programs are deposited in BRCs as part of the conditions attached to any award.
- BRCs need to provide greater support to researchers in terms of training and advice on standards, quality control, and integrate more with the national activities in key related priority research areas.
- Governments must ensure that infrastructure aspects of the support for research are funded through relevant research programs.
- BRCs must create partnerships with centers of excellence working with and developing new technologies and databases to ensure that linkage is possible

between these leading edge aspects of research and the physical resources held in BRCs.

There is not one financial model that can be applied to all culture collections or BRCs. A combination of governmental funding, income through commercial products and services and research or contract project funding offers the best chance for long-term sustainability.

9.3 OPERATION

BRCs operate to high standards: this includes quality management, compliance with legislation, and, appropriately, the authenticity of biological materials and associated information. The resources a collection provides must meet user needs, be traceable to source, give reproducible performance, and continue to be available over time. BRCs are beginning to publicize their operational management procedures and harmonize their approach by employing common best practices. Here, the World Federation for Culture Collections has provided support with information resources and providing guidance. Full coverage of BRC procedures is presented elsewhere (1,2,7,12); some key elements, long-term preservation, compliance with legislation, quality management, and services provided are presented here.

9.3.1 Preservation of Holdings

The primary objective of preserving and storing an organism is to maintain it in a viable state without morphological, physiological, or genetic change until it is required for future use. Ideally, complete viability and stability should be achieved, especially for important research and industrial isolates. Preservation techniques range from continuous growth methods through to methods that reduce rates of metabolism to the ideal situation where metabolism is suspended (12). Continuous growth techniques involve frequent transfer from depleted to fresh nutrient sources, which initially provide optimum growth conditions; such techniques are not recommended for preservation. The need for frequent subculture can be delayed by storing cultures in a refrigerator, freezer (at -10 to -20°C), under a layer of paraffin oil or in water. Continuous growth techniques are not considered here as they are mainly used for short-term maintenance and they allow deterioration and loss of properties during storage. Drying of the whole cell, propagule, or resting stage of an organism (e.g. spores, cysts, or sclerotia), can be achieved by air drying, in or above silica gel, in soil or sand. Again as such techniques are not always successful and often only allow low numbers of cells to recover; these techniques are not covered here (12).

The methods selected by BRCs must suspend metabolism, which normally involves reducing the water content available to cells by dehydration or cryopreservation. Freeze-drying (lyophilization) is the sublimation of ice from frozen material at reduced pressure and requires storage in an inert atmosphere: either under vacuum or at atmospheric pressure in an inert gas. This technique is not applicable to all cell types. Cryopreservation generally implies storage at temperatures of around -70°C that impede chemical reactions but preferably below -139°C when water structure is normally stable (13). This can be achieved in mechanical deep freezers (some are capable of reaching temperatures of -150°C) or in/above liquid nitrogen (Fig. 9.1).

Desiccation has been used successfully for the preservation of many microorganisms. The removal of water suspends metabolism of the cell. The techniques considered here are freeze-drying and a technique often known as L-drying (12). After a suitable preservation technique is selected and the strains successfully stored, a distribution and seed stock should be kept. An inventory control system should be used to manage stock for distribution and use. After preservation, the viability, purity, and identity should be rechecked and compared with the original results before the culture is made available outside the collection.

Figure 9.1. Cryopreservation in liquid nitrogen. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

The viability, purity, and stability of strains must also be monitored during storage.

No single preservation technique has been successfully applied to all microorganisms, although storage in liquid nitrogen appears to approach the ideal (14). Even this technique can induce changes in physiology, and genetic instability has been observed in some isolates of fungi when suboptimal techniques were applied (15). Preservation protocols often need optimization (16). Organisms that have yet to be cultured in the laboratory, those that require growth on their host, and many delicate organisms can be successfully cryopreserved. In contrast, centrifugal freeze-drying allows only the more robust organisms to survive. In general, it is restricted to some of the microorganisms such as bacteria, fungal spores, viruses, and yeasts. Factors affecting survival are becoming better understood at the subcellular level, but many strains from a wide range of species remain difficult to preserve. Cell growth conditions, suspension media, cryoprotectant, and cooling rates must all be optimized. There is no apparent relationship between survival and taxonomic position, although structure such as thickness and composition of cell wall, volume–surface ratio, and the shape of the cell play an important part; the factors determining survival tend to be strain specific (12). Unfortunately, a preservation method that is satisfactory for one strain of a species may be unsuitable for others. If strain stability is of paramount importance, the choice of maintenance method becomes critical.

Lyo-injury can occur during the cooling and/or drying stages (17). The phase changes encountered during the drying process can cause the liquid crystalline structure of the cell membranes to degenerate to the gel phase, which disrupts the fluid-mosaic structure of the membrane (17). This causes leakage of the membrane, which may culminate in cell damage. Optimal survival can be improved with the use of a suitable lyoprotectant. This medium should be readily available, easy to prepare, and provide protection during the freeze-drying process (i.e. to protect the spores/cells from ice damage during cooling and storage problems such as oxidation). Skimmed milk is a suitable lyoprotectant and is sometimes used in combination with inositol. Saccharides such as trehalose (17,18) protect membranes by attaching to the phospholipids, replacing water and lowering the transition temperature. Other suspending media can be used, for example, Tan *et al*. (18) suggest that a mix of dextran and trehalose improves viability. The recommended final moisture content following drying is between 1 and 2% (w/v). To monitor freeze-drying, a means of measuring vacuum both in the chamber and close to the vacuum pump is required. A pressure rise test can be conducted to determine the end point of the drying process. When the values are equal, water has ceased to evaporate from the material being dried and drying is probably complete. This is confirmed by determining the residual water content, for example, determined by dry weight or by the use of chemical methods (19). The stability of the freeze-dried product is dependent on the stability of the frozen water, a glass, which is the result of the dehydrated lyosolution. The product should be stored below the glass transition temperature, where the solid shifts into the liquid phase.

The technique of centrifugal freeze-drying, which relies on evaporative cooling, can be used successfully for the storage of the bacteria, many sporulating fungi, and yeasts (12). However, this is not a method that can be adapted and changed easily, as it is dependent upon the scope of the equipment. The variety of final freeze-dried product available demonstrates this (Fig 9.2). Optimization of cooling rate to suit the organism being freeze-dried can be applied using a shelf freeze-drier. The sealing of the ampoules or vials is most important, and heat sealed glass is preferred to butyl rubber bungs in glass vials as these leak over

Figure 9.2. There is a vast array of freeze-drying equipment on the market, ranging from laboratory bench models through pilot scale plant to huge industrial installations. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

long-term storage, release toxic gases, and allow deterioration of the freeze-dried organism. There are many advantages of freeze-drying over other methods, including the total sealing of the specimen and protection from infection and infestation. Cultures generally have good viability/stability and can be stored for many years. Ampoules take up little space and can be easily stored. In addition, cultures do not have to be revived before postal distribution. However, there are disadvantages, some isolates fail to survive the process and others have reduced viability and may show genetic change (15,20), though unless high viability is retained it is difficult to differentiate between this and selection of spontaneous mutants by freeze-drying (21). Ampoules of freeze-dried organisms must be stored out of direct sunlight and chilled storage reduces the rate of deterioration and extends shelf-life.

The ability of living organisms to survive freezing and thawing was first realized in 1663 when Henry Power successfully froze and revived nematodes (13). Polge *et al*. (22) became the first "modern-day" scientists to report the freezing of living organisms when they successfully froze and thawed avian spermatozoa in glycerol. Liquid nitrogen is the preferred cooling agent for cryopreservation, although liquid air or carbon dioxide can be used. Lowering the temperature of biological material reduces the rate of metabolism until, when all internal water is frozen, no further biochemical reactions occur, and metabolism is suspended (23). Provided adequate care is taken during freezing and thawing, the culture does not undergo change, either phenotypically or genotypically (24).

Cryoprotection is achieved by the following:

1. noncritical volume loss by the reduction of ice formation;
2. an increase in viscosity that slows down ice crystal growth and formation and solute effects;
3. reduction in the rate of diffusion of water caused by the increase in solutes.

Glycerol 10% (v/v) gives very satisfactory results and is generally the cryoprotectant of choice for most organisms. Dimethyl sulfoxide (DMSO) penetrates rapidly and is often more satisfactory but it can be toxic and mutagenic, and exposure in the unfrozen state must be kept to a minimum (25,26). Sugars and large molecular substances, such as polyvinyl pyrrolidine (PVP) (27), have been used but in general have been less successful (12). Trehalose may be better but is expensive. Establishing the optimum cooling rate has been the subject of much research (12,28,29). Slow cooling at 1°C/min over the critical phase has proved most successful (12), but some less sensitive isolates respond well to rapid cooling, some without protectant. Slow warming may cause damage owing to the recrystallization of ice, therefore rapid thawing is recommended. Slow freezing and rapid thawing generally give high recoveries for many organisms (21).

As with other methods of preservation, cryopreservation, in or over liquid nitrogen, has advantages and disadvantages. Advantages include the length of storage, which is considered to be effectively limitless if storage temperature is kept below −139°C. Most of the organisms survive well, giving the method a greater range of successful application. Organisms remain free of contamination when stored in sealed ampoules. The samples can be stored in the liquid phase, which regulates the low storage temperature better but increases hazards on retrieval and if seals are permeable the liquid can penetrate. If storage is in the gaseous phase above the liquid, temperature can fluctuate but can be stabilized by storing in an inner chamber which is immersed in liquid. Disadvantages of liquid nitrogen storage include the high cost of apparatus such as cryostorage tanks and a continual supply of liquid nitrogen. A regular supply cannot be obtained in some parts of the world and therefore the technique cannot be used. If the supply of nitrogen fails (or the double-jacketed, vacuum-sealed storage vessels corrode and rupture), then the whole collection can be lost. Backup storage is required at a separate site as with all preservation techniques. There are also safety considerations to be made: the storage vessels must be kept in a well-ventilated room equipped with an automatic monitoring device for oxygen content of air, as the constant evaporation of the nitrogen gas could displace the air and asphyxiate workers.

9.3.2 Biological Resource Management and the Law

Organisms are isolated, grown, characterized, preserved, and are transported between laboratories within countries and often across borders or continents. They are sent for identification, reference, research, or for production purposes from colleague to colleague, from and to culture collections. All these actions must be carried out safely and must be compliant with the various legislation and regulations that control these matters. Not only is there legislation in place (Table 9.1) but also from time to time it is changed or added to. Some of the key areas covered are health and safety, quarantine regulations, ownership of Intellectual Property Rights (IPR), the Convention on Biological Diversity, safety information provided to the recipient of biological materials, and regulations governing shipping of dangerous organisms. It is not only in the laboratory that there is cause for concern, as, for example, a microorganism in transit might put carriers, postal staff, freight operators, and recipients at risk, some organisms being relatively hazard free while others are quite dangerous. It is essential that safety and shipping regulations are followed to ensure safe transport. There are several other pieces

[a] Taken from OECD Best Practice Guide Lines (2).

of legislation that restrict the distribution of microorganisms of which a microbiologist must be aware. The World Federation for Culture Collections (WFCC), the European Biological Resource Centre Network (EBRCN) partners, and the OECD Task Force have drawn together a list of treaties, directives, and legislation that impact on culture collection operations (Table 9.1).

The starting point for correct control procedures is a risk assessment (7,12,30), which must include all hazards involved. For example, with microorganisms, it is not just pathogenicity that is considered, but also other hazards like the production of toxic metabolites and the ability to cause allergic reactions. It is the responsibility of the microbiologist to provide such assessment data to a recipient of a culture to ensure its safe handling and containment.

Best practice involves the following:

- adequate assessment of risks;
- provision of adequate control measures;
- provision of health and safety information;
- provision of appropriate training;
- establishment of record systems to allow safety audits to be carried out;
- implementation of good working procedures.

Various classification systems exist to grade the degree of hazard and risk, which include the definitions for classification by the World Health Organisation (WHO); United States Public Health Service (USPHS); Advisory Group on Dangerous Pathogens (ACDP); European Federation of Biotechnology (EFB); and the European Union. In Europe, the EC Directive (93/88/EEC) on Biological Agents sets a common base line, which has been strengthened and expanded in many of the individual member states. The definition and minimum-handling procedures of pathogenic organisms are set by appropriate authorities in each country and are often the same or similar for all EC countries. Microorganisms are normally classified on their potential to cause disease to humans into four groups (30):

Group 1. A biological agent that is most unlikely to cause human disease.

Group 2. A biological agent that may cause human disease and which might be a hazard to laboratory workers but is unlikely to spread in the community. Laboratory exposure rarely produces infection and effective prophylaxis or treatment is available.

Group 3. A biological agent that may cause severe human disease and present a serious hazard to laboratory workers. It may present a risk of spread in the community but there is usually effective prophylaxis or treatment.

Group 4. A biological agent that causes severe human disease and is a serious hazard to laboratory workers. It may present a high risk of spread in the community and there is usually no effective prophylaxis or treatment.

All strains must be assigned to appropriate risk groups; this includes a positive assignment to risk group 1 unless otherwise considered hazardous. All other groups have lists of species included but there is no such list for those organisms not considered hazardous. Hazard information must be recorded and made available to recipients of this material. It is not only the handling of organisms that harm humans that are controlled. All those who wish to obtain or work with plant or animal pathogens must also be aware that there are regulations that impact on operations. Cultures of nonindigenous plant pathogens require a permit to import, handle, and store from the appropriate Government Department. Under the terms of such a licence, the shipper is required to see a copy of the Ministry permit before such strains can be supplied. It is best practice that the holder of such organisms must ensure that nonindigenous pathogens or controlled indigenous pathogens are not distributed unless the recipient has an appropriate licence. However, this is not always straightforward as not all countries provide lists.

A biologist must first seek permission before collecting biological material; rules for access and benefit sharing may differ from country to country. Terms and conditions for use or further distribution may exist, for example, Intellectual Property Rights or those negotiated with Prior Informed Consent, granted under the Convention on Biological Diversity (CBD). A collector is required to agree to terms on which benefits will be shared should they accrue from the use of the organisms. The benefit sharing may include monetary elements but may also include information, technology transfer, and training. A BRC must ensure transparency retaining the link between the source country and end user of genetic resources. Biological materials must be received and supplied within the spirit of the CBD ensuring material transfer agreements are in place. A BRC must maintain contact and follow recommendations of its national CBD Contact Point (31). When biological material is distributed to others, information should always be provided to enable recipients to comply themselves. This involves data on ownership of IP and must include a safety data sheet indicating which hazard group it belongs to and what containment and disposal procedures are necessary. A safety data sheet accompanying a microorganism should include the following:

- the hazard group of the organism being despatched
- a definition of the hazards and assessment of the risks involved in handling

- requirements for the safe handling and disposal of the organism.
  - containment level
  - opening procedure for cultures and ampoules
  - transport
  - disposal
  - procedures in case of spillage.

When shipping cultures, the International Air Transport Association (IATA) Dangerous Goods Regulations (DGR) may be relevant, which require that shippers of microorganisms of hazard groups 2, 3, or 4 must be trained by IATA certified and approved instructors (every 2 years). They also require shippers declaration forms, which should accompany the package in duplicate and specified labels should be used for organisms in transit by air (32). Essentially, IATA DGR requires that packaging used for the transport of hazard group 2, 3, or 4 meets defined standards of a UN combination package, IATA packing instruction 602 (class 6.2) (32). Packaging must meet EN 829 triple containment requirements for hazard group 1 organisms (33).

There is considerable concern over the transfer of selected infectious agents capable of causing substantial harm to animal, human, and plant health and to the environment. There is potential for such organisms to be passed to parties not equipped to handle them or to persons who may make illegitimate use of them. Of special concern are pathogens and toxins causing anthrax, botulism, brucellosis, plague, Q fever, tularaemia, and all agents classified for work at Biosafety Level 4 (risk group 4). The "Australia Group" of countries has strict controls for movement outside their group but has lower restrictions within. Collections that hold dangerous organisms that are pathogens or produce toxins that could be misused or cause harm must recognize requirements for biosafety and biosecurity. Biosafety concerns the health aspect, the protection of people during normal functioning of a BRC, and biosecurity concerns the legal and regulatory arrangements governing the possession and circulation of biological products reputed to be hazardous, and sanctioning malicious use of such products. The degree of hazard that a biological resource presents must be treated separately to the issue of biosecurity, for example, the prevention of terrorism. The question of biosafety arises wherever biological material and associated information is handled. Biosecurity and biosafety affect many aspects of culture collections, their operation, and their external relations:

- worker safety and health aspects
- security of facilities and transport
- public and environmental protection (containment)
- safeguarding resources
- prevention of bioterrorism.

Hazardous biological material must be available for study to provide public health solutions and tools for protection and therefore collections must be able to store, conserve, and distribute such materials, ensuring that their own development and activity does not increase risks. Access to such resources must be controlled and thus culture collections have a role in enhancing the general level of biosecurity. The OECD BRC Beat Practice (2) has laid down guidance mechanisms that reduce the possibility of misuse; it is critical that such controls do not impede the legitimate use of such agents. Current rules and regulations differ from country to country and demonstrate clear problems of exchange. The OECD Best Practice initiative provides common rules that can be used worldwide. If during an epidemic of a new disease (e.g. SARS), exchanges of materials between laboratories and countries were not possible then the identification of the causative organism and the production of potential treatments would have been impeded. There have to be culture collections to meet the needs of science, but culture collections are inherently vulnerable. There must be a guarantee that they will not serve the purposes of terrorist movements, facilitate theft of hazardous products or endanger confidentiality, staff safety, intellectual property, and so on. Exchanges between collections and users must be traceable, for example, through Material Transfer Agreements (MTAs).

Identifying those organisms that should be controlled is not straightforward because there are so many lists that are not coordinated. The Australia group provides a list of what are considered to be the most dangerous pathogens but individual country lists of these differ. Nevertheless, a collection must follow its national rules, but how does it check the validity of the requestor and the end use of the material to be supplied? Can it rely on the statement of a potential customer? A collection does not have the power or the resources to investigate. The UK National Collections have been set rules so that when the end use or validity of the potential recipient is in doubt, there is a mechanism for the government to investigate.

Governments could in the long run prohibit direct trade in hazardous biological products between unauthorized parties. The purpose of the restrictions of the OECD best practice is to prevent uncontrolled transfers, to monitor distribution, and ensure traceability of products transferred by culture collections—not to interfere with research or with property rights. The obligation for international transfers to go through collections could be an important factor for increasing trust and therefore stimulating trade.

9.4 QUALITY MANAGEMENT

There are numerous sources of information on best practice, guidelines, and protocols for the management of biological resources. They have been compiled by the expertise in individual collections and of organizations such as the WFCC, EU projects such as the European Biological Resource Centres Network (EBRCN), the Common Access to Biological Resources and Information (CABRI) consortium, and the UK National Culture Collection (UKNCC). Such standards have been drawn together by the OECD BRC Task Force (2). However, mechanisms must be adopted to ensure user confidence that these practices are being followed. One system that might be adopted by the national Governments where the BRCs reside might be that of the International Standards Organisation (34). Currently, there are a number of standards or guides that could be used that cover at least part of the activities of BRCs. Several collections have already adopted ISO 9001: 2000 certification (Table 9.2), a system that ensures quality through critical management of processes. The system requires that procedures and practices are documented and that auditing procedures are put in place to ensure that what is said is actually carried out. A key element of the ISO 9001: 2000 is directed at improving customer satisfaction and the implementation of product improvement mechanisms. Examples of standards developed for microbial and cell culture collection*s* are as follows:

- the WFCC *Guidelines for the establishment and operation of collections of microorganisms* (35);
- the Microbial Information Network for Europe (MINE) project standards for the member collections (36);
- UKNCC quality management system (37);
- CABRI guidelines (38);
- the OECD Best Practice Guidelines for Biological Resource Centres (2).

There are also standards that can be applied to microbiology laboratories such as Good Laboratory Practice (GLP), ISO 17025, ISO Guide 34, *General requirements for the competence of reference material producers*, and, as described above, ISO 9001: 2000. Industry is expressing the need for quality control and standards within collections. The UKNCC quality management system set minimum standards (12) and the CABRI electronic catalog project (38) has made available a set of guidelines to aid collections to put best practice in place. These cover critical elements in the handling, storage, characterization, and distribution and handling of associated information. Ultimately, BRCs should adopt the OECD best practice (2) to ensure user satisfaction and reproducibility.

TABLE 9.2. Collections Operating Independent Third-Party Assessed Certification or Accreditation Quality Management Systems

Collection	System
AGO—Arocrete Group Co., Taiwan	ISO 9001:2000
BIOCEN (BioCC)—Centro Nacional de Biopreparados, Cuba	ISO 9001:2000
CABI—CAB International Genetic Resource Collection, UK	Part of services to ISO 17025
CBS—Centraalbureau voor Schimmelcultures	ISO 9001:2000
CCCM—Czech Culture Collection of Microorganisms	ISO 9001:2000
CCRC—Culture Collection and Research Center, FIRDI, Taiwan	ISO 9001:2000
CECT—Coleccion Espanola de Cultivos Tipo, Spain	ISO 9001:2000
CIP—Collection de l′Institut Pasteur, France	ISO 9001:2000
DSMZ—Deutsche Sammlung von Mikroorganismen und Zellkulturen, Germany	ISO 9001:2000
ECACC—European Collection of Cell Cultures, UK	ISO 9001:2000
ICLC—Interlab Cell Line Collection; Italy;	GMP
IFM—Quality Services Pty Ltd, Australia	ISO Guide 34

LMBP—Plasmd collection, Belgium	ISO 9001:2000
LMG—University of Gent, Belgium	ISO 9001:2000
MUCL—Mycology, University Louvain la Neuve, Belgium	ISO 9001:2000
NBRC—NITE Biological Resource centre, Tsukuba, Japan	ISO 9001:2000
NCIMB—National Collection of Industrial, Food, Marine Bacteria, UK	ISO 9001:2000
NCPV—National Collection of Pathogenic Viruses, UK	ISO 9001:2000
NCTC—National Collection of Type Cultures, UK	ISO 9001:2000
NCYC—National Collection of Yeast Cultures, UK	ISO 9001:2000

Best practice demands that the culture collection performs authentication tests and establishes baseline information for in-storage maintenance checks and validation after preservation. The OECD best practice guidelines (2) advise that competent persons carry out such operations and that a maintenance plan for periodic control is put in

place for each organism preserved. The OECD best practice provide guidance at two levels, that applicable to all BRCs holding biological material and a second level that makes domain-specific recommendations. In 2007, the latter covered the microbial domain, being the most advanced followed by the guidelines for human-derived material. At the general level, it is recommended that biological material be preserved by at least two methods but if two distinct methods are not applicable, it is recommended that cryopreserved stocks be maintained in separate locations. It is best practice to lay down master cell banks from which further stocks for distribution can be sourced. The details of the techniques are laid down in the domain-specific criteria (2). The guidance requires that the number of transfers or generations of original material before preservation and storage be kept to a minimum, the master stock be created from the original material, and that sufficient distribution stocks are produced to minimize the need to go back to stocks for replenishment. The material should be stored under environmental parameters that assure the stability of properties, and additionally details of inventory control, lead times, and restocking practices be documented and that duplicate collections be maintained. The guidance requires the validation of methods and the recording of such details. Finally, quality audits and review procedures should be in place. Such practices are becoming more common in collections as automation and technology is developed to help manage such processes. In mycology, data is available on many common species to enable the selection of best protocols and assess stability but it is far from complete. Cryopreservation is by far the best technique for the storage of fungi (12,15) but there is not one protocol for all. Of the 250 species investigated at CABI, 248 had different optimum cooling rates from 0.5 to 200°C/min, although most fungi survive well, albeit with some cell death at 1°/min cooling in 10% glycerol as cryoprotectant. Molecular techniques such as DNA fingerprinting are used to assess stability, and poor technique has been shown to cause polymorphisms (15).

The more specific best practice guidelines for the microorganisms are aimed to ensure that the organisms held and supplied are authentic and of the highest standard. The methods used should be such that the key properties of the microorganisms are retained and should ensure their consistency amongst the BRCs supplying them. To meet requirements, BRCs must put in place documented and audited processes. On receipt, a unique number is assigned to the strain and its identity confirmed using, for example, morphological characteristics, if appropriate or sequencing of the 16S ribosomal RNA or the ITS region of the genome. This adds to the strain data, which can be used as a baseline for monitoring the strain following preservation and storage. Additional characters that can be useful to test stability are growth rates, descriptive data, photomicrographs, metabolic profiles, and genome fingerprinting techniques. Strains must be pure or defined mixtures. The purity of strains should be checked and recorded before preservation, immediately after, and, depending on the method, during storage. For fungi, this is normally done through microscopic examination or growth in broth particularly to detect bacterial contamination. The preferred standard would be that no contamination at all is accepted. There are exceptions where strains cannot be grown without their symbiont, host, or feeder organisms; these are not contaminants but it would be imperative that the components of such mixtures are described, recorded, and defined. Viability of strains, normally expressed as a percentage of propagules to produce colony growth, should be checked and recorded before preservation, immediately after and during storage. The frequency of testing depends upon the method used and the organism involved: cryopreserved strains need testing least frequently, freeze-dried materials more regularly, depending on the storage temperature. The data obtained demonstrates if a strain is deteriorating during storage. Preferred levels of viability are often set according to the organism. In the case of fungi, survival is normally relatively high or nil but in the bacteria titre drops vary and may well be in excess of threefold. Once set, any deviation from the standard requires explanation and must be recorded.

A program of tests to ensure stability of strains must be put in place. Known properties can be checked periodically but full metabolic profile checks are seldom necessary on a regular basis. However, to be able to judge stability, a less stable property should be selected to indicate how well a strain is being maintained. It must always be borne in mind that preservation protocols are not natural and that cells need a period of time to recover. Optimized techniques and standard procedures should be adhered to. It is necessary that procedures are documented, so that all coworkers and their successors can follow them and that in the future the methods and the treatments used can be traced. This would include all measuring and recording techniques from viability and purity checks through preservation methods to characterization and the checking of properties. The accepted level of deviation from measurable parameters must be set and records maintained to show that performance is within the accepted limits. A procedures manual is essential to ensure continuity and new staff must be trained to ensure the attainment of the standards set. Training must not only include how to carry out methods but also the accepted levels of result, monitoring, and what must be recorded and where data is maintained. All equipment used in the BRC must be regularly maintained and calibrated and must operate to set limits. All details must be recorded so that you can ensure traceability and reproducibility.

There is little point in establishing a collection without considering the long-term security of its holdings. If procedures are put in place that cannot be maintained in the future, then a considerable waste of time and resources is inevitable. Freeze-dried collections need little maintenance. A frozen collection needs only to be kept cold. A collection must ensure that there is a backup, organisms should be stored by a minimum of two techniques, and that both working and security stocks are maintained. It is also advisable to keep a duplicate collection in another secure building or site as a reserve. At least all important strains should be stored on another site with all the information about them as a disaster measure. It is essential that adherence to set standards is monitored at every level. The appointment of auditors from other departments, or even from outside the organization (required for many accreditation schemes), is beneficial. The recording of such monitoring is vital to demonstrate competence, and self-checks should be part of a good management system. There are several national and international schemes that can be followed to give a standard of quality assurance accepted by a collection's customers. There is no accreditation scheme that has been specifically designed for culture collections but using the OECD BRC best practice alongside recognized schemes is being explored and deemed appropriate by several accreditation bodies. High standards are required to meet the requirements of the users of microbial resource collections of today. At the very least, this requires set methods and levels of acceptability, recording of results, and an independent monitoring system to enable the long-term security and sustainability of holdings. Underpinning the quality system is the maintenance of the biological resources without change.

The underlying ethos is that the user benefits from the accreditation of culture collections through better access to authentic and reproducible materials in a transparent and traceable way. There must be benefits for the collection to provide incentive to change. There is an ever-increasing demand for authentic reference materials as more and more industries are adopting certification or accreditation as a means to demonstrate quality and competence. This may be the driving force for the business elements of a collection's strategy for long-term sustainability, but it is also an increasing requirement of funders of research who seek high quality science and solutions. The ability to demonstrate the competence to carry out and manage high quality research is being recognized by Research Councils and Government Departments. Third-party evaluation through accreditation or certification may be the only way to demonstrate this.

9.5 SERVICES

A BRC offers other services in addition to supply of biological materials and associated information. Among such services are the identification of organisms, their biochemical and molecular characterization, bioaudits, challenge testing, training and contracting, and consultancies engaging their broad multidisciplinary expertise (12). The individual member collections of the WFCC offer identification by a range of techniques for many organisms including actinomycetes, algae, animal cells, bacteria, cyanobacteria, filamentous fungi, nematodes, protozoa, mycoplasma, and yeasts. Techniques used for strain identification include anatomical and morphological analysis, FAME analysis, several automated commercial systems, biochemical and molecular fingerprinting, and sequencing. The collections that provide the service and methods used are listed on the World Data Centre for Microorganisms (WDCM) website (6) and in Table 9.3.

BRCs strive to optimize preservation protocols and to develop new ones. Most research is aimed at improving cryopreservation methodology with emphasis on species specific criteria. In addition to their culture collection activities, most collections, in association with their parental organizations can offer external organizations

TABLE 9.3. Some Identification Methods Used by Collections for Strain Identification

{PRIVATE} Organism	Technique				
	Morphological	MIDI	BIOLOG	Biochemical	Molecular Fingerprinting and Sequencing
Actinomycetes	+	+		+	+
Algae	+			+	+
Animal cell lines					+
Bacteria	+	+	+	+	+

TABLE 9.4. Service Activities of Culture Collections

Service/Activity	Benefits
Patent deposit service	A facility for deposition of strains included in patent applications in to meet national legislation and also where applicable in compliance with the Budapest Treaty.
Safe deposit service	Provides the microbe-based industries with a facility to preserve their strains for long- term storage; ensuring a backup strain is kept in a safe and secure facility. Loss of these industrially important strains could mean a tremendous setback in the operations of a company.
Microbial diversity R&D	Contract research, for example, novel microorganisms with potential applications in agriculture, medicine, industry, and so on.
Preservation by lyophilization	Preserving strains for laboratories without such facilities and providing them with the ampoules to store and use.
Human resource development	Training courses and other modes of continuing education contributing to the enhancement of quality of research in areas related to patenting, bioprospecting, and conservation of microorganisms for various applications in the pharmaceutical, food, and other microbiologically based industries. Capability building where gaps exist. Training of trainers, to provide in-country teaching resource,
Supply of cultures	Cultures that are being distributed may be used in the production of certain desirable end-products in the food, pharmaceutical and other microbe-based industries and screened for other properties. Reference strains are a must in microbial systematics work, thus providing authenticated cultures for instruction and research purposes improves the quality of research and teaching. Microbial cultures are also used in strain improvement work to further enhance the organism's desirable traits, foe example, alcohol production, antibiotic production, and so on. Standard test strains with reproducible properties.
Complete microbiological analysis/total count	Providing information on the microbial content of a given sample, which is important in the formulation of microbe-based products like biofertilizers, inoculum, and so on. Knowledge of the right kinds and number of microorganisms is necessary to produce high-quality products for field application to improve yields of agricultural crops and other products. Providing information on the quality of raw materials that will be used in production. Knowledge of the types of microflora in the raw material will enable a producer to decide whether to discard a contaminated raw material or modify their production processes.
Microbiological analyses of food and water	Provides information on the quality of food and water—whether they are safe for human consumption or are suitable for use in the production of certain products requiring high-quality water.
Identification services	Provides value-added information on the morphological, biochemical, and molecular fingerprinting, chemical composition and sequencing; also other properties of an unknown isolate.
photomicroscopy anti microbial sensitivity testing	Information generated by fluorescence microscopy giving indication of organism sensitivity to antimicrobials.
cytotoxicity assays	Information generated on toxicity of cells and their products.
phytosanitary testing	Presence or absence of specific pathogens on crops and commodities.
developing screens	Producing assays to detect properties of strains.
development of diagnostic kits for the early detection of pathogens	To aid in the early detection of animal and human foodborne and water-borne pathogens.

a diverse range of consultancy and contract services (Table 9.4). Areas such as biodeterioration, biodegradation, biological control, biodiversity, ecology, parasitology, pest management, biochemistry, molecular biology, taxonomy, identifications, metabolite and enzyme screening, analytical chemistry, food and beverage microbiology, process development and large-scale culture, stored product microbiology, plant pathology, evaluation of microbial identification kits, and environmental monitoring are covered (6,12).

A range of deposit services are offered, BRCs normally accept deposits of strains that meet their accession criteria and that are of value to the scientific community into their open collections, making them available in their public catalogs. There are other deposit services they may offer, if a depositor wishes to store materials but not make them publicly available collections often offer a confidential safe deposit service. Patents may be taken out to protect Intellectual Property Rights (IPR). In many cases, the organism involved must be part of the disclosure and many countries

either recommend or require by law that a written disclosure of an invention involving the use of organisms be supplemented by the deposit of the organism into a recognized culture collection. Most patent lawyers recommend that the organism is deposited, regardless of it being a requirement, to avoid the possibility of the patent being rejected. To remove the need for deposit of organisms in a collection in every country where patent protection is desired, the "Budapest Treaty on the International Recognition of the Deposit of Micro-organisms for the Purpose of Patent Procedure" was concluded in 1977 and came into force toward the end of 1980 (39). This recognizes named culture collections as "International Depository Authorities" (IDA) and a single deposit made in any one is accepted by every country party to the treaty. Any collection can become an IDA, provided it has been formally nominated by a contracting state and meets certain criteria. There are 32 IDAs around the world (Table 9.5) that accept patent deposits of human and animal cell lines, algae, bacteria, cyanobacteria, fungi, nematodes, nonpathogenic protozoa, plant seeds, and yeasts.

9.5.1 Organization and Information Resources

To meet new and increased demands, collections have recognized the need to network. Culture Collection organizations such as the WFCC and the ECCO act as fora for discussion bringing together a critical mass of collections and users to try and coordinate activities, exchange information, and technologies to facilitate progress in this vital task. This is happening at the national, regional, and global levels.

9.5.2 The World Federation for Culture Collections

The WFCC, a key global organization, was founded in 1970, its roots dating back to 1963, and since 1973 is a multidisciplinary commission of the International Union of Biological Sciences (IUBS) and since the separation of the International Union of Microbiological Societies (IUMS) from IUBS in 1979 it has operated as an interunion commission (10). It seeks to promote activities that support the interests of culture collections and their users. Member collections of the WFCC register with the World Data Center for Micro-organisms (WDCM) and there are currently ~520 registered collections (6) in 67 countries with

UKNCC	UK National Culture Collection –UK affiliation of national collections	http://www.ukncc.co.uk

over 2000 staff. A congress is held every 3 years to discuss advances in technology and common policies with regard to biodiversity and the role of culture collections. The WFCC keeps its members informed on matters relevant to collections in its Newsletter and has working programs addressing patent depositions, biosafety and biosecurity, safeguard of endangered collections, capacity building, and quality standards. Since 1986, the WFCC has overseen the activities of the World Data Centre (WDCM), which is now the data center for the WFCC and Microbial Resource Centers (MIRCENs) Network. It was established in 1966 and produced the first hard copy volume of the *World Directory of Collections of Cultures of Microorganisms* in 1972, while based at the University of Queensland, Australia. The WDCM relocated in 1986 to RIKEN, Saitama, Japan and then again in 1999 to the National Institute of Genetics, Japan. The WDCM collections hold in excess of 1.7 million strains (Table 9.6), 44% are fungi, 43% bacteria, 2% viruses, 1% live cells, and 10% others (including plasmids, plant, animal cells, and algae).

The WFCC is the largest independent global organization that represents professional individuals and culture collections, which preserve biodiversity and enable their proper use. They target living microorganisms, cell lines, viruses, and parts and derivatives of them. Key values are authenticity and genetic integrity of the material and validity of the information provided. The WFCC supports the professionals, organizations, and individuals with interests in culture collection activities through the following:

- networking, providing information and expertise, and facilitating communication;
- facilitating access to the collection resources;
- providing training and promoting partnerships;
- encouraging the development and implementations of quality and security procedures and the use of common standards and regulations;
- representing member interests in international organizations and fora; and
- promoting the establishment of culture collections, their promotion, and perpetuation.

TABLE 9.6. World Data Centre for Microorganisms (WDCM)

Country	Number of Collections	Number of Strains	% of Total Number of Strains
Africa	11	12,255	0.7
Asia	177	322,195	18
Europe	173	1,005,930	57.3
America	121	326,297	19
Oceania	43	89 786	5
Total	*525*	*1,756,463*	

In the growing bioeconomy, WFCC's members face increasing global demands for worldwide and controlled access to biological resources, public security, industrial quality of their holdings and associated data, and long-term genetic stability of the material. The key to the use of microorganisms from culture collections is the retention of their properties as research and development must be based on authentic and well-preserved biological material. The WFCC have been helping collections in this respect for over three decades and have produced *Guidelines for the Establishment and Operation of Culture Collections* (35). It is a goal that strains of organisms are supplied from member collections with traceability, conforming to national and international regulatory requirements, and that they are preserved in such a way as to retain their full potential.

9.5.3 The Asian Consortium for Microbial Resources

The Asian Consortium for the Conservation and Sustainable Use of Microbial Resources (40) was established by the consensus of representatives of 12 Asian countries during the *10th International Congress of Culture Collection (ICCC-10)* held at Tsukuba in 2004. Head of culture collections and government officers were involved in the meeting along with research microbiologists. The objective of the consortium is to promote collaboration among government or public organizations in Asian countries for the purposes of enhancing conservation and suitable use of microbial resources in Asia. The current member countries are Cambodia, China, Indonesia, Japan, Korea, Laos, Malaysia, Mongolia, Myanmar, Philippines, Thailand, and Vietnam.

The planned activities of the consortium are as follows:

1. development of human resources;
2. promotion of research and development on microbial resources and their application in industrial and other uses;
3. collaboration through the network of biological resource centers;
4. exchange of views and information;
5. enhancement of public awareness on the consortiums activities for the conservation and sustainable use of microbial resources; and
6. organization of scientific meetings (seminars, workshops, etc.) and other related matters

The General Assembly Meeting of the Asian Consortium for Microbial Resources is held annually to set up task forces for Bioresource Information Management and for Human Resource Development.

9.5.4 European Culture Collections' Organization

The European culture collections have collaborated since 1982 when the European Culture Collection Curators Organisation was established to bring together the managers of the major public service collections in Europe to discuss common policy, exchange technologies, and seek collaborative projects. The organization opened itself to staff and users of collections and is now named *the European Culture Collection Organisation (ECCO)*. There are currently 65 members, of which there are 57 collections holding ~350,000 strains. The members have been involved in producing practical approaches to international rules and regulation. Initiatives led by the Belgian Co-ordinated Collections of Microorganisms (BCCM™) have produced a practical code of practice for collections to operate within the Budapest Treaty (41) and the Micro-Organisms, Sustainable Access and use, International Code of Conduct (MOSAICC), which provides guidelines for operation within the spirit of the Convention on Biological Diversity (42). There have been several collaborative projects developed out of discussions between ECCO members that have placed the European Collections at the cutting edge of culture collection activities and research. Examples are the European Biological Resource Centre Network (EBRCN), which followed on from the Common Access to Biological Resources and Information (CABRI) electronic catalogue project. Information on members, activities, and meetings can be accessed via the web site (43).

9.5.5 Microbiological Resource Centres

In 1974 UNEP, UNESCO, and ICRO established the Microbiological Resource Centres (MIRCEN) network. The objectives of this network are to preserve and exploit microbial gene pools, make them accessible to developing countries, and to carry out research and development in environmental microbiology and biotechnology. The 34 MIRCENs carry out various activities that meet these ends including training and provision of information. Further details can be obtained from the MIRCEN Secretariat at the United Nations Educational Scientific and Cultural Organisation (UNESCO), Paris, France (44). The production of MIRCEN News in 1980 helped publicize the activities of the network; this has now broadened in content and is published as the World Journal of Microbiology and Biotechnology.

9.5.6 National Federations and Affiliations

There are several countries that have established national organizations that support, foster, or coordinate culture collection activities (Table 9.7). Among them is the United Kingdom. The UK Federation for Culture Collections (UKFCC) was established at its inaugural meeting on the 10 April 1975 at Imperial College London. Membership of the Federation is open to all those involved with culture collections and the users of cultures including those from academia and commercial organizations.

The Objectives of the UKFCC are as follows:

- aid the establishment and promote the use of culture collections
- facilitate communication between culture collections and their users
- make every effort to save endangered collections of important cultures;
- encourage establishment of special reference collections and identification services;
- promote research in systematics, microbial diversity, and preservation;
- promote the training of personnel in the operation of culture collections;
- encourage distribution of culture data using up-to-date information technology;
- represent culture collections and their users at national and international forums;
- organize conferences and symposia on topics and problems of common interest;
- seek funding possibilities to support UKFCC objectives;
- keep abreast of current and future legislation such as postal regulations, quarantine rules, patent laws, and public health issues; and
- liaise with relevant National Government Departments, funding bodies, and steering groups such as the UK National Culture Collection Steering Group.

Similar objectives are the founding stones of other national organizations that can be found in Belgium, Brazil, China, Cuba, the Czech Republic, France, Indonesia Japan, Portugal, The Philippines, Thailand, and the United States (Table 9.7).

Affiliations of Collections have also been established either as national organizations such as the United Kingdom National Culture Collection (UKNCC) or project consortia. The UKNCC linked 9 collections with over 100,000 strains of algae, bacteria, cell lines, fungi, protozoa, and viruses (37). The online database is easy to use and offers a convenient way to look for materials using a simple interface. The UKNCC secretariat coordinated some of its member's communication and research activities, producing joint catalogues, publicity materials, and the publication, the UKNCC Biological Resource Book (12). The members offer both a culture/cell supply service and an identification service; organisms supplied include actinomycetes, algae, animal cells, bacteria,

TABLE 9.7. Culture Collections Holding 10,000 Strains in the World Data Centre for Microorganisms

Collection	Country	Organism	Number
Agricultural Research Service Culture Collection	USA	Fungi, bacteia	78060
American Type Culture Collection	USA	Bacteria, Archaea, fungi, viruses, plasmids, cell lines	73507
Bioresource Collection and Research Center	Taiwan	Bacteria, fungi, viruses, cell lines	10398
CABI	UK	Fungi and bacteria	29000
Canadian Collection of Fungal Cultures	Canada	Fungi	10000
Centraalbureau voor Schimmelcultures, Fungal and Yeast Collection	Netherlands	Fungi	61000
Center for Fungal Genetic Resources	Korea	Fungi	24531
China General Microbiological Culture Collection Center, Institute of Microbiology, Chinese Academy of Sciences	China	Bacteria, fungi	14433
Culture Collection, University of Goteborg	Sweden	Bacteria, Fungi	40500

cyanobacteria, filamentous fungi, nematodes, protozoa, mycoplasma, and yeasts. Similar initiatives have brought together Belgian collections, the Belgian Coordinated Collection Collections of Microorganisms (BCCM^{TM}) (45), and European collections through the electronic catalogue Common Access to Biological Resources and Information (CABRI) (38).

9.6 SUMMARY

Despite the 525 collections registered with the World Data Centre for Microorganisms and the 1.7 million strains held by them (Table 9.6), there are still gaps in coverage. Not all species are represented in these collections; currently there are 423,894 fungus names listed by Index Fungorum (46). Published names do not equate to accepted species because fungi will often have different names for the anamorph and teleomorph states and other synonyms. There are currently around 80,000 described fungi and a significantly larger number still to be discovered, which may exceed 1.5 million (47). Considering that many of these cannot yet be grown in culture, collections are doing quite well but there is still some way to go to represent what is in nature. It may not be necessary to ensure all species are represented in collections but at the very least conservation programs for microbes should be established with a balance between

TABLE 9.8. Collections Designated as International Depository Authorities

Collection	Country	Organisms Covered
AGAL, Australian Government Analytical Laboratories	Australia	Microorganisms
BCCM™ IHEM, Scientific Institute of Public Health - Louis Pasteur	Belgium	Fungi, yeasts

VKPM, Russian National Collection of Industrial Microorganisms	Russia	Bacteria, fungi, phages, plasmids, yeasts

in situ and *ex situ* maintenance. The impact of climate change and man's activities affect microorganisms as they do plant and animal life but this hidden resource is often forgotten. There is also an imbalance between where collections are established and where most biological diversity resides. It is often the case that biodiversity rich countries are poor in resources. Table 9.6 demonstrates that 76% of the organisms held are in collections in Europe and the Americas, most of the latter in collections in North America and Canada (Table 9.8). Indeed, the 28 collections (each holding more than 10,000 strains) that are listed in Table 9.8 are from 15 countries and they hold 39% (678,760) of the total numbers of strains held by WDCM registered collections. It is therefore essential that capacity building programs, such as that envisaged by the GBRCN and offered by collections and their organizations such as the WFCC are developed to help establish the facilities and resources to support countries with the greatest need. BRCs offer much needed services to researchers and industry giving access to high quality materials and expertise to ensure their work is based on authentic cultures and validated information.

CULTURE PRESERVATION

ROBERT L. GHERNA
American Type Culture Collection, Rockville, Maryland

10.1 INTRODUCTION

The ubiquitous presence of microorganisms, as well as their metabolic diversity, has made them important factors in industrial applications and product development. Bacteria, fungi, and yeasts have been used for the production of food, medicinals, solvents, enzymes, and numerous other products. They have also been used as standards for bioassay and bioremediation applications. In addition, advances in bioengineering have enabled the incorporation of genes into microorganisms for the production of mammalian proteins and peptides.

During the past 20 years, cell line technology grew dramatically to enable the isolation and maintenance of a wide variety of tissue lines from any species of interest. The initial use of cell lines for vaccine production was expanded by developments in cell hybridization, transduction and transfection, and genetic manipulation to include the production of monoclonal antibodies, cytokines, and other pharmaceutical products. Lines that have been genetically engineered have been successfully expanded and grown in fermenters for large-scale production.

The development of microbial and cell cultures represents an enormous investment in time and money and is an important asset to industry. These cultures must be protected from accidental loss by means of standardized preservation techniques. The primary aim of culture preservation is to maintain the culture such that it is as close as possible to the original strain or line exhibiting the desired phenotypic or genetic traits. Often, industrial cultures are not analogous to taxonomic strains in that they have been modified to have special properties, either rapid growth, more active metabolic rates, or other features.

Many methods have been used to preserve bacteria and fungi, but not all species respond in a similar way to a given method. Unfortunately there is no universal method that can be applied to all microorganisms. It should be emphasized, however, that the success or failure of any preservation technique also depends on the use of the proper growth medium and cultivation procedures and on the age of the culture at the time of preservation. This is particularly true when working with microorganisms that contain plasmids or recombinant DNA, or that exhibit growth phases such as morphogenesis or spore formation.

The following provides practical information for the maintenance and preservation of bacteria, fungi, yeast, and cell lines. It should be noted, however, that not all microorganisms will be preserved by these methods, and some experimentation with cryoprotective agents and other factors may be necessary for success. Additional information on bacterial, fungal, and cell-line preservation may be found elsewhere (1–3).

10.2 CULTURE AND PRESERVATION OF BACTERIA

10.2.1 Short-Term Preservation

10.2.1.1 Subculture. Most bacteria can be preserved by periodic serial transfer to fresh medium. The period between transfers varies with the organism, medium employed,

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

and the external conditions. In general, minimal media are preferred for subculturing because they lower the metabolic rate of the organism and thus prolong the interval between transfers. In rich media, growth is often much faster, with the accumulation of metabolic products. These compounds may alter environmental conditions such as pH and gas phase and shorten the interval between transfers. Some bacteria such as pathogens need complex media (4) for growth, or their retention of specific physiological properties require the addition of complex compounds to the medium. The subculturing interval for these organisms must be determined by experience.

When preserving bacteria by serial transfer, it is important to use containers that can be securely sealed. Glass test tubes or 6-mL bottles with rubber-lined screw caps are widely used. The bacteria can be grown with slightly loose caps until adequate growth is obtained and then tighten to prevent dehydration. Solid media are preferred to broth because contaminants can be readily seen. Duplicate tubes should be maintained as a precaution against loss, at least until the subculturing interval is determined. The cultures should be examined for purity after each transfer, and abbreviated characterization tests must be run periodically to ensure retention of desired traits. Storage in a refrigerator is the preferred method for subcultures. Many bacteria can be kept for 3–5 months between transfers if proper precautions are taken to avoid dehydration of the medium.

It should be noted, however, that the maintenance of cultures by serial transfer is precarious, time-consuming, and expensive. The frequent transfer of cultures can result in contamination, mislabeling, and the selection of strain variants.

Other methods involve storing cultures at refrigeration temperatures, drying in sterile soil, glass beads, filter paper, and other substrates. Detailed descriptions of these methods can be found in Refs 5–7.

Short-term maintenance and preservation procedures are not recommended for industrial strains because a number of problems can occur using these methods. The main hazards are contamination, population changes through selection resulting in the loss of key genetic and physiological properties, and the expense of maintaining cultures under these conditions.

10.2.1.2 Ordinary Freezing. The use of the freezer compartment of a refrigerator or an ordinary freezer with a temperature range of 0 to -20°C to preserve bacteria is not recommended because the freezing process (see Long-Term Methods, Deep Freeze) damages the cells. In addition, most refrigerators that have a freezer compartment in the range of 0 to -20°C are frost free. The frost-free state is achieved by an alternating warming and cooling cycle, which can result in further damage to the cells and a loss of viability.

10.2.2 Long-Term Methods

10.2.2.1 Freeze-Drying or Lyophilization. Freeze-drying, or lyophilization, is one of the most economical and widely used methods for long-term preservation of bacterial cultures and other microorganisms. Many metabolically diverse bacterial species have been successfully preserved by this technique and have remained viable and unaltered for more than 60 years.

Freeze-drying is a complex process that involves the removal of water and other solvents from a frozen product by sublimation (8,9). Sublimation occurs when a frozen liquid goes directly to a gaseous phase without passing through the liquid phase. There are three stages in the freeze-drying process: (i) prefreezing of the suspension to ensure a solid frozen starting material, (ii) primary drying during which most of the water is removed through sublimation, and (iii) secondary drying to remove the bound water.

The rate of cooling during the prefreezing step and the final temperature of the frozen material can affect the freeze-drying process. The removal of water during the primary drying stage requires an environment that allows the water molecules to migrate from the frozen material. This is achieved by using a vacuum pump. A large-capacity pump must be used to prevent the water vapor load from compromising the efficiency of the system. The procedure also requires a moisture trap or condenser to collect and remove the water molecules before they enter the vacuum system. The condenser temperature must be lower than the frozen material for sublimation to occur. The sublimation rate is dependent on the differential vapor pressure between the frozen material and the condenser. Because the vapor pressure varies with the temperature, heat can be carefully applied to the frozen cell suspension to increase the vapor pressure and promote a faster primary drying rate. Precautions must be taken during the application of heat to prevent the frozen cell suspension from thawing. Most commercial instruments have sophisticated controllers that allow the input of heat to the frozen material to achieve maximum drying rates without damaging the product.

When the primary drying is complete, some bound water remains. This water cannot be eliminated by sublimation and requires the application of external heat to the material under low pressure and low condenser temperature. The moisture remaining in freezed-dried cells is termed residual moisture. A residual moisture content of 1%–3% seems to be required for the long-term shelf life of bacteria. For an in-depth review of the complex freeze-drying process, the reader is referred to several excellent reviews (10–12).

Centrifugal freeze-drying and prefreezing are two of the most commonly used methods of lyophilization of bacteria. In centrifugal freeze-drying, the suspensions are initially frozen by evaporative freezing under a vacuum while centrifuging to prevent frothing due to removal of dissolved

gases. After primary freeze-drying, the vials are constricted using a narrow flame and then placed on a manifold for secondary freeze-drying. A detailed discussion of centrifugal freeze-drying can be found in articles by Rudge (13) and Lapage (14). The prefreezing method employs a controlled rate of cooling to freeze the cell suspension and then a primary drying phase, as discussed earlier.

The simplest system consists of a vacuum pump capable of an ultimate pressure of less than 10 μmHg (a pump rated at 35–50 L/min is usually adequate), a small stainless steel condenser for cooling with dry ice, a thermocouple vacuum gauge to monitor the vacuum system, and heavy-walled vacuum/pressure tubing to connect the components. The connection of these modules into a single system is often termed a component freeze-dryer. The main components are the vacuum pump, thermocouple vacuum gauge, and a condenser that can be attached to several manifolds, to which glass vials can be attached by means of vacuum-tubing nipples, or the manifolds can be connected to a stainless steel pan containing the vials. The manifold system is relatively simple, and it has been used successfully by many laboratories to preserve cultures. A small amount of cell suspension (0.2 mL) containing a cryoprotectant is dispensed into sterile ampules, which are plugged with sterile cotton. A 1-in. piece of nonpowdered amber latex IV tubing is attached to the rim of each ampule (by using a tube stretcher) and then to the manifold. The ampules are then immersed in an ethylene glycol (50%) dry-ice bath at −40°C to freeze the cell suspension. The freeze-drying cycle is initiated by starting the vacuum pump and allowing the temperature of the bath to rise of its own accord to ambient temperature. In general, runs can be started early in the afternoon and allowed to proceed overnight. At the end of the drying cycle, the ampules are sealed using a double-flame air/gas torch and stored at 2–8°C. For specific details on the equipment and methods see articles by Gherna (15) and Simione and Brown (16). Details of other procedures and equipment are given by Haynes *et al*. (17).

The American Type Culture Collection (ATCC) has successfully lyophilized many of the bacteria described in the literature. It currently uses three methods:

1. *Component Freeze-Dryer*. Samples are freeze-dried in cotton-plugged inner vials, which are then sealed in outer vials under vacuum.
2. *Commercial Freeze-Dryer*. Cultures are freezed-dried in the double-vial system in a commercial freeze-dryer.
3. *Preceptrol Cultures*. Cultures are lyophilized in a commercial freeze-dryer using glass serum vials that are sealed with a rubber stopper and metal cap.

It should be noted that after the drying cycle is complete in the commercial freeze-dryer and Preceptrol methods, the vacuum in the drying chamber is replaced with cooled nitrogen gas (2–8°C) that has been passed through a 0.2-μm Pall filter. The condenser temperature must not be allowed to rise above −50°C. The nitrogen gas may have to be passed through a copper coil immersed in liquid nitrogen.

10.2.2.1.1 Culture Preparation. Successful freeze-drying depends on using healthy cells grown under optimum conditions on the medium of choice for each strain, which ensures the retention of the desired features of the bacterium. Bacteria can be grown on agar or in shaken or static broth cultures. The cells are harvested at maximum stability and viability, in the late logarithmic or early stationary phase, and suspended in a medium. The cell suspension should contain at least 10^7–10^{10} cells/mL in order to achieve optimal results. Anaerobic cultures must be grown, harvested, and dispensed under anaerobic conditions (18).

The viability of freeze-dried cultures is greatly influenced by the suspending medium. The choice of suspending medium for freeze-drying depends on the type of bacteria and on the method used.

The ATCC uses two suspending media for the commercial freeze-drying method:

1. Reagent 18
   - 0.75 g trypticase soy broth
   - 10.0 g sucrose
   - 5.0 g bovine serum albumin fraction V
   - 100.0 mL distilled water
   - filter sterilized through a 0.2-μm filter.
2. Reagent 20
   - 10.0 g bovine serum albumin fraction V
   - 20.0 g sucrose
   - 100 mL distilled water
   - filter sterilized through a 0.20-μm filter.

Reagent 18 is more commonly used for freeze-drying bacteria and fungi. Reagent 20 is employed for bacteria that are adversely affected by trypticase soy broth and is added to an equal volume of cell suspension in the broth.

In the component freeze-drying method (double-vial), the additive is a 20% (wt/vol) sterile solution of skim milk, prepared by autoclaving a 20% skim milk solution at 116°C for 20 min in 10-mL tubes. For cultures grown on agar surfaces, the cells are washed off with the 20% skim milk solution. Broth cultures are centrifuged, and the cell pellet is resuspended with the sterile skim milk to give a suspension of 10^8 cells/mL. Skim milk should not be used for bacteria that are inhibited by milk, instead use a 24% (wt/vol) sterile sucrose solution diluted equally with growth medium to yield a 12% (wt/vol) sucrose solution (final concentration) for the single-vial manifold or commercial

freeze-dryer method. As soon as the cell suspension is prepared, it should be dispensed into the ampules. The interval between dispensing and freeze-drying should be kept to a minimum to avoid possible alteration of the culture. Other investigators have used 10% (wt/vol) dextran, horse serum, inositol, raffinose, trehalose, and other cryoprotective chemicals in the suspending medium (19–21).

Most bacteria can be lyophilized using these methods; for those cultures that require special conditions, the reader is referred to Ref. 16. The same methods have been employed successfully to freeze-dry most bacteriophages; exceptions are stored in liquid nitrogen. In general, bacteriophages can be grown in a soft agar layer or in broth. The phages are harvested by scraping off the soft agar with a sterile glass rod or rubber policeman, macerating and dispensing into a sterile centrifuge tube, and centrifuging at low speed to sediment the agar and most of the unlysed bacteria. Broth-gown cultures are centrifuged at low speed to remove the unlysed bacteria. The supernatant is then filtered through a 0.45-μm and then through a 0.2-μm Millipore filter. The filtrate should be titrated to determine the concentration of phages; a titer of 10^8 pfu/mL is desirable. The phage can be freeze-dried using 20% skim milk and the component freeze-dryer method.

Freeze-dried bacteria and bacteriophages can be stored at 2–8°C. A longer shelf life has been obtained when cultures are stored at −30 or −70°C in a mechanical freezer. Freezed-dried cultures should not be stored in a freezer compartment of a frost-free refrigerator because of the alternate heating and freezing cycles, nor should they be stored at room temperature.

Although lyophilization has facilitated the long-term preservation of bacteria, viability checks must be done before and after lyophilization to determine the effectiveness of the process. Quality control procedures must be in place to check for purity, retention of essential characteristics and periodic viability to determine the shelf life of the culture.

10.2.2.2 Deep Freeze. The long-term preservation of bacterial species not amenable to freeze-drying has been achieved through storage in the frozen state at a temperature of −70°C or, more advisable, at the temperature of liquid nitrogen (−196°C) or liquid vapor phase (−150°C).

The freezing process results in several events that can be destructive to the cells. As the bacterial suspension begins to cool, the liquid water turns to ice at 0°C (the exact temperature depending on the nature of the bacterial suspension). Ice formation occurs first in the external aqueous environment, resulting in an increased concentration of solutes outside the cells. The differential osmotic pressure causes water to migrate from the cells. The rate and extent of the water loss are dependent on the rate of cooling and the permeability of the cells. Removal of too much water leads to a concentration of solutes within the cells that may be harmful. If too much water is left in the cells, internal ice crystals may form, which would result in intracellular damage. It is important to maintain the critical balance between the two events by controlling the rate of cooling while freezing the cells, and warming as rapidly as possible when the cells are thawed. Chemical compounds such as glycerol and dimethyl sulfoxide (DMSO) can be added to the cells to minimize the damage caused by freezing. These compounds, labeled cryoprotective agents (see Cryoprotectants), exhibit certain properties that are essential for good cryoprotection (22,23). They must be nontoxic to the cells, show good permeability, and bind either the electrolytes that accumulate or the water molecule to delay freezing.

The physiological condition of the cells plays an important role in survival of freezing. In general, actively growing cultures harvested at the mid to late logarithmic phase of growth will survive the freezing process better than those harvested at an earlier or later phase. The bacteria should be grown under optimum conditions in the appropriate medium that best retains the prominent characteristics of the strain. Bacteria can be grown on broth that is static or shaken, or on agar. Shaken cultures generally reach optimal cell density faster than agar-grown cultures. Some strict anaerobes require prereduced media and anaerobic procedures for harvesting and dispensing.

Cells grown in broth cultures are harvested by aseptic centrifugation, and the resultant pellet is resuspended in sterile broth containing 30–50% (vol/vol) sterile glycerol. Bacteria grown on agar are harvested by aseptically washing the growth with sterile broth containing the cryoprotectant. Dispense 0.4 mL of the cell suspension, containing at least 10^8 cell/mL into each sterile, prelabeled vial. Plastic presterilized screw-capped vials (such as Nunc) are recommended for bacteria. Place the filled vials into a mechanical freezer set at −70°C. The cells are recovered by rapidly thawing the frozen cell suspensions in a 37°C water bath.

A wide variety of bacterial have been successfully preserved at −70°C using glass beads and 15% glycerol as the cryoprotectant (24). The glass beads are prepared as described in Ref. 15, and 30 beads are placed in 2-mL glass screw-cap vials and sterilized for 15 min at 121°C. The vials must be prelabeled with ink that will not come off at ultralow temperatures. Cell suspensions are prepared containing $\sim 10^8$ organisms/mL in sterile 15% glycerol, and 0.5 mL is dispensed into each vial. The vials are shaken gently to ensure that all the beads are wetted with the bacterial suspension, and then the excess liquid is aseptically removed with a sterile pasteur pipette. The vials are placed into a mechanical freezer at −70°C. The cells are recovered by aseptically removing a bead from the vial with a sterile spatula or forceps and placing the bead in sterile broth. It should be noted, however, that the contents of the vial

should not be allowed to thaw; this can be prevented by placing the vial in crushed dry ice and removing the bead after ensuring the beads will remain frozen. This technique has been used to preserve bacteria obtained from extreme environments such as hypersaline pools.

Precautions must be taken against electrical shutdowns and compressor malfunctions. Adequate back-up systems (such as alarms, back-up freezers, or an electrical generator) will help to prevent the loss of a valuable collection. However, additional alarm systems are recommended, such as the sound/off power-temperature monitor (Arthur H. Thomas Co.), which has a temperature range of −75 to +200°C. The unit is battery powered and can be mounted on a wall.

10.2.2.3 Ultrafreezing or Cryopreservation. Although the long-term maintenance of bacteria in liquid nitrogen has been considered expensive, the successful preservation of physiologically diverse bacteria by this method, along with minimal handling and lower labor cost, makes this method feasible to use. The ATCC has successfully preserved many bacteria and bacteriophages, including fastidious ones, in liquid nitrogen for over 36 years without the loss of phenotypic properties.

A large variety of liquid-nitrogen refrigerators are now commercially available, with a wide assortment of features and storage capacities. The sizes range from 10 to 1000 L, allowing storage of 300–40,000 ampules.

The physiological condition of the cultures plays an important role in the survival of bacteria under liquid-nitrogen freezing. Bacteria are grown in the appropriate medium and harvested at mid-late logarithmic phase of growth (25). Cultures grown in broth are harvested by aseptic centrifugation, and the resultant pellet is resuspended with sterile fresh medium containing either glycerol or DMSO. For agar-grown cells, the growth is washed off from the agar surface with sterile broth containing the appropriate cryoprotectant. Cryoprotective agents must be added to the suspending medium to protect cells from freeze damage. Cryoprotectants fall into two main classes: compounds such as glycerol and DMSO, which are permeable and appear to provide both intracellular and extracellular protection against freezing; and agents such as dextran, glucose, lactose, mannitol, polyglycol, polyvinylpyrrolidone, and sucrose, which seem to exert their protective effect external to the cell membrane. The first class of cryoprotectants has proven to be the most effective, and in general, glycerol and DMSO seem to be equally effective in protecting a wide range of bacteria. It is advisable to conduct a tolerance test on new species to ascertain whether the cryoprotectant is toxic or beneficial.

DMSO and glycerol are routinely used at concentrations of 5% (vol/vol) and 10% (vol/vol), respectively, in the proper suspending medium. Glycerol is normally prepared as a double-strength (20%, vol/vol) solution and then mixed with an equal amount of the cell suspension. Glycerol is sterilized by autoclaving at 121°C for 15 min and stored in 6-mL volumes at 2–8°C. DMSO is filter sterilized with a 0.22-μm-pore-size Teflon (polytetrafluoroethylene) membrane (Gelman or Millipore) that has been prewashed with methanol and DMSO, collected in 10- to 15-mL quantities in sterile test tubes, and stored in the frozen state at 5°C (DMSO freezes at 18°C) and protected from light. An opened bottle of DMSO should not be used for more than 1 month because of the accumulation of oxidative breakdown products.

Cell suspensions containing at least 10^8 cells/mL are dispensed into prelabeled sterile vials. There are a variety of vials available commercially, ranging from prescored glass to sterile plastic. With glass vials, care must be taken when sealing and storing because improperly sealed glass vials can explode when retrieved from the liquid nitrogen as a result of the rapid expansion of the liquid nitrogen that enters the vials through microscopic holes. Plastic screw-cap vials that are not properly sealed can fill with liquid nitrogen if stored in liquid phase; retrieval of the vials to a warmer temperature can result in liquid nitrogen expansion, causing the contents of the plastic vials to spray into the laboratory environment. Plastic screw-cap vials should always be stored in the vapor phase. Protective gloves and face shields should be worn when handling frozen liquid-nitrogen vials.

The rate of cooling is important in liquid-nitrogen storage. In general, the best results for preservation of bacteria have been achieved with slow cooling. This step can be controlled using programmable controllers such as the Linde BF 3-2 (Union Carbide Corp.), which has an adjustable cooling rate. The cells are frozen at a controlled rate of 1–3°C/min to −40°C and then at a more rapid rate of 10°C/min to −90°C. After this temperature is reached, the vials are transferred to a liquid-nitrogen tank and stored in the liquid phase at −196°C or above in the vapor phase at −150°C.

If a programmable freezer is not available, slow cooling can be obtained by placing the filled glass or plastic vials in a stainless steel pan at the bottom of a mechanical freezer at −60°C for 1 h and then plunging the vials into a liquid-nitrogen bath for 5 min. The rate of cooling to −60°C is ∼1.5°C/min. The frozen vials can then be stored in the liquid-nitrogen tank in the liquid or vapor phase.

It has been reported that the best recovery of cultures from liquid-nitrogen storage is obtained by rapid thawing (26,27). This has also been the experience with cultures frozen at the ATCC. The events during thawing are complex, and slow warming rates can lead to ice crystal formation; a rapid warming rate of ∼100°C/min will minimize the damage due to ice formation. A rapid rate of warming

can be achieved by quickly immersing the frozen vials in a 37°C water bath with moderate agitation until all the ice melts. This usually takes about 50 s for glass vials and 90 s for polypropylene ones.

Cryopreservation of strict anaerobic bacteria must be performed under anaerobic conditions. Technical details of the procedures involved have been described by Hill *et al*. (28). The reader should consult various sections of *Bergey's Manual of Systematic Bacteriology*, volumes 1–4 (29–32), for information on the maintenance and preservation of representative bacterial genera.

The successful cryopreservation of plasmid-containing bacteria depends on the stability of their plasmids (33). These organisms are less genetically stable and more likely to lose their foreign genetic material (34). In general, bacteria containing unstable plasmids should be grown on antibiotic-containing liquid medium at 30°C, frozen with 10% (vol/vol) glycerol, and stored in the vapor over liquid nitrogen.

10.3 CULTURE AND PRESERVATION OF FUNGI AND YEAST

10.3.1 Short-Term Preservation

10.3.1.1 Subculture. Many filamentous fungi can be successfully maintained by serial transfer on suitable media. It is important, however, to use optimal media and growth conditions to ensure healthy cells that retain their morphological and physiological characteristics. A list of suitable media and incubation temperatures for a variety of fungi is provided by Onions and Pitt (35). In general, a medium that promotes good sporulation is considered to be the most desirable. When possible, it is best to cultivate the fungi on agar slants in test tubes or culture bottles. Transfers should be made only from the growing edges of the culture, taking precautions to ensure that contamination is prevented. Some fungi degenerate when maintained on the same medium for extended periods, thus media should be alternated from time to time. A minimal medium such as potato/carrot agar can often be used to induce sporulation in a culture that has deteriorated (36). Also, the continual transfer of spores from some aging fungal cultures such as *Mucorales* can result in a deterioration of the culture; the transfer of mycelium and spores seems to minimize this problem.

The interval between transfers varies from fungus to fungus; some require transfer every 2–4 weeks, the majority every 2–4 months, while others may survive for 12 months without transfer. Cultures grown on agar slants can be stored at room temperature. Storage in the refrigerator or cold room at 5–8°C can extend the transfer period to 4–6 months. However, there are some fungi, such as the thermophiles, that are sensitive to storage at these temperatures.

The maintenance of fungi by serial transfer has many disadvantages. The most notable are contamination, selection of variants, mislabeling of cultures, infestation with mites, and labor intensity.

Yeasts have been successfully maintained by serial transfer on either solid or liquid media. In general, many yeasts will survive for longer periods when grown on solid media rather than in broth, especially nonfermentative yeast. Fresh medium is inoculated with actively growing cells and incubated at the appropriate temperature. After sufficient growth occurs, the cells are stored at refrigerated temperature (+4°C). The majority of yeast species will remain viable for a least 6 months. The interval between transfers must be determined by experimentation. Serial transfer is not recommended for extended maintenance because genetic drift has been observed. In addition, ascosporogenous strains may sporulate on agar slant media stored for prolonged periods, resulting in strain variability.

Many fungi and yeast can be preserved for years by drying on a suitable menstruum such as soil, silica gel, and filter paper (37), and drying under vacuum from the liquid state (L-drying) (38).

10.3.1.2 Silica Gel. Sterile anhydrous silica gel (6–22 mesh, nonindicator) is prepared by dispensing the gel into growth bottles so that they are one-quarter filled, and sterilizing in an oven at 180°C for 2–3 h. The bottles containing the sterile gel are cooled by placing in a pan containing ethylene gycol and dry ice to the depth of the gel layer or by placing the bottles in water in a mechanical freezer at a temperature of −17 to −24°C. Fungal spores are suspended in a sterile 5% skim milk solution that has been cooled to 4°C. The spore suspension is added to the cooled silica gel until three-quarters of the gel has been moistened. It is important to avoid saturating the gel. The growth bottles are left in the ice bath for ∼20–30 min and then agitated to ensure thorough dispersion of the suspension. The bottles are held at 25°C for ∼1–2 weeks until the crystals easily separate when shaken. Inoculated bottles are sealed with screw caps and stored over indicator silica gel in an airtight container at 4°C. To recover the fungal spores, a few crystals are sprinkled on an appropriate medium and incubated. This method has been used successfully for a variety of fungi (39). This method has produced variable results with yeast; some are not viable after 3 months of storage, whereas other survive after 2–5 years (40).

10.3.1.3 Soil. A variety of fungi have been maintained in soil (41). The method involves the inoculation of ∼1 mL of a spore suspension into soil that has been sterilized by autoclaving twice, 24 h apart, at 121°C for 15 min. The soil is incubated at room temperature for 5–10 days and then stored in a refrigerator at 4–8°C. Cultures are recovered by inoculating a suitable medium with a few grains of soil.

10.3.1.4 Paper. Yeasts have been preserved by drying on paper discs or squares and storage over the desicant silica gel (42). Whatman No. 4 filter paper is cut into small squares or discs about 10 mm across and placed on a small aluminum foil, which is folded into a packet and autoclaved at 121°C for 15 min. The sterile discs or squares are inoculated by immersing into drops of a heavy yeast suspension prepared in 5% skim milk. The packets are dried in a desiccator for 2–3 weeks at 4°C and then placed in an airtight container and stored at 4°C. Cultures are recovered by aseptically removing a piece of filter paper and inoculating the appropriate solid or liquid medium. Yeast maintained in this manner have been viable after 2–3 years.

10.3.1.5 L-Drying. L-drying refers to liquid-state drying in such a way as to prevent freezing. Drying occurs under vacuum at temperatures generally no colder than 5–10°C. The method has been improved and simplified by Malik (43) for the preservation of sensitive microorganisms that are damaged by freezing or freeze-drying. The technique has been used to successfully preserve some yeasts and filamentous fungal spores.

10.3.2 Long-Term Methods

10.3.2.1 Freeze-Drying or Lyophilization. The equipment, cryoprotectants, and theoretical aspects of freeze-drying have already been discussed. Fungi are grown under optimum conditions using media that will produce maximum sporulation. Mature spores are harvested by flooding the agar cultures with ~2 mL of a 20% sterile skim milk solution. The skim milk must be cold when used, and thus it is stored at 2–8°C until required. The spores are gently scraped from the surface of the culture to yield a suspension containing at least 10^6 spores/mL. The spore suspension is pipetted back into the tube containing the remaining milk and mixed thoroughly. If more than one tube is used, repeat the procedure and pool the suspension in one tube to yield a concentration of at least 10^6 spores/mL. The spores of cultures grown in broth medium are centrifuged and resuspended in sterile 20% skim solution. Approximately 0.2 mL of the spore suspension is dispensed into sterile vials for freeze-drying. The interval between harvesting the spores and dispensing must be minimized because many spores begin to germinate when suspended in liquid. Spores should not be in the skim milk for more than 2 h before being processed. Filled vials should be refrigerated while awaiting further processing.

The fungi are freeze-dried using one of the ATCC methods already described. Lyophilized spores can be stored at 2–8°C. Extended shelf life can be achieved by storing the vials at −70°C in a mechanical freezer.

Freeze-dried fungal cultures are rehydrated with 0.5–0.9 mL of sterile water, then transferred to tubes containing 6 mL sterile water and allowed to soak for 50–60 min before transferring to solid medium.

At the ATCC, yeasts are processed in the same manner as bacteria for the component freeze-drying method. Cultures are grown on the appropriate solid medium and suspended in sterile 20% skim milk or reagent 18 to a concentration of at least 10^6 cells/mL. The suspension is mixed thoroughly, and 0.2 mL is dispensed into each vial. The cultures are freezed-dried using the component freeze-drying method described earlier.

10.3.2.2 Ultrafreezing or Cryopreservation. The preservation of fungi at ultralow temperatures of liquid nitrogen (−196°C for liquid phase and −150°C for vapor phase) is presently considered the best method of storage. The method can be applied to both sporulating and nonsporulating strains, as well as those fungi that have been genetically altered or harbor plasmids. The freezing rates and cryoprotective agents described for bacteria are also applicable to the freezing of fungi. Spores or mycelial fragments are harvested by flooding slants or plates with 10% glycerol or 5% DMSO and gently scraping the surface of the cultures. The fungal suspension is dispensed in 0.5-mL amounts into sterile plastic freezing vials and frozen at a controlled rate. Fungi that produce sticky mycelia or whose mycelia grow embedded in the agar can be prepared for freezing by cutting agar plugs containing new growth (hyphyl tips) with a sterile cork borer (5 mm). Three or four plugs are place into each sterile plastic vial with 0.4 mL of 10% glycerol and frozen at a slow controlled rate.

Cultures grown in broth are fragmented in a sterile Waring blender in a biological hood and suspended in equal parts of 20% glycerol and growth medium or equal parts of 10% DMSO and growth medium to give a final concentration of 10% glycerol (vol/vol) or 5% (vol/vol) DMSO, respectively. Some strains must be concentrated by centrifugation in order to obtain sufficient material for freezing. Pathogens must not be macerated in a mechanical blender because of the hazard of aerosol dispersion.

Some cultures, such as *Agaricus* strains, can consist of seeds, grains, or pollen and be frozen without the presence of a cryoprotectant. Slime molds can be preserved by freeze-drying or freezing. Spores, microcysts, and spherules are preserved by a controlled freeze in 10% glycerol and stored in the liquid-nitrogen vapor phase. Thawing of the frozen culture should be done rapidly in a 37°C water bath with moderate agitation. Once the ice melts, the culture can be transferred to a suitable medium.

Yeast cells have been successfully preserved by controlled freezing to liquid-nitrogen temperature (−196°C liquid, −150°C vapor phase). The yeast cultures are handled in the same manner as bacteria and grown as described

in the freeze-drying section for yeast. Cell suspensions are prepared in 10% glycerol to a concentration of at least 10^6 cells/mL. The yeast are frozen under controlled conditions as described in the bacterial section.

Several reports have described the loss of plasmid expression or the induction of respiratory-deficient mutants in yeast as a result of freeze-drying or improper freezing (44). Nierman and Feldblyum (33) reported that when plasmid-containing *Saccharomyces cerevisiae* were preserved by freezing in liquid nitrogen, no loss of viability was observed, and the fraction of plasmid-containing cells was the same before and after freezing. The preservation of plasmid-containing yeast is superior in liquid nitrogen with a controlled freezing rate than by freeze-drying.

10.4 CULTURE AND PRESERVATION OF CELL CULTURES

10.4.1 Long-Term Preservation

10.4.1.1 Ultrafreezing or Cryopreservation. Storage in liquid nitrogen is currently the best method of preserving cultured cells. Cryopreservation methods for a variety of cell lines are well developed and used extensively for culture storage. For a detailed description of standard cryopreservation protocols see reports by Freshney (45) and Hay (46).

The general events that occur during freezing and the effect of the cooling rate, cryoprotective agents, and a controlled rate of cooling have been discussed in the bacterial section.

Cell suspensions are prepared in the same manner used for routine subcultivation; trypsin is added if necessary to produce a uniform suspension. The cell suspension is centrifuged at $\sim 100g$ for 10 min, and the resultant pellet is resuspended in an appropriate amount of fresh medium containing a cryoprotectant. Normally, 5–10% DMSO or glycerol is employed. The freeze medium should be prepared just prior to use by mixing fresh growth medium and the cryoprotective agent and kept at room temperature. The remaining cryoprotectant is discarded because oxidative contaminants can accumulate. A cell suspension containing $\sim 10^6$–10^7 cells/mL is satisfactory. The cell suspension is dispensed in 1-mL amounts into each glass vial or plastic ampule and frozen at a controlled rate of 1°C/min to about −50°C. The vials are immediately transferred into liquid nitrogen for storage in the liquid or vapor phase. Rapid thawing is essential for recovery of frozen cells, thus the frozen vials are immersed directly into a 37°C water bath and agitated until the suspension is completely thawed. The thawed cell suspension is transferred to 10 mL of sterile growth medium and centrifuged at $100g$ for 10 min. The supernatant containing the cryoprotectant is discarded, and the cell pellet is resuspended in fresh medium and propagated using standard procedures.

10.4.1.2 Quality Control. It is important that all preservation methods include standard operating procedures for the determination of culture purity, viability, retention of morphological and physiological characteristics, production of desirable products, and other key attributes. Purity checks must be conducted before and after processing microorganisms for freeze-drying and microorganisms and cell lines for freezing. Generally, the cell suspension is diluted and inoculated into suitable medium and incubated at optimum temperature. After growth appears, the cultures are examined for purity. It is also important to conduct pre- and post-preservation viability checks for freeze-drying and freezing to determine the effectiveness of the process. In addition, periodic viability assays should be performed to ascertain the shelf life of the culture.

Cell lines should also be examined for *Mycoplasma* contamination, because it has been estimated that about 10% of cell lines are contaminated (47). It is also important to conduct tests to verify cell-line identity; several rapid techniques have been developed that use DNA probes to identify the cell lines (48).

10.4.1.3 Documentation. Documentation plays an important role in the maintenance and preservation of cultures. Important data include the identity of the culture, isolation source and methods, the individual who isolated it, geographical location, morphological and physiological characteristics, maintenance data, and other salient features. If the culture was obtained from another investigator, the documentation should include the name of the investigator, culture history if available, and date of acquisition. The greater the amount of data recorded and regularly updated, the greater the value of the culture.

11.1 INTRODUCTION

Several species and strains of the genus *Bacillus* have been used for decades to produce useful products such as α-amylases for food industry, including sweeteners and bread manufacture, and in biofuel production using starch substrates on a very big scale, as well as proteases for laundry detergents. The simple media required for optimum growth and production are well known and many protocols for cultivating the organisms have been optimized over many years. This chapter will review the characteristics of several of the most utilized industrial species, both as enhanced producers of natural products and as hosts for products derived from genetic engineering. Many of the genomes of useful bacilli have been sequenced, which should greatly facilitate their use through new and innovative strategies.

11.1.1 Advantages of Bacilli

Within the Gram-positive bacteria, *Bacillus* represents one of the most interesting genera. Since they lack the outer cell membrane found in Gram-negative bacteria, bacilli are able to secrete large amounts of proteins into their surrounding medium. The secretion of various proteins enables the cell to attack and convert highly polymeric nutrients such as polysaccharides, nucleic acids, peptides, and lipids into monomeric or dimeric building blocks, that are then taken up by the cell. This phenomenon allows *Bacillus* to grow on many simple substrates. The genus also lacks the endotoxins associated with the outer membrane of Gram-negative organisms. Moreover, members of the genus that are used as hosts for the production and secretion of (recombinant) proteins in industry are also nonpathogenic. The major industrial strains are *Bacillus subtilis*, *Bacillus licheniformis*, *Bacillus amyloliquefaciens*, *Bacillus clausii*, *Brevibacillus brevis*, and *Bacillus megaterium*. The first four species are closely related (1). In contrast, *B. brevis* and *B. megaterium* are less related to each other as well as to the others (1). *B. subtilis* and *B. licheniformis* are designated as Generally Recognized As Safe (GRAS) by the Food and Drug Administration of the United States (2).

11.1.2 Bacilli in Industry

Bacilli were used for many years in the food and feed industry for the production of proteins and metabolites. Recently, since the industry has become more aware that the oil supplies of the world are not endless, the so-called "white biotechnology" is gaining in importance. "White Biotechnology" stands for the biotechnological production of chemical bulk products and fine chemicals using microorganisms. In 2008, the German company BASF SE (Ludwigshafen, Germany) spent $135 million in research and development in the white biotechnology sector. Within this branch of biotechnology, enzymes of bacilli represent around 60% of the approximately € 2 billion worldwide industrial market of homologous and heterologous enzyme production (3). The genus *Bacillus* has long been used for the production of enzymes including several α- and β-amylases for starch modification in the baking industry and also to a much greater extend for starch processing in general on a level of over 30 millions of tons for ethanol manufacture, and sweetener production (glucose and glucose/fructose syrup) (4,5). Furthermore, the production of penicillin acylases essential for the synthesis of novel β-lactam antibiotics (6), neutral proteases, employed in the leather tanning industry since the early twentieth century and glucose dehydrogenase as well as eukaryotic proteins are major products. Besides the production and secretion of different kinds of proteins, bacilli are known to produce metabolites including pyruvate (7) and vitamin B_{12} (8). Many pharmaceutically and industrially relevant natural and recombinant proteins produced by bacilli are summarized in Table 11.1 (*B. megaterium* products are given in Table 11.5).

11.2 MAJOR INDUSTRIAL STRAINS

11.2.1 *Bacillus subtilis*

Over the last 30 years, *B. subtilis* strain 168 has been the Gram-positive model organism. The first version of

TABLE 11.1. Production Yields of Some Industrially and Pharmaceutically Relevant Proteins which were Successfully Produced in *B. subtilis*, *B. licheniformis*, and *B. brevis*[a]

Recombinant Protein	Bacillus Strain	Yield (mg/L)	Secretion (Yes/No)	References
α-Amylase (*Bacillus amyloliquefaciens*)	*B. subtilis*	1000–3000	Yes	10
α-Amylase (*Bacillus licheniformis*)	*B. licheniformis*	n.d.	Yes	11
	B. brevis	3500	Yes	12
α-Amylase (*Bacillus stearothermophilus*)	*B. brevis*	3000	Yes	12
α-Amylase (human)	*B. brevis*	60	Yes	13
β-Amylase (human)	*B. brevis*	1600	Yes	12
β-Tubulin (*Plasmodium falciparum*)	*B. brevis*	2	Yes	14
Cellulase	*B. brevis*	100	Yes	15
Chitosinase (*Bacillus amyloliquefaciens*)	*B. brevis*	150	Yes	16
Cholera toxin B (*Vibrio cholerae*)	*B. brevis*	1400	Yes	17
Gelatin	*B. brevis*	500	Yes	18
Gramicidin, linear	*B. brevis*	20.3	Yes	19
Epidermal growth factor (human)	*B. brevis*	240	Yes	20
Epidermal growth factor (human)	*B. subtilis*	7	Yes	21
Epidermal growth factor (mouse)	*B. brevis*	50	Yes	22
Mouse/human chimeric Fab′	*B. brevis*	100	Yes	23
Interferon-α2 (human)	*B. subtilis*	0.5–1.0	Yes	24
Interleukin-1 receptor antagonist (human)	*B. brevis*	200	Yes	25
Interleukin-2 (human)	*B. brevis*	120	Yes	26
Interleukin-6 (human)	*B. brevis*	200	Yes	27
Lipase A	*B. subtilis*	600	Yes	28
Penicillin G acylase	*B. subtilis*	n.d.	Yes	29
Pepsinogen (swine)	*B. brevis*	11	Yes	12
Polyhydroxyalkanoate (PHA) depolymerase A (*Paucimonas lemoignei*)	*B. subtilis*	1.9	Yes	30
Proinsulin	*B. subtilis*	1000	Yes	31
Protective antigen (*Bacillus anthracis*)	*B. brevis*	300	Yes	32
Protein disulfide isomerase	*B. brevis*	1100	Yes	33
Single-chain variable fragment (ScFv)	*B. subtilis*	10–15	Yes	34
Staphylokinase	*B. subtilis*	337	Yes	35
Streptavidin	*B. subtilis*	35–50	Yes	36
Subtilisin Carlsberg (*Bacillus licheniformis*)	*B. licheniformis*	n.d.	Yes	37
	B. subtilis	n.d.	Yes	37
Thioredoxin (*Aliciclobacillus acidocaldarius*)	*B. subtilis*	500	Yes	38

[a]Based on Ref. 9, page 217

its genome sequence was published in 1997 (39). In 2009, a revised, resequenced, and reannotated version of this reference genome has been published (GenBank AL009126) (40). Furthermore, easy access to the genome sequence, gene-centered information as well as many reference data are provided to the community by the SubtiList database, and are now integrated in the GenoList database system (41). Due to the broad genetic knowledge and techniques available, *B. subtilis* has been used extensively for industrial production. However, unlike strain 168, most industrial strains are not naturally transformable. In addition, *B. subtilis* has eight extracellular alkaline proteases that degrade secreted heterologous proteins, and further, cannot stably maintain plasmids. These problems have been addressed by constructing a strain that has been finally mutated for all eight proteases (WB800) (42) and by using *Bacillus* θ-replicating plasmid derivatives such as pAMβ1 (43,44). *B. subtilis* genetics, metabolism, and applications have been thoroughly covered in several books and reviews (39,45–47). Some proteins industrially produced with *B. subtilis* are summarized in Table 11.1. As a remarkable example thermostable α-amylases are used in starch hydrolysis at about 105°C in the first process step (4).

11.2.2 *Bacillus licheniformis*

Historically, *B. licheniformis* is one of the first industrial hosts for the production of thermostable enzymes, especially its amylases and alkaline proteases (subtilisin) (11,37). The genome sequences of two identical *B. licheniformis* strains were published in 2004 (ATCC 14580/DSM13: GenBank CP000002 and AE017333), both revealing a very close similarity to *B. subtilis* on the nucleotide level of about 84.6% (48,49). Under anaerobic conditions, *B. licheniformis* is able to grow by a mixed acid fermentation process similar to *B. subtilis* (50). In 2005, Nahrstedt and coworkers described a gene knock-out system for this organism (51). Several mutant strains were constructed which are deficient in sporulation and DNA repair (51) or show UV hypersensitivity (52). Further, mutants deficient in producing some extracellular proteins to enhance secretion of target proteins were developed (53). Industrially relevant proteins produced with *B. licheniformis* are also listed in Table 11.1.

11.2.3 *Brevibacillus brevis* (formerly *Bacillus brevis*)

The genome sequence of *Brevibacillus brevis* (formerly *Bacillus brevis*) was published in 2009 (strain NBRC 100599, GenBank AP008955). With a genome size of almost 6.3 Mbp its genome is one of the largest of all bacilli. It is only distantly related to the *B. subtilis* group (54). *B. brevis* is commonly found in soil, air, and water. Although it is not as well-studied as *B. subtilis*, much research has been done in Japan by Udaka, Yamagata, and coworkers since 1981 (5,12,17,20,33,55). *B. brevis* secretes large amounts of proteins into its environment which are correctly folded, soluble, and active. Yields of secreted protein in industry are between 11 mg and 3.5 g per liter (Table 11.1). Plasmids with high and low copy numbers are available (5,55). *B. brevis* shows very low levels of extracellular protease activity. Based on this, Kajino and coworkers isolated a protease-deficient mutant, in which extracellular protease activity was only about a quarter compared to the parent one (55). Unfortunately, little genetic analysis has been reported for this organism.

11.2.4 *Bacillus amyloliquefaciens*

B. amyloliquefaciens, with a name that was derived from its ability to liquefy amylose (starch), is well known for its amylases used in the baking industry. Moreover, it is used for the production of the alkaline protease subtilisin, as has been mentioned. *B. amyloliquefaciens* is naturally competent. Genetic transformations can easily be done using a modified protocol of *B. subtilis* (56). Many of the enzymes from *B. amyloliquefaciens* are now produced heterologously in other bacilli or *Escherichia coli*, including α-amylase (57) or chitosinase (16) (Table 11.1). The restriction endonuclease *Bam*HI is also derived from this organism. The complete genome sequence was published in 2007 (strain FZB42, GenBank CP000560) and promises to increase its usefulness (56).

11.2.5 *Bacillus clausii*

B. clausii can be isolated from soil and water. The genome sequence of *B. clausii* was published in the beginning of 2005 (strain KSM-K16, GenBank AP006627). On the basis of 16S rRNA, *B. clausii* is very closely related to *B. subtilis* (1). An advantage of *B. clausii* is its ability to tolerate environments with high pH levels. It produces alkaline-tolerant enzymes, particularly alkaline proteases (58). It is reported to have a beneficial effect in the human gut and is being considered for use as a probiotic (59).

11.3 BACILLUS MEGATERIUM

B. megaterium was first described by de Bary more than a century ago (60). Named for its large size of 1.5 × 4 μm, "megat(h)erium" (Greek: "big animal"), this microorganism is one of the largest bacteria (Fig. 11.1). Due to the dimension of the vegetative form and spores, *B. megaterium* is well suited for morphological research, such as cell wall and cytoplasmic membrane biosynthesis, sporulation, spore structure and cellular organization, DNA partitioning, and protein localization (61). In the

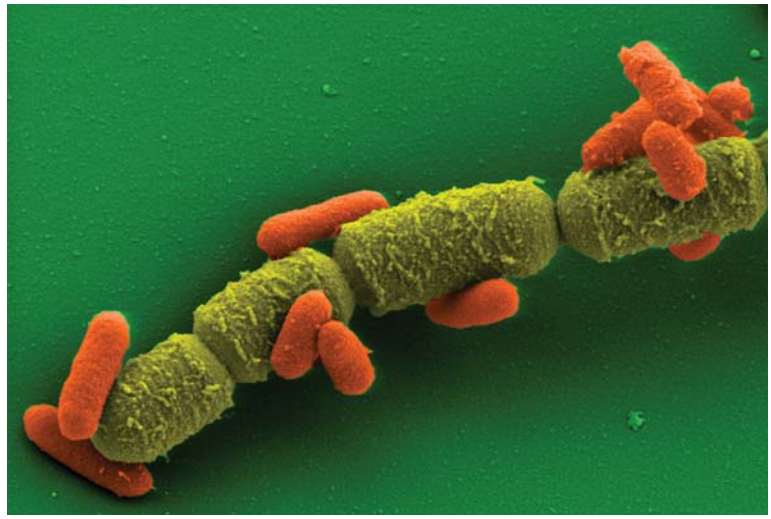

Figure 11.1. Electron microscope image of *Bacillus megaterium* and *Escherichia coli* cells. Large, yellow cells: *B. megaterium*; small, red cells: *E. coli*. Aldehyde-fixed cells were dehydrated with a graded series of acetone, critical-point-dried with liquid CO_2 and sputter-coated with gold. Sample examination was done in a field emission scanning electron microscope (FESM) Zeiss DSM982 Gemini. Magnification × 15,000. Subsequently, cells and background of the picture were stained. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

1960s, *B. megaterium* was *the* model organism for intensive studies on sporulation since it sporulates and germinates very efficiently. Primarily a soil bacterium, *B. megaterium* is also found in diverse environments from rice paddies to dried food, seawater, sediments, fish, normal flora, and even in bee honey (62). Because of its production of several biotechnological relevant substances, *B. megaterium* is of general interest for industry. It produces penicillin acylase used to construct semisynthetic penicillins (e.g. ampicillin) and is the major producer of vitamin B_{12}. It is nonpathogenic; this makes *B. megaterium* useful in the food and pharmaceutical industries.

Two genomes of two *B. megaterium* strains, QM B1551 and DSM319 (further described in the sections "*Bacillus megaterium* Strain QM B1551" and "*B. megaterium* Strain DSM319"), both important for biotechnological use, have currently been sequenced. Their chromosomes are circular and about 5.1 MBp in size. Taxonomically, *B. megaterium* is placed into the *B. subtilis* group of bacilli (62,63), although there is only a small degree of homology in the genome structure between *B. megaterium* and *B. subtilis*. Genome-wide comparisons revealed that only a region of approximately 2 MBp around the origin of replication of the *B. megaterium* chromosome is synthenic to currently sequenced *Bacillus* genomes (in preparation).

The utilization of a wide variety of carbon sources allows this organism to grow on low-cost substances. In contrast to other bacilli, *B. megaterium* can use the glyoxylate pathway as a "shortcut", since isocitrate lyase AceA (EC 4.1.3.1) and malate synthase GlcB (EC 2.3.3.9) are present. Under anaerobic conditions, *B. megaterium* is able to use the mixed acid fermentation pathway as found in *B. subtilis* (50). All key enzymes involved in this fermentation process were identified in *B. megaterium*, especially lactate dehydrogenase Ldh (EC 1.1.1.27), acetolactate synthase AlsS (EC 2.2.1.6), acetolactate decarboxylase AlsD (EC 4.1.1.5), phosphate acetyltranferase Pta (EC 2.3.1.8) and acetate kinase AckA (EC 2.7.2.1). Respiration with nitrate as electron acceptor, from which most other bacilli are able to get their energy under anaerobic conditions, is not possible in *B. subtilis* because it lacks a membrane bound nitrate reductase of the Nar-type. One of the major advantages of *B. subtilis* is that it does not possess any obvious alkaline proteases degrading recombinant gene products. Therefore, a large amount of intact functional protein is produced with little or no degradation products (64,65).

B. subtilis was one of the first biotechnological vitamin B_{12} producers (61,66,67). It is known for its ability to synthesize vitamin B_{12} both, in the presence and absence of oxygen (68). Starting in the early 80s, major parts of the biosynthetic pathway of B_{12} production in *B. subtilis* have been genetically and biochemically characterized (8,62,67–69). The genes for oxygen-independent vitamin B_{12} biosynthesis genes are organized in two distinct, independent operons. The larger one consisting of *cbiW*, *cbiH*, *cbiX*, *cbiJ*, *cbiC*, *cbiD*, *cbiET*, *cbiL*, *cbiF*, *cbiG*, *cbiA*, *cysG*, *cbiY*, and *btuR* has already been described (68,70); the smaller one consists of *cbiB*, *cobU*, *cobS* and *cobC*. This natural ability of *B. subtilis* to

produce vitamin B_{12} was combined using tools developed for this organism (refer "*Bacillus megaterium* Toolbox for Recombinant Protein Production"). Using these experiments, the intracellular yields of vitamin B_{12} were enhanced up to 40-fold. The strategies used illustrate the versatility of the organism. They included recombinant overexpression of single genes and whole operons, integration of strong promoters upstream of genes and operons involved in B_{12} production, directed enzyme engineering to enhance enzyme stability, overproduction of recombinant vitamin B_{12} binding proteins to prevent vitamin B_{12} dependent feedback inhibition, as well as an antisense RNA strategy to inactivate mRNA of genes involved in competing pathways (71).

11.3.1 *Bacillus megaterium* Strain QM B1551

Strain QM B1551 is second only to *B. subtilis* in the amount of genetics and multiply marked, characterized strains, hundreds of which are now available from the Bacillus Genetic Stock Center (BGSC, Ohio State University). It carries seven indigenous plasmids (pBM100-pBM700) with characterized, compatible replicons. These seven indigenous plasmids have different copy numbers and comprise approximately 11% of the total cellular DNA. The size spectrum of the plasmids ranges from only 5.4 kb to over 164 kb (72). The two smallest ones replicate by the rolling circle mechanism, whereas the larger five are θ-replication plasmids, four of which have cross-hybridizing replicons (73). The rolling circle replicons show similarities to sequences on plasmids known from *Bacillus thuringiensis* and *Bacillus anthracis* (74). All five θ-replicons appear to be unique. They may form at least one new class of compatible replicons (75). Beside the replicons, the plasmids of *B. subtilis* QM B1551 carry several interesting genes; for example, genes coding for proteins involved in cell division, in germination, in heavy metal resistance, in cell wall hydrolysis, and in rifampin resistance. Even a complete rRNA operon is located on one of the plasmids (74,75). *B. subtilis* strain PV361, a derivative of strain QM B1551 (76), lacks all seven plasmids. Surprisingly, this plasmidless strain is able to grow on rich and minimal medium and shows no differences in sporulation compared to QM B1551. It does require rich medium for germination, however. Therefore, the plasmids of QM B1551 may play a role in its adaptation to various environmental conditions. The genome of QM B1551 including all seven plasmids has now been completely sequenced and annotated. The QM B1551 genome has no alkaline proteases. Plasmid vectors are stable without selection for over 100 generations (75). Several techniques are available for its manipulation.

11.3.1.1 Transduction. A transducing phage, MP13, was isolated and characterized (77,78) and was used to map over 50 chromosomal loci. A mapping strain kit is also available (79). There are mutants for auxotrophy (80–82), recombination, division, DNA repair (83), antibiotic resistances, sporulation and germination and its neutral protease (84). Many genes have been cloned and characterized over the last few years including ATP synthetase (85), the *spoIIA* and *spoVA* operons (84) and several germination genes (86). Most are available from BGSC as mentioned above. For a more extensive discussion see a previous review (62).

11.3.1.2 Transformation. Although conditions to develop natural competence for the uptake of DNA have not been described for *B. subtilis* so far, other genetic methods to transform this organism, including poly(ethylene) glycol (PEG) protoplast transformation, have been developed (65,87). Recently, successful electrotransformation (ETF) of *B. subtilis* and *B. licheniformis* were reported by Xue and coworkers (1999) (88) and modified by Scott Grayburn for *B. subtilis* QM B1551 (unpublished data) (refer section titled "ETF of *Bacillus megaterium* QM B1551 and Derivatives"). While the frequency of ETF is still low, it is consistent and simple enough to use routinely, and competent cells can be frozen. Minor adjustments of cell density, number of washes, and osmolarity should optimize the protocol and make the technique useful for several other *B. subtilis* strains as well.

11.3.1.3 Integrative Genetics. Transposon Tn917 in several configurations constructed by Youngman, Perkins, and Losick (89) has been successfully integrated into QM B1551 to generate many mutations, assay promoter function, and clone sporulation genes (84,90). Integrative plasmids have also been used to map *ssp* (SASP) genes (76) and vectors that integrate into the *xyl* or *gdh* genes have been constructed (91). A simple, integrative suicide vector, pKV1, is also available (76).

11.3.2 *Bacillus megaterium* Strain DSM319

Beside *B. subtilis* strain QM B1551, much research has been done using strain DSM319 (92). In contrast to QM B1551, this strain naturally does not contain any plasmids. The genome of DSM319 has been sequenced and is available in GenBank.

For many recombinant industrial applications, bacterial strains which are genetically debilitated when released into the environment are required. Several strains of *B. subtilis* DSM319 have been constructed by different genetic approaches. Mutants that have lost their ability to form viable endospores have been made (93) including transposon knock-out mutants (66). Generated mutants are available in the laboratories of Friedhelm Meinhardt (Institute for Molecular Microbiology and Biotechnology, Muenster, Germany) and Wolfgang Hillen (Microbiology, Erlangen,

Germany). Another mutant useful for recombinant gene expression under xylose control is the mutant strain WH323 which is deficient in xylose utilization. Using this strain the inducer xylose cannot be consumed as carbon source (94). *B. subtilis* shows only low overall protease activity. To further lower residual extracellular protease activity, the gene for the major extracellular protease (NprM) was successfully knocked out resulting in strain MS941 (95). Protease activity of the mutant strain was reduced by 98.6% compared to that of the parental wild-type strain (95).

11.3.3 *Bacillus megaterium* Toolbox for Recombinant Protein Production

There are many tools now available to facilitate the cloning, secretion, expression, and purification of recombinant products in *B. subtilis*.

11.3.3.1 Vectors. Several vectors used in a *B. subtilis* host have been used successfully in *B. subtilis*. They are very stable and last for 60–100 generations without selective pressure in *B. subtilis*. These include transposon Tn917 vectors like pLTV1 and pTV1–pTV51 made by Youngman (96). Vector pLTV1 contains a small *E. coli* plasmid with origin, an ampicillin based selection marker and a *lacZ* gene that can be used to make random reporter gene fusions for expression screening and to clone the upstream region. Further, there are other vectors, several of which include the pE194 origin from *Staphylococcus* (97). They have been successfully tested in *B. subtilis* (74). Plasmid pHV33, one of the first *Bacillus* shuttle plasmids, has been used to generate several genomic libraries (Vary, unpublished). The series of defined copy number plasmids including pHT304, pHT315, and pHT3101 (98) generate within the host cell 4, 15, and 101 copies respectively. Plasmid pHT315 has proven to be a good general cloning plasmid. Vector pVG6 is a derivative of pSG1151 (99) that can be used to generate green fluorescent protein (GFP) fusions in *B. subtilis*. pKV1 and pVG6 are being deposited at BGSC.

For several decades, much effort was devoted to optimizing vector systems for recombinant gene expression and protein production in various bacterial organisms. Several of these vector systems are commercially available like the pET-series for *E. coli* (Novagen; pET-System-Manual; 11th edition) or the pMUTIN-series for *B. subtilis* (100). Kaltwasser and coworkers described the construction of six *B. subtilis* vectors allowing the fusion of a target gene to six different epitopes and localization tags. In addition to these epitope tags, like the Myc-epitope (101) and localization tags (99), fusion to further affinity tags for recombinant protein purification is common (102).

In 1991, Rygus and Hillen identified a xylose inducible promoter system in the genome of *B. subtilis*. Using this promoter, they constructed a vector for regulated gene expression in *B. subtilis* which was named pWH1520 (103). Within a few years, many more vectors were designed that are useful for recombinant protein overproduction in this Gram-positive organism. These vectors vary in their origin of replication (*ori*), their antibiotic selection marker gene, and their multiple cloning site (MCS). Moreover, different promoter systems for the recombinant gene expression are used. The vectors differ in the presence or absence of coding sequences for affinity tags upstream or downstream of the MCS and of sequences coding for leader peptides for protein export (Fig. 11.2).

11.3.3.2 Origins of Replication. Several molecular protein production strategies require genes carried on two different, compatible plasmids. For example, in so-called "codon plus" strains of *E. coli*, the coproduction of vector encoded tRNAs for rare codons and the target recombinant protein uses two independently replicating vectors (104). The initial T7-promoter system in *E. coli* was also based on two vectors (105). For the stable parallel replication of two or more vectors, origins of replication (ori) belonging to different compatibility classes are required. The origin of replication *oriU* and the gene *repU* constitute a replicon suitable for *B. subtilis*. This replicon is derived from the plasmid pBC16, a *Bacillus cereus* plasmid, which is replicated by the rolling circle mechanism (106,107). The *oriU* and *repU* genes are localized on the plasmid pMM1520 and all its derivatives (108). Replication of vectors carrying this replicon is not temperature sensitive.

The characterization of seven indigenous plasmid replicons of *B. subtilis* QM B1551 in pBM100 to pBM700 provide seven more compatible plasmids (refer to previous sections "*Bacillus megaterium* Strain QM B1551"). While pBM100 and pBM200 replicate by the rolling circle mechanism, pBM300–pBM700 use θ-replication. The copy numbers of these seven plasmids vary from 1 to 224 (72). Further, the temperature sensitive origin of replication originated from the plasmid pE194 (97) can be used in parallel to pMM1520 and all of the seven pBM100–pBM700 plasmids. This temperature sensitive origin is used for gene knock-out and chromosomal integration experiments in *B. subtilis* (69,71,95). A plasmid carrying the pE194 origin of replication is replicated independently from the genome at a temperature below 37°C. After raising the temperature to 42°C, the plasmid does not replicate. The plasmid can be integrated into desired regions of the chromosome if regions of homology to the chromosomal locus are encoded (69,71,95).

Several plasmid origins of replication useful in *B. subtilis* are listed in Fig. 11.2. Vectors carrying some of these origins are summarized in Table 11.2. In addition, most vectors used in *B. subtilis* also work in *B. subtilis*

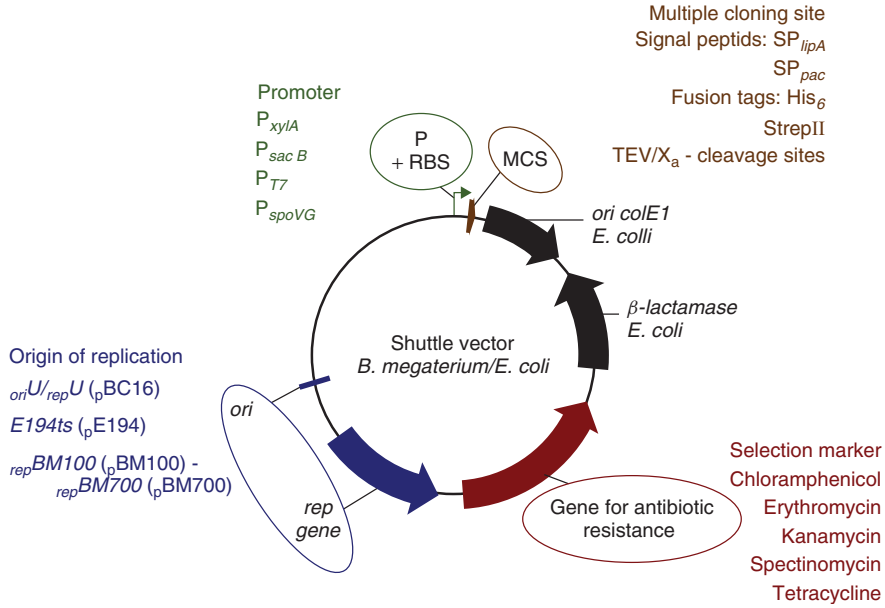

Figure 11.2. Map of a *Bacillus megaterium*/*Escherichia coli* shuttle vector. Characters functional in *B. megaterium* which can be changed modularly are indicated. P_{xylA}: promoter of *xylA*; P_{T7}: T7 RNA polymerase dependent promoter; P_{sacB}: promoter of *sacB*; P_{spoVG}: promoter of *spoVG*; His_6: 6x histidin tag; StrepII: streptavidin II tag; TEV: tobacco etch virus protease cleavage site; X_a: factor X_a protease cleavage site; SP_{lipA}: signal peptide of the lipase A; SP_{pac}: signal peptide of the penicillin G acylase. Characters functional in *E. coli* are indicated as *β-lactamase* (antibiotic resistance gene) and *ori colE1* (origin of replication). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

with the exception of those that require integration into the genome.

11.3.3.3 Antibiotic Resistance Genes. Different antibiotic resistance genes can be used for selection in *B. subtilis*. In 1995, Guérout-Fleury and coworker developed vectors containing so-called "antibiotic-resistance cassettes" for *B. subtilis* which can also be used in *B. subtilis* (112). The genes forming these cassettes have been cloned into the polylinker region of *E. coli* plasmids in a way that they can be recovered by different combinations of restriction enzymes to further clone them into different *B. subtilis* vectors. Among those are genes for resistance to tetracycline (e.g. pWH1520 (103), pMM1520 (108), and derivatives), erythromycin (e.g. pHBintE (69) and derivatives), kanamycin (e.g. pHBintN (71) and derivatives), and spectinomycin. Moreover, chloramphenicol can be used as selection marker in *B. subtilis* (e.g. pYZ11 (109), pKM307 (75), pGB22, and derivatives). Vectors carrying these different marker genes are summarized in Table 11.2.

11.3.3.4 Promoters and Multiple Cloning Sites. In 1991, Rygus and Hillen identified a xylose inducible promoter P_{xylA} with its repressor protein XylR in the genome of *B. subtilis* strain DSM319 (113). Originally, this promoter is located upstream of an operon encoding genes involved in xylose utilization. Based on this xylose inducible promoter, they developed a xylose-dependent plasmid-borne system for the overproduction of recombinant proteins. This plasmid encoded system includes the coding sequences for XylR, the promoter P_{xylA} and the first 195 bp of the *xylA* gene followed by an MCS. The corresponding plasmid was called pWH1520. In further studies, this promoter was modified and further optimized for recombinant gene expression in *B. subtilis*. The catabolite response element (*cre*) sequence was eliminated and an enhanced MCS was inserted (108). In the resulting plasmid pMM1520, glucose, and other sugars present in nutrient rich medium no longer inhibit recombinant gene expression by catabolite control. Moreover, the MCS allows simple cloning of target genes by the use of 15 different DNA restriction enzyme cleavage sites. This MCS was further included in all vectors based on pMM1520 to allow simple subcloning. A major advantage of this system is that the xylose inducible promoter does

not show any basal expression in *B. subtilis* in the absence of xylose (114).

To further enhance the toolbox for *B. subtilis*, Gamer and coworkers made use of the fact that two different plasmids belonging to two different compatibility classes can coexist in this organism (refer section on "Antibiotic Resistance Genes") (111). The T7 RNA polymerase (T7 RNAP)-dependent expression system that was developed in the early 1980s for *E. coli* (105) is based on the RNAP of the bacteriophage T7. This expression system combined several advantageous features, such as stringent selectivity of the RNAP toward its cognate promoter and its high processivity. To utilize the system in *B. subtilis*, the expression of the *rnap* gene was put under control of the xylose inducible promoter, while the expression of the gene of interest is controlled by the T7 RNAP. The MCS following the T7 RNAP dependent promoter has the same sequence as found in pMM1520 and derivatives to allow easy subcloning of recombinant genes between different expression vectors. The recombinant expression of the target gene with the T7 RNAP-dependent promoter increases the yield of recombinant protein up to sixfold compared to the xylose inducible one (111).

Another promoter used for recombinant protein production in *B. subtilis* is the promoter of the *B. subtilis* sporulation gene *spoVG* (115). The promoter containing vector pVG1 was combined with the *Bacillus* vector pE194 (116) to construct the multifunctional plasmid pAS5. The heterologous promoter has been used successfully for the recombinant industrial overproduction of the HIV antigen in *B. subtilis* (115).

Sucrose, a very cheap disaccharide, can also be used to induce recombinant protein production under the control of P_{sacB}, a sucrose inducible promoter. In 2007, this promoter was identified in the genome of *B. subtilis* strain DSM319 and cloned. In contrast to the xylose inducible

promoter, this one shows basal activity even in the absence of sucrose (117).

11.3.3.5 Affinity Tags for Protein Purification. The production of recombinant proteins in an apparently pure form for characterization, crystallization, or applications in the pharmaceutical industry has become a major goal in research and application. For this purpose, appropriate expression vectors provide the genetic setup for the in-frame fusion of peptides or proteins with high ligand binding specificity to the target protein. During the last few years, several epitope peptides and proteins have been developed for overproduction and purification of recombinant proteins. These affinity ligands have proven to have a minimal effect on the tertiary structure and the biological activity of the fusion protein. In addition to large fusion peptides like the glutathione *S*-transferase (GST) or the maltose-binding protein (MBP), small peptide tags like polyhistidine (His-tag) or a streptavidin binding polypeptide (Strep-tag) are commonly used (118). Various vector systems are commercially available for *E. coli* (104).

Two different affinity tags, the StrepII-tag (119) and the polyhistidine (His_6-) tag (120), were chosen as N- or C-terminal fusion partners for target proteins produced or/and secreted in *B. subtilis*. They are encoded on the expression plasmids either upstream or downstream of the MCS. For some of the resulting fusion proteins the corresponding N-terminal affinity tag may be removed via protease digestion, either by the tobacco etch virus (TEV) (121) or the factor X_a protease (122). The vectors were successfully tested using GFP as model protein. After cell disruption, between 25–71% of the recombinantly intracellularly produced GFP was recovered after a single purification step (Table 11.3). The secretion of recombinant target protein avoids the need for cell disruption. This protein can be purified directly from the cell-free growth medium by incubation with the affinity purification matrix. In such experiments with a levansucrase as model protein, between 26–43% of affinity tagged secreted enzyme was purified from the cell-free growth medium (123).

Vectors containing the different affinity tags for intra- as well as for extracellular production of recombinant proteins are listed in Table 11.4 and their structure is shown in Fig. 11.3.

11.3.3.6 Signal Peptides for Protein Secretion. In bacilli, 90% of all secreted proteins are transported via the

(This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Sec-dependent pathway demonstrating the major importance of this mechanism for the secretion of proteins. After the protein is synthesized at the ribosomes, the N-terminal signal peptide is recognized by proteins of the Sec system. The newly synthesized protein is kept in an unfolded state and transported through a channel in the cytoplasmic membrane into the space between membrane and cell wall. A special type I signal peptidase anchored at the surface of the cell membrane removes the signal peptide by cleavage at its recognition sequence. Chaperons in the space between cytoplasmic membrane and cell wall assist in protein folding. Finally, the protein diffuses through the cell wall into the growth medium (summarized in Ref. 124).

For the secretion of heterologous proteins into the surrounding growth medium of *B. subtilis*, the toolbox contains sequences for two different signal peptides. The recently discovered extracellular *B. subtilis* esterase LipA was secreted in high amounts into the culture medium of *B. subtilis* (125). The LipA signal peptide consists of 28 amino acids. The three typical regions of an Sec-pathway dependent signal peptide were identified in the LipA signal peptide by the SignalP algorithm (126). Using this signal peptide, 1,800 U/L of heterologously produced penicillin G acylase and 4 mg/L of recombinant levansucrase were secreted. Further, the signal peptide of the extracellular penicillin G acylase Pac, which is also secreted by the Sec pathway, was used to secret up to 1,500 U/L of Pac into the surrounding growth medium (Table 11.5).

11.3.3.7 Codon Usage of the Recombinant Genes. The codon bias of heterologous genes often provides a limiting factor for the expression in a certain host system. Hence, the so-called codon adaptation index (CAI) of a gene for the host is of importance. The CAI permits the calculation of a comparable value for the codon usage. The calculation of this value requires the definition of a set of highly expressed genes of an individual organism (127). The codon usage of all its other genes is calculated with respect to this subset of genes (128).

TABLE 11.5. Proteins Recombinantly Produced in *B. megaterium*

Protein	Origin	Promoter	Location	Yield	References
β-Galactosidase	*Escherichia coli*	P_{xylA}	Intracellular	4.937 Miller U	103

Mutarotase	*Acinetobacter calcoaceticus*	P_{xylA}	Intracellular	73.7 U/mg protein	103
Penicillin G amidase	*Bacillus megaterium*	P_{xylA}	Extracellular	1.800 U/L	134
Protective antigen	*Bacillus anthracis*	P_{xylA}	Extracellular	1 mg/L	135
Urokinase-like plasminogen activator	Human	P_{xylA}	Intracellular	400 U/mL	103
Thermobifida fusca hydrolase	*Thermobifida fusca* (codon adapted)	P_{xylA}	Extracellular	6.098 U/L	129
Toxin A	*Clostridium difficile*	P_{xylA}	Intracellular	500 μg/L	136

An optimal adapted gene shows a CAI value of 1. In several studies, genes encoding the hydrolase TfH from *Thermobifida fusca* (129), the formiate dehydrogenase Fdh from *Mycobacterium vaccae* (130), and a human ceratin binding domain KbdB were expressed before and after adaptation of their codon usages to *B. subtilis*. All of the native genes showed CAI values below 0.3. Very little or none of the recombinant gene product was obtained. This phenomenon was previously described for *E. coli* (131). The design and synthesis of the artificial genes with a CAI > 0.9 for *B. subtilis* resulted in good production of all recombinant gene products in *B. subtilis* (129,130). Rare codons have been found in bacilli coding for leucine, serine, arginine, and proline. The different codon usage for those amino acids is summarized in Table 11.6.

11.3.4 Commercial Protein Production Systems for *Bacillus megaterium*

For several years now, the company MoBiTec (Goettingen, Germany) has been commercializing a vector system for recombinant protein production in *B. subtilis* based on the xylose inducible promoter P_{xylA}. Starting with the vector pWH1520 (103), MoBiTec now markets all production and secretion vectors which are listed in Table 11.4. Using these vectors, recombinant gene products can be produced intra- as well as extracellularly with or without an affinity tag for protein purification. These vectors have been successfully used by several different laboratories to produce recombinant proteins from prokaryotes and eukaryotes. Proteins produced under control of the xylose inducible promoter are summarized in Table 11.5.

11.3.5 Culture Heterogeneity in *Bacillus megaterium*

In 2007, Biedendieck and coworkers described culture heterogeneity during intracellular recombinant protein production with *B. subtilis*. Using the production of GFP under control of the xylose inducible promoter as a model in fluorescent activated cell sorting experiments, it was shown that only around 70% of the genetically homogenous cells in a high cell density cultivation were producing GFP (114). The phenomenon of culture heterogeneity was previously reviewed for *B. subtilis* (137). Dubnau and Losick described the phenomenon that genetically identical bacteria behave differently across the population for the expression of genes involved in competence development, sporulation, swimming, and chaining (137).

11.3.6 Outlook: Genomics and Systems Biotechnology

The availability of the genome sequences of two important *B. subtilis* strains in addition to the establishment of genetic tools offers a promising future for systems biotechnology approaches. Genome-wide comparisons have already shown that just two of the 5.1 MBp of the *B. subtilis* genome are synthenic to other bacilli. Although all genes in the nonsynthenic region (especially those on *B. subtilis* QM B1551 plasmids) were annotated and raw gene names were assigned, most of these genes are lacking clear

[a]Codons for all amino acids were counted and their relative frequencies were calculated for one amino acid (frequency/acid) as well as for all codons in the genome (overall frequency). All frequencies are given in percent. Rare codons (with a frequency <10% per acid) are printed in italics. Codon usage was calculated based on the program JCat (128).

functional annotations and biochemical investigations. To overcome this lack of information, comparative and functional genomics in combination with systems biotechnology might provide solutions. Based on the information of the genome sequences, DNA-microarrays were designed and successfully employed (unpublished data).

Along these lines, investigations were made of the responses of a protein-producing *B. subtilis* culture to changes in the cultivation and induction conditions and proteome analyses were performed (138). Furthermore, to complete the picture first metabolome studies were carried out (139,140).

The first steps using *B. subtilis* as a model organism for systems biotechnology have already been taken. Currently, the establishment of bioinformatics models for the prediction of cellular processes with use of these high-throughput data is underway.

11.4 PROTOCOLS FOR BACILLUS MEGATERIUM

Genetic competence is well studied in the Gram-positive model organism *B. subtilis* 168. So far, no conditions have been found for the development of natural competence for *B. subtilis*. The genome data reveals that *B. subtilis* lacks two of the competence genes, *comFB* and *comGG*, found in *B. subtilis* (141,142). Nevertheless, reasonable transformation frequencies are attained using PEG protoplast transformation. Consistent, but low transformation frequencies are now possible by the ETF protocol below. PEG transformation of QM B1551 is more efficient using RHAF medium and is detailed in (73). An ETF protocol for QM B1551 and a PEG transformation protocol for DSM319 are included here.

11.4.1 Electrotransformation of *Bacillus megaterium* QM B1551 and Derivatives

This protocol is based on the electroporation procedure described for *B. subtilis* and *B. licheniformis* by Xue and coworkers (88) and was modified by Scott Grayburn (unpublished data) by increasing the sorbitol and cell density and performing fewer washes.

11.4.1.1 Preparation of Competent Cells.

1. Inoculate 5 mL *growth medium* with cells of *B. subtilis* QM B1551 or derivatives. Grow on a shaker at 225 rpm and 37°C overnight.
2. Use 3 mL of the overnight culture to inoculate 45 mL of preheated (37°C) *growth medium* in a 250 mL

shaking flask and incubate at 225 rpm and 37°C for 1–2 h. Grow the cells to $OD_{600\ nm}$ of 0.85–0.95.

3. Cool the cell suspension in ice water for 10 min.
4. Harvest the cells by centrifugation at 5.000 × *g* for 5 min at 4°C in a prechilled rotor. Decant the supernatant and place tubes in ice.
5. Resuspend the cell pellet in 24 mL (1 volume) of cold (4°C) *electroporation medium* by vortexing. Harvest the cells by centrifugation at 5,000 × *g* for 5 min at 4°C in a prechilled rotor. Wash the pellet in *electroporation medium* a total of two times.
6. Resuspend the cell pellet in 1.2 mL of cold (4°C) *electroporation medium*. Maintain on ice. Any leftover cells can be frozen (refer step 5 of transformation).

11.4.1.2 Transformation. Please note that everything is kept on ice during handling.

1. Prechill 1.5 mL centrifuge tubes and electroporation cuvettes (1 mm gap, Fisher cat. No. FB101) in ice.
2. Mix 60 μL of resuspended cells with 1 μL (100 ng/μL) of plasmid DNA in a prechilled 1.5 mL tube by drawing the cell–DNA mixure into and out of a 200 μL pipette tip three times. Transfer to an electroporation cuvette.
3. Use the BTX electro cell manipulator 600 for electrical pulses (BioRad MicroPulser). Settings for BTX: Mode T 2.5 kV resistance, R5, S = 2 kV*.
4. After the pulses are completed, add 1 mL *recovery medium* directly to the cuvettes on ice. Transfer the liquid to the sides of glass culture tubes. Transfer to a shaker at 37°C and 225 rpm.
5. Make 0.2 mL aliquots of any leftover electrocompetent cells in 1.5 mL tubes and store the cells at −80°C.
6. After 3 h of incubation, pour the entire transformation mixtures onto Lunia-Bertani (LB) plates containing antibiotic and spread the cells evenly across the plate. Allow liquid on the plates to soak into the agar at 37°C then invert the plates and incubate overnight at 37°C.

11.4.1.3 Media and Solutions.

- *10N NaOH*
  - Dissolve 40 g NaOH in water and bring to a final volume of 100 mL.
- *Growth medium (500 mL)*
  - 5 g tryptone
  - 2.5 g yeast extract
  - 5 g NaCl
  - 45.55 g D-sorbitol.

  Adjust the pH by adding 0.25 mL 10N NaOH.
- *Recovery medium (100 mL)*
  - 6.92 g mannitol in 100 mL growth medium.
- *Electroporation medium (500 mL)*
  - 45.55 g D-sorbitol
  - 45.55 g mannitol
  - 50 mL glycerol.

11.4.2 Protoplast Transformation of *Bacillus megaterium* DSM319 and Derivatives

11.4.2.1 Preparation of Protoplasts.

1. Inoculate 50 mL *LB-medium* in a 300 mL shaking flask with cells of *B. subtilis* DSM319 or derivatives. Grow for 16 h at 100 rpm or 8 h at 200 rpm (must not reach stationary phase) at 37°C.
2. Inoculate 50 mL *LB-medium* with 1 mL of preculture in 300 mL buffled flask.
3. Grow the cells to an $OD_{578\ nm}$ of 1 at 37°C and strong shaking (250 rpm).
4. Harvest cells in a sterile 50 mL tube for 15 min at 5000 × g and 4°C.
5. Resuspend the pelleted cells in 5 mL freshly prepared *SMMP*.
6. Fill cell suspension in 15 mL tube and add 50 μL freshly prepared and sterile filtered lysozyme solution (1 mg/mL in *SMMP*).
7. Incubate at 37°C and very soft shaking until 20–80% of cells are protoplasted (microscope).
8. Harvest protoplasted cells by centrifugation for 10 min at 1300 × *g* at room temperature.
9. Remove supernatant very carefully using a pipette and resuspend cells in 5 mL *SMMP*. Cell pellet is soft and fragile, do not vortex! Repeat twice.
10. Add 750 μL 87% (v/v) sterile glycerin, mix softly (rolling) and make aliquots of 500 μL.
11. After freeze at −80°C, protoplast can be kept for about 2 months, but competence will sink gradually.

11.4.2.2 Transformation.

1. Dry 5 μg DNA and resuspend in 10 μL SMMP for 20 min at 37°C.
2. Add 500 μL of protoplasts to the Eppendorf tube with DNA and transfer into 15 mL tube containing 1.5 mL *PEG-P*. Mix softly (rolling).

3. After an incubation for 2 min at room temperature, add 5 mL freshly prepared *SMMP* and mix very carefully (rolling).
4. Harvest cells by centrifugation for 10 min at 1300 × *g* and room temperature.
5. Carefully remove the supernatant by using a pipette. Usually the cell pellet is not visible.
6. Carefully resuspend the cells in 500 μL *SMMP* (do not vortex!) and transfer them into a 1.5 mL Eppendorf tube.
7. Incubate for 90 min at 30–37°C and soft shaking (100 rpm).
8. In the mean time, prepare 2.5 mL of CR5-Topagar in 15-mL tubes and incubate at 43°C in a waterbath.
9. Pipette the cells to the tube containing the topagar and mix gently by rolling.
10. Pour the topagar containing the cells on prewarmed (37°C) antibiotic agar plates.
11. Incubate for 24 h at 30–37°C, separate grown colonies into single colonies and check microscopically.

11.4.2.3 Media and Solutions.

- *LB-medium (500 mL)*
  - 5 g tryptone
  - 2.5 g yeast extract
  - 2.5 g NaCl.
- *2 × AB3 (Antibiotic Medium No. 3) (200 mL)*
  - 7 g AB3 (Difco).
- *2 × SMM (solubilize in the given order) (250 mL)*
  - 1.16 g malic acid
  - 0.8 g NaOH
  - 2.03 g $MgCl_2 \times 6H_2O$
  - 85.58 g sucrose.
    Adjust pH with HCl to 6.5
    Sterilize by filtration.
- *SMM*
  - 2 × AB3 and 2 × SMM 1:1 (freshly prepared!)
- *PEG-P solution (50 mL)*
  - 20 g PEG-6000 in 1 × SMM
    Autoclave 11 min.
- *Solution A (250 mL)*
  - 51.5 g sucrose
  - 3.25 g MOPS
  - 0.3 g NaOH.
    Adjust pH to 7.3 with NaOH
    Sterilize by filtration.
- *Solution B (142.5 mL)*
  - 2 g agar
  - 0.1 g casamino acids
  - 5 g yeast extract.
- *8 × CR5-salts (625 mL)*
  - 1.25 g K_2SO_4
  - 50 g $MgCl_2 \times 6\ H_2O$
  - 0.25 g KH_2PO_4
  - 11 g $CaCl_2$.
- *12% proline (25 mL)*
  - 3 g proline
    Sterilize by filtration.
- *20% glucose (100 mL)*
  - 20 g glucose.
- *CR5-topagar (2.5 mL)*
  - 1.25 mL solution A
  - 0.288 mL CR5-salts
  - 0.125 mL 12% proline
  - 0.125 mL 20% glucose
  - 0.713 mL solution B (after liquefaction).

12.1 BACKGROUND

12.1.1 The Use of Human Cell Lines in Research

One of the chief appeals of biotechnology products is the ability to give patients medicines that resemble the natural molecules present in the human body as a way to minimize the risk of adverse events or unknown toxicological effects, as opposed to using new and chemically synthesized drugs. The goal of achieving increased fidelity also demands an increase in the complexity of the production process, and the industry has resorted to source these products initially from cadavers, animal and human sera, to more recently recombinant DNA technologies to satisfy the need for solving unmet medical needs, shortages in supply, and safety concerns of these therapeutic products (Fig. 12.1). This progression in the sources for these products is driven not only by the economics of the production process but also by the need to improve the assurance of patients' safety without compromising on quality.

Until recently, a major drawback of using nonhuman recombinant expression systems to express human proteins was the inability to obtain the complete human characteristics of these protein products (1). Even though the safety of "partially true" recombinant human products obtained from nonhuman cell lines (such as BeneFix™) or even transgenic animals (such as Atryn™) were acceptable for approval, in some instances these recombinant molecules are cleared much faster than the plasma-derived ones due to differences to the native human molecule being replaced, requiring higher or more frequent dosing to achieve the intended clinical effect (2).

More recently, technology improvements for making recombinant human proteins from nonhuman sources have been made. For instance, Glycofi's technology (acquired by Merck Inc. in 2006), has engineered human glycosylation pathways in the yeast *Pichia pastoris* (3) in order to express secreted recombinant fully human antibodies. In addition, a multitude of novel research approaches had been recently demonstrated to mimic human pathways in nonhuman expression systems (1) including transgenics (4), and even bacteria have been shown to be able to express full-length, nonglycosylated human antibodies (5). These efforts overcome in part some of the difficulties of expressing complex human proteins in nonhuman expression systems as a way to make these molecules more economical to produce. However, either the inability to obtain the complete protein structure due to, perhaps, differences in protein folding (1) or the lack of commercially viable production yields are still the obstacles to truly achieve the autonomy of producing human biotherapeutics from human sources such as serum plasma, tissues, or even stem cells.

Fundamental research in medical pharmacology is still being carried out using human cells to test the different mechanisms of human disease and interactions between different molecules *in vitro* (6). However, very little progress has been made in facilitating the extrapolation of these

results to clinical settings by supplying the same human proteins along the clinical development cycle and into commercial production. Typically, once a target has been identified and validated *in vitro* using human cells or tissues, the protein reagent (agonist or antagonist) is then expressed in a nonhuman expression system before going into first-time in human clinical trials in an effort to overcome the economic and/or technical hurdles of obtaining these molecules from their natural sources in large amounts. Historically, this has been circumvented by using animal cells as a close approximation due to the lack of available human cell lines that address safety concerns and achieve industrial performance for robustness and product yields. The industry has been forced to use what is available in research laboratories, even if that meant nonwell characterized animal cell lineages. When expressing human proteins in animal cells (i.e. human amino acid sequence), there is still the potential for either carrying nonhuman posttranslational modifications (PTMs) into the final product or incomplete human PTMs. In either case, both safety and efficacy of the intended protein drug could be suboptimal. Products derived from animal cells are still being approved on the basis that clinical studies show acceptable safety and efficacy in short term clinical studies. Nevertheless, there is evidence suggesting that nonhuman PTMs such as the presence of α-1,3 gal in some of the approved protein products may pose safety risks to humans (7). Mouse cell lines contain α-1,3-galactosyltransferase activity which adds galactose residues to proteins in the α configuration, designated as Gal($\alpha 1 \rightarrow 3$)Gal. Humans indeed recognize this structure as foreign (8) being the main reason for preventing xenotransplantation of animal organs into humans (4).

Even if these antigenic responses by patients to nonhuman proteins or nonhuman components in protein therapeutics may not necessarily carry a safety risk to the patient, it could certainly affect the efficacy of the product as this response may increase the clearance of the protein therapeutic, thereby reducing the bioavailability of the clinically tested dose. In fact, even "fully human" antibodies (such as Humira™) produced in Chinese hamster ovary (CHO) cells show immunological responses to the product (9).

The definition of "fully human" antibody has only considered the amino acid sequence, and not to the rest of the required structures present in the protein molecule. This is important to bear in mind when trying to develop the next generation of safer and more effective therapeutics. Not only the correct molecular moiety but also the correct molecular linkages have to be in place in order to provide true fidelity to the natural protein. And in some cases, evolution has resulted in some subtle but critical differences among the posttranslational modifications different species of mammals will perform on proteins, not to mention among members of the other different animal kingdoms and microorganisms.

For instance, the presence of α-2,6-sialyl-transferase enzyme in humans is particularly critical as a different linkage for the same sugar moiety to a protein immunoglobulin G (IgG) will cause a faster clearance in the human body (1,4,8). In this regard, CHO cells, a widely used recombinant protein expression system, lack this enzyme activity and they add sugars to proteins via 2,3-linkages (4,8). In addition, other typically human glycosylation reactions, such as fucosylation, are much more diminished in CHO cell lines having to resort to engineer these nonhuman

cell lines to accomplish the desired modifications to approach a true human profile in the final molecule by expressing human *N*-acetyl-D-glucosaminyltransferase and α-1,3-fucosyl-transferase III (1). It is worth noticing that in some instances, lower amounts of fucosylation (or lack of it) may lead to improved attributes to products. One remarkable example is the discovery that reduced or absence of fucosylation of antibodies increase their antibody-dependent cell cytotoxicity (ADCC) (10). In other cases, increased sialylation of antibodies has been recently elucidated to be associated to their antiinflammatory effects (11). In this particular case, the linkage of sialic acid is critical for this effect and only 2,6-linkages, typical of human cells and not of animal cells, work.

In addition, nonhuman cell lines can make modifications to proteins which could be immunogenic to humans. For instance, the enzyme CMP-*N*-acetylneuraminic acid hydrolase which glycosylates CMP-*N*-acetylneuraminic acids (NANA) to CMP-*N*-glycolylneuraminic acid (NGNA) is present in CHO cells but not in humans (1,12). This NGNA structure could be immunogenic if injected (1) and it can also be incorporated into human proteins if provided exogenously in the diet (12). The connection between this NGNA structure and human disease is being established (12), thereby increasing the putative risks that CHO-derived protein therapeutics containing this NGNA structure may carry. Eliminating this enzymatic activity by altering the genotype of CHO cells or by using cell lines that do not contain it will certainly alleviate these concerns.

12.1.2 The Use of Human Cell Lines in the Production of Cell Culture Products in Manufacturing

12.1.2.1 Early Products. The first demonstration of using human cell lines for making a human therapeutic is the approval and marketing of Wellferon. Wellferon, a human interferon α, was first approved in 1986 in the United Kingdom for hairy cell leukemia, and produced and marketed by the Wellcome Foundation Ltd. (now part of GlaxoSmithKline PLC) (13). This product was made in Namalwa cells, which are human lymphocytes obtained from an African female who has died of lymphoma (Burkitt's tumor). The production process consisted in stimulating the production of interferon α by infecting these Namalwa cells with Sendai virus. The cell culture contained animal-derived components and this product was manufactured with the standards and testing available in the 1980s and early 1990s. It was subsequently withdrawn from the market in 1999 due to the competition from recombinant products made much more cheaply and arguably more safely in *Escherichia coli*, such as Roferon and Intron. In retrospect, the production process to make Wellferon would not satisfy current demands for safety in the production process, but it did demonstrate the suitability of using human cells for making active and safe protein therapeutics.

In most of the cases illustrated in Table 12.1, the proteins produced in human cells are actually induced. That is, endogenous capability of the host cells is enhanced rather than exogenous transfer of genes to express a given protein. However, this list is provided as evidence of the safety of using human cells for making protein therapeutics. The only two examples of an approved recombinant protein expressed in human cells to date are Elaprase™ and Xigris™. However, the availability of adequate human cell lines specifically developed for their use in commercial production such as the PER.C6® cells, having its history and safety well documented (14) to backup the use of such cell line in making human therapeutics offer a renewed perspective for the production of human therapeutics in human cell lines. The PER.C6 human cells are the only cells developed exclusively for the production of therapeutics such as gene therapy, vaccine, and protein products, and its extensive testing for safety and adequacy is documented in a Biological

TABLE 12.1. Approved Protein Products from Human Cells

Product Name	Protein	Human cell	Sponsor	Date approved
Wellferon	Interferon α	Namalwa	Wellcome Foundation Ltd.	1986 (UK) (withdrawn in 1999 by Glaxo Wellcome)
Xigris	Activated Protein C (recombinant)	HEK 293	Eli Lilly & Co.	2001 (US)
Dynepo	Erythropoietin	Human fibroblast	Shire Pharmaceuticals	2002 (EU)
Replagal	Human alfa galactosidase (agalsidase alfa)	Human fibroblast	Shire Pharmaceuticals	2001 (EU)
Elaprase	Idursulfase (recombinant)	Human fibroblast	Shire Pharmaceuticals	2006 (US)

TABLE 12.2. Clinical Trials of Recombinant Proteins Expressed in Human Cells

Protein	Human Cell Line	Sponsor	Clinical Trial Stage	Indication(s)
Antirabies IgG (cocktail of 2 IgGs)	PER.C6®	Crucell/Sanofi Pasteur	Phase 2	Rabies exposure (prophylaxis and therapy)
Anti-GM-CSF IgG	PER.C6®	Morphosys	Phase 1	Inflammatory diseases
GLP-1	Recombinant mesenchymal stem cell	Biocompatibles International PLC	Phase 1/2	Stroke
Undisclosed	PER.C6®	AME/Lilly	Phase 1	Undisclosed

IgG, immunoglobulin G; GM-CSF, granulocyte monocyte-colony stimulating factor.

Master File with the US Food and Drug Administration (USFDA) (15).

The maturing of the technologies employed in using human cells for gene expression is making it possible currently to achieve record level productivities of IgGs of more than 10 g/L in fed-batch (16) and of more than 25 g/L in continuous processes such as the XD™ technology (17). At the same time, IgM levels are reaching over 3.5 g/L in fed-batch using human cells (18). These yields far exceed the current best practices achieved in other nonhuman cell lines, such as CHO cells due to the intrinsic properties of, for instance, the PER.C6 cells for their use in biopharmaceutical production. Many other human proteins of therapeutic value are also being expressed in human cells due to the intrinsic nature of human cells being the natural host to make these complex proteins requiring the correct PTMs for activity and, possibly, for lowering the risk of immunological responses against these therapeutics. These record yields in productivity provide a very attractive opportunity to decrease the production costs without sacrificing product quality.

These developments are opening a renewed interest in using human cells which is demonstrated by the increasing number of clinical trials of proteins derived from recombinant human cell lines (Table 12.2).

12.1.3 Future Trends in the Expression of Genes in Human Cells

Although the overwhelming majority of therapeutics products and recombinant proteins in clinical trials are currently made in nonhuman cells, it is expected that future use of human cells will increase (15) as this system provides the natural host for making human recombinant therapeutics. Significant efforts have been devoted to modifying *in vitro* some of the human proteins expressed in nonhuman systems (19) in order to achieve the desired "humanness" for these molecules. The alternative path of engineering nonhuman expression systems to mimic human posttranslational modifications, and thereby expressing a truly fully human molecule, need to overcome multiple technical challenges such as achieving expression levels that reach economic feasibility, attaining the proper balance of the enzymes involved in these anabolic pathways (3,20), obtaining stable cell lines expressing the entire array of exogenous enzymes without losing product expression level, and a tolerable level of freedom to operate.

The increase use of human cell lines for making recombinant therapeutic proteins will also make it possible to address the relative differences in safety and efficacy with currently nonhuman recombinant sources, especially for chronic indications where the long-term harmful effects of drugs are hard to evaluate in limited-term clinical trials. For instance, there is already solid evidence that improved amino acid sequences of proteins such as the so-called fully human antibodies (i.e. amino acid sequence) are much better tolerated and more efficacious (stronger binding to antigen) than their chimeric counterparts (21). However, these fully human antibodies when expressed in nonhuman cell lines can carry nonhuman posttranslational modifications and/or immunogenic residues from the host expression cell line, which may lead to immunogenic responses in humans (22). These effects can be avoided not only by engineering nonhuman expression systems, but also by increasing the overall production cost. At the end, safer and efficacious products made economically are to be the goals to aim when pursuing the medicines of the future.

12.2 THE SAFETY AND REGULATORY ASPECTS OF USING HUMAN CELL LINES FOR GENE EXPRESSION

The safety of recombinant protein biologics manufactured using human cell substrates is ensured by a process of regulatory oversight whose codification and maturity have been realized through the last 70 years to support the manufacture and release of viral vaccines for use in humans. The development of the earliest human viral vaccines was sponsored by various US military agencies to offer prophylaxis for US military servicemen deployed to Asian theaters

of combat during World War II where the debilitation of entire units with vector-borne pathogens threatened combat readiness and effectiveness. These early prototypical vaccines were developed with the most unsophisticated *in vivo* culture methods, for example, mouse brain, to propagate the virus for the formalin inactivated Japanese encephalitis virus vaccines, embryonated hens' eggs for the manufacture of the first inactivated influenza virus vaccines (23), and the live attenuated 17D yellow fever virus vaccine from M.Theiler and the Rockefeller Foundation (24). These manufacturing substrates and primitive methods of processing and containment provided theoretical opportunities for the adventitious contamination of the vaccine viruses with other viruses of human or nonhuman origin. Despite these theoretical opportunities for compromise, these prototypical vaccines offered highly favorable equations of benefit and risk supporting widespread administration in epidemiological contexts of endemic infection and morbidity. Indeed similar favorable benefit risk equations supported the development and widespread use of both inactivated and oral polio virus vaccines manufactured on primary monkey kidney cell cultures to control epidemic disease, and live vaccinia vaccines deployed for the global eradication of small pox prepared as lyophilized preparations of lymph fluid (pus) from bovine skin infected by scarification with various vaccinia virus strains.

These early vaccine manufactures using nonhuman substrates were not without incident, most notably the contamination of inactivated and attenuated poliovirus vaccines with Simian Virus 40 propagated in the rhesus monkey cell substrates and the contamination of live virus vaccines manufactured in embryonated eggs with avian leukosis viruses. Although it now appears through long-term prospective studies that the widespread SV40 contaminations resulted in no long-term untoward medical consequences to vaccine recipients (25), these episodes made frighteningly real the theoretical hazards of biologics manufacture with cell substrates from nonhuman sources whose spectrum of virus sensitivity and endogenous viral burdens were not well characterized or understood.

With these hazards in mind, the use of human cell lines for the manufacture of biologics and vaccines would appear to offer the advantages that National Institute of Health (NIH) supported medical science investigations of the last 50 years have been mostly focused on the isolation and thorough characterization of viruses which replicate in humans causing human disease. These investigations have led to the development of numerous assay systems appropriate for the propagation and sensitive detection of adventitious viruses of human origin and tropism and a familiarity beneficial to detection and elimination.

Despite the theoretical advantages of familiarity, to vaccine safety of the use of human cell lines to propagate vaccines and biologicals, the adoption of human cell lines awaited the development of the WI-38 and MRC-5 primary human lung diploid cell strains at the Wistar Institute (26) and National Institutes of Medical Research (27) in the decade of the 1960s, nearly 20 years after the proposal of M. Hilleman to adopt the human cervical carcinoma cell line as a substrate for his manufacture of an inactivated adenovirus vaccines for use in military recruits in 1954 (28). The rejection of the US Armed Forces Epidemiology Board (AFEB) of Hilleman's proposal for HeLa cells to support biologics manufacture owed largely to the ignorance at the time of the etiological role of human viruses in the development of human cancers, especially reasonable and prudent concerns in an era in which retroviruses were shown to be responsible for a range of avian and murine leukemias and solid tumors and subsequently the oncogenicity of the human retroviruses human T-cell leukemia virus type-1 (HTLV-1) and HTLV-2, various human papilloma viruses (HPVs), the human Epstein-Barr virus (EBV), and the Kaposi sarcoma virus–associated human herpes virus (HHV)-8 were shown to be etiological agents of various human cancers.

The adoption of the normal diploid primary WI-38 and MRC5 cell substrates for the manufacture of numerous live attenuated vaccines for both pediatric and adult populations, including measles, mumps, rubella, varicella vaccines, and most recently second generation vaccinia virus vaccines has been attended by impeccable records of safety and manufacturabiity. Moreover, a similarly impressive record of vaccine safety and manufacturability have been recorded with the use of embryonated eggs, primary chick embryo fibroblasts to manufacture influenza virus vaccines and the African green monkey kidney continuous cell line VERO, and both attenuated poliovirus and rotavirus vaccines. This record of safety and consistent large-scale manufacture using cell substrates which are exquisitely sensitive hosts for a wide range of human virus replication, argues compellingly that the use of human cell substrates in contemporary manufacturing settings with human operators poses no special risks to the safety of the human biological product. Indeed, it remains an irony that the only recent example of adventitious viral contamination that compromised the consistency of large-scale biotechnological manufacturing campaigns is the well-described episodes of bioreactor contamination with mouse minute virus (29), contamination introduced not through human agency but presumably through raw material contamination.

The principles of current good manufacturing practice (cGMP) which have emerged through decades of virus vaccine manufacture are described and codified in various regulatory documents, most notably the seminal two documents, *"Points to Consider in the Characterization of Cell Lines Used to Produce Biologicals"* of the USFDA (30) and the International Conference on Harmonization

(ICH) guideline *"Note for Guidance on the Quality of Biotechnological Products; Derivation and Characterization of Cell Substrates Used for the Production of Biotechnological/Biological Products"* (31).

In brief, these documents provide regulatory guidance to manufacturers to ensure the safety of biologicals manufactured in human cell substrates. In short, this is achieved by the combination of: (i) an extensive documentation of the origin and processing of the cell substrate intended for use as a Master Cell Bank, as well as a thorough documentation of all materials of animal origin used for their manufacture, (ii) the manufacture of Master Cell Banks and bulk biological product according to cGMPs in facilities meeting mandated standards of microbiological containment with demonstrated validation and appropriately trained operators, and (iii) an extensive panel of release testing for adventitious microbial and virological agents using a broad panel of nonspecific but highly sensitive *in vivo* and *in vitro* assays to reveal adventitious viral contamination through biological effect supported by biochemical and molecular assays of considerable specificity and sensitivity and breadth for the detection of known human pathogenic viruses.

These principles of manufacture practice have been validated by a long history of successful manufacture of live virus vaccines and with the continued development and refinement of manufacturing facilities and processes, and they can be expected to serve the manufacture of important biologicals and recombinant proteins whose essential attributes are most thoroughly and consistently endowed with the use of human cell substrates.

12.3 GENE EXPRESSION IN HUMAN CELL LINES

In the late nineteenth century, the German zoologist, Wilhelm Roux successfully cultured embryonic chick cells *in vitro* in a simple saline solution, thus establishing the basic principles of tissue culture. Over the following decades, many other scientists were able to propagate a variety of animal cells in culture. The earliest work focused on primary cell cultures, which are derived directly from a specific animal tissue. A large panel of human diploid cell lines (HDCLs), derived from a variety of fetal tissue, was developed at the Wistar Institute in Philadelphia and first described in a paper published by Leonard Hayflick (26). These cell lines were designated WI-1 through 25. Additional HDCLs were later isolated at the Wistar Institute and other laboratories, including the WI-38 line which is still used for virus vaccine production. The FS-4 line, derived from human neonatal foreskin fibroblasts, has been used extensively to study the antiviral and biological functions of human interferons and cytokines (32). The isolation of primary cell lines from human tissue remains an active area of research today, and a number of companies offer the ability to create novel HDCLs. One particular application is to use such cell lines as "biorepositories", for research on a number of human diseases and for clinical pathology. However, a major drawback with primary cell lines is that they have a finite life span, and are often heterogeneous in nature (i.e. comprised of different cell types), which can limit their usefulness as a research tool or production platform (33,34). Transformed cell lines, on the other hand, can be propagated in culture indefinitely, and as such are often referred to as *immortal cell lines*. Cell lines derived from many tumor types exhibit this transformed phenotype. Moreover, as the acquisition of the immortalizing or transformed phenotype is often the result of rare mutation events to the cellular genome, such cell lines are typically clonal, or homogeneous. Currently, such cell lines are in common use as models for studying the origins of the cancer itself, as well as for understanding mechanisms underlying cellular processes such as growth, division, differentiation, and gene expression.

While a number of cell lines have been successfully isolated from patient tumors, the first continuous cancer cell line and perhaps the most widely used cell line in research is the HeLa cell line (35). HeLa cells were isolated in 1951 by George Otto Gey, who was the head of tissue culture research at Johns Hopkins University. HeLa cells exhibit an epithelial morphology, and grow adherently (although suspension-adapted cultures have also been described). The cell line has a fast doubling time, which has been attributed to low levels of the tumor suppressor protein p53. HeLa cells were isolated from a patient with aggressive cervical cancer named *Henrietta Lacks* (the name HeLa is derived from the first two letters of the patient's names). The cells were removed without the patient's knowledge or permission, and were later commercialized. The issue of patient rights sparked a bioethics debate which was noted by the Supreme Court in the case *John Moore v the Regents of the University of California*, in which the court ruled that a deceased person's body or tissue are not their property, and can therefore be commercialized.

One of the earliest uses of the HeLa cell line was in the development and testing of different poliovirus strains, and the HeLa cell was established as a model for testing the new Salk vaccines being developed in the 1950s. This early virus vaccine program, established by the National Foundation for Infantile Paralysis, culminated in the shipment of over 600,000 cultures of HeLa cells to production laboratories at the Tuskegee Institute (35). This use of an immortalized human cell line for the propagation of human disease-causing viruses, and for the development of vaccines, was an early example of biotechnology. However, further use of immortalized human cell lines for this purpose was hindered by the

recommendations from the USAFEB, which stated in 1954 that adenovirus vaccine production for use in the military should use "normal cells" as the substrate, rather than cell lines established from human tumors (i.e. HeLa). The main concerns raised by the board were that cells derived from tumors may be contaminated and may confer oncogenicity to patients, making them susceptible to cancer. These recommendations continue to resonate with regulatory agencies, and the only cultured animal cells currently in use for the production of viral vaccines in the United States are primary cells (derived from monkey, chick, or mouse), continuous animal cell lines (VERO) and nontumorigenic human diploid cell lines (e.g. WI38, MRC-5). Recently, however, there have been attempts to reintroduce immortalized human cells for the production of viral vaccines. Certain viral strains, such as human immune deficiency virus (HIV), cannot be adequately propagated in traditionally accepted cell substrates. The Office of Viral Research and Review (OVRR) and the Center for Biologics Evaluation and Research (CBER) at the FDA have commented on so-called designer cell substrates, which are described as "neoplastic cells derived from normal human cells transformed by defined viral or cellular oncogenes or by immortalizing cellular genes." Specifically, in 2001 the FDA requested to the Vaccines and Related Biological Products Advisory Committee the use of two immortalized human cell lines, HEK293 and PER.C6, for the production of viral vaccines. Both cell lines express the immortalizing E1 genes from adenovirus Ad5. However, OVRR/CBER believes that "there is an extremely low probability that residual DNA from adenovirus 5-transformed human cells could transfer traits that could induce neoplastic development in vaccinees."

In addition to HeLa cells, many other cell lines derived from human cancers are widely used in research laboratories (Table 12.3). Each of these tumor-derived cell lines offers researchers unique attributes and opportunities for study. For example, because such cell lines originate from a variety of tissues, different cell type specific proteins (such as cytokine receptors) may be expressed on the cell surface. Similarly, individual cell lines may respond differently to experimental stimuli. Thus, Jurkat cells may allow a researcher to study T-cell signaling pathways, U937 cells may be used for understanding the behavior of monocytes and macrophages, and K562 cells may be used to study erythrocyte function. The differential responses to stimuli also allow such cells to be used as *in vitro* models for evaluating the functionality and efficacy of new drugs being developed for the treatment of human diseases, particularly those which target specific cell types. The A549 and BxPC-3 cell lines, derived from lung and pancreatic cancers respectively, have been used to test the binding of tissue-specific antibodies being developed for the treatment of these cancers. For all of these aforementioned cell lines, their derivation from human tissues is an important feature, which distinguishes them from cells lines derived from other species. The "humanness" of these cell lines reflects the intrinsic differences across species, encoded within the genome and expressed as differences in the complement of cellular proteins involved in structural, regulatory, enzymatic, and other functions.

TABLE 12.3. Examples of Tumor-Derived Human Cell Lines

Cell Line	Origin Tissue
A-549	Lung carcinoma
BCP-1 cells	PBMC
BR 293	Breast
BxPC3	Pancreatic adenocarcinoma
DU145	Androgen insensitive carcinoma
H1299	Lung
HCA2	Fibroblast
HeLa	Cervical cancer
HepG2	Hepatocellular carcinoma
HL-60	Myeloblast
HT-29	Colon epithelium
Jurkat	T-Cell leukemia
JY cells	Lymphoblastoid
K562 cells	Lymphoblastoid
NALM-1	Peripheral blood
THP1 cell line	Monocyte
U373	Glioblastoma-astrocytoma
U937	Leukemic monocytic lymphoma
WM39	Skin
WT-49	Lymphoblastoid
YAR	B-cell

PBMC, peripheral blood mononuclear cells.

However, not all immortalized human cell lines are derived from human neoplasms. The transformed phenotype can also be induced by oncogenic or transforming viruses, and more specifically by individual genes expressed in the genomes of these viruses. Indeed, the HeLa cell line, while isolated from a cervical carcinoma, was likely derived from normal epithelial tissue that became infected and thereby transformed with HPV. The HPV-16 and -18 gene E6 binds to and inactivates the tumor suppressor protein p53 (36). Other human cell lines have been created by transformation with HPV-16 and -18 DNA, as well as with the DNA from other transforming viruses. HEK293 and PER.C6 cell lines, derived from kidney and retinal tissue respectively, express the adenovirus E1 genes (specifically the Ad5 E1A and E1B genes). The adenovirus E1 protein also binds to (and inactivates) p53, as well as to another tumor suppressor protein, Rb (37,38). Freshly isolated B-cells may be transformed by EBV, although it has been reported that such cell lines are not truly immortalized and have a finite life span (39).

The ability to transform specific cell types with viral genes ("designer cell substrates") offers researchers

additional tools for studying cellular processes in human cells. Such cell lines also provide opportunities for the large-scale biopharmaceutical expression and production of viral vaccines and recombinant proteins. Because such cell lines can be transformed with specific viral genes (and tested for the expression of these genes), and the history of creating such cell lines can be formally documented, regulatory agencies have found the use of these cell lines to be acceptable for the manufacturing of therapeutic products. This has allowed cell lines such as HEK293 and PER.C6 to be used as platforms for the production of recombinant adenoviruses, as well for the production of recombinant proteins such as monoclonal antibodies and blood coagulation factors. Not all virus-transformed human cell lines, however, are suitable for large-scale manufacturing, as other attributes, such as fast growth rates and the ability to grow in suspension culture must also be exhibited.

Such cell lines must also be capable of high level expression in order for them to be competitive with alternative and well established production platforms, such as *E.coli* or CHO cells. A potentially attractive feature of human cell lines for the production of recombinant proteins is that the glycan modifications—carbohydrate side chains that are added to the protein as it is being processed inside the cell—are fully human and therefore less likely to be immunogenic than animal-derived cell lines. In contrast, the glycan structures of proteins expressed in CHO cells such as NGNA (12), host cell proteins (22), or other animal cell lines may be recognized as foreign if introduced to patients. Human cell lines, like other mammalian cell lines, are capable of complex protein folding and disulfide bond formation.

Interestingly, in addition to contributing to the transformed or immortalizing phenotype in human cell lines, the Ad5 E1A and E1B genes may also confer additional phenotypes that make cell lines such as HEK293 and PER.C6 attractive options as industrial production host cell lines—resistance to apoptosis and transactivation of viral promoters, such as human cytomegalovirus (hCMV). These features allow cell lines to achieve high cell densities and high cell-specific productivities, which ultimately leads to very high levels of recombinant protein.

12.3.1 Vectors and Gene Transfer Methods

The wide variety of human cell lines available for study, from both normal and neoplastic tissues, reflects the desire to choose model systems with the appropriate endogenous gene expression or developmental profiles. However, many research programs and industrial applications require heterologous gene expression, also known as *recombinant gene expression*, rather than the expression of endogenous genes. Such applications may range from the use of fluorophore tagged proteins or mRNAs to monitor and track cellular processes to the overexpression and secretion of proteins that can be used therapeutically to treat disease.

Since the early 1990s, when the biotech industry firmly demonstrated the ability to successfully commercialize recombinant therapeutic proteins such as insulin and erythropoietin, the design and development of expression vectors—replicating pieces of DNA that contain the recombinant gene(s) expressed in a cell line—have been the focus of intense study. While much of this work has been done in the context of gene expression in CHO cells (and other cell lines of nonhuman origin), many of the same principles can be applied to the expression of recombinant proteins in human cell lines. Expression vectors that are designed to direct very high levels of gene expression commonly utilize strong viral or cellular promoter sequences upstream of the gene to be expressed. One example of such a promoter is derived from the hCMV. While expression vectors containing the hCMV promoter have been used for recombinant protein expression in CHO cells, such promoters have also been shown to support very high levels of heterologous gene expression in human cell lines such as PER.C6 (ref.). The use of efficient enhancer elements, signal peptides, polyadenylation sequences, and selection markers are also important considerations in the design of expression constructs.

Similarly, methods and technologies developed for the introduction or insertion of the expression vector into CHO cells can generally be applied to human cell lines as well. Common methods in use, nowadays, include lipid or liposome-based transfection and electroporation. Interestingly, one of the earliest methods of transfecting DNA was developed by Frank Graham and Alex van der Eb, who also developed the human transformed cell lines HEK293 and PER.C6. The calcium phosphate method, which delivers DNA complexed with a calcium phosphate precipitate, occurs through a poorly understood process, and is relatively inefficient. However, it is relatively inexpensive, and can be scaled up to transfect large numbers of cells.

12.3.2 Clone Selection Methods

The transfer of genes into cells (as part of an expression vector) and the stable integration of the gene into the host cell genome is an inefficient process. The result is that the majority of cells in culture following a transfection reaction remain untransfected. The ability to isolate (clone) cells, which have been stably transfected must therefore require a means to differentiate transfected cells from untransfected cells. Positive selection methods, such as fluorescence activated cell sorting (FACS), may be used to isolate those clones which exhibit a desired phenotype or attribute (such

as expression of the recombinant protein). Alternatively, untransfected cells may be negatively selected, which will result in a pool of cells that is enriched for transfected subpopulations. This is commonly achieved by coexpressing the gene(s) of interest with a selectable marker, or a gene, which confers resistance to a cytotoxic substance (such as an antibiotic). Such methods have been used for many years in the development of mammalian cell lines and have been successfully adapted for use with industrial cell lines of human origin such as PER.C6.

Following the selection of a number of clones (single cells which express the gene of interest), the clones can be further screened for appropriate phenotypes. Such phenotypes may include growth rate, productivity, and/or product quality attributes. A relatively simple approach is used for cell lines that are generated in PER.C6 cells. Following transfection, cells are cultured in the presence of a selection agent to enrich the population for drug-resistant clones (which also express the gene of interest). The enriched population is plated in 96-well tissue culture plates as single cells, by limiting dilution, and the individual wells can subsequently be assayed for the expression of the secreted protein in the culture supernatant, typically by using an enzyme-linked immunosorbent assay (ELISA)-based method. Cells that express relatively high levels of the protein can then be scaled up to larger culture formats. This method eliminates the need to include serum in the culture media (as is required for many adherent cell types), and allows cell lines to be isolated from a single originator cell, which defines them as monoclonal. Serum, most commonly derived from fetal bovine origin, provides a mixture of nutrients and growth factors, which are favorable for supporting cell growth. However, there has been concern in the industry that serum may also be a potential source of adventitious agents, most notably bovine spongiform encephalopathies (BSEs). Cell culture media have been developed that can support the high density growth of human cell lines in a serum-free formulation (see section titled "Cell Culture Media, Cultivation and Handling Methods"). Cell lines can be further selected for other attributes, such as performance in a fed-batch culture, or specific product quality profiles, by running a comparative study with a number of candidate cell lines.

12.3.3 Cell Culture Media, Cultivation, and Handling Methods

As with other mammalian cell lines, in general, human cell types can be divided into two major categories: those that are able to grow in suspension (anchorage-independent) and those that require a physical support for growth (anchorage-dependent). In either case, the products produced can be secreted into the production medium or can be accumulated inside the cells. The properties of the cells and the location of the produced product dictate the method used for growth and production, and consequently, the selection of a suitable type of bioreactor.

Those human cell lines that require physical support for growth such as A549 and WI-38 fibroblast cells are typically cultured in T-flasks, roller bottles, or on microcarriers in spinners. These cells are typically cultured in standard basal media such as Dulbecco's Modified Eagle's Medium (DMEM) or Ham's F12 supplemented with serum to promote attachment (40). A number of serum-free medium for anchorage-dependent human cell cultures are also available from vendors such as Invitrogen, many of which are based on the molecular, cellular, and developmental biology (MCDB) line of medium developed by Ham *et al*. in the Department of MCDB at the University of Colorado in Boulder, Colorado (41–52). In many cases, however, the individual companies prefer to use their own in-house proprietary medium. These in-house media are usually free of animal-derived components and are often chemically defined.

For industrial applications, cells that grow in suspension are preferred (53–58). Although some of the human cell lines—those with fibroblast-like characteristics in particular are anchorage-dependent, HEK293 and PER.C6 cells have been adapted to grow in suspension. Without the need for a solid substrate on which to anchor, these cells may be more easily handled and expanded using standard suspension cell culture techniques and without the need for any specialized equipment. Similar to suspension-adapted CHO and NS/0 cells, human cell lines such as PER.C6 cells are typically cultured in shake flasks or spinners. These cells may be cultured in standard basal media such as DMEM supplemented with serum. Also, a number of serum-free media for both HEK293 and PER.C6 cells are commercially available from vendors such as HyClone, Invitrogen, and JRH (acquired by Sigma Aldrich Fine Chemicals or SAFC).

In routine culture, cells are allowed to grow to mid-log phase before splitting by dilution. Depending on the growth rate and the medium used for cultivation, this typically occurs between 3 and 5 days after inoculation. This is accomplished by simply inoculating a new culture vessel with the existing culture to achieve between 0.2 and 0.5 million cells/mL. Depending on the growth rate and the medium used for cultivation, the cell concentration from 3 to 5 days after inoculation may be as high as 5 million cells/mL. This means that split ratios of greater than 1:20 is sometimes possible. However, a normal split ratio of 1:10 is more typical. Nevertheless, this illustrates one feature of some human cell lines—namely their ability to grow to high cell densities. If left to continue to grow, some human cell lines may grow to very high densities—much higher than typically observed for CHO or NS/0 cells. For example, PER.C6 cells have been

observed to achieve viable cell concentration greater than 10 to 15 million cells/mL in batch mode without any feeding.

12.3.4 Production Parameters and Methods

Methods typically used for culturing human cell lines for recombinant protein productions in the biotech industry is not appreciably different than those used for other mammalian cell lines, such as hybridomas, CHO or NS/0. As with these cell lines, two main production processes are utilized with human cell lines—fed-batch and continuous perfusion. Fed-batch production process remains the main work horse for recombinant protein production with human cell lines due to its operational simplicity, reliability, and flexibility for implementation in multipurpose facilities (59). Typical feed strategy is based on the metabolic requirement of the specific human cell line for the maintenance of growth and productivity. Feed media are designed by using metabolic characterizations of several cell lines and assembling a nutrient concentrate consisting of glucose, amino acids, vitamins, lipids, trace elements, and growth factors (60,61). Similarly, the feeding schedule involves the addition of the nutrient concentrate based on cell-specific requirements in order to supply the nutrients only as required by the culture and to limit overflow metabolism or the buildup of nutrients or metabolites that may result in reduced process performance and product quality (62–64).

Human cell lines also have been successfully used in perfusion culture systems (60,65,66) to produce commercial recombinant proteins (67). In perfusion systems, fresh medium is continuously added to the bioreactor. Simultaneously, spent medium is continuously removed while the cells are retained in the bioreactor. A number of cell retention devices have been described, which may be internal or external to the reactor, with some being commercially available. The advantages of perfusion systems are many. By continuously adding fresh medium to the bioreactor, the cells are provided with the critical nutrients needed to multiply and for protein synthesis. At the same time, continuous removal of the spent medium from the bioreactor ensures that potentially toxic metabolic by-products do not accumulate. The cell retention device ensures that productive cells remain in the bioreactor, where they continue to produce the desired product. The disadvantages of the system is that large amounts of medium need to be used and the product is being continuously removed from the bioreactor in the spent medium, which results in a large volume of a very dilute harvest. This requires a very intensive concentration and clarification operation, besides the need to store the harvest under sterile conditions until processing. Recently, a modified perfusion system called XDwas described as combining the advantages of fed-batch with perfusion processes by retaining the product in the bioreactor along with the cells throughout the process (17,68). With this process, viable cell concentrations greater than 150 million cells/mL have been achieved using the PER.C6 human cell line. Assuming an average cell diameter of approximately 15 μm, concentration of 150 million cells/mL means that 1 L of working volume contains approximately 270 mL of solid cell mass, which is close to high density microbial fermentation-like condition. By amassing these many cells and retaining the product in the bioreactor, which is the main feature of the XD process, a volumetric productivity of over 27 g/L IgG in 18 days has been reported with this system using PER.C6 cells using only 15 equivalent volumes of bioreactor in cell culture medium (17). Again, spent medium in the XD process is removed directly into waste. In this XD process, the culture viability is always high (over 95%) and product quality is unchanged throughout the process as the cells are under quasi steady-state conditions and growing at their maximum growth rate, and they are also producing product at their maximum specific productivity. Consequently, it is possible to achieve the maximum theoretical volumetric product concentration for a given cell line (for a given specific productivity) once the biomass in the bioreactor has reached the maximum packed cell volume.

12.4 SCALE-UP OF RECOMBINANT HUMAN CELL LINES CULTIVATION

The clinical and commercial success of biologics has led to the need for very large-scale production in mammalian cell culture. This has resulted in rapid expansion of global manufacturing capacity, an increase in size of reactors and a greatly increased effort to improve process efficiency with concomitant manufacturing cost reduction. Like other nonhuman mammalian cell cultures, recombinant human cell lines are typically cultured in stirred tank bioreactors. Human cell lines such as HEK 293 and PER.C6 cells have been cultured at large-scale fed-batch and perfusion modes. For instance, various PER.C6 human cell lines have been used to produce monoclonal antibodies in fed-batch, and XD systems at up to 250 L scale (16) and Xigris™ is produced by HEK293 cells in 500 L bioreactors using a hollow fiber perfusion system (67).

A relatively recent innovation is the use of disposable stirred tank bioreactors. Disposable bioreactors have the advantage of facilitating process validation and allowing users to have flexibility in the facility design and operation (69–78). Until recently, wave bioreactors were the only available disposable system for mammalian cell cultures. However, vendors such as Xcellerex and HyClone (part of Thermo Fisher Scientific) among an ever-growing list of suppliers now offer disposable stirred tank bioreactors with sizes up to 1000 L (HyClone) and 2000 L (Xcellerex). It is

expected that even larger disposable bioreactors will come on market in the near future. Recombinant human cell lines, PER.C6 cells in particular, have been cultured in both stainless steel and disposable stirred tank bioreactors up to 250 L for high yield protein production (16).

Recombinant human cell lines that are anchorage-dependent are most often cultivated on microcarriers at larger scales (79–89). Microcarriers are small solid spherical particles, which can be suspended in liquid culture medium. Porous microcarrier beads are also frequently used with anchorage-dependent cells. The advantage of porous microcarriers is that the surface area to volume ratio is much larger, enabling higher number of cells to be cultured on each bead. By using these porous microcarriers suspended in culture medium, standard stirred tank bioreactors may be used to culture and scale-up anchorage-dependent cells much easier. The disadvantage of culturing cells on microcarriers is that, as they grow into layers, diffusion limitations of nutrients and metabolic waste products develop. Consequently, cells in the inner layers are often nutrient-starved and are not productive. Nevertheless, for anchorage-dependent cultures, microcarrier systems provide the most straightforward method for culturing and scaling-up anchorage-dependent cell lines.

Human cell lines that grow as single cells in suspension may be cultivated and scaled up in much the same manner as nonhuman mammalian cultures such as CHO and NS/0 cell lines used nowadays for the industrial production of most of the approved recombinant protein therapeutics. Human cell lines share much of the same characteristics, limitations, and sensitivities as most nonhuman mammalian cell lines. Consequently, much of the considerations of scaling-up recombinant human cell lines are very similar to those that pertain to the scale-up of nonhuman mammalian cell cultures. These considerations typically include homogeneous mixing, shear, mass transfer (oxygen supply and carbon dioxide removal), and potential damage from bubbles (72–74,90,91). Interestingly, some human cell lines have been demonstrated to be very resistant to shear damage. For example, PER.C6 cells are typically cultured in 5 L-stirred tank bioreactors equipped with two pitch-blade impellers with an agitation rate of up to 300 rpm (16). This translates to a tip speed of approximately 1 m/second, which is approximately three to five times higher than those typically used in CHO or NS/0 cells cultures (56). The advantage of this insensitivity to shear is that much of the typical scale-up limitations typically encountered for other mammalian cultures may be resolved much more easily by using shear resistant cell lines such as PER.C6 cells. For example, efficient mass transfer (k_La) may be maintained during scale-up by increasing agitation rates without the concern of shear-induced damage. This means that need for increasing aeration rates used at larger scale to maintain gas mass transfer (i.e. oxygen supply and carbon dioxide removal) may not be necessary. Consequently, there is less risk of foaming and resultant bubble damage during scale-up (92). Also, with the possibility of using high agitation rates, the cultures are better mixed, resulting in better mass and heat transfer, more homogeneous and evenly mixed systems, and less localized insults to the cells from bolus addition of pH titrants or nutrients that may be toxic at high concentrations. Lastly, due to the high bulk shear associated with high agitation rates, cells tend to clump less even at very high viable cell concentrations (16).

This relative insensitivity to shear-associated insults is especially valuable in perfusion and XD systems where viable cell concentrations can reach extreme levels. With PER.C6 cells, the high mass transfer rate necessary to meet the oxygen demand and CO_2 removal requirement resulting from high viable cell concentration may be met in part by pushing the agitation rate to microbial fermentation-like levels. At extremely high cell densities of, for instance, over 100 million cells per mL, agitation alone is usually not sufficient to increase the mass transfer coefficient (k_La) in order to match the oxygen transfer rate and the oxygen uptake rate by the cells (17). Consequently, the oxygen-sparging rate will also need to be increased, which may lead to foaming issues. Problems with foaming may be avoided by the use of medical grade antifoams—a number of varieties are commercially available from various vendors. Human cell lines generally tolerate the presence of antifoam. However, the use of antifoam is tempered by the difficulties one may encounter during protein purification.

12.5 CONCLUDING REMARKS

The field of biotechnology has proven value to society by providing valuable and unique medicines to solve unmet medical needs. The evolution in the methods for producing these biologicals reflects the constant dialogue that both the industry and regulatory bodies have engaged over the years of product testing and collection of clinical data. Owing to the proven safety record and amenability to industrial production requirements, the advent of using human cell lines is imminent. And judging by the evidence of potentially harmful structures present in products made in animal cells to humans, it is possible that manufacturing methods will have to adopt more natural substrates for expressing and producing human therapeutics.

GENE EXPRESSION IN *PICHIA* AND OTHER METHYLOTROPH YEAST

KOTI SREEKRISHNA
Procter & Gamble Co., Cincinnati, Ohio

13.1 INTRODUCTION

A wide variety of expression systems for production of proteins of interest have become available with the advent of recombinant DNA technology since the 1970s. The various expression systems include those based on bacteria, lower eukaryotes (yeasts and fungi), invertebrates (insect cells and larvae), vertebrates (cells and transgenic animals), and plants (cells and transgenic plants). Each of these systems has unique advantages. Yeasts and fungi have robust growth characteristics like bacteria. They are also readily amenable to genetic manipulation. Furthermore, they can perform many posttranslational modifications found in higher eukaryotes. The purpose of this chapter is to highlight the strategies that have been used for optimal protein expression with the *Pichia* yeast expression system, which in the past few years has turned out to be versatile and impressive yeast for production of proteins.

13.2 BACKGROUND

Pichia pastoris is a methylotrophic yeast. It is able to use methanol as sole carbon source for energy as well as for growth (1,2). It was originally developed by Phillips Petroleum Company (Bartlesville, Oklahoma) as an organism of choice for bioconversion of natural gas (methane) into food (single cell protein). This may sound ironic, because nowadays every one is talking bioconversion of food crops to fuels (biofuels). Phillips Petroleum Company in the 1970s developed an efficient *Pichia* fermentation process [cell density >130 g dry cell weight per liter and biomass productivity >10 g/(L h)] (3,4). Though impressive, it could not compete with the economics of production of soy protein. After this set back, Phillips in the early 1980s directed its future course with *Pichia* into two areas:

1. *Speciality Food or Feed Application.* A rather impressive 100,000 L fermentation plant to churn out tons of *Pichia* for potential speciality food applications was completed in 1988. However, by 1993, the idea to use *Pichia* for speciality food/feed was abandoned as *Pichia* did not have generally regarded as safe (GRAS) status and Phillips Petroleum Company decided to focus on its core business of oil exploration, production, and petrochemicals.
2. *Development of Pichia Expression System for Production of High Value Recombinant Proteins.* *Pichia* possesses a highly regulated pathway for the utilization of methanol (2,4). Synthesis of the enzymes of methanol metabolism are undetectable in the absence of methanol, but increase rapidly when methanol is used as the sole carbon source. The most dramatic effect is seen for alcohol oxidase (AOX1), which accounts for >30% of cellular protein (5). An extensive proliferation of the peroxisomes, known to sequester AOX1 and dihydroxy acetone synthase, is also observed in cells grown on methanol (5–7).

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

Perhaps the decision of Phillips to exploit the above noted unique features of *Pichia* to develoa protein expression system was highly fortuitous, because the molecular genetic tools that had just become available for *Saccharomyces cerevisiae*, such as yeast–*E.coli* shuttle vectors, transformation protocols, and site-specific integrative transformation (8,9) were found to be readily applicable to *Pichia*. With the advent of cloning of *AOX1* promoter (10,11), availability of auxotrophic *Pichia* strain [GS115 (*his4*) developed by George Sperl] and *Pichia* transformation protocols (12,13), successful high level expression of several proteins was readily demonstrated. They include, intracellular expression of Hepatitis B surface antigen particles (14), *E. coli* β-galactosidase (LACZ) (15), human tumor necrosis factor (TNF) (16), as well as greater than gram per liter level of secretion of *S. cervesiae* invertase (SUC2) (17), and human serum albumin (HSA) (18). *Pichia* expression technology patent was granted to Phillips Petroleum Company in 1988 (11) and thus, by the late 1980s, *Pichia* expression system was well on its way to leave the nest.

In the fall of 1988, Phillips Petroleum Company made a conscientious decision to license the system to other companies. Fortunately for Phillips licensing team (Katherine Bartosh, L.V. Benningfield, Mary Jane Hagenson, Jack Phillips, and Koti Sreekrishna), their very first commercial licensee (Glaxo–Wellcome) with just 2 days of training at Phillips produced some impressive expression results (19–23). Phillips was able to license the technology to 20 companies in 4 years. Along side, it also started distributing the *Pichia* expression kit, free of cost to any academic institution that approached the company for the kit. This was getting out of hand, and thus the company transferred distribution rights, free of cost, to Invitrogen Corporation (Carlsbad, California) in 1993. Since then, Invitrogen Corporation (http://www.invitrogen.com) has been aggressively distributing *Pichia* expression kit at reasonable cost and with some user friendly modifications. They are largely responsible for wide usage of *Pichia* technology. In the same year (1993), Phillips sold *Pichia* technology to Research Technology Corporation (Tucson, Arizona) (http://www.rctech.com). They have licensed the technology thus far to 160 companies. To date, >500 proteins have been expressed in the *Pichia* yeast (24) and over 3000 scientific chapters published. There are over 100 publications on fermentation optimization alone.

Hepatitis B vaccine and interferon-α derived from *P. pastoris* have been commercialized in India since 1999 and 2002, respectively, by Shantha Biotechnics (http://www.shanthabiotech.com) (25). Now the company makes >100 million units of hepatitis vaccine per year and sells these vaccines in 50 countries. The cost of vaccine has dropped to 15 cents a dose (24). Recombinant human insulin produced in *Pichia* is also marketed in India since 2003, by joint venture between Shantha Biotechnics and Biocon (http://www.biocon.com) (24,25).

HSA expression technology originally demonstrated at Phillips Petroleum Company (18) and transferred to Green-Cross Corporation (Osaka, Japan) has been further developed and scaled up to produce one million dosage vials (12.5 g per vial) of authentic rHSA/year by Mitsubishi Pharma Corporation (Osaka, Japan) (26,27). This truly is a testimony to the high expression level and scale-up possible with *Pichia* (25). (Please refer to http://www.rctech.com for a more complete list of *Pichia*-produced products under various stages of commercialization.)

13.3 STRATEGIES FOR OPTIMIZATION OF PROTEIN EXPRESSION

The typical *Pichia* expression vectors are all yeast–*E. coli* shuttle plasmids (see "Glossary of *P. pastoris* Vectors"). The most commonly used vectors are based on *AOX1* promoter (10,11) (see section titled "Alternative Promoters for Expression" below for other promoters available for *Pichia* expression). Numerous selectable marker genes available include *HIS4* (His^+ selection) (12), *ARG4* (Arg^+ selection) (28), A*DE1* (Ade^+ selection) (29), and *URA3* and *URA5* (Ura^+ selection) (29,30), which can be used in conjunction with the appropriate *Pichia* auxotrophic strains. Several dominant selection markers that can be used for transformation of any *P. pastoris* strain are also available. These include *SUC2* (allows growth on sucrose) (13), Kan^R (G418/Geneticin selection) (23,31), Zeo^R (Zeocin selection) (32), Bsd^R (Blasticidin selection) (http://www.invitrogen.com), FLD1 (Formaldehyde selection) (33), and Sor^R (Soraphen A selection) (34).

A wide assortment of proteins have been produced in *Pichia*, which include human insulin (35), glucagon-like peptide (GLP) (36), G-protein coupled receptors (GPCRs) (37), Aquaporin (AQP1) (38), as well as correctly assembled human collagen fibers (39) and fibrinogen chains (40). These are among >500 proteins that have expressed in this system (24). Obviously, not all proteins are expressed at multiple grams per liter range. The expression level is largely influenced by inherent properties of a protein. Some proteins are readily expressed at high levels with minimal manipulation, while some proteins barely reach milligram levels, despite tremendous effort. Encouragingly, in many instances, the initial production yield of a protein can be dramatically enhanced by addressing the multiple factors that influence protein expression (41–43). The purpose of this review is to highlight the various expression-optimization strategies.

13.3.1 Cellular State of the Expression Cassette

The expression cassette can be introduced into *Pichia* by way of chromosomal integration or autonomous replication. Chromosomal integration is preferable because of the following advantages: (i) stability of expression cassette; (ii) ability to generate clones that stably maintain multiple copies of the expression cassette (see section titled "Gene Dosage: Exploiting the Clonal Variation of Expression"); (iii) control over the site of integration (for example, *AOX1*, *HIS4*, *ARG4*, *URA3* loci); and (d) ability to engineer different modes of integration (with or without eviction of the *AOX1* coding sequences) (see section titled "Methanol Utilization Phenotype of the Host: Mut^+ or Mut^s").

Plasmids based on autonomous replication sequence (*ARS*) such as pHIL-A1 (see "Glossary of *P. pastoris* Vectors") although can be introduced into *Pichia* cells with a high transformation frequency, they are rapidly lost from the population of dividing cells, and eventually integrate at one or more of the homologous sites on the chromosome (12,13). Owing to their ability of transform *Pichia* at high frequency ($>10^5$ μg^{-1}) and ease of plasmid rescue, the autonomous plasmids are useful for cloning genes in *Pichia* by functional complementation.

13.3.2 Site of Integration of the Expression Cassette

The *AOX1* promoter used in *Pichia* expression vectors is active irrespective of the site of integration (*AOX1*, *HIS4*, *ARG4*, *ADE1*, or *URA3* loci). However, AOX1 locus is the preferred site of integration for stable expression, because integration at the other loci can result in loss of the expression cassette due to intrachromosmal cross over between the mutant and good copy of the gene (unpublished observations). If the vector also contains a dominant selection marker (discussed earlier), then selection pressure can be applied for stable maintenance of expression cassette at those sites.

13.3.3 Methanol Utilization Phenotype of the Host: Mut^+ or Mut^s

Transformation of a *P. pastoris his4* strain (GS115) using linear DNA expression cassette with the ends bearing homology to the 5′ and 3′ regions of the *AOX1* chromosomal locus results in the site-specific eviction of the *AOX1* structural gene at a high frequency (5–20% of the His^+ transformants) (16,28). Such clones can be readily distinguished by replica-plating the colonies from the initial His^+ selection plate on to a minimal methanol (MM) medium plate. The clones that have undergone eviction of *AOX1* grow slower (Mut^S) compared to Mut^+ clones with an intact AOX1 gene, because, in such clones, growth on methanol is dependent on the alcohol oxidase encoded by *AOX2*, which is expressed at much lower level (weaker promoter) (44). The Mut^+ clones arise due to circularization of the linear DNA expression cassette inside the yeast cell prior to integration. Thus, both Mut^S and Mut^+ clones result in the same experiment.

Alternatively, one can use the *Pichia* strain KM71 (*his4 arg4 aox1*Δ*:SARG*), which has been rendered Mut^S by replacing much of the chromosomal *AOX1* with *S. cerevisiae ARG4* (28).

For intracellular expression, it is critical to use Mut^S cells because they will have a lower level of *AOX1* and the expressed protein of interest can be more readily purified. Furthermore, the precious cellular machinery can be more fully utilized for the expression of protein of interest. For protein secretion, the choice of Mut^+ or Mut^S is less stringent and more a matter of preference as the impact is more on feed protocols than the secretion level. In fact, the secretion levels of HSA are similar with both Mut^+ and Mut^S cells (45).

13.3.4 Gene Dosage: Exploiting the Clonal Variation of Expression

Early on a dogma prevailed among the researchers of the *Pichia* system, based on limited experience (14,15), that increasing the gene dosage did not impact expression because of the remarkable strength of the *AOX1* promoter. This dogma was shattered on the Good Friday of March 28, 1986, with my observation of dramatic clonal variation (<1% to >30%) in the expression of human TNF, that was subsequently attributed to gene dosage. Furthermore, the high copy number was stably maintained even after several days of growth in high cell density fermentor. The observation with TNF expression was readily exploited for expression of tetanus toxin fragment C (21), *Bordetella pertussus* pertactin P69 (20), and mouse epidermal growth factor (EGF) (19), and has been a key strategy for successful expression of hundreds of proteins in the *Pichia* system. However, in numerous cases, a single copy of the expression cassette is sufficient and deliberately increasing the copy number had no significant effect on the production (14,15,17,18). In some rare instances, an increase in copy number has a deleterious effect on the production level as has been noted with secretion of human insulin-like growth factor (IGF) (46) and *Necator americanus* (hookworm) secretory protein (Na-ASP1) (47).

Because the effect of gene copy number on expression is unpredictable, it is prudent to examine the production level as a function of gene dosage. The spheroplast method of transformation of *Pichia* results in transformants with a wide range of copy numbers (16,48). Evaluation of as few as 100 individual clones for protein production is generally adequate to arrive at a good producer. Though bit laborious, spheroplast method of transformation yields clones with wide range of gene dosage at a high

frequency (48). If other methods of transformation such as using LiCl or electroporation, which do not yield high frequency of multicopy clones, then one can use more efficient screens. These include use of colony hybridization with DNA probes or using appropriate vectors that would allow selection based on increased level of resistance to one of G418/geneticin (23,31), zeocin (32), formaldehyde (33), blasticidin (http://www.invitrogen.com), or soraphen A (34). Increased drug resistance does not automatically ensure multicopy integration and several dozen resistant colonies must be analyzed for copy number and expression.

Another approach to identify high producers may be to use a visual tag to the protein being expressed. In one instance, C-terminal green fluorescent protein fusion was used as a visual reporter to identify human Mu-opioid receptor expressing clones (49). *Rhizopus oryzae* lipase (ROL) bearing an N-terminal GFP tag was more efficiently secreted in *Pichia* compared to one with a C-terminal GFP tag (50). Recently, a fusion protein ZZ-EGFP consisting of ZZ domain of staphylococcal protein A (SpA) with enhanced green fluorescent protein (EGFP) was also secreted in the *Pichia*, with a hexahistidine tag (51). GFP tag may serve as a visual reporter to readily identify high producing clones. It can also be useful for on-line monitoring of protein production in the fermentor (52) However, on-line monitoring can be complicated by high levels of riboflavin (excitation/emission = 450/530 nm) secreted by *Pichia* (50), which in itself has been used for monitoring biomass production (53). By using a fluorescent protein tag outside the interfering range, one may be able to reliably monitor simultaneously both cell and product yield on-line.

Vectors such as pAO815 (54,55) have also been described that would allow *in vitro* construction of expression cassette concatamers. This approach is useful to accurately correlate copy number to expression level over a narrow range of gene dosage.

13.3.5 Translational Optimization: 5′ Untranslated Region

The nucleotide sequence and the length of the 5′ untranslated region (5′UTR) are detrimental to optimal protein translation. The leader length of the highly expressed *AOX1* mRNA is 114 nucleotides long, and the sequence is A + U rich (10,11). For optimal synthesis of heterologous proteins, it is essential that the 5′UTR should closely resemble that of the *AOX1* mRNA. Ideally, it is preferable to make it identical to that of *AOX1* mRNA. The expression level of HSA is increased >50 fold by optimizing the 5′UTR to mimic that of *AOX1* mRNA (18). Expression plasmids such as pHIL-D7 (42) can be used to make an exact construct. This plasmid has unique *Asu* II and *Eco* RI sites immediately following 5′*AOX1*. The second *Asu* II site that was originally present in 3′*AOX1* has been eliminated. Therefore, the sequence TTCGAAACG can be added immediately upstream of the ATG start codon of the gene of interest, and an *Eco* R I site can be engineered downstream of the stop codon for insertion at *Asu* II–*Eco* RI sites of pHIL-D7 (42).

13.3.6 Transcriptional Optimization

Genes with high A + T nucleotide clusters are poorly transcribed in *Pichia* due to premature termination of the transcription. For example, ATTATTTTATAAA, present in HIV-gp120 has been identified to block transcription in *P. pastoris*, and the premature termination is overcome by altering the sequence to TTTCTTCTACAAG (22). Because we are not aware of all the problematic A + T rich clusters, a general strategy with A + T rich genes is to redesign them using *P. pastoris* preferred codons (48,54), http://www.kazusa.or.jp/codon/) so as to have an A + T content in the range of 30–55%. By using this approach, it has been possible to construct *Pichia* strains for efficient production of several proteins, which include tetanus toxin fragment C (20), *Bacillus sphaericus* BSP1 and BSP2 heterodimeric mosquitocidal toxin (55), anticoagulant protein ghilanten (56), spider silk proteins (57), human endostatin (58), and human lactoferrin (59).

13.3.7 Product Secretion

For a protein which is normally secreted, that is the preferred mode of expression, for multiple reasons. It is easier to recover product from extracellular medium as there will be relatively fewer proteins. Also, many proteins that are normally secreted remain predominantly insoluble when expressed in the intracellular compartment, as has been seen with HSA and salmon growth hormone (unpublished observations). Likewise, a protein that is not normally secreted may be difficult to secrete. However, in some cases, such as human TNF, it is possible to express at high levels in the intracellular compartment (16). Interestingly, the intracellular human tetrameric catalase has successfully been expressed as a secreted protein in *Pichia* (60).

A wide variety of heterologous proteins have been secreted in *Pichia*. In several instances, HSA (18), invertase (17), bovine lysozyme (61), barley alpha amylases (62), cathepsin E (63), and thaumatin (64) the native signal sequence is adequate. In the case of matrix metalloproteinases, although native signal sequences work (41), both secretion and product yield are improved while using the *S. cerevisiae* pre-proalpha mating factor (αMF) secretion signal sequence (65,66). Likewise, with *Candida rugosa* lipase 1, although native signal works, both product stability and yield are tremendously improved with the use of pre-proαMF signal sequence (67). For thaumatin

secretion, native signal works, but not the pre-proαMF signal sequence (64), whereas for human interferon-alpha 2b (IFN-a2b), native signal sequence does not work, but pre-proαMF works (68).

Pre-proαMF secretion signal sequence has worked well for secretion of large variety of proteins, including the smaller-sized products such as aprotinin (69), EGF (19,69), IGF-1 (70), and ghilanten (56). The processing of pre-proαMF secretion signal involves three steps. The first is the elimination of the pre-region by signal peptidase, second, KEX2, and YPS proteinases cleave out the proregion (71,72), and finally, N-terminal Glu–Ala repeats are removed by the action of dipeptidyl-aminopeptidase (Dpap). The efficiency of each processing step depends on amino acid sequence adjacent to the processing site as well as the tertiary structure of the secreted protein. All these factors contribute to incomplete processing and/or reduced yield of mature protein (73–75).

In making αMF signal sequence constructs, it is generally preferable to retain the Glu-Ala spacers adjacent to the Kex2-like protease cleavage site (. . . Val-Ser-Ser-Leu-Glu-Lys-Arg-^{Kex2p}Glu-Ala-^{Dpap}-Glu-Ala-^{Dpap}-fused protein). The presence of Glu-Ala spacers help to alleviate the steric interference imposed by the fused protein, resulting in an efficient cleavage of the prosequence by the *Pichia* Kex2 like protease (69). The Glu-Ala spacer is subsequently cleaved by diamino peptidase (Dpap coded by *STE13*) to yield the protein of interest free of additional N-terminal amino acid residues. Interestingly, it has recently been reported that the pre-proαMF without the Glu-Ala repeats directed the secretion of correctly processed human IFN-a2b at 200 mg/L level, whereas the pre-proαMF having the Glu–Ala spacer, although secreted an equivalent amount of IFN-a2b, the secretion signal was inefficiently processed (68). Thus, ideally all variations must be explored to arrive at the best fit for a given protein.

Other secretion signal sequences used in *Pichia* include those of acid phosphatase (Pho1p), hybrid of Pho1p secretion signal with αMF and Kex2p cleavage site, invertase, lysozyme, HSA, *Phaseolus vulgaris* agglutinin, inulinase, and alpha amylase, glucoamylase, and *S. cerevisiae* killer toxin I (42,59,76).

13.3.8 Choice of the Secretion Signal

Only in a limited number of cases has a thorough comparison been made on the relative efficacies of different signal sequences and variations thereof (for example, (59,64,68,69)). In the case of invertase secretion, both the extent of glycosylation and secretion rate are enhanced when the native signal sequence is substituted with the pre-proαMF signal sequence (69), although both yields are greater than gram per liter level of the product. However, in the case of proteins that are more susceptible to proteolysis, improvement in secretion rate can increase production level as has been noticed with MMP-1 (41,65,66). Based on the relatively high success of pre-proαMF signal sequence, it makes sense to test that signal (and variations there of) first, side by side with the native secretion signal sequence, before exploring other signal sequences.

13.3.9 Production Enhancement by Manipulation of Media and Growth Conditions

More often than not, a secreted protein is rapidly degraded in the *Pichia* medium due to extracellular proteases, cell-bound proteases, as well as by intracellular proteases released to medium due to cell death and cell lysis. Multiple stress factors (especially in high cell density fermentor), which include starvation, pH shift, temperature change, change of carbon source, buildup of toxins, and reactive oxygen species (ROS) are considered to cause cell death and cell lysis (77).

One of the approaches to increase the stability and yield of the secreted protein in the culture medium is by manipulating the pH of the medium to arrive at the optimal pH for blocking a problem protease. Suggested pH range for experimentation is between 2.8 and 8 (see section titled "Media Compositions"). This pH range does not affect the growth significantly. HSA yield was significantly improved by raising the pH from 5.2 to 6, with adequate aeration. The yield was further enhanced by the addition of yeast extract (1%) and peptone (2%) (45,48,78,79). Production of mouse EGF was favored at pH 6 in the presence of casamino acids (19). Casamino acids is preferable to yeast extract + peptone, because the peptide components of peptone (such as collagen fragments) can interfere in product analysis and recovery (41). For both IGF-I (70) and cytokine growth-blocking peptide (80), pH 3 was found to be optimal. Greater than twofold increase in production of cellulose-binding module cellulose 6A and lipase B (CBM-CALB) is noted by reducing the pH from 5 to 4 in a bioreactor run (81).

Hirudin variant 2 (rHV2) secreted in *Pichia* was found to be degraded to four active fractions, including the intact rHV2 (Hir 65) and three C-terminally truncated forms Hir 64, Hir 63, and Hir 62 (82). Degradation of hirudin was reduced by using growth-rate-limiting quantities of methanol (3.09 g/L methanol; specific growth rate maintained at 0.02–0.047 h^{-1}) (82). Degradation of hirudin was also reduced by increasing NH_4^+ to relieve the stress of nitrogen starvation (83). Ascorbic acid (4 mmol/L) was used to quell ROS and improve cell viability. Under these conditions intact and total hirudin production reached 2.90 and 5.03 g/L, respectively, in contrast to 1.75 and 4.70 g/L in the absence of ascorbic acid (84).

Lower cultivation temperature is shown to improve product yield in several instances, which include CBM-CABL (22°C) (81), laccase (20°C) (85), galactose oxidase (25°C)

(86), Rh midkine (20°C) (87), human AFP (23°C) (88), herring proteins (23°C) (89), and human bile salt activated lipase (BSSL, 20°C) (90). *Pichia* cultivated at temperatures as low as 15°C, greatly enhanced the yield of ScFV production due to reduced protease level (91). Secretion level of bivalent T cell immunotoxin A-dmDT390-bisFy(G_4S) was also enhanced at 15°C, which was attributed to reduced protease levels, improved folding, as well as reduced toxicity of the immunotoxin to *Pichia* (92). Thus, we may say that the low temperature expression helps to increase the yield of aggregation-prone, unstable, and toxic products in *Pichia*.

Addition of 5 m*M* EDTA to the medium also improves accumulation of proteins expressed in *Pichia* (41). Supplementation of the induction medium with 0.4 *M* L-arginine, 5 m*M* EDTA, or 2% casamino acids in the BMMY induction medium (see section titled "Media Compositions") increased scFV expression (91). It should be noted that medium manipulation can significantly alter the profile of endogenous protein components in the culture media, such that previously unnoticed proteins accumulate at high levels. For example, we have noticed that addition of 5 m*M* EDTA causes accumulation of a protein of approximately 50 kDa in the extracellular medium (41). This protein has the aa sequence DIIWDYSSEKIMGVNLGGWL. . ., which matches closely with the exo-β-1,3-glucanase of *S. cerevisiae* (93) and *Candida albicans* (94). We have also noticed that overexpression of human tissue inhibitor of matrix metalloproteinase (TIMP1) in *Pichia* leads to greater gram per liter accumulation of a 18–22 kDa *Pichia* protein of sequence ADYMC?GLAIYGAWEC? GPEAGPFDSEC?LLATD (41).

13.3.10 Production Enhancement Using Protease-Deficient Strains

In addition to the optimization of media and growth conditions, the product yield can be further improved by using a protease-deficient *Pichia* strains generated by knocking out a *Pichia* protease or by overexpressing a protease inhibitor (for example, TIMP1 strain as noted above).

Protease-deficient *Pichia* strains SMD1168 (*his4*, *pep4*), SMD1165 (*his4*, *prb1*), and SMD1163 (*his4*, *pep4*, *prb1*) have been constructed (95). These strains have a disruption in the genes encoding proteinase A (*PEP4*) and/or proteinase B (*PRB1*) (56). Proteinase A is a vacuolar aspartyl protease necessary for the activation of vacuolar proteases, such as carboxy peptidase Y and proteinase B. In the absence of proteinase A, *Prb1p* is not fully active. Thus, *pep4* strain (SMD1168) is also expected to have a lower level of Proteinase B activity. The *prb1* strain (SMD1165) lacks proteinase B, whereas *pep4prb1* strain (SMD1163) lacks all three of the protease activities. These strains in general have low storage viability and are less robust (42,43). Nevertheless, these protease-deficient strains, in combination with other strategies to improve product stability, have been used to improve the production yield of IGF-1 (46), ghilanten (56), laccase (96), and human catalase (60). Disruption of *KEX1*, which codes for a carboxy peptidase, resulted in expression of full-length endostatin in *Pichia* (97). Recently, using a gene pop-in/pop-out gene replacement approach (98), the *KEX1* was deleted from a *Pichia* hirudin production strain. This resulted in most significant improvement in intact Hir65 production, which approached 2.4 g/L for the *KEX1* deleted strain compared to 1.1 g/L seen with the strain without *KEX1* deletion (99).

13.3.11 Enhancement of Protein Secretion by Overexpression of Chaperone Proteins

Pichia is able to perform many posttranslational modifications found in higher eukaryotes, which include correct folding, disulfide bond formation. Folding and disulfide bond formation in some cases can be the rate-limiting step in protein expression leading to protein aggregation (100). It is not clear which single chaperone is most important or which combination optimally cooperates in this process.

Overexpression of *Pichia* protein disulfide isomerase (PDI), which is important for protein folding in the endoplasmic reticulum (ER), was able to increase the secretion of Na-ASP1 protein in high copy clones (47). As noted before, high copy clones of Na-ASP1 secreted less material than single-copy constructs, perhaps due to overburdening the *Pichia* secretory/protein folding machinery, which was corrected by PDI overexpression.

A33scFV in *Pichia* is expressed at 4 g/L level, which rose to >10 g/L by overexpression of immunoglobulin binding protein (Bip) (101). The noted impressive increase is attributed to increase in folding capacity. PID overexpression did not have any effect on A33scFV expression. This was unexpected because A33scFV contains disulfide bonds. Furthermore, simultaneous overexpression of both BiP and PDF also did not have any effect in this system. It was also noted that PDI expression in the A33scFV strain caused a six-fold increase in endogenous BiP expression, suggesting that PDI was inducing an unfolded protein response due to excess chaperone and recombinant protein in the ER. In another study it was found that the chaperone combinations YDJiP/PDI, YDJiP/Sec63, and Kar2p/PDI synergistically increase secretion levels 8.7, 7.6, and 6.5 times, respectively (102).

A transcriptomics-based approach to identify novel factors enhancing heterologous protein secretion by analyzing differential transcriptome of a *Pichia* strain overexpressing human trypsinogen versus that of a control strain has identified 524 genes to be significantly impacted. This was narrowed down to 13 genes, all upregulated in the expression strain, as potentially important. The respective *S. cerevisiae* homologs of these genes were cloned and tested. All genes

except one showed a positive effect on Fab fragment secretion, of which *PDI1*, *ERO1*, *SSO2*, *KAR2*, *BiP*, *and HAC1* are previously characterized secretion helpers; the newly identified ones to have role in product secretion are *Bfr2* and *Bmh2* (involved in protein transport); *Ssa4* and *SSe1* (chaperones); *Cup5* (vacuolar ATPase subunit); and *Kin2* (a protein kinase subjected to exocytosis) (103). The chaperone game has just begun and we can foresee exploitation of this approach more fully in the years to come.

13.3.12 Protein Glycosylation and "Humanization" of *Pichia* N-linked Glycosylation

Pichia is able to perform both O-linked and N-linked glycosylation of secreted proteins (17). O-linked glycosylation involves addition of oligosaccharides to the hydroxyl groups of Serine and Threonine residues of the secreted proteins. The O-linked residues in mammalian cells are composed of variety of sugars (*N*-acetyl glucosamine, galactose, sialic acid), whereas in *Pichia* it is solely made up of mannose sugar. There is no defined consensus primary amino acid sequence for O-glycosylation and different hosts may O-glycosylate at different positions of the same protein. Even if a protein is not O-glycosylated in the native host, it may receive O-glycosylation in *Pichia*. For example, IGF-1 is not O-glycosylated in human host, whereas in *Pichia*, about 15% of the IGF-1 produced is O-glycosylated (46).

N-linked glycosylation involves addition of oligosaccharide chains to Aspargine at the recognition sequence Asn-X-Ser/Thr. It begins in the ER with the transfer of a lipid-linked oligosaccharide unit, Glc(3)Man(9)GlcNAc(2) (Glc = glucose; Man = Mannose; GlcNAc = *N*-acetyl glucosamine) to Asn of Asn-X-Ser/Thr (104). This unit is then trimmed to Man(8)GlcNAc(2). At this point onwards, the lower eukaryotes and higher eukaryotes deviate in the subsequent modifications that take place in the Golgi apparatus.

The mammalian Golgi performs a series of trimming and additions leading to three classes of N-linked glycans: "high mannose" [Man(5–6)GlcNAc(2)], "complex" (mixture of several different sugars) and "hybrid" (combination of the high mannose and the complex) with a common core, Man(3)GlcNAc(2). In *Pichia* secreted glycosylated proteins (native as well as heterologous) only "high mannose" kind typically with 8 to 9 mannose residues in length [Man(8–9)GlcNAc(2)] predominate with smaller amounts of chains with more mannose residues. In *S. cerevisiae*, only "hypermannose" kind with 50–150 mannose residues in length [Man(50–100)GlcNAc(2)] are present resulting in a hyperglycosylated protein. *Pichia* appears not to have any terminal α-1,3 linked mannose (105,106) that are unique to fungal glycoproteins and render recombinant proteins produced in fungi unsuitable for human pharmaceutical uses (105). This should not be misconstrued to think that *Pichia*-produced glycoproteins are perfect for human pharmaceutical use, because with only "high mannose" kind, it is a far cry from mammalian-type glycosylation. The high mannose glycans are believed to reduce the half-life of the glycoprotein *in vivo* and may be immunogenic, thus limiting the potential therapeutic value of *Pichia* derived glycoproteins (107). Over the past two decades, several groups have attempted to overcome this problem, yet with limited success. Recently, however, major advances in the glyco-engineering of the *Pichia* yeast have culminated in the production of fully humanized sialylated glycoproteins (108). With the advent of glycoengineered *Pichia* host with humanized N-linked glycosylation potential, the goal of production of authentic human glycoproteins in *Pichia* is getting closer than ever (59,109).

13.3.13 Coexpression of Proteins and Proteins Complexes

Coexpression approach may not only be useful for increasing expression, often it may be necessary to express two or more heterologous proteins at the same time. The first example of coexpression is that of the BSP1 (43 kDa) and BSP2 (52 kDa) components of *B. sphaericus* mosquitocidal toxin (55). Since then, there have been other reports of coexpression (47,101–103,110,111). Many proteins function as members of multicomponent complexes and successful expression strategy necessitates coexpression of subunits (39–41,110). The simplest way to engineer strains for coexpression is by sequential transformation or by cotransformation. Numerous dominant selection markers are available, which can be readily used for introducing multiple constructs at the same time.

13.3.14 Fusion Proteins

Fusion protein expression has many advantages. Often it can help stabilize a protein, and can also be valuable for expression of peptides. The most popular fusion partner is the highly expressed HSA (112). Often therapeutic proteins fused to HSA can be used directly for therapeutic applications. Albuferon is a long-lasting fusion protein between human interferon α-2b and HSA, which is being codeveloped by Human Genome Sciences and Novartis for treatment of Hepatitis C (113). Both fusion configurations HSA–IFN α-2b and IFN α-2b–HSA were expressed in *Pichia*. Although both expressed well, and showed comparable antiviral activity, IFN α-2b–HSA was more homogenous and stable. Heterogeneity and instability of HSA–IFN α-2b was caused by incomplete disulfide bridge formation between Cys^{1} and Cys^{98} of IFNα-2b due to structural perturbation of IFN α-2b by HSA. Other active fusion proteins successfully expressed in *Pichia* include HSA–PTH (1–34,114).

13.3.15 Overcoming Protein Toxicity

Occasionally the protein being expressed may be toxic to *Pichia*. Whether a protein is toxic to *Pichia* can be ascertained by comparing the growth of transformants on 1% sorbitol (or 100 m*M* alanine) as sole carbon source to that on sorbitol or alanine + methanol. Because, sorbitol and alanine are nonrepressive carbon sources (42,115), methanol is able to induce *AOX1* promoter in their presence. The other nonrepressive carbon sources include mannitol and trehalose (115). If the expressed protein is toxic, the growth in the presence of methanol will be drastically impaired. Even if the protein is toxic, it is still possible to express, because of the tight regulation of *AOX1* promoter. A stepwise induction is suggested. First the cell mass is built up using glucose as sole carbon source, taking care to see that glucose is not limiting. Under these conditions *AOX1* promoter remains completely repressed. Subsequent to this, protein production is initiated with methanol feed.

13.3.16 Alternative Promoters for Expression

Although *AOX1* promoter has been used extensively, with great success, several other promoters are available for exploration. The only potential drawback with the *AOX1* promoter, if we may say so is the need for methanol, which is a potential fire hazard especially in quantities needed for megaton plants. Also, the use of methanol may not be appropriate for production of food products. Furthermore, the unique, unsurpassed tight regulatory and highly inducible features of *AOX1* promoter may not be needed in every instance. Thus, promoters that are not induced by methanol may be useful in some instances for expression of certain genes. The following are alternative promoters:

1. The constitutively active *GAP* (glyceraldehyde-3-phosphate dehydrogenase) promoter (116).) The advantages of this promoter is that the protein can be produced more straightforwardly without having to make media shifts and the promoter strength is quite high. It is also convenient for production of isotope labeled proteins for NMR studies. GAP promoter is not a good choice for the production of proteins that may be toxic.
2. Methylamine (or methanol) inducible *FLD1* (formaldehyde dehydrogenase) promoter (117). This retains many of the tight regulatory features of *AOX1* promoter. Promoter strength is quite high. A key advantage is that it can be induced using methylamine, which is inexpensive, as a sole nitrogen source (with glucose as carbon source). It is repressed in medium with glucose and ammonium sulfate.
3. Methanol or oleate inducible *PEX8* (a peroxisomal matrix protein gene) promoter (118). The promoter strength on methanol is considerably weaker than that of *AOX1* or *FLD1* promoters.
4. Constitutively active weak *YPT1* (a GTPase involved in secretion) promoter (119). The YPT1 promoter provides a low but constitutive level of expression in media containing glucose, methanol, or mannitol as carbon sources (119). This may be useful for coexpression of chaperones to enhance protein folding and secretion in production strains.
5. Ethanol and stationary phase inducible ICL1 (isocitrate lyase 1) promoter (120). ICL1 promoter is inducible with ethanol and repressed by glucose in the exponential phase. In the stationary phase ICL1 is expressed even in the presence of glucose.

One aspect that investigators have to keep in mind in using these alternate promoters for commercial applications is that they may have to pay royalty as the patents are still active, unlike *AOX1* promoter patent, which has expired.

13.4 FERMENTATION PROCESS

Typically two-phase fermentation is used. In the first phase (biomass stage), cells are grown until glycerol is depleted. In the second phase (protein production stage), gene expression begins by feeding methanol to the bioreactor. There are numerous factors that impact production yield in a bioreactor, including culture medium composition, strain, pH, temperature, agitation rate, dissolved oxygen, induction condition, and fermentation strategy. Several of these factors have been already discussed (see section titled “Production Enhancement by Manipulation of Media and Growth Conditions”. Basic protocols for *P. pastoris* fermentation have been abundantly described in literature (e.g. (42,121), and http://www.biotechlab.net/UserFiles/File/787348_Ref_Invitrogen2002.pdf.). Improvements which have been made to basic protocol have been recently reviewed (122,123). Few salient features are reviewed here.

13.4.1 Fermentation Media and Operational Conditions

Basal salt medium (BSM) is the most common medium for high cell density fermentation, although it may not be the optimum and may have some important problems (unbalanced composition, precipitates, ionic strength, etc.). Therefore, alternative media such as FM21 (44) and FM22 (121,122) have been described. The BSM medium provides, in general, high concentration of basic elements, all at the upper level of the recommended range proposed by Wegner (3). Conversely, FM21, and the D’Anjou media (123) have a low concentration of chemical elements, around the low limit suggested by Wegner (3). The concentrations of

the elements in FM22 media are similar to BSM with the exception of potassium. One of the most important points in a medium formulation is the nitrogen source. In BSM, and FM21, nitrogen is solely added as ammonium hydroxide when controlling pH. This is also true to a large extent for FM22. However, in the D'Anjou medium all nitrogen is supplied at the initial formulation and it is not added during the culture. Nitrogen starvation starts around 50 g/L of biomass (123). The lack of nitrogen is directly related to the increase in proteolytic activity resulting in the degradation of extracellular protein. Thus, in BSM and FM22 media, where nitrogen is added to control pH, this effect could be present when high biomass concentration is reached. The optimal conditions (medium, pH, temperature, etc.) are dependent on the strain used and thus have to be adjusted accordingly using the guidelines and considerations noted (see section titled "Production Enhancement by Manipulation of Media and Growth Conditions").

13.4.2 Dissolved Oxygen (DO) Control

Dissolved oxygen (DO) is an important factor for protein productivity in a bioreactor. It can be controlled with combination of agitation rate, and the air (or O_2) flow rate. During the glycerol batch phase (20–24 h), the DO is controlled by adjusting the agitation rate up to 800 rpm for a typical 4-L bioreactor, and around 450 rpm for 60-L reactor, and then manually adjusting the air (or O_2) flow rate into bioreactor. Upon exhaustion of glycerol, the DO will rise rapidly. Typically, DO should be maintained around 30%, but need to be further optimized on a case by case basis.

13.4.3 Growth Kinetics

In the methanol unlimited fed-batch and continuous cultures with Mut^+ cells, growth inhibition at high methanol concentration is noted. Specific growth rate increases with methanol concentration up to a maximum value named theoretical maximum specific growth rate μ'_{max}, corresponding to a critical substrate concentration (Scrit), beyond which it declines. Methanol concentration lower than Scrit, represent growth-limited state and for values higher than Scrit, represent the growth inhibited state. A comparison of the kinetic parameters obtained for the different heterologous proteins indicate that the growth rate is influenced by the protein being expressed (123).

13.4.4 Fed-Batch Fermentation Operational Strategy

Fed-batch fermentation protocols include three different phases. A glycerol batch phase (GBP), a transition phase (TP), and finally a methanol induction phase (MIP).

1. *Glycerol Batch Phase (GBP).* The objective of GBP is to rapidly generate biomass prior to protein production. The maximum specific growth rate of wild-type *Pichia* on glycerol (0.18 h^{-1}) is higher than growing on methanol (0.14 h^{-1}) (69) and this methanol μ_{max} is, generally, lower when *Pichia* is producing a heterologous protein. GBP strategy is common for Mut^+, Mut^-, and Mut^S *Pichia* strains and typically 40 g/L glycerol is used; concentration over 40 g/L could inhibit growth. Brierley and coworkers recommended a maximum glycerol concentration of 6% (70) and ethanol levels between 0.5 and 2.4% were detected when glycerol concentration was over 7% (124). The observed biomass to substrate yield (YX/S) (biomass expressed as dry cell weight) is about 0.5. Thus, a final biomass around 20 g/L is obtained at the end of GBP. The glycerol exhaustion (end of batch phase) is indicated by a sharp increase in the DO, which is the most common parameter used for initiation of TP.
2. *Transition Phase (TP).* TP has two objectives, one is to further increase biomass level and the other is to cause de-repression of the *AOX1* promoter due to the absence of excess glycerol prior to MIP. Constant glycerol feeding rate (125) or an exponential glycerol feeding rate is used to reach a growth-limited level. Cell growth predictions, for different exponential feeding profiles have been shown by Zhang and coworkers (126). The maximum glycerol specific consumption rate is 0.0688 g/(g h). The final biomass levels reached at the end of the TP is generally above 30 g/L. During TP, glycerol feeding rate is generally complemented with a methanol feeding rate to augment the de-repression of *AOX1* promoter. With mixed feeding, cultures can be primed for methanol induction, which leads to a substantial reduction in the length of MIP, as has been demonstrated in lipase production (127). Also, the methanol supplement can strongly support cells to synthesize *AOX1* (128). Different methanol profiles have been used for the TP, which include the following:
   - raising methanol feeding rate as a function of response of DO up to a 7.6 mL/(h L) (129);
   - maintaining methanol concentration at set points 4 g/L (125) or 1–2 g/L (130);
   - about 1 h starvation phase prior to MIP to assure that glycerol is completely consumed (131);
   - a decreased glycerol feeding rate and constant methanol feeding rate (132,133).
3. *Methanol Induction Phase (MIP).* The methanol feeding strategy, which also dictates the specific growth rate, is one of the key factors for maximizing protein production (126,128), since protein production is directly or indirectly associated with cell growth (134). Moreover, MIP may depend on the operational conditions (e.g. temperature,

pH, and culture medium), phenotype, and specific characteristics of the heterologous protein produced. The synthesis, processing, and secretion of the protein could also affect cell growth. Different approaches have been proposed to optimize MIP. These strategies are reviewed in (123).

13.4.5 Methods for Monitoring Methanol Concentration

One of the key parameters of *AOX* promoter based *Pichia* expression system is the methanol concentration, which is both a substrate and inducer. High levels of methanol are toxic to the cells and low levels of methanol may not be adequate for induction of expression. For optimal protein production, methanol induction strategy is critical. This has to be implemented keeping in mind the genetic background of the strain (Mut^+, Mut^S, or Mut^-), which has been addressed in the fermentation guidelines provided by Invitrogen Corporation (http://www.biotechlab.net/UserFiles/File/787348_Ref_Invitrogen2002.pdf) and in other published reviews (42,121–123). Keeping a constant methanol concentration during the induction phase is beneficial to optimal protein production (121). DO spike method has been used historically to estimate the methanol concentration. This technique, however, exposes the cells to potentially noninducing levels of methanol and cannot be easily implemented with Mut^- clones or with mixed substrate feeds. Off-line methods for methanol quantification include gas chromatography, HPLC (high performance liquid chromatography), and enzymatic determination, which are used in connection with a batch or fixed preprogrammed methanol addition strategy. A near infrared spectroscopy (NIRS) technique has also been used to model key analytes (biomass, glycerol, methanol, and product concentration) in the production of a therapeutic protein in high cell density culture (135). These off-line methods require a pretreatment of the sample and there will be precious time lapse for implementation. The sequential injection analysis (SIA) developed by Surribas and coworkers is able to measure seven samples per hour with low standard deviation (136). YSI 2700 select analyzer (http://www.ysilifesciences.com/) from Yellow Springs Instruments (Yellow Springs, Ohio) can be readily connected to a bioreactor for SIA. However, continuous extraction of samples increases contamination probability, besides sample loss.

Fortunately, many on-line methanol sensors have been successfully adopted to monitor *Pichia* fermentors (123), which are as follows:

- Raven methanol sensor from Raven Biotech Inc. (Vancouver, BC, Canada), which uses a probe inserted into the bioreactor (http://www.ravebiotech.com/products.html).
- TGS822 sensor for the detection of organic vapors from Fiagro Electronic Co. Ltd (Tahin, China) (http://www.etesters.com/products/details.cfm/part/TGS822/productID/58856492-802e-f41e-d604-2d325dd53216).
- Directly detecting the methanol vapor in the stream gas outlet by diverting it to an MC-168 methanol monitor and controller (PTI Instruments, Inc., Kathleen, Georgia) equipped with a TGS822 methanol sensor.
- Alkosense probe (Frings America, Illinois) (137). This measuring principle is based upon the selectivity of the semipermeable membrane system, which rejects low volatility substances like sugar and glycerin, as well as most organic substances including organic acids. If easily volatilized components are present, that is ethanol and methanol, the system will not be able to differentiate between the various components, and will measure the combined concentrations. (http://www.fringsamerica.com/markets/brewing/alkosens.asp).

If the growth kinetics of a *Pichia* production strain is preestablished, then the methanol feed rate can be adjusted according to the specific growth rate during the induction phase. This can be an effective way to maintain optimal methanol concentration in the bioreactor. In fact, this strategy has resulted in 2.5-fold higher productivity of lipase (127). To improve the expression level, glycerol and methanol were fed simultaneously, followed by a single methanol feed, and resulted in the highest productivity [12,888 U/(L h)], which is 13.6-fold higher than the DO-based strategy. On-line methanol measurement, which permits implementation of closed-loop control algorithm (138) can be more effective than open-loop control strategies or indirect methanol feed rate from other fermentation parameters/variables as specific growth rate in particular, from industrial point of view for a reproducible fermentation at a constant methanol set point.

13.4.6 Methanol Control Schemes

To produce small quantities of heterologous protein, the methanol feeding strategy from http://www.biotechlab.net/UserFiles/File/787348_Ref_Invitrogen2002.pdf or as found in (42) is adequate. When the objective is to reproducibly maximize product yield and for quality control, the selection of the optimal methanol feeding strategy in the induction phase is necessary. When on-line methanol concentration monitoring is not available two different methanol feeding strategies, DO spike method, and an open-loop methanol control strategy are most commonly used (121). Both these strategies and their limitations have been elegantly reviewed (123). In the DO spike method, methanol feeding rate is modified in order to avoid methanol exhaustion as indicated by a sharp increase in dissolved oxygen. Neither methanol concentration nor specific

growth rate are constant in this strategy, and thus it is difficult to study the effect of these variables on the production of the heterologous protein. DO spike method has an additional problem, if an inhibitory methanol level is reached, a sharp increase in DO will be observed, the response of the system will be then to increase the methanol feeding rate leading to methanol accumulation to toxic levels in the bioreactor. In the method based on the methanol control using an open-loop structure, a feeding rate profile derived from mass balance equations to theoretically maintain a constant specific growth rate (μ) is used. This approach is based on simple cell growth models with no on-line information about the system. To implement this method, a constant YX/S for the fed-batch induction phase is considered and, biomass concentration and volume are supposed to be known at the beginning of the preprogrammed feeding strategy. Zhang and coworkers, empirically developed a methanol feeding strategy based on a growth model, obtaining μ to maximize the protein production (126). D'Anjou and Daugulis have demonstrated the usefulness of a rational, model-based approach for improving the productivity by using an exponential feeding strategy with mixed glycerol–methanol substrate in a fed-batch (130). Although open-loop systems could be easy to implement they do not respond to possible perturbations of the system. Simplest closed-loop control strategy is the "on–off" control mode. Some works have been published with apparently satisfactory results (for example, (126,133)). However, due to the complexity of the system, a simple "on–off" control strategy is inadequate for precise control of methanol concentration in the bioreactor leading to fluctuations in methanol concentration around the set point.

13.4.7 Mixed Substrates

One strategy to increase the productivity of *Pichia* expression is the use of a multicarbon substrate in addition to methanol. It is a simple way to augment the energy supply to cells in the culture broth (128,133,139). A mixed feed reduces the induction time, increases cell density, and volumetric productivity (140). The mixed feeding strategy is generally employed for Mut^s *Pichia* fermentations because of the slow methanol utilization, which requires large induction times (above 100 h), although it has also been used for Mut$^+$ strains (141). Glycerol has been the most feeding cosubstrate used at limited rates, ensuring good cell growth while inducing the expression of the heterologous protein. However, although the volumetric productivity increased, the specific productivity of recombinant protein is lower because glycerol represses the *AOX1* promoter (142). Inan and Meagher compared different carbon sources in terms of their ability to support growth and expression of an *AOX1-lacZ* fusion in shake flasks studies of a *P. pastoris* Mut$^-$ strain (115). As predicted, glucose, glycerol, ethanol, and acetate supported growth but repressed the expression of β-gal. On the contrary, growing on media containing alanine, mannitol, sorbitol, and trehalose expressed as much or higher amount of β-galactosidase compared to the Mut$^+$ strain. Recently, lactic acid has also been referred as nonrepressing substrate (142). The use of a less repressing carbon source may result in higher specific production rates, improving overall productivity, and eliminating the need for such tight control of residual substrate levels. Among them, sorbitol is a widely accepted nonrepressive carbon source for *P. pastoris* and methanol can be added to the sorbitol feed at any desired point to initiate induction of expression (41).

13.4.8 Continuous Fermentation

Continuous production mode in comparison to fed-batch fermentation, offers advantages in terms of higher volumetric productivity, product quality, product uniformity, significant reduction in exposure of the product to the proteolytic enzymes, oxidative damage or inactivation, and overall reduction of downtime (143,144). Continuous operation using methanol as sole carbon source under control of *AOX1* promoter is practically limited to Mut$^+$ cells. The low maximum specific growth rate of Mut^s phenotype limits the operational dilution rate and thus, the productivity of the process. However, Boze and coworkers in a continuous process at a dilution rate of 0.012/h with a Mut^s obtained a 6.4-fold higher productivity and 2.3 times higher specific productivity of porcine Follicle-stimulating hormone (FSH) compared to that achieved with fed-batch process (145). As discussed under "mixed substrate" section, one approach to increase the productivity of Mut^s phenotype is the use of a mixed carbon feed. Glycerol and sorbitol are the most commonly used cosubstrates jointly with methanol. With glycerol, the continuous strategy is to select a dilution rate far enough from μmax to ensure that no glycerol is allowed to accumulate in the broth, and also methanol concentrations have to be maintained at levels sufficient to fully induce heterologous protein production, yet not so high as to be inhibitory to cell growth or heterologous protein expression (130). D'Anjou and Daugulis performed a set of continuous stirred tank reactor or CSTR (continuous fermentation) experiments to determine the relationship between the dilution rate (in a range between 0.01 h^{-1} and 0.09 h^{-1}), the specific methanol consumption rate, and the specific production rate in the heterologous production of a sea raven antifreeze protein using mixed methanol–glycerol feed (146). The specific methanol consumption rate as a function of the dilution rate showed a maximum at approximately $D = 0.05$ h^{-1}. Maximum production was achieved at the lowest dilution rate. However, the maximum specific production rate (Q_p) was achieved at the highest dilution rate. This behavior

confirms that product formation is related to growth by a constant yield coefficient. Finally, they demonstrated that a CSTR system will yield a higher productivity compared with a fed-batch system. Readers are directed to Refs (122) and (123) for further discussions on CSTR.

13.4.9 Cyclic Fed-Batch Culture (CFBC)

A simple cyclic fed-batch culture (CFBC) consisting of a constant medium feed with periodic withdrawals of culture resulted in a product yield (13.4 mg HSA/g biomass) similar to that obtained using the complex multiphase industrial production strategy (13.7 mg HSA/g biomass) has been reported (147). Thus, using a much simpler protocol, it is possible to obtain yields comparable to that seen with more complex multiphase feed strategy.

13.4.10 Hypoxic Fed-Batch Cultivation

High cell density fermentation of *Pichia* has to cope with many technical limitations, most importantly the transfer of oxygen. By applying hypoxic conditions to chemostat cultivations of *Pichia* expressing an antibody Fab fragment under the GAP promoter, a 2.5-fold increase of the specific productivity Q_p at low oxygen supply was observed. At the same the biomass decreased and ethanol was produced, indicating a shift from oxidative to oxidofermentative condition. Based on these results a feedback control for enhanced productivity in fed-batch processes, where the concentration of ethanol was kept in the culture at 1% (v/v) by regulated addition of feed medium. This strategy was tested successfully with three different production strains, leading to a three- to sixfold increase in Q_p and threefold reduced fed-batch times. Taken together, volumetric productivity Q_p increased 2.3-fold (148).

13.4.11 Optimization of Trace Metals

A study of trace metals effect on growth and yield of LACZ production in GS115 Mut^+ strain has shown that both Mg and Zn are essential to support growth, but the amount required is considerably lower than the level typically used. Supplementation with Ca, Co, Mo, Fe, Mn, I, and B were not required to sustain cell mass. When the medium was reformulated with only Mg and Zn, the cells grew for 12–15 generations, which are expected for high cell density fed-batch fermentation. Product yields of LACZ was significantly affected by trace metals. When optimizing a fermentation process, the objective is also to decrease production costs, including indirect issues such as compliance to regulatory agency restrictions, impacts to downstream processing steps, effect of the medium components to equipment maintenance, etc. Clearly, reduction or elimination of trace metals potentially impacts all these intangibles (149). This study shows the importance of critically examining and accordingly adjusting the trace metal levels for a given production strain.

13.5 CONCLUSIONS AND FUTURE PERSPECTIVES

Pichia undoubtedly has proven to be a reliable system for expression of a wide assortment of proteins, many of which are expressed at several grams per liter levels. It is impressive to see how enthusiastic researchers from all corners of the world are willing to make it work, because it seems as though a researcher feels, it is his/her own fault, if the protein of interest did not work in *Pichia*! This bears testimony to the grand track record of *Pichia*. With the recent success seen in expression of several membrane proteins, I am sure we will hear many more success stories in that category as well. With the availability of glycoengineered *Pichia*, we can foresee that *Pichia* will gradually replace mammalian cell expression system for production of authentic human pharmaceuticals. *Pichia* surface display has just surfaced (150); we can anticipate all sorts of novel surface display applications in the years to come. *Pichia* expressing fish growth hormone has been directly fed to fish to dramatically impact growth rate (151); *Pichia* expressing *B. sphaericus* mosquitocidal toxins (55) is an effective biopesticide when fed to mosquito larvae, and likewise, *Pichia* expressing garlic lectins (152) shows potent insecticidal activity toward aphids. With wider acceptance of genetically modified organisms, we can foresee wholesome *Pichia* applications in biopesticide (55,152), biocatalysis (153,154), and perhaps even *Pichia* burger—why not? It is able to assemble collagen fibers so efficiently, just clone in that beef savory-peptide; we are on our way to a *Pichia* burger. May be the Phillips Petroleum Company's initial *Pichia*-SCP dream, will be realized after all.

I can see someone out there read *Pichia* genome, create knockout and knockin strains for every *Pichia* ORF, and study their impact on recombinant protein expression in a bioreactor! Thinking of bioreactors, I am a bit puzzled why *Pichia* has not yet been adopted for cultivation in wave bioreactors offered by GE Healthcare (http://www.wavebiotech.com/products/wave_bioreactor/system500/index.html). Wave technology is a completely closed system with disposable bioreactor chamber, scalable to 500 L, easy to operate, and provides controllers for dissolved oxygen, pH, CO_2, O_2, and other optional modules. Designed for R&D, process development and cGMP production use, the Wave Bioreactor is gaining popularity for mammalian and insect cell cultivation and has recently been adopted for *S. cerevisiae* (155). Culture medium and cells only contact a presterile, disposable chamber called a Cellbag that is placed on a special rocking platform. The rocking

motion of this platform induces waves in the culture fluid. These waves provide mixing and oxygen transfer, resulting in a perfect environment for cell growth. The bioreactor requires no cleaning or sterilization, providing the ultimate ease in operation and protection against cross-contamination.

With the expiry of the key *Pichia* patent, and presence of literally hundreds of *Pichia*-experts around the globe, many more industrial outfits will embrace *Pichia* and we can anticipate many more *Pichia* derived proteins and vaccines to be commercialized in the near future. May be we will see *Pichia* engineered to fix CO_2, as well as makes its own O_2, so that we would not have to worry about feeding methanol or oxygen to bioreactors—certainly a sigh of relief!

13.6 MEDIA COMPOSITIONS

Stock solutions (42)

10 × YNB: 13.4 g of yeast nitrogen base without amino acids (YNB) in 100 mL of water and filter sterilize.

500 × B: 20 mg D-biotin in 100 mL water and filter sterilize.

100 × H: 400 mg L-Histidine in 100 mL water (heat if necessary) and filter sterilize.

10 × D: 20 g D-glucose in 100 mL water. Autoclave or filter sterilize.

10 × GY: Mix 10 mL of glycerol with 90 mL water and filter sterilize.

10 × M: Mix 5 mL methanol with 95 mL water and filter sterilize.

Minimal media compositions (42)

MD: Mix 100 mL of 10 × YNB, 2 mL of 500 × B, and 100 mL of 10 × D with 800 mL autoclaved water (include 15 g bacto-agar for plates).

MM: Mix 100 mL of 10 × YNB, 2 mL of 500 × B, and 100 mL of 10 × M with 800 mL autoclaved water (include 15 g bacto-agar for plates).

MGY: Mix 100 mL of 10 × YNB, 2 mL of 500 × B, and 100 mL of 10 × Gy with 800 mL autoclaved water (include 15 g bacto-agar for plates).

Supplemental medium (42)

MDH: Mix 100 mL of 10 × YNB, 2 mL of 500 × B, 100 mL of 10 × D, and 10 mL 100 × H with 790 mL autoclaved water (include 15 g bacto-agar for plates).

MMH: Mix 100 mL of 10 × YNB, 2 mL of 500 × B, 100 ml of 10 × M, and 10 mL 100 × H with 790 mL autoclaved water (include 15 g bacto-agar for plates).

MGYH: Mix 100 mL of 10 × YNB, 2 ml of 500 × B, 100 mL of 10 × MGY, and 10 mL 100 × H with 790 mL autoclaved water (include 15 g bacto-agar for plates).

Complex media composition (42)

YPD: Dissolve 10 g bacto yeast extract, 20 g peptone, and 20 g glucose in water (also include 15 g bacto-agar for plates) and autoclave for 20 min.

YMPD: Dissolve 3 g of yeast extract, 3 g of malt extract, 5 g of peptone, and 10 g of glucose in 1 L of water and autoclave.

YMPGY: Same as YMPD with the exception that 10 mL of 100% glycerol is used instead of 10 g glucose.

Secretion media composition (42)

BMGY: Mix 100 mL of 1 *M* potassium phosphate buffer, pH 6, 100 mL of 10 × YNB, 2 mL of 500 × Biotin, and 10 mL of glycerol. Filter sterilize and add to an autoclaved solution of 10 g yeast extract and 20 g peptone in 788 mL water (15 g bacto-agar is included for plates),

BMMY: Same as BMGY, with the exception that 5 mL methanol is added in the place of 10 mL glycerol.

Note: Yeast extract and peptone in the above media can be replaced by 1% casamino acids.

The following buffers are used to adjust the pH of BMGY and BMMY to desired pH:

Phosphate buffer for pH range 5.7–8

Alanine–HCl buffer for pH range 2.8–3.6

Aconitic acid–NaOH buffer for pH range 3–5.7

Citrate buffer for pH range 3–6.2

Avoid succinate buffer, because succinic acid will repress induction of the *AOX1* promoter.

13.6.1 Fermentation Medium and Reagents

Basal salts medium (BSM) derived from Wegner (3)

For 1 L, mix together the following ingredients:

H_3PO_4 (85%) 26.7 mL

$CaSO_4 \cdot 2H_2O$ 0.93 g

K_2SO_4 18.2 g

$MgSO_4 \cdot 7H_2O$ 14.9 g

KOH 4.13 g

Glycerol 40 g

Water to 1 L

After autoclaving, adjust the pH to 5 with 28% NH_3 (concentrated ammonium hydroxide). It is normal that the medium becomes cloudy at pH 5. The added ammonium hydroxide serves as nitrogen source during fermentation.

FM21 basal salt media, derived from Wegner (3)

For 1 L, mix together the following ingredients:

H_3PO_4 (85%) 3.5 mL

$CaSO_4 \cdot 2H_2O$ 0.15 g

K_2SO_4 2.4 g
$MgSO_4 \cdot 7H_2O$ 1.95 g
KOH 0.65 g
Glycerol 40 g
Water to 1 L

FM22 basal salt media (121)
For 1 L, mix together the following ingredients:
KH_2PO_4 42.9 g
$CaSO_4 \cdot 2H_2O$ 18.2 g
$(NH_4)_2SO_4$ 5 g
K_2SO_4 14.3 g
$MgSO_4 \cdot 7H_2O$ 1.95 g
Glycerol 40 g
After autoclaving pH is approximately 4.5

PTM1 trace salts derived from Wegner (3)
Mix together the following ingredient in 1 L of water:
$CuSO_4 \cdot 5H_2O$ 6 g
NaI 0.08 g
$MgSO_4 \cdot H_2O$ 3 g
$Na_2MoO_4 \cdot 2H_2O$ 0.2 g
H_3BO_3 0.02 g
$CoCl_2$ 0.5 g
$ZnCl_2$ 20 g
$FeSO_4 \cdot 7H_2O$ 65 g
Biotin 0.2 g
H_2SO_4 5 mL
Water to a final volume of 1 L
Filter sterilize and add 4.35 mL/L to the autoclaved starting medium.
Note: There may be a cloudy precipitate upon mixing of these ingredients.
The precipitate does not have any adverse effect on growth of *Pichia*.
If precipitation is a concern, then PTM4 (see section titled "PTM4 Trace Salts"), which has lower amounts of copper, iron, zinc, and sulfuric acid may be used.

PTM4 trace salts (122)
Mix together the following ingredient in 1 L of water:
$CuSO_4 \cdot 5H_2O$ 2 g
NaI 0.08 g
$MnSO_4 \cdot H_2O$ 3 g
$Na_2 \cdot Na_2MoO_4 \cdot 2H_2O$ 0.2 g
H_3BO_3 0.02 g
$CoCl_2$ 0.5 g
$ZnCl_2$ 6.7 g
$FeSO_4 \cdot 7H_2O$ 21.6 g
Biotin 0.2 g
H_2SO_4 1.7 mL
Water to a final volume of 1 L
Filter sterilize and add 4.35 mL/L to the autoclaved starting medium.

5% (w/v) antifoam solution (AF) (122)
Dissolve 25 g of KFO^{TM} 673 antifoam (food grade, KAOB Chemicals, Inc., WY, USA) in 500 mL water, filter sterilize, and add 2 mL/L to the starting medium. Additional amounts may be added as needed to eliminate foam during the fermentation.

13.7 GLOSSARY OF *P. PASTORIS* STRAINS

Y-11430-SC5 (wild type) (NRRL)
X-33 (wild type) Invitrogen
GS115 (*his4*)—this Mut$^+$ strain is also known as GTS115 (54)
KM71 (*his4, aox1::SARG4*)—this is Mut^S strain (28)
PPF1 (*his4, arg4*) (28)
MC100-3 (*aox1::SARG4, aox2::HIS4, his4, arg4*)—this is Mut$^-$ (44)
Protease-deficient strains
SMD 1168 (*his4*, *pep4*) (95)
SMD1165 (*his4*, *prB1*) (95)
SMD 1163 (*his4*, *pep4*, *prB1*) (95).

GENE EXPRESSION IN RECOMBINANT ANIMAL CELLS AND TRANSGENIC ANIMALS

Richard M. Twyman
John Inness Centre, Norwich, United Kingdom
Bruce Whitelaw
Roslin Institute, Roslin, Midlothian, United Kingdom

14.1 INTRODUCTION

The ability of mammalian cells to take up DNA from their surrounding medium was first shown in the early 1960s (1). However, gene transfer to animal cells had been appreciated even since the 1940s, when viruses were first shown to carry their own nucleic acid. It is now known that animal cells can take up DNA naturally from a variety of sources, such as from incompletely hydrolyzed DNA molecules in the digestive tract (2). However, the *predetermined* genetic manipulation of animal cells only became possible at the beginning of the recombinant DNA era. This saw the development of a range of tools and techniques for the cloning and *in vitro* manipulation of particular DNA fragments, permitting the construction of *recombinant DNA* molecules containing novel combinations of sequences from diverse sources. Such techniques facilitated the design of *vectors*, purpose-constructed delivery vehicles used to introduce and establish foreign DNA sequences in animal cells. This, and the inclusion of transcriptional and translational control sequences in vectors to drive foreign gene expression, forms the basis of genetic engineering in animal cells.

In most cases, the underlying aim of a particular gene transfer experiment is to express a protein, either for commercial or research purposes or for gene therapy. In many cases, the recombinant protein is not typically synthesized by the host cell (e.g. it may be a protein from a different species or a protein that is normally restricted to a different cell type), in which case it may be described as a *heterologous protein*. Alternatively, it may be an endogenous protein, but the aim may be to overexpress it, or express it under unusual circumstances. Finally, the recombinant protein may be a particular mutant form of an endogenous protein, or one that has been modified so it is targeted to a different intracellular compartment.

The expression of recombinant proteins in animal cells is now a well-established technology and has been used in a huge variety of experimental systems. As a commercial approach to protein production, large-scale cultures of engineered mammalian cells have been used to synthesize antibodies, hormones, growth factors and cytokines, blood clotting factors, and the surface proteins of numerous viruses for use as recombinant vaccines (3). More recently, the same gene transfer technology has been used to alter endogenous gene expression or make targeted genome rearrangements in host cells. Vectors producing antisense RNA can be used to inhibit the expression of specific endogenous genes. Novel vectors can also be used as insertional mutagens and to facilitate the identification and cloning of genes by reporting their expression patterns. Others can replace endogenous genes by homologous recombination and can even generate specific chromosome rearrangements. The scope of such experiments may be limited to animal cells in culture, but if fertilized eggs, early embryos, or embryonic stem (ES) cells are used as host cells for gene transfer, it is possible to regenerate chimeric or fully transgenic

animals expressing recombinant proteins or carrying specific germline alterations. The reintroduction of engineered cells into living animals and gene transfer to animal cells *in vivo* are also becoming established as technologies for gene therapy and the generation of chimeric animals for research.

14.2 OVERVIEW

14.2.1 Animal Cells Used for Genetic Manipulation

For the analysis of animal genes, it is usually beneficial, and in many cases essential, to use animal cells as hosts. Animal cells alone provide the correct genetic and biochemical background for such studies. Furthermore, animal proteins expressed in animal cells are more likely to be correctly processed and modified compared with those expressed in bacteria or microbial eukaryotic systems. For these reasons, there has been an intense effort over the past 20 years to develop efficient vectors and DNA transfer procedures for use with animal cells. Generally, this means *mammalian* cells and cell lines. However, other vertebrate cells are used for specialized purposes (e.g. the chicken DT40 cell line for homologous recombination). Furthermore, insect cell lines are used for the highly efficient baculovirus-based transient expression system, and as they are cheap to maintain, insect cells have recently emerged as hosts for recombinant protein expression in their own right (4). One exception to this apparently polarized exploitation of the diversity within the animal kingdom is in the field of transgenesis. The eggs and early embryos of many animals—nematodes, mollusks, annelids, insects, fish, amphibians, birds, and mammals—have been subjected to gene transfer procedures to produce animals containing transient episomal foreign DNA or carrying stable germline modifications. In addition, the large oocytes and eggs of the South African clawed frog *Xenopus laevis* have been widely exploited as a transient heterologous expression system for the analysis of protein function (5).

14.2.2 Protein Expression

For protein expression, the DNA sequence to be expressed is typically cloned in a bacterial host and then introduced into animal cells either by transfection (direct DNA transfer) or transduction (carried within a virus particle). In each case, cloning and transfer involve the use of specialized vectors carrying all the DNA sequences required for transcription and translation (Table 14.1.). Sometimes such a strategy is chosen because the foreign sequence cannot be expressed in any other host (e.g. if it contains introns that are incorrectly spliced in microbial systems). Characterizing the properties of cloned genes by expression in mammalian cells may also be one route to isolate a particular gene or cDNA sequence from a DNA library, an approach termed *expression cloning*. In many cases, cloned sequences are introduced into animal cells to be subjected to some kind of functional analysis, such as testing various mutant forms of a protein or regulatory element for their activity. Alternatively, protein production may itself be the goal, allowing biochemical and structural analysis and commercial production for research, industrial, or medical use. The exploitation of animal cells is particularly important if correct posttranslational modification is required for efficient protein activity or if the product is intended for human therapeutic use, because incorrect modification often renders recombinant human proteins immunogenic. Where protein synthesis is itself the ultimate aim, a small number of cell lines have been specially developed to complement particular vectors, such as COS-7 cells for simian virus 40 (SV40)-derived replicons, HEK 293 cells for adenoviral vectors, and Sf9 cells for baculovirus vectors. Gene transfer procedures for such cells have been carefully optimized.

Many of the strategies discussed require only transient protein expression. The foreign DNA need only remain intact and functional in the host cell for a short time or the host cell itself need only survive transiently. This type of system is sufficient for protein harvesting if a large amount of protein can accumulate over a short period of time. It is also sufficient for many types of functional analysis, because the given assay can be completed rapidly. In other situations, however, it may be necessary to generate a cell line producing recombinant protein on a long-term basis. This approach is used where a continuous supply of protein is required or where the cell line is used as a basis for further study. Such applications require foreign genes to be stably and permanently maintained in their animal cell hosts. This can be achieved in two ways: first by stable integration of foreign DNA into the genome and second by the use of stably maintained episomal vectors. Stable maintenance and long-term expression are also required where manipulated cells are used to generate transgenic animals or as part of a gene therapy program. Like engineered cells, transgenic animals may be used purely for functional analysis or as novel strains for exploitation in further experiments. Transgenic animals can also be used as living factories, producing correctly modified commercially valuable proteins, for example, in their milk.

14.2.3 Recent Advances in Gene Transfer Technology

While protein expression remains the predominant use for animal cells, attention has recently switched to a powerful set of novel applications that exploit the same gene transfer techniques directly to modify animal genomes or

TABLE 14.1. Reasons for the Genetic Manipulation of Animal Cells

Protein expression	1. For the production of large amounts of a protein that is either naturally scarce or the completely novel product of recombinant DNA technology, especially applicable for the production of biologically active proteins with specific forms of posttranslational modification, which are carried out incorrectly in microbial expression systems 2. For confirmation of the identity of a cloned gene by immunological assay of its product 3. For the study of protein function, transport, localization, and so on within animal cells 4. For the comparison of normal and mutant proteins 5. For the expression of proteins from genomic sequences containing introns, which are not spliced or incorrectly spliced in microbial systems 6. For gene augmentation therapy, the expression of proteins in animal cells to correct a genetic defect in a live animal 7. For the production of transgenic animals expressing a foreign protein
Regulatory analysis	1. For transient analysis of gene regulatory sequences in cells using reporter constructs 2. For the analysis of gene regulatory sequences using reporter constructs in transgenic animals 3. For the cloning and analysis of higher order function elements (origins, centromeres, matrix attachment regions, boundary elements, etc.)
Gene inhibition	1. For the inhibition of endogenous gene function using antisense RNA, ribozymes, intrabodies, or dominant negative alleles either for functional analysis in cells/transgenic animals or for gene inhibition therapy
Mutagenesis and targeting	1. For untargeted gene mutation by random insertional mutagenesis 2. For mutagenesis screening and cloning by tagging or plasmid rescue 3. For the entrapment of genes or regulatory elements 4. For targeted disruption of an endogenous gene (gene knockout) 5. To introduce a subtle mutation (allele replacement) 6. To replace one gene with another (gene knock in)

the expression of endogenous genes. *Gene targeting* is the replacement of one allele with another by homologous recombination, leaving the rest of the genome unchanged. This technique facilitates allele replacement and gene disruption (gene knockout) to create tailor-made mutant cells. The expression of endogenous genes can also be influenced by using expression constructs to generate antisense RNA, sometimes associated with ribozymes. These interact with and destroy cellular mRNAs, and hence block gene expression at the posttranscriptional level. Both gene targeting and antisense RNA strategies are extremely powerful when combined with current methods for generating transgenic animals, because they allow the creation of specific mutants with particular genes interrupted, replaced, altered by subtle mutation, or inhibited. The random insertion of cloned DNA also has many applications, for example, saturation mutagenesis, gene cloning by tagging or plasmid rescue, and the trapping of endogenous genes and regulatory elements using randomly inserted reporter gene constructs. Once again, this technology is most powerful when used in transgenic animals, allowing the isolation of genes and regulatory elements with specific expression patterns or the isolation of genes associated with particular mutant phenotypes.

Of particular interest is the use of site-specific recombination systems from bacteriophage and yeast to control gene expression and generate targeted genome rearrangements, often in an inducible or regulated fashion. The design of fully synthetic or hybrid inducible gene expression systems should eventually allow the experimenter to exercise complete and predictable control over foreign genes transferred to animal cells and in transgenic animals.

14.2.4 Transfer and Fate of DNA Introduced into Animal Cells

DNA can be introduced into cultured animal cells by two routes. The first exploits the natural ability of animal viruses to infect cells and deliver the viral genome either to the cytoplasm (most RNA viruses) or nucleus (most DNA viruses). Recombinant viruses carrying foreign DNA can thus be used to transfer foreign genes into the cell, a process termed *transduction*. Most DNA viruses, as well as the retroviruses (which have a DNA stage of the replication cycle), have been used to deliver foreign genes to the nucleus. Some replicate episomally (e.g. herpes viruses), while others integrate (e.g. retroviruses). Exceptionally, the poxviruses are DNA viruses that replicate in the cytoplasm. They, and some RNA viruses, have been exploited for cytoplasmic gene delivery and expression, which can be advantageous in certain experiments (e.g. for producing antisense RNA). The general advantage of transduction as a gene delivery method is its high efficiency: In certain systems, every cell in a culture dish can receive foreign DNA. It is also possible to exploit the natural tropism of a virus to infect particular cells in a tissue; for example, Epstein–Barr virus (EBV) is

lymphotropic. On the down side, there is often a complex series of manipulations involved in the preparation of recombinant viruses. Most viruses also exhibit cytopathic effects, and there are safety concerns over the use of recombinant human viruses. The alternative and simpler strategy is direct DNA delivery, where the cell is forced to internalize DNA present in the surrounding medium or where there is direct physical delivery of DNA into the nucleus, such as by microinjection. These unnatural DNA uptake routes are grouped under the term *transfection*. Direct delivery is by far the most commonly used strategy due to its simplicity and the requirement for only small, easily manipulable vectors. However, it is much less efficient, and strong selection systems must be used to identify successfully transfected cells.

The fate of the DNA introduced into cells depends on the vector system being used. Many viruses, and plasmids derived from them, carry *cis*-acting elements that facilitate episomal replication, allowing the DNA to be replicated and expressed without integration. Alternatively, foreign DNA may integrate into a random chromosomal site and replicate as a normal part of the genome. Integration generally represents a permanent modification, while episomal maintenance may be permanent or transient, depending on the nature of the replicon and its effect on the cell. Genes carried on vectors with no capacity for episomal maintenance may also be expressed transiently, but are soon diluted from the cell population. In some cases, the use of nonreplicating vectors, or even simple donor DNA without vector, ensures that only cells that have stably integrated the DNA will be selected.

14.3 PLASMID EXPRESSION VECTORS FOR ANIMAL CELLS

14.3.1 Classes of Expression Vector and Common Modular Components

An expression vector contains regulatory elements allowing the expression of any foreign DNA it carries. The simplest expression vectors, *transcription vectors*, allow transcription but not translation of cloned foreign DNA and are designed for *in vitro* use (Fig. 14.1a). They allow the production of large quantities (up to 100μg/reaction) of recombinant RNA and are often equipped with dual, opposing promoters allowing both message sense and antisense RNA to be synthesized, for example, for use as probes in hybridization experiments. Significantly, such vectors utilize the very specific promoters from *Escherichia coli* bacteriophages such as T3, T7, and SP6, which do not function in animal cells. More complex vectors can therefore be designed to incorporate this *in vitro* transcription system without interfering with the function of eukaryotic transcription units in animal cells. Simple transcription vectors lack other regulatory sequences, including transcriptional termination sites. RNA of specified length can therefore be produced from such vectors only by linearization (run-off transcription). Although designed for *in vitro* use, transcription vectors play an essential role in certain protein expression systems.

Typical *protein expression vectors* allow both the transcription and translation of cloned DNA, and thus facilitate the production of recombinant protein (Fig. 14.1b). Such vectors are equipped with transcriptional regulatory sequences and sequences that control RNA processing and

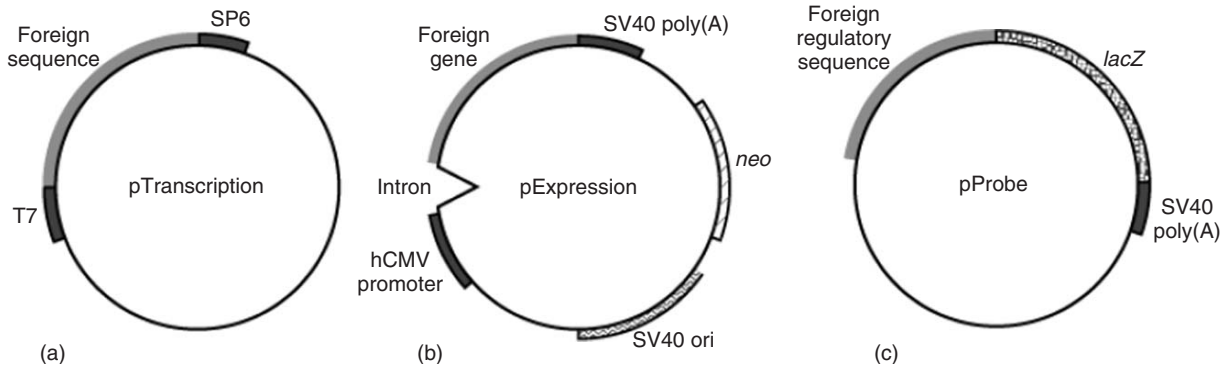

Figure 14.1. Generic maps of different types of expression vector: (a) a transcription vector, which carries promoters allowing the *in vitro* transcription of foreign DNA; (b) a protein expression vector, which contains the regulatory elements (promoter–enhancer, intron, and polyadenylation site) allowing the transcription and translation of foreign DNA; such vectors may also carry a marker gene for selection of transformants or a viral origin of replication for episomal maintenance; (c) a regulatory probe vector, which carries a reporter gene and allows the characterization of cloned regulatory elements.

protein synthesis (6). They are designed for use in both cell culture and *in vivo*. In cases where the objective of the expression experiment is simply to produce as much protein as possible, *overexpression vectors* are used, which are designed to maximize both transcription and translation. Where more moderate protein expression levels are appropriate for the experiment, or where large amounts of protein would be toxic to the cells, inducible regulatory elements may be used. A common fusion strategy is to express recombinant proteins with an N-terminal signal peptide. This allows secretion from host cell, so that the protein can be purified from the growth medium without resorting to cell lysis.

Further expression vectors are designed not for the analysis of cloned gene products, but cloned regulatory elements (7). Such *regulatory probe vectors* carry a screenable marker gene, such as *lacZ*, and allow the insertion of putative regulatory elements that can be used to drive marker gene expression (Fig. 14.1c). Different vectors are available for the analysis of different types of *cis*-acting element. *Promoter probe vectors* carry a reporter gene with an initiation codon but no upstream regulatory sequences and are used for the identification and dissection of putative promoters. *Enhancer probe vectors* carry a reporter gene driven by a minimal promoter, allowing analysis for the upregulation of basal activity. There are also vectors available for the analysis of transcriptional terminator/polyadenylation sites and splice signals. Specialized probe vectors called *entrapment vectors* are used for the identification and isolation of novel regulatory elements following random integration into the genome.

The typical modular components of an expression vector for animal cells can be divided into five major categories (6):

- *Plasmid backbone sequences:* Sequences required for cloning in bacteria and for *in vitro* manipulation
- *Plasmid maintenance sequences:* Many vectors also carry sequences of viral origin that allow episomal replication in animal cells
- *Components of the animal gene transcription unit:* Sequences used for the efficient expression of foreign genes, including promoter and enhancer elements, a polyadenylation site, an intron, sequences for translational control, and sequences for protein targeting in the host cell
- *Marker genes:* Either for visible quantification or characterization of gene expression or for selection of transfected cells
- *Sequences to simplify protein purification:* In overexpression vectors, there may be additional sequences encoding a signal peptide (to facilitate secretion), a protein tag (to allow, e.g. affinity purification of the fusion protein), and a protease cleavage site (to remove the tag after purification).

14.3.2 Plasmid Backbone Sequences

All expression vectors for use in animal cells are *shuttle vectors*; that is, they can be propagated in cells of more than one species. In most cases, the alternative host is *E. coli*, allowing large quantities of plasmid DNA to be prepared and isolated from bacterial culture. Such vectors contain an origin of replication derived from the plasmid ColE1 and a dominant marker for selection in bacterial cells. This marker is usually an antibiotic resistance gene. However, suppressor tRNAs are used in some host–vector systems.

In addition to these basic maintenance sequences, other backbone sequences include those used for *in vitro* manipulation (8). The most important of these is the *multiple cloning site*, a cluster of unique restriction enzyme sites allowing the insertion of foreign DNA, using a variety of subcloning strategies, at a site that does not disturb vector functions. For many vectors, recombinant screening is facilitated by locating the multiple cloning site within a marker gene so that recombinants can be screened for loss of marker activity. The simplest and most popular system is *blue–white selection*. This is based on the marker gene *lacZ*, whose product β-galactosidase converts the chromogenic substrate X-gal (5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside) into a blue pigment. Recombinant vectors, in which the marker is interrupted, lack β-galactosidase activity. Therefore, on X-gal supplemented medium, recombinant colonies appear white and nonrecombinant colonies blue. The best contemporary vectors are extremely versatile and contain a bacteriophage f1 (or similar) origin of replication, facilitating the production of single-stranded DNA for sequencing, *in vitro* mutagenesis, and so on, and opposed bacteriophage promoters allowing the synthesis of sense and antisense RNA corresponding to the insert (e.g. for *in situ* hybridization).

Generally, the bacterial and animal components of shuttle vectors are functionally segregated. The animal DNA does not function in bacteria, and therefore does not interfere with cloning. Similarly, the *E. coli* backbone sequences are not intended for use once the plasmid has been introduced into animal cells, and they do not interfere with maintenance or expression. However, certain plasmid sequences have been shown to inhibit vector function in mammalian cells. The first example was a fragment of the pBR322 backbone that inhibited the activity of the SV40 origin of replication in monkey cells (9). Such *poison sequences* are often poorly defined, but they may be responsible for the varying efficiencies of otherwise similar expression vectors. Occasionally, eukaryotic insert sequences can interfere with cloning in bacteria—this usually involves rearrangement of

the insert due to the presence of repetitive DNA sequences, but can also result in nonrecovery of recombinant vectors from bacterial culture. Some vectors are designed to use certain sequences both in bacterial and animal cells. A recent series of expression vectors from Invitrogen utilizes a single dominant selectable marker for resistance to the antibiotic Zeocin. This can be selected in bacteria and mammalian cells because the gene is controlled by dual tandem promoters (a synthetic bacterial promoter and the human cytomegalovirus promoter), and hence significantly reduces the size of the vector allowing the propagation of larger inserts. Bacterial promoters, such as the T7 promoter and the *E. coli lac* promoter, have also been used as part of animal gene transcription units. They have been exploited as heterologous inducible promoters, allowing efficient inducible expression of cloned genes if the appropriate transcription factors are provided in *trans*.

14.3.3 Plasmid Maintenance Sequences

The transfection of animal cells with bacterial plasmids results in a low frequency of transformation due to stable integration of the DNA into the host genome. Such vectors are not maintained episomally because the bacterial ColE1 origin does not function in eukaryotes. Any extrachromosomal DNA is rapidly diluted and degraded in nontransformed cells. Certain mammalian viruses, however, propagate their genomes as episomal plasmids on either a long-term (latent) or a short-term (lytic) basis. The inclusion of viral origins in recombinant plasmids allows expression vectors to be propagated in the same manner.

Lytic origins, such as the SV40 *ori* and EBV *ori*Lyt, can promote massive extrachromosomal replication of expression vectors if appropriate regulatory proteins are supplied in *trans*. This prolific amplification of the foreign DNA allows high level recombinant protein synthesis, but this rapidly becomes toxic to the host cell, resulting in cell death within a few days. Vectors with lytic origins are thus suitable for transient expression, but not for long-term protein synthesis. Conversely, latent origins, such as EBV *oriP* and the bovine papillomavirus (BPV) origin, allow stable maintenance of expression vectors at a low copy number. This is not toxic to the cell, and such vectors are suitable for long-term propagation and facilitate the stable expression of recombinant proteins.

14.3.4 Regulatory Sequences

All protein expression vectors carry a transcription unit containing the sequences required for efficient gene expression. These comprise transcriptional regulatory sequences, RNA processing signals, and sequences for protein synthesis and targeting. The major components are as follows:

- *Promoter and enhancer sequences:* The promoter is the site where RNA polymerase II binds to the transcription unit, and *cis*-acting elements upstream of the promoter also control its cell-type specificity and induction in response to external signals. Enhancers are *cis*-acting elements that work with endogenous promoters to increase their transcriptional activity; they may also impart cell type and inducible specificity on gene expression. The promoter and enhancer elements chosen for particular expression strategies depend on the experimental parameters. There are three types of systems: (i) endogenous systems, (ii) promiscuous viral systems, and (iii) inducible systems. Where a particular level or pattern of gene expression is required (e.g. when directing gene expression to specific tissues in transgenic mice), an endogenous promoter/enhancer system may be employed. Where high level expression and versatility are required, the strong and promiscuous regulatory elements found in mammalian viruses are often used. These include the SV40 early promoter and enhancer, the human cytomegalovirus promoter/enhancer, and the Rous sarcoma virus long terminal repeat (LTR) promoter/enhancer. These widely used elements function in many cell types, often beyond the scope specified by the host range of the virus, allowing the same expression vectors to be transfected into a range of different cell lines. Where precise control of gene expression is desired, or where the recombinant protein is toxic to the cells, inducible systems may be used. These may be of endogenous origin (e.g. heat induction), in which case endogenous genes may also be activated. Alternatively, they may be heterologous systems that have to be activated by supplying appropriate transcriptional regulators in *trans* (e.g. *E. coli lac* and *tet* systems, the *Drosophila melanogaster* ecdysone system). Both endogenous and heterologous systems may suffer from leakage (high background expression) or a low induction ratio, so there has been an effort to develop hybrid or completely artificial induction systems, for precise control of foreign gene expression.
- *RNA processing sequences:* These include a transcriptional termination/polyadenylation site and often an intron. Termination and polyadenylation sites are essential for stable RNA production. Introns are not necessary for the efficient expression of all genes, but in many cases, the inclusion of an intron has been shown to improve protein expression levels. For some genes, this may be because splicing is required for continued transcription or RNA stability. Alternatively, the recruitment of particular proteins during splicing may facilitate translation when the mRNA is exported from the nucleus.

- *Sequences for efficient translation and protein targeting:* The most important consideration is the Kozak consensus, a sequence surrounding the initiation codon whose context sponsors efficient ribosome scanning and initiation. The size of the 5′ untranslated region (UTR) is also kept as short as possible, as secondary structure in the transcript can inhibit translation. If a 3′ UTR is included into the vector, AU-rich instability sequences are avoided. A further sequence included in some vectors is a picornaviral internal ribosome entry site (IRES), allowing the production and translation of polycistronic mRNAs. Sequences that target recombinant proteins to particular cellular compartments may also be included. Nuclear localization sequences are used to target proteins to the nucleus. Signal peptides target proteins to the secretory pathway, which may be essential for correct posttranslational modification. KDEL retention signals (KDEL specifies a tetrapeptide sequence in the single-letter amino acid code) may be used to favor intracellular protein accumulation.

14.3.5 Marker Genes

A *marker gene* is one conferring a readily identifiable phenotype. Many expression vectors carry marker genes or are introduced along with a second vector carrying a marker gene. Such genes can be divided into two classes serving distinct functions.

Visible or *screenable markers (reporter genes)* provide visible evidence of transfection and gene expression. Under the control of a constitutive promoter, reporter genes can be used to determine transfection efficiency. Such vectors are often used for cotransfection with a series of experimental vectors to provide an internal experimental control. If a reporter gene is linked to a heterologous regulatory element, it can be used to quantify the expression levels and patterns associated with that regulatory element. If a reporter gene is joined to a foreign gene and expressed as a fusion protein, it can be used as a flag to determine protein localization or exploited for protein purification (see the following section). Entrapment vectors, which integrate into the genome and reveal the attributes of proximal genes and regulatory elements by reproducing their expression patterns, can exploit both these principles.

Selectable markers encode products conferring resistance (positive selection) or sensitivity (negative selection or counterselection) to a particular treatment. These are used to select stably transfected cells from a background of nontransfected cells or other rare products of transfection (e.g. cells that have undergone homologous recombination as opposed to those that have integrated the DNA randomly).

14.3.6 Sequences for Protein Purification

The synthesis and accumulation of recombinant protein in the cytoplasm of stably transfected cells has several disadvantages, including toxicity effects and dependence on cell lysis for protein isolation. However, by expressing recombinant proteins with an N-terminal signal peptide, proteins can be secreted from the cell and purified from the medium, reducing toxicity and allowing long-term protein production by repeated passaging. Many current expression vectors include sequences incorporated specifically to simplify the purification of overexpressed proteins (10). These sequences fall into three classes: fusion polypeptides, fusion epitopes, and oligo(amino acid) tails. Each provides a tag with which to purify the protein product of any gene expressed using that vector (Table 14.2.). Fusion polypeptides include β-galactosidase, glutathione-*S*-transferase, and staphylococcal protein A. In each case, there is a particular ligand to which this polypeptide binds, allowing the recombinant fusion protein to be captured and then eluted. Fusion epitopes are short peptides providing a single epitope of a particular protein, such as c-Myc, for recognition by a monoclonal antibody. The advantage of epitopes is that their small size and surface location usually does not interfere with the native folding or activity of the recombinant protein, which is sometimes a problem when using the larger fusion polypeptides. Similarly, a short oligo(amino acid) tail provides an unobtrusive tag, allowing purification by simple chromatographic procedures or again using antibodies. The tail is usually 2–20 residues in length. A further sequence often included in such vectors is a consensus cleavage site allowing the overexpressed protein to be separated from its fusion tag. A number of simple sequences may be chemically or enzymatically cleaved (e.g. cyanogen bromide cleaves after methionine residues). More complex cleavage sites, such as the motif recognized by enterokinase, are useful because they are unlikely to appear within the recombinant protein by chance.

14.4 OTHER DIRECT TRANSFER VECTORS

14.4.1 Yeast Artificial Chromosome Expression Vectors

Simple engineering strategies, such as protein synthesis and transient analysis, can be performed with cDNAs or minigene constructs cloned in plasmid or viral vectors. Although such constructs provide the essential information for protein structure, it is well established that endogenous gene expression is influenced not just by local regulatory elements but also by distant sites that may exert a direct regulatory influence or may control chromatin structure or

TABLE 14.2. Sequences Included in Mammalian Expression Vectors to Simplify the Purification of Overexpressed Proteins

Sequence	Comments
	Secretion
Signal peptide	An N-terminal 15–30 amino acid peptide which, by interacting with a signal recognition particle, causes ribosomes to attach to the ER membrane and pass the nascent polypeptide into the ER lumen for secretion; many signal peptides have been characterized and some exploited in mammalian expression vectors; for example, the mouse Ig-κ chain signal peptide is used in the Invitrogen vector pSecTag
	Fusion polypeptides
β-Galactosidase	Approximately 120-kDa polypeptide, binds to APTG
Glutathione-*S*-transferase	Approximately 30-kDa polypeptide, binds to glutathione
Staphylococcal protein A	Approximately 30-kDa polypeptide, binds to IgG and elutes at low pH
	Fusion polypeptides
c-Myc	11 amino acid epitopes, recognized by mouse monoclonal antibody 9E10; elutes at low pH
FLAG	Hydrophilic eight amino acid epitopes recognized by commercially available antibody anti-FLAG M1/M2
	Oligo(amino acid) tails
$(His)_6$	Purified by metal chelate affinity chromatography or anti-$(His)_6$ antibodies
$(Cys)_4$	Purified by affinity to thiopropyl groups
	Cleavage sites
Collagenase	Cleavage site is -Pro-xxx-↓-Gly-Pro-xxx-↓
Enterokinase	Cleavage site is -$(Asp)_4$–Lys-↓
Factor Xa	Cleavage site is -Ile-Glu-Gly-Arg-↓ at pH 8.0

Abbreviations: APTG, ***p***-aminophenyl-***β***-D-thiogalactopyranoside; ER, endoplasmic reticulum; FLAG, amino acid one-letter code for residues within the "FLAG" epitope.

the extent of DNA methylation. Hence, to reproduce the native expression characteristics of an endogenous gene fully, a transgene may need to be bracketed by hundreds of kilobase pairs of flanking sequence. Inserts >50 kbp cannot be cloned in standard plasmid, cosmid, or viral vectors due to packaging constraints, instability resulting from recombination, the selection of spontaneous deletion mutants, and the likelihood of shearing the DNA during *in vitro* manipulation.

Such limitations have been overcome by developing yeast artificial chromosome (YAC) vectors (11). These are linear vectors carrying the essential *cis*-acting elements of a yeast chromosome and are stably propagated in yeast cells at a low copy number. The components required are a yeast centromere (*CEN*), an origin of replication (autonomous replicating sequence, *ARS*) and telomeres (*TEL*). The vectors also carry a multiple cloning site for the insertion of foreign DNA and selectable markers for stable maintenance (such markers generally restore prototrophy to an auxotrophic yeast strain). Of the various large-capacity vectors developed for use in bacterial and mammalian cells (reviewed in Ref. 11), YAC vectors have many advantages, including their capacity (theoretically up to 2 Mbp, which should enable even the largest mammalian genes to be cloned) and the amenability of yeast for homologous recombination. This allows yeast vector sequences to be replaced by mammalian selectable markers before transfection, a process termed *retrofitting*. It also allows specific mutations to be introduced into the foreign DNA. Recombinant YAC clones are fragile and subject to shear, but several methods have been developed for their efficient transfection into mammalian cells, including lipofection, fusion with yeast spheroplasts, and microinjection into the pronuclei of fertilized eggs (see later). ES cells have been the predominant targets for YAC transfection, and such techniques yield transgenic mice with at least the same efficiency as obtained using more traditional and smaller transgenes.

The generation of YAC transgenic mice is not a trivial process, because recombinant YAC DNA is difficult to purify intact and is highly susceptible to fragmentation once inside the cell. Typically, transgenic animals integrate several YACs, some with terminal deletions reflecting intracellular fragmentation events. Despite these difficulties, YACs have been used to study the expression of a number of human and mouse genes in a transgenic environment, using constructs ranging in size from 40 kbp to over 1 Mbp (11). In most cases, transgene expression was shown to closely mirror the expression of the endogenous gene, suggesting that the inclusion of flanking material can isolate transgenes from position effects, which often influence basic expression constructs. The applications of this technology include mutational analysis, the generation of animal models for human disease, the analysis of *cis*-acting elements in their natural context, and the analysis of higher order genome function (e.g. genomic imprinting and X-chromosome inactivation). YACs have also been used as the basis of one class of mammalian artificial chromosome (MAC), as discussed later.

14.4.2 Targeting Vectors

Some plasmid vectors do not carry the typical components of a eukaryotic transcription unit and are therefore not strictly expression vectors. There are two uses for such constructs: gene targeting and random integration.

Gene targeting is the replacement of specific target DNA sequences with foreign DNA carried in a vector by homologous recombination and/or gene conversion (12). *Targeting vectors* are used to replace genomic DNA sequences, and to replace sequences in viral genomes already in the cell, to generate recombinant viral vectors (see later). Like expression vectors, targeting vectors carry plasmid backbone sequences and selectable markers, but they lack eukaryotic maintenance sequences because the vectors are not designed for amplification or recovery—their sole purpose is delivery of the foreign DNA to the homologous target. For this reason, such vectors are often termed *gene delivery vectors* or *suicide vectors*. The most important feature of a targeting vector is the region of homology with the intended target, as this is an absolute requirement for homologous recombination. The design of the homology region allows either insertion by single crossover or transplacement by double crossover.

14.4.3 Insertional Mutagenesis and Entrapment Vectors

The use of vectors for random integration into genomic DNA serves two purposes. First, integrating vectors can be used to generate mutants. Mutagenesis in classical genetic analysis traditionally involves exposing a population of organisms to high levels of a mutagen, and then recovering mutant offspring by suitable selection and screening. The mutagens employed are either chemical (e.g. ethylmethane sulfonate added to food) or physical (e.g. bombardment with X-rays). More recently, *biological* mutagens have been exploited. These are based on transposable elements, DNA sequences that naturally jump from one site to another in the genome, often happening to interrupt genes. Transposable elements cloned in plasmid vectors can be introduced into animal cells and will jump to random sites in the genome resulting in insertional mutagenesis. This strategy has been widely used to generate *Drosophila* mutants: vectors carrying recombinant *Drosophila* transposons called *P elements* have been microinjected into eggs, leading to the recovery of mutant offspring (13). Transposable elements require both *cis*-acting sequences and *trans*-acting enzymes for mobilization. The strategy used to control P element mutagenesis in *Drosophila* is to coinject eggs with two plasmids, one containing a defective P element (lacking the *trans*-functions) and another containing a helper P element, which has been rendered nonmobilizable by deleting its *cis*-functions (these are termed *wings-clipped elements*). This enables the defective P element to jump once, from the plasmid to a random location in the genome, and then remain stably integrated. Insertional mutants have also been generated in mice, initially by the chance integration of transgenes or retroviral vectors designed for other purposes and later by specially dedicated integration vectors (14).

Second, integrating vectors can be used as *entrapment vectors* to identify local genes and regulatory elements (Fig. 14.2a). In this case, the transposable element contains a reporter gene that responds to local promoter or enhancer elements at the site of integration. The classic example is the *Drosophila enhancer trap* (15). A recombinant P element transferred to the *Drosophila* germline carries *lacZ* under the control of a minimal promoter. The randomly integrated cassette is then influenced by any local enhancer, and the reporter gene expression pattern reveals the expression parameters of the gene normally controlled by the enhancer. *Gene traps* use the same strategy to identify genes. In this case, the reporter gene may be located downstream from an AUG codon or a splice acceptor site. The first type of gene trap is activated on insertion into the first exon of an endogenous gene, while the other is activated if inserted into an intron. Entrapment strategies are widely used in *Drosophila* to identify novel genes on the basis of their expression parameters. More recently, the same approach has been used in other animals, including mice (16), where libraries of ES cells carrying reporter insertions can be used to generate transgenic animals (17). ES cells are the preferred target for such experiments as the interpretation of insertional mutation phenotypes generated by the pronuclear injection of mouse eggs may be complicated by the extensive genome rearrangements that often accompany this procedure. More refined approaches can be used to identify specific classes of genes, for example, the use of a reporter gene that requires an N-terminal signal sequence for expression effectively selects for mutations in genes that encode secreted proteins. Also, a gene trap comprising two selectable markers and designed to express the site-specific recombinase Cre will induce a permanent switch between the markers when integrated adjacent to a constitutive promoter (Cre recombinase is discussed later). This approach can be used to identify genes expressed in a temporally restricted manner through the generation of a cell autonomous marker (no switching of marker genes). The integration of a gene trap vector is generally mutagenic, and depending on the gene, the mutant phenotype may be observed in heterozygotes or homozygotes. Such vectors thus serve a dual role—interesting new genes can be identified both

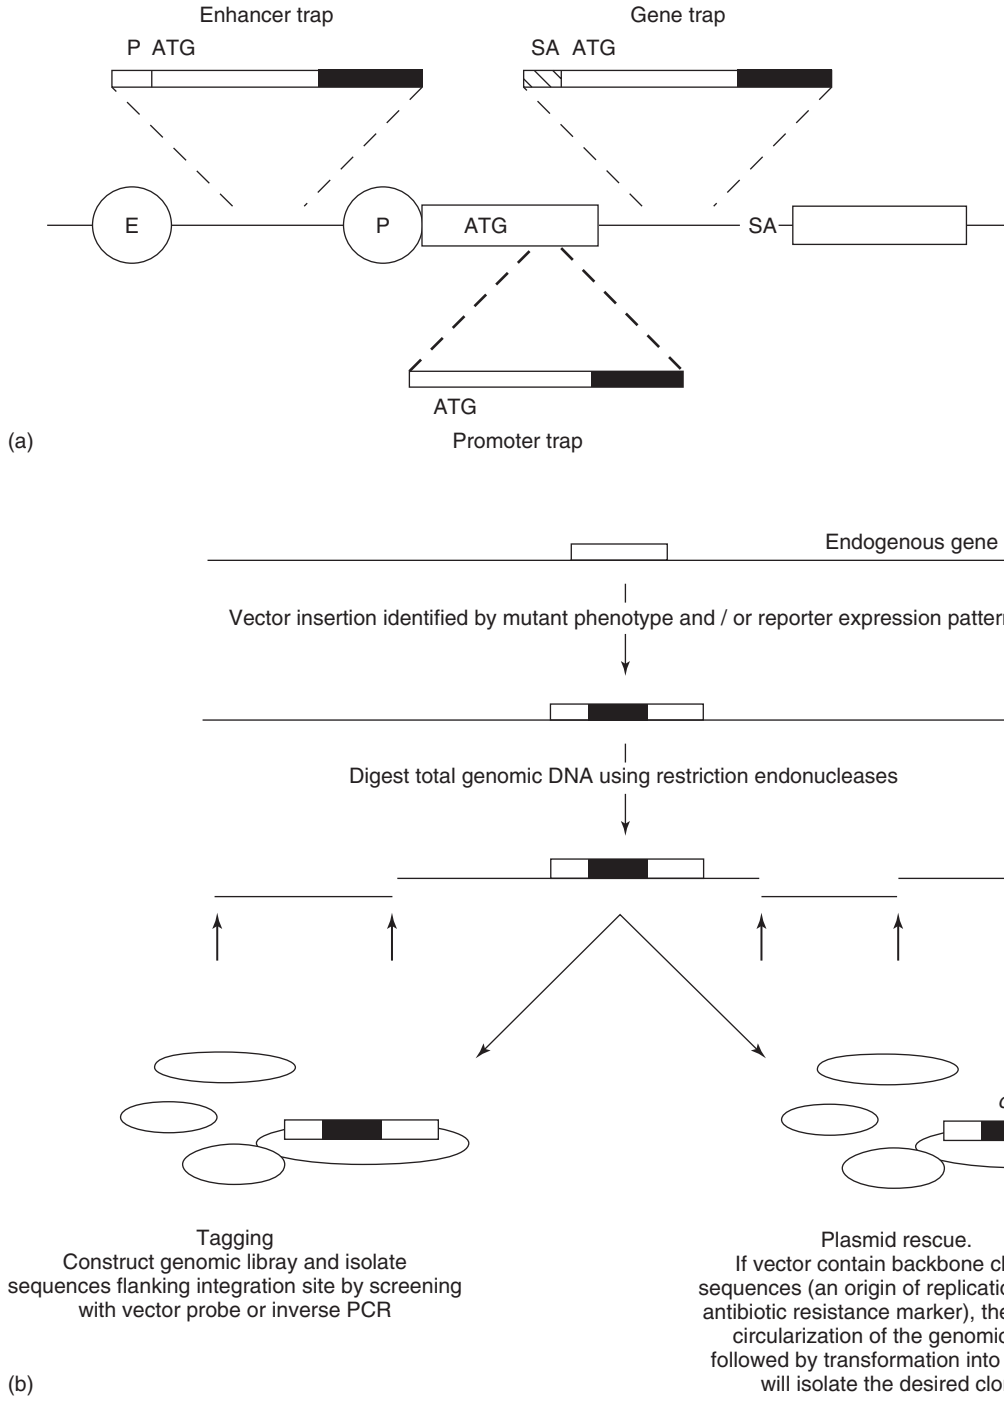

Figure 14.2. Insertional mutagenesis and entrapment vectors: (a) different forms of entrapment vector. The enhancer trap vector carries a minimal promoter, and gene trap vectors may carry a "naked" start codon (this type of vector is also known as a *promoter trap*) or a splice acceptor. (b) Insertional mutagenesis and entrapment vectors may be used to clone local genes either by tagging or plasmid rescue.

by their reporter expression pattern and by their mutant phenotype. Note that retroviruses (see later) are often used for insertional mutagenesis and trapping in mammals. Their unusual mode of replication allows them to be classed as transposable elements as well as viruses; so their activity is very similar to *Drosophila* P element vectors.

Basic integrating vectors do not require any special sequences in addition to the plasmid backbone, and even this can be dispensed with—insertional mutants in mice can be generated by introducing foreign DNA fragments into fertilized eggs without a vector. Entrapment vectors require a marker gene and minimal regulatory elements, but both basic integrating vectors and entrapment vectors lack eukaryotic maintenance sequences, because they are not deigned for amplification or recovery. However, careful design of such vectors can prove very useful. One consideration is the uniqueness of the introduced sequence. In *Drosophila*, the introduction of single P elements into fly strains normally lacking P elements enables genes identified by insertional mutagenesis to be cloned by *tagging*, which involves screening a genomic library generated from the mutant line for the unique sequence of the integrated element (Fig. 14.2b). Any clone isolated by this technique would contain the integrated foreign DNA and surrounding genomic DNA. This could then be used to screen genomic and cDNA libraries from wild-type flies to identify and isolate the noninterrupted version of the gene. This is an extremely convenient reverse genetics approach in the study of gene function (18).

An even more elegant refinement is the technique of *plasmid rescue* (19). In this case, the vector is designed so that the sequence that integrates into the genome contains certain plasmid backbone elements: the origin of replication and a bacterial selectable marker. The isolation of flanking DNA can then be achieved without library construction: Genomic DNA from the mutant line is digested with a restriction endonuclease cutting at a single site in the vector, and the resulting genomic DNA fragments are ligated to form circles. These can be introduced into bacterial cells *en masse*, but only those carrying a plasmid origin and marker will replicate under the selective regime (Fig. 14.2b). Bacterial colonies growing on selective media thus contain circularized genomic fragments carrying the inserted DNA sequence and flanking genomic DNA.

14.5 DIRECT DNA TRANSFER

14.5.1 Overview of Cell Transfection

The direct transfer of DNA into animal cells can be accomplished by a number of techniques that either force the cells to take in DNA by breaching the cell membrane or exploit the natural ability of cells to internalize certain molecules in their environment. The DNA introduced into cells by transfection may be maintained transiently or permanently. In transient transfection, the DNA may be nonreplicative, in which case it is diluted and lost from the population of cells over a few hours, depending on its stability. For plasmids containing an SV40 origin of replication, episomal replication occurs in certain simian cells, but the high replication rate eventually causes cell death. In both the cases, foreign genes may be expressed transiently, with a rapid onset of protein synthesis, but for a limited duration. Transient transfection is useful for expression cloning, rapid assays for protein activity, and establishing the potential of different promoters. Transient transfection is not an efficient method for the overexpression and purification of recombinant proteins on a long-term basis and cannot be used to generate transgenic animals. For stable transfection (also termed *transformation* because the genotype of the cell is altered), foreign DNA must be maintained permanently in the cell. If the exogenous DNA is nonreplicative, stable transfection must occur by integration of the DNA into the genome. Alternatively, the foreign DNA may be carried in an episomal vector, whose moderate replication rate does not cause cell death. Stable transfection is required for the long-term production of foreign proteins, for gene silencing by antisense RNA synthesis, and for the generation of transgenic animals.

What governs whether a given DNA molecule will transiently or stably transfect a cell depends on the type of vector. Those carrying episomal maintenance sequences control their own fate: SV40-based vectors kill simian host cells by high level episomal replication; so stably transfected cells are not recovered. However, vectors carrying the EBV latent origin are stably maintained in permissive cells because their replication rate is moderate and is tolerated by the host. For nonreplicating DNA, however, both transient and stable transfections occur concurrently. The efficiency of transient transfection varies considerably among different cell types and according to the transfection method, but is always several orders of magnitude higher than that of stable integration. Thus, in transient transfection, a small number of cells will also be stably transfected, but these will not generally be noticed in the short experimental timescale. In stable transfection experiments, many cells are initially transiently transfected, but the DNA is soon diluted and destroyed. Selection is used to identify the rare cells where foreign DNA has integrated into the genome, and by this time, the "transient" DNA is no longer present. Stable integration is thought to occur by illegitimate recombination—end-joining between broken chromosomal DNA and vector DNA. In some cells, an alternative to illegitimate recombination is homologous recombination. The efficiency of this process is extremely low in most cells, and even in particularly amenable cells (such as ES cells and the DT40 line), it is still a rare process and occurs several orders of magnitude

less frequently than random integration. Homologous recombination occurs only if the vector carries a homology region, where ectopic pairing can occur between the genome and the vector, facilitating crossing over or gene conversion. Due to the rarity of this event and the relative frequency of random integration, very powerful selective strategies must be employed to identify targeted cells.

14.5.2 Transient Transfection: Nonreplicating Vectors

In transient transfection, DNA is not integrated into the genome. Instead, when taken up by cells, it is transferred to the nucleus, where it remains for a short period of time in an extrachromosomal state (6,20). Almost any vector and any cell line can be used for this type of transient transfection, and recombinant proteins can be synthesized as long as the vector contains a mammalian expression cassette. The onset of protein expression is rapid, but the yield depends not only on the regulatory elements in the vector but also on the transfection efficiency (i.e. how much DNA is taken into each cell) and the stability of the extrachromosomal DNA. Covalently closed circular plasmid DNA survives 12–48 h in many cell lines before it is degraded and diluted, allowing the transient expression of foreign genes from simple vectors lacking eukaryotic maintenance sequences. Some cell lines are renowned for the stability of transfected DNA, allowing survival and foreign gene expression for over 80 h. One example is the adenovirus-transformed human embryonic kidney line 293 (21). Covalently closed and supercoiled plasmid DNA is required for efficient transient transfection. Relaxed DNA (i.e. nicked circles or linear DNA) is a poor template for transcription and is prone to exonucleolytic degradation. Ideally, high quality plasmid DNA, prepared using either cesium chloride equilibrium density gradient ultracentrifugation or anion exchange chromatography, should be used for transient transfection.

14.5.3 Transient Transfection: Runaway Polyomavirus Replicons

The polyomaviruses are a genus of small DNA viruses from the papovavirus family. Each virion comprises a nonenveloped, icosahedral capsid and a circular double-stranded DNA genome of approximately 5 kbp. The best-characterized species is SV40, whose productive host range is limited to certain permissive monkey cells. SV40 was the first animal virus to be exploited as a vector because, like bacteriophage λ, it was considered a model system and its molecular biology was studied in great detail. The first SV40-based vectors were viral transduction vectors. Despite many successes, however, the use of such vectors has been severely curtailed by the limited capacity for foreign DNA (maximum insert size: 2.5 kbp), reflecting the small size of the capsid.

A breakthrough came with the discovery that plasmids containing a polyomavirus origin of replication were propagated in the same way as the virus genome, that is, as episomal replicons in permissive cells (22). Replication also requires the presence of a viral-encoded *trans*-acting regulator termed the *T-antigen*. However, as the polyomavirus replicon is not packaged into viral capsids, there is no effective limit to insert size. A number of polyomaviruses have been exploited to develop episomal vectors, including SV40 for monkey cells, murine polyomavirus for mouse cells, and BK virus for human cells. The related BPV has also been used. BK virus and BPV-derived replicons can be maintained episomally at a moderate copy number and allow long-term protein expression. The replication of SV40- and murine polyomavirus-derived vectors is uncontrolled. In permissive cells, with readily available T-antigen, such vectors can replicate to an astonishingly high copy number (up to 10^5 vector molecules per cell). This facilitates high level recombinant protein synthesis, making such host–vector systems among the most efficient available. Unfortunately, this prodigious replication and gene expression cannot be sustained by the host cell, and cell death occurs within a few days. SV40 and polyomavirus replicons are therefore suitable only for transient transfection because so much DNA is synthesized that the cell cannot survive.

In some polyomavirus vectors, the T-antigen coding sequence is included, enabling propagation in any permissive cell line. Other vectors lack the T-antigen, which must then be supplied in *trans*. The development of the COS cell line simplified the use of SV40-based vectors. This is a derivative of the African Green Monkey cell line CV-1, which is stably transformed with a partial SV40 genome (hence COS: CV-1, origin, SV40). The integrated SV40 origin is mutated and nonfunctional, but the early transcription unit is functional, allowing constitutive expression of the T-antigen. This can stimulate the replication of any SV40 replicon in the same nucleus, and therefore allows the episomal propagation of SV40 vectors lacking their own T-antigen transcription unit (22). A whole series of SV40-based expression vectors has been designed for use in COS cells, some also utilizing SV40 transcriptional regulatory elements, others containing heterologous elements (20). Cell lines have also been developed for the propagation of murine polyomavirus replicons, such as the mouse cell line MOP-8 (23). Some of the most versatile transient expression vectors contain both SV40 and murine polyomavirus origins (e.g. the pcDNA1 vector series). Notably, while the SV40 origin of replication may function only in certain permissive monkey cells, the promoter and enhancer sequences of this and other viruses are extremely promiscuous. SV40 replicons can therefore be used for transient transfection of any mammalian cell type, although protein yields are much lower than for monkey cells because there is

no episomal replication. In nonpermissive cells, SV40 DNA may also integrate into the genome resulting in stable transformation. Recently, it has been possible to generate permissive monkey cell lines stably transformed with episomal SV40-based vectors by using conditionally expressed or temperature-sensitive T-antigens, which have more moderate replication rates (24,25).

14.5.4 Reporter Genes in Transfection Analysis

Transient transfection is often used to study gene expression, function, and regulation in animal cells because it is rapid, repeatable, and simple to perform, allowing the comparative analysis of many different expression constructs simultaneously. The alternative strategy of producing cell lines for each construct is laborious and expensive. In addition, the integrated foreign DNA is subject to random position and dosage effects that may obscure the true relationship between different constructs. Following the introduction of foreign DNA into animal cells, it is possible to study gene expression directly, for example, by northern blot, nuclease protection, RT-PCR, immunological assay, or assay for protein activity. This strategy suffers several disadvantages, including the time-consuming assays, the requirement for gene-specific probes, and the fact that if the transfected gene is similar to an endogenous gene, it may be impossible to discriminate between them.

A reporter gene is a screenable marker gene, that is, a gene whose product is easily detected using a simple assay (7). Reporter genes are often used to detect and characterize gene regulatory elements by inserting the putative elements upstream of the marker in specialized regulatory probe vectors. The recombinant vectors are then introduced into one or more types of animal cell, and quantitative assays for the reporter molecule allow the experimenter indirectly to gauge the level of transcriptional activity conferred by the regulatory elements (26). Inducible regulatory elements can be tested for their response to particular stimuli by measuring the induction of reporter gene expression. Cell type or developmental specificity can be assayed by causing cells to differentiate *in vitro* or by testing reporter constructs in transgenic animals known as *reporter transgenics*. A common strategy is to generate a series of mutated versions of a given reporter construct to narrow down particular *cis*-acting motifs in regulatory elements. Upstream signaling events can also be studied, for example, by addressing the response of reporter genes to the perturbation of specific signaling pathways.

Reporter genes are not used only to analyze regulatory elements. By fusing a reporter gene to the coding region of a second foreign gene, a fusion protein may be generated that generally retains reporter activity. This can be used to study protein localization in the absence of a specific antibody or to simplify protein purification. One of the most important uses of reporter genes in transient transfection is to normalize data for transfection efficiency. The yield of protein obtained from a dish of transiently transfected cells is highly dependent on transfection efficiency, which can vary widely within an experiment according to the transfection method used. When comparing the activities of different constructs, it is necessary to discriminate between variation caused by genuine functional differences between constructs and that caused by fluctuations in transfection efficiency. A reporter gene hitched to a constitutive viral promoter can provide an excellent internal control.

There are many different reporter genes used in animal systems, each with specific advantages and disadvantages (Table 14.3) (27–36). Reporter molecules also differ greatly in their half-lives, an important consideration to study rapid inductive responses and longer term effects. General properties that make ideal reporter genes include the following:

- The availability of rapid, sensitive, and inexpensive product assays
- Minimal background activity
- The reporter assay should be quantitative and have a broad linear range to detect both major and minor differences in activity
- A small coding region, so that expression vectors and fusion proteins are a reasonable size
- The product should not be toxic or otherwise affect the host cell.

14.5.5 Stable Transfection Using Nonreplicating DNA

In stable transfection, transformed *cell lines* are produced, which can synthesize recombinant proteins on a long-term basis, lasting months to years. Stable transfection thus requires foreign DNA sequences to be maintained in the cell in such a manner that the cell can function normally (5,20,37). This can occur in two ways. First, foreign DNA may integrate into the genome, where it is maintained as a new chromosomal locus by endogenous DNA replication. Second, foreign DNA can be maintained episomally on a vector that replicates at a moderate rate and hence does not affect cell viability. In both the cases, transformed cells may be maintained under a selective regime, ensuring that the foreign DNA is still present.

The most popular strategy for generating stable cell lines is the integration of foreign DNA into the genome. This strategy does not require specialized vectors, as the integration mechanism involves illegitimate recombination, where any DNA sequence can serve as a substrate. A foreign gene that has integrated into the host genome is termed a *transgene*. Stable integration has been achieved with many different types of vector, including those with no eukaryotic maintenance sequences. Even linear foreign

TABLE 14.3. Properties of Genetic Reporter Systems Used in Animal Cells

Reporter gene (product)	Comments
lacZ (β-galactosidase) *Activity:* Catalyzes the hydrolysis of β-galactosides, for example, lactose and many specialized derivative substrates for different assay formats *Assays:* β-Galactosidase assays are nonisotopic. *In vitro* assay formats based on colorimetric (with substrate ONPG) or fluorometric (with substrate MUG) detection systems lack sensitivity, but chemiluminescent systems using 1,2-dioxetane derivatives are highly sensitive. High resolution *in vivo* histological assays are also available. The chromogenic substrate X-gal can be used for fixed tissue, and the fluorescent substrate FDG can be used for live cells *Advantages:* Versatile, sensitive and many assay formats available *Disadvantages:* Some mammalian cells have high endogenous β-galactosidase activity *Other comments:* β-Galactosidase is a stable protein *References:* 27, 28	*Source: E. coli*
cat (chloramphenicol acetyltransferase) *Activity:* Catalyzes the transfer of acetyl groups from acetyl coenzyme A to chloramphenicol *Assays: In vitro* assays are isotopic, involving chromatographic separation of acetylated and nonacetylated forms of ^{14}C-chloramphenicol. Such assays have low sensitivity and are expensive, but more recently developed immunological and fluorometric assays are better. *In vivo* CAT assays rarely used due to low resolution *Advantages:* Minimal background activity in mammalian cells *Disadvantages:* Low sensitivity, expense, reliance on isotopic assay format *Other comments:* CAT is a highly stable protein *Reference:* 29	*Source: E. coli* transposon Tn9
SEAP (secreted alkaline phosphatase) *Activity:* Removes phosphate groups from a variety of substrates *Assays:* Nonisotopic, sensitive *in vitro* assays using either colorimetric, fluorometric, or chemiluminescent formats to detect secreted protein. Not used for *in vivo* assays *Advantages:* Secreted protein can be assayed in growth medium without lysing cells, allowing multiple assays for the same culture and further manipulation of cells following assay *Disadvantages:* High endogenous levels of alkaline phosphatase in some mammalian cells (although SEAP is heat tolerant, allowing endogenous enzyme to be inactivated by heat treatment). Reporter system depends on correct function of the secretory pathway *References:* 30, 31	*Source:* Truncated form of human *PLAP*
luc (firefly luciferase) *Activity:* Light produced in the presence of luciferase, its substrate luciferin, oxygen, magnesium ions, and ATP *Assays:* Nonisotopic bioluminescent assays are used *in vitro* and *in vivo*. These are highly sensitive and can be performed in live cells, using lipophilic luciferin esters *Advantages:* Sensitive, minimal background activity in mammalian cells *Disadvantages:* Requires expensive detection equipment, some assay formats have limited reproducibility *Other comments:* Luciferase has a high turnover rate and is thus useful for the study of inducible systems *References:* 28, 32, 33	*Source:* The firefly *Photinus pyralis*
GFP (green fluorescent protein) *Activity:* Intrinsic ability to fluoresce under blue or UV light *Assays:* Nonisotopic. Used for *in vivo* assays in live animals. Allows monitoring of changes of gene expression in real time, and fusion GFPs allow protein sorting events to be followed *Advantages:* Intrinsic activity (no substrate requirements), sensitivity, use in live organisms *Disadvantages:* The signal from *A. victoria* GFP is not intense enough for some systems *Other comments:* Improved GFPs with stronger emission, and emission at different wavelengths, have been generated by mutation allowing multiple studies in a single cell *References:* 33–36	*Source:* The jellyfish *Aequorea victoria*

Abbreviations: ATP, adenosine **5′**-triphosphate; CAT, chloramphenicol acetyltransferase; FDG, fluorescein-di-**β**-D-galactopyranoside; GFP, green fluorescent protein; MUG, 4-methylumbelliferyl-**β**-D-galactoside; ONPG, ***o***-nitrophenyl-**β**-D-galactopyranoside; PLAP, human placental alkaline phosphatase; SEAP, secreted alkaline phosphatase; UV, ultraviolet; X-gal, 5-bromo-4-chloro-3-indolyl-**β**-D-galactopyranoside.

DNA fragments without a vector are suitable substrates for integration. In fact, in contrast to transient transfection, which is more efficient using supercoiled plasmids, the frequency of stable integration is increased using linear DNA because this is a better substrate for illegitimate recombination. The integration mechanism is extremely inefficient, that is, three to four orders of magnitude less efficient than transient transfection and viral gene transfer. Transformants are typically recovered at a frequency of 10^{-5} to 10^{-6}. For this reason, selectable markers must be used to identify and selectively propagate the rare, stably transformed cells.

Another important factor in stable transfection by integration is the random nature of the integration event. Typically, multiple copies of the transfected DNA integrate at a single donor site, following end-to-end ligation to form a transient low complexity structure termed a *transgenome*. Some transfection methods allow a degree of control over copy number (e.g. electroporation parameters can be set to favor single copy integration), while others, such as calcium phosphate-mediated transfection, are not controllable. The position of integration and the number of transgene copies integrated are therefore highly variable, and both can influence transgene expression. This results in varying expression levels between independently derived transformed clones, and the phenomenon of transgene silencing, where even cells with stably integrated and intact transgenes fail to express recombinant proteins.

14.5.6 Selectable Markers Used in Mammalian Cell Lines

Under some circumstances, the foreign DNA introduced into a cell may confer a phenotype that can itself be selected or used as a visible assay for stable transfection. This is unusual, however; so a selectable marker gene is normally introduced along with the nonselectable foreign DNA to allow transformed cells to be propagated under conditions where the high background of nontransformed cells will die. Initially, selectable markers were included on the same vector as the nonselectable foreign DNA, so that the two would cointegrate and selection for the marker would necessarily identify cells carrying the nonselectable gene of interest. However, it was shown that two discrete plasmids cotransfected into mammalian cells also resulted in a high frequency of *cotransformation* (i.e. where the initially unlinked genes were integrated together, usually at the same locus) (38). Typically, a 10:1 ratio of nonselectable to selectable vector is used, so that cells transformed with the marker are highly likely to be cotransformed with the nonselectable DNA. The markers are used to select founder cells that give rise to stably transformed cell lines. Cells are allowed to grow under the appropriate selective regime for about 10 generations. At this point, individual clones of surviving cells are isolated and used to found new lines.

The first selectable marker to be widely used was *Tk*, encoding the enzyme thymidine kinase (TK) (39). This is an *endogenous marker*; it is an activity already present in most mammalian cells, and therefore requires a tk^- cell background for positive selection. Like most endogenous markers, *Tk* encodes a nonessential enzyme involved in nucleotide biosynthesis. Such markers have been developed because there are two alternate nucleotide biosynthesis pathways in mammalian cells, allowing viable mutant cells for each pathway to be isolated and chemical inhibitors of each pathway to be identified. Under normal growth conditions, TK is not required because dTTP can be synthesized from carbamyl phosphate (the *de novo pathway*). However, if cells are grown in medium containing the inhibitor aminopterin, the de novo pathway is blocked and dTTP must be synthesized from thymine (the *salvage pathway*), which requires TK. Other endogenous markers are listed in Table 14.4, and their role in nucleotide biosynthesis is summarized in Fig. 14.3. The problem with such markers is that the number of cell types available for transfection is limited to those where appropriate mutant lines have been developed. Thus, although tk^- mutant cells are easily selected using 5-bromodeoxyuridine, there has been a drive to develop new markers that can be used in all mammalian cells.

Such *dominant selectable markers* (dominant because they are derived from an exogenous source and there is no competing activity in any mammalian cell) are often drug resistance genes of bacterial origin (3,6,20,37). Cells can be propagated in normal medium and then transformed cells can be positively selected by adding the drug at the appropriate concentration. Commonly used dominant selectable markers are listed in Table 14.4. One disadvantage of bacterial markers is that the concentration range over which the selective agents are active is narrow. These markers are not suitable for stepwise selection for increased transgene copy number. *In situ* transgene amplification is one way to overcome position effects and generate high yield transformed cell lines, but this requires markers that can be selected in a stepwise manner over a range of selective conditions (40,41). The predominant example of this type of *amplifiable marker* is *Dhfr*, which encodes the enzyme dihydrofolate reductase (DHFR). Increasing resistance to methotrexate, a competitive inhibitor of DHFR, usually correlates to increased *Dhfr* gene copy number and coamplification of the nonselected donor gene. Amplifiable markers are highly efficient, but *Dhfr* is endogenous, and the background of wild-type cells that express and amplify their wild-type *Dhfr* locus can be a problem. For this reason, such markers tend to be used in mutant cell lines, which again restricts the number of cell types available for transfection.

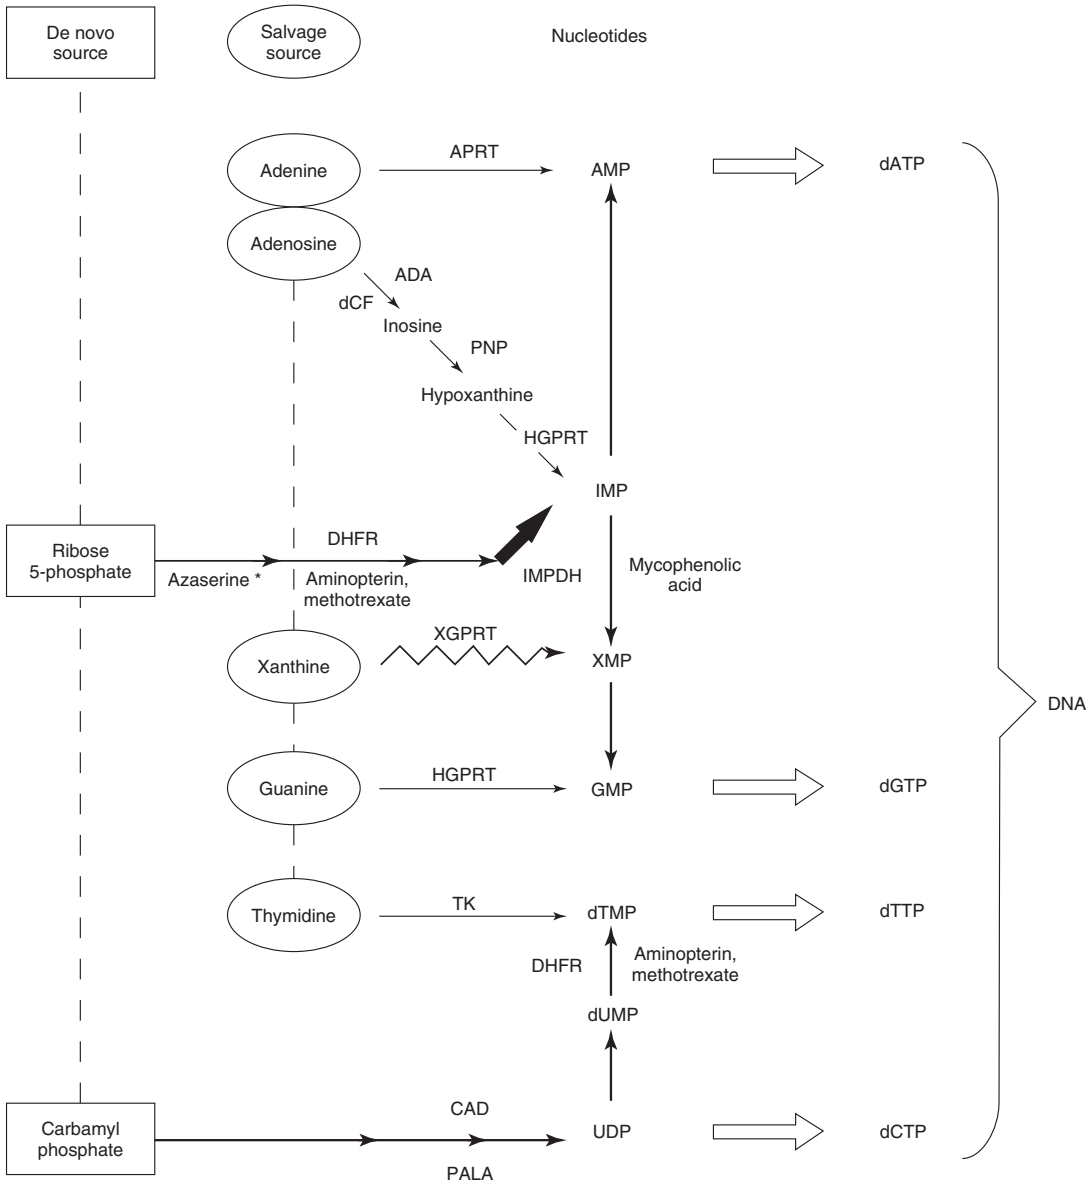

Figure 14.3. Nucleotide biosynthesis and commonly used endogenous selectable markers. De novo nucleotide synthesis (boxed precursors) follows the thick arrows. In the absence of d e novo substrates, or where the d e novo pathway is blocked, the cell can use pyrimidine and purine salvage pathways (circled precursors), following the thin arrows. Mammalian cells cannot convert xanthine to XMP, but this reaction is carried out by the *E. coli* enzyme XGPRT, encoded by the *gpt* gene, allowing this to be used as a dominant selectable marker in mammalian cells (zigzag arrow). The nucleotides are converted into dNTPs (open arrows) and incorporated into DNA. The salvage enzymes are not required for cell growth when d e novo substrates are available; so salvage pathway mutants are viable under normal growth conditions. However, if the d e novo pathway is blocked using any of the inhibitors (shown in bold), genes encoding salvage pathway enzymes can be used as selectable markers when salvage precursors are also provided. For example, *Tk* can be used to circumvent aminopterin-inhibited d e novo dTMP synthesis if the salvage precursor, thymidine, is included in the growth medium. Alternatively, d e novo and salvage inhibitors can be overcome by amplifiable selection, for example, PALA, an inhibitor of d e novo UDP synthesis, can be overcome by amplification of the *Cad* gene, and methotrexate, an inhibitor of several d e novo and salvage reactions, can be overcome by amplification of the *Dhfr* gene. Salvage pathway markers can also be counterselected using toxic base or nucleoside analogs. These are toxic when incorporated into DNA via the salvage pathway, but innocuous if nucleotides are synthesized d e novo. For example, 5-bromodeoxyuridine (bdUr) is a thymidine analog incorporated into DNA following conversion into a nucleotide by TK. In the absence of TK, bdUr is not phosphorylated and is not incorporated into DNA. Azaserine blocks several d e novo reactions, the most important of which is shown. Abbreviations of enzymes and inhibitors: APRT, adenine phosphoribosyltransferase; ADA, adenosine deaminase; CAD, carbamyl phosphate synthase/aspartate transcarbamoylase/dihydroorotase; dCF, deoxycoformycin; DHFR, dihydrofolate reaductase; HGPRT, hypoxanthine–guanine phosphoribosyltransferase; IMPDH, inosine monophosphate dehydrogenase; PALA, *N*-phosphonacetyl-L-aspartate; PNP, purine nucleoside phosphorylase; TK, thymidine kinase; XGPRT, xanthine–guanine phosphoribosyltransferase.

TABLE 14.4. Selectable Markers Used in Animal Cells: Endogenous Markers, Dominant Selectable Markers, and Amplifiable Markers (3,6,20,37,40,41)

Endogenous markers

These markers are involved in nonessential endogenous biosynthetic pathways. Most of the markers are enzymes involved in the nucleotide biosynthesis salvage pathway, and such markers can be used both for positive and negative selection. Positive selection is achieved using salvage pathway mutant cell lines in combination with drugs that block the de novo nucleotide biosynthesis pathway. Negative selection is achieved using toxic base analogs that are incorporated into DNA only if the salvage pathway is used. Alternative endogenous markers are expressed at a low level in animal cells and can be used for selection in the presence of a certain inhibitor. The endogenous functions of the markers and the activity of the inhibitors are summarized in Fig. 14.3

Marker	Product and function	Principles of selection
Ada	ADA; converts adenosine to inosine	Xyl-A (9-β-D-xylofuranosyl adenosine) is an adenosine analog, which is toxic if incorporated into DNA. ADA detoxifies Xyl-A added to the growth medium by converting it to Xyl-I, its inosine equivalent. There is a low background of ADA activity in most mammalian cells and 2′-deoxycoformycin, an ADA inhibitor, is therefore included in the selection medium
Aprt	Adenine phosphoriboyl-transferase; converts adenine to AMP	*Positive selection:* Adenine, and azaserine, to block de novo dATP synthesis, so only cells using salvage pathway survive *Negative selection:* Toxic adenine analogs (e.g. 2,6-diaminopurine) that are incorporated into DNA only in cells with APRT activity
Cad	Carbamyl phosphate synthase; aspartate transcarbamylase; dihydro-oroatase. These are the first three steps in de novo uridine biosynthesis	*Positive selection:* PALA (*N*-phosphonacetyl-L-aspartate) inhibits the aspartate transcarbamylase activity of CAD
Dhfr	DHFR; converts folate to dihydrofolate and then to tetrahydrofolate	*Positive selection:* DHFR is required for several reactions in de novo and salvage nucleotide/amino acid biosynthesis; hence, selection is carried out in nucleotide-free medium. However, *Dhfr* is typically used as an amplifiable marker with the inhibitor methotrexate (see third section of the table)
Hgprt	Hypoxanthine–guanine phosphoribosyl-transferase; converts hypoxanthine to IMP and guanine to GMP	*Positive selection:* Hypoxanthine and aminopterin, to block de novo IMP synthesis; so only cells using salvage pathway survive. Selected on HAT medium* *Negative selection:* Toxic guanine analogs (e.g. azaguanine) that are incorporated into DNA only if there is HGPRT activity in the cell
Tk	TK, converts thymidine to dTMP	*Positive selection:* Thymidine, and aminopterin to block de novo dTTP synthesis; so only cells using salvage pathway survive. Selected on HAT medium* *Negative selection:* Toxic thymidine analogs (e.g. 5-bromodeoxyuridine and ganciclovir) that are incorporated into DNA only if there is TK activity in the cell

Dominant selectable markers

These markers are derived from a different species and confer an alien drug resistance phenotype on the transfected cell

Marker	Product (and source species)	Principles of selection
AS	Asparagine synthase (*E. coli*)	Bacterial enzyme uses ammonia as amide donor unlike mammalian equivalent. Hence, cells transformed with *AS* grow on asparagine-free medium containing the toxic glutamine analog albizziin

(*continued*)

TABLE 14.4. (*Continued*)

ble	Glycopeptide-binding protein (*Streptoalloteichus hindustantus*)	Confers resistance to glycopeptide antibiotics bleomycin and pheomycin (and its derivative, Zeocin™)
gpt	Guanine–xanthine phosphoribosyltransferase (*E. coli*)	Analogous to *Hgprt* in mammals, but possesses additional xanthine phosphoribosyltransferase activity allowing survival in medium containing aminopterin and mycophenolic acid (Fig. 14.3)
hisD	Histidinol dehydrogenase (*Salmonella typhimurium*)	Confers resistance to histidinol
hpt	Hygromycin phosphotransferase (*E. coli*)	Confers resistance to hygromycin-B
neo	Neomycin phosphotransferase (*E. coli*)	Confers resistance to aminoglycoside antibiotics (e.g. neomycin, kanamycin, and G418)
pac	Puromycin *N*-acetyltransferase (*Streptomyces alboniger*)	Confers resistance to puromycin
trpB	Tryptophan synthesis (*E. coli*)	Confers resistance to indole
	Markers used for *in situ* gene amplification	
These markers can be amplified *in situ* by increasing the concentration of a competitive inhibitor in the medium. Many amplifiable markers are also used as endogenous or dominant selectable markers, but in some cases, the drug used for amplification may not be the same as that used for standard selection		
Marker	Product	Amplifying selective drug
Ada	ADA	Deoxycoformycin
AS	Asparagine synthase	β-Aspartylhydroxamate
Cad	Aspartate transcarbamylase	*N*-phosphonacetyl-L-aspartate
Dhfr	DHFR	Methotrexate
gpt	Xanthine–guanine phosphoribosyltransferase	Mycophenolic acid
GS	Glutamine synthase	Methionine sulfoxamine
Hgprt	Hypoxanthine–guanine phosphoriboosyltransferase	Aminopterin
Impdh	Inosine monophosphate dehydrogenase	Mycophenolic acid
Mt-1	Metallothionein 1	Cd^{2+}
M^{res}	Multidrug resistance: P-glycoprotein 170 gene	Adriamycin, colchicine, and others
Odc	Ornithine decarboxylase	Difluoromethylornithine
Rnr	Ribonucleotide reductase	Hydroxyurea
tk^-	TK	Aminopterin
Umps	Uridine monophosphate synthase	Pyrazofurin

14.5.7 Maximizing Transgene Expression by Gene Amplification

When cultured cells are exposed to toxic concentrations of certain drugs, rare individual cells survive because they happen to have undergone a mutation that confers drug resistance. The first such system to be investigated in detail was resistance to the folic acid analog methotrexate, which is a competitive inhibitor of DHFR (42). Resistant cells were shown to fall into three classes: those with reduced methotrexate uptake; those with point mutations in the *Dhfr* gene, making the enzyme less susceptible to inhibition; and those carrying multiple copies of the *Dhfr* locus, allowing the production of enough enzyme to out-compete the inhibitor. This latter class can be selected stepwise by successive increases in drug dosage, resulting in the propagation of clones with highly amplified *Dhfr* gene arrays and allowing cell growth in concentrations of methotrexate up to 10^5 times greater than the dose lethal to wild-type cells. The amplified copies may be maintained as large intrachromosomal tandem repeat units known as *homogeneously staining regions* (HSRs) or as small extra chromosomes termed *double minutes*. The drug does not *induce* gene amplification but facilitates the selection of rare cells that have undergone random amplification.

Cloned copies of the *Dhfr* gene and its cDNA, reintroduced into cells by transfection and randomly integrated into the genome, are also amplified by drug selection. However, it is not just the essential coding region that is amplified. Extensive flanking sequences of up to 10^6 bp of DNA may be coamplified. This amplification of nonselected flanking material can be exploited in gene transfer experiments. Vectors have been constructed in which a gene such as *Dhfr* is included adjacent to the

multiple cloning site where the nonselectable foreign gene is inserted. The stable transfection of this construct allows tandem cointegration of the amplifiable marker and the nonselected gene. Alternatively, the *Dhfr* vector can be cotransfected with a second vector carrying nonselectable foreign DNA. Cotransfected vectors tend to cointegrate at the same locus. Cointegration is followed by a regime of intensifying drug selection, resulting in the propagation of cells containing highly amplified arrays of both the marker and nonselected transgenes (40,41).

This strategy facilitates high level recombinant protein synthesis and can overcome position-dependent transgene silencing because amplification can continue until there are so many transgene copies that the amount of mRNA synthesized is no longer the limiting factor for protein expression. Alternatively, a specific regime of drug treatment can be used to select for transformants where the transgene is not subject to negative position effects. However, because *Dhfr* is an endogenous marker, drug selection can amplify the endogenous *Dhfr* gene as well as transfected copies. *Dhfr* is therefore most advantageous when used in a $dhfr^-$ cell line, so that nontransfected cells are not coselected on the basis of endogenous gene amplification. Several derivatives of the Chinese hamster ovary (CHO) cell line have been described that lack DHFR activity. These include DUKX-B11 (DXB-11), which has one active *Dhfr* gene (43), and DG44, which is a homozygous null cell line (44). Two strategies have been used to extend the range of cell lines available for DHFR selection. First, a mutant form of the *Dhfr* gene, which is highly resistant to methotrexate, can be used to select for methotrexate resistance even in cells carrying two normal copies of the normal *Dhfr* gene. However, the level of amplification is restricted because large doses of methotrexate are required to inhibit the endogenous genes. Second, the *Dhfr* marker can be cotransfected with a dominant selectable marker such as *neo*. Thus, cells can be treated with increasing concentrations of methotrexate, and also selected with constant levels of G418, to counterselect wild-type cells (which would otherwise survive through amplification of the endogenous *Dhfr* gene). *Dhfr* was the first selectable marker to be used for amplification and remains the most popular. Other markers (Table 14.4) have also been used, but they suffer from the prevalence of nonamplified resistance mutants or cytotoxicity at high drug concentrations. Only glutamine synthase has been used as frequently as *Dhfr*.

14.5.8 Stable Transfection Using Episomally Maintained Vectors

Replicating, extrachromosomal vectors for stable transfection possess a number of distinct advantages over integrating vectors. First, recombinant proteins are expressed at a moderate level, which is uniform among independently derived clonal lines. This is because there are no position effects (the construct does not integrate) and no dosage effects (the plasmid reaches a stable episomal copy number, regardless of initial transfection efficiency). Second, stable transfection by episomal maintenance is equivalent in efficiency to transient transfection, that is, up to 10^5 times more efficient than stable transfection by integration. Finally, because the vectors are episomal, they can be separated easily from chromosomal DNA: This is particularly advantageous in techniques such as expression cloning, which rely on the recovery of cloned DNA. While nonreplicating plasmids suffice for stable transfection by integration, episomal plasmids require maintenance sequences derived from viruses whose genomes are also maintained episomally. In addition to SV-40-derived vectors, three other viruses that have been widely exploited to construct episomal vectors are BPV, BK virus (a human polyomavirus), and EBV.

The papovavirus family includes the polyomavirus and papillomavirus genera. SV40 and the related murine polyomavirus have been used to develop a range of transient expression vectors that replicate to high copy number and eventually cause cell death. The human BK polyomavirus is stably maintained at a moderate copy number (approximately 500 copies per cell) in human cells. Plasmid vectors carrying the BK virus origin of replication are maintained as long as the BK virus T-antigen is available, and cell lines stably transformed with such vectors have been continuously propagated for over a year (45). BK virus-derived replicons contain a selectable marker (e.g. *neo*) as well as plasmid backbone sequences, BK virus functions, and the mammalian transcription unit. This allows high level recombinant protein expression to be achieved by increasing the drug concentration in the medium and hence selecting for increased copy number. In this way, stable cell lines carrying up to 9000 copies of the vector can be generated, although the copy number falls when selection is removed. This vector system is extremely versatile: Variants have been described with different promoters and selectable markers, and a number of different host cell lines have been used, including HeLa, COS-7, and 293 (45,46).

The papillomaviruses are related to the polyomaviruses but possess larger, more complex genomes and encode proteins on only one DNA strand. They infect higher vertebrates, including man, and cause benign growths called *papillomas* or *warts*. BPV can infect cultured mouse cells but cannot produce progeny virions. Instead, 50–100 copies of the genome are maintained episomally as plasmids, and it is this property that has been exploited to develop a series of episomal expression vectors. Like SV40 and other polyomaviruses, the early functions of BPV cause growth transformation. The earliest BPV-derived vectors therefore comprised the entire BPV genome cloned in a bacterial plasmid with a mammalian expression

cassette, and transfected cells were identified by their transformation to a continuously proliferative state. The early functions are carried on a 5.5-kbp sector of the BPV genome, which is termed the 69% transforming fragment (BPV_{69T}), and this appears to be sufficient for establishment and maintenance of the episomal state (47). This fragment forms the basis of a more versatile series of expression vectors that also contain a mammalian selectable marker to extend the range of possible host cells (48). The ability of BPV_{69T} vectors to replicate efficiently is increased in some cells by certain mammalian genomic sequences, which are included in the BV-1 vector series (49). BPV vectors can establish long-term, moderate-level foreign gene expression in a broad range of mammalian cell types, such as 3T3 and C127 fibroblasts. There is no limit to insert size, allowing both cDNAs and full genes to be expressed. However, BPV vectors suffer from several limitations. First, although the viral genome is small in comparison to, for example, herpes virus or vaccinia virus, it is still too large (>10 kbp) to manipulate easily *in vitro* and lacks the cloning versatility of other plasmids. Second, there are problems with vector stability (50). Recombinant vectors may undergo recombination or deletion, resulting in the loss of foreign DNA, and in certain cell lines, the vector may integrate into the genome. Recombination between vectors can occur, so that either single plasmids or oligomers may be propagated. These effects are largely unpredictable, depending on multiple parameters such as cell line, vector type, and insert structure. The same parameters also affect replication efficiency; so the episomal copy number may vary from 20 plasmids per cell to over 300 copies.

Due to the instability of BPV replicons, many researchers have turned to EBV as an episomal expression vector (51). EBV is a human herpes virus whose productive host range is limited to primates and a few other mammals (e.g. dogs). The virus is naturally lymphotropic and commonly infects B cells, causing infectious mononucleosis. The virus has a large, double-stranded linear DNA genome that circularizes shortly after penetration by interaction between terminal repeat sequences. In culture, the virus can cause lytic infection, resulting in cell death, but most infected cells are transformed into a proliferative state and the virus genome is maintained as a latent, episomally replicating plasmid, with a copy number under 1000. Although the tropism of the virus is limited by its interaction with a specific receptor found on very few cell types, the circular EBV genome is maintained in many primate cells and thus shows great potential as a broad cellular host-range expression vector. However, the species host range is still limited to primate and dog cells—rodent cell lines are not permissive for episomal EBV replication. Only two regions of the EBV genome are essential for the establishment and maintenance of latent replication: the bipartite origin of replication *oriP* and the gene encoding the *trans*-acting regulator of transcription and replication, EBV nuclear antigen-1 (*EBNA-1*). These sequences form the basis of EBV latent expression vectors, which are maintained at a copy number of 2–50 per cell. A distinct origin, *ori*Lyt, and a different regulator termed *ZEBRA* are required for lytic replication, thus *oriP*/EBNA-1 vectors do not amplify in cells undergoing lytic EBV infection. Recently developed EBV vectors containing both origins can be maintained as low copy-number vectors in latently infected B-cell lines and amplified approximately 500-fold when cells are transfected with constitutively expressed *BZLF-1* (the ZEBRA gene) to induce lytic replication. EBV vectors may contain *oriP* only (in which case EBNA-1 must be supplied in *trans*) or both *oriP* and the EBNA-1 coding region driven by a mammalian promoter (in which case the vectors are helper independent). EBV vectors must also carry a selectable marker, because (i) transformation efficiency is still <10%, and (ii) in the absence of selection, both *oriP* and *oriP*/EBNA-1 vectors are passively lost at the rate of 2–6% of cells per generation. A number of markers have been successfully used, including *Tk, neo*, and *gpt*. Many foreign genes have been successfully expressed using EBV vectors, including those encoding enzymes, growth factors and receptors, structural proteins, and heterologous viral proteins (51). EBV replicons can be recovered intact from mammalian cells, facilitating their use for expression cloning. The EBO series of vectors has been designed for this purpose (52). Furthermore, because of their large capacity, the inclusion of bacteriophage λ cohesive end (*cos*) sites allows such vectors to be maintained in *E. coli* as cosmids (53). The most recent advance in EBV-replicon technology is the development of EBV vectors as human artificial episomal chromosomes. Such vectors represent one of a number of strategies for the design of MACs and can carry up to 350 kbp of genomic DNA (54).

14.6 TRANSFECTION METHODS

14.6.1 Overview

Forcing animal cells to take up DNA from the surrounding medium using a variety of chemical and physical methods is termed *transfection* and can be a highly efficient way to introduce DNA either transiently or stably into cultured cells or cells *in vivo*. When the term *transformation* is applied to animal cells, it usually refers to a stable change in genotype brought about either by incorporation of the transfected DNA into the genome or by its long-term episomal maintenance. However, the same term is also used to indicate *oncogenic* transformation (growth transformation), the change in phenotype resulting from the activation of an oncogene, causing, for example, loss of substrate

dependence, uncontrolled proliferation in the absence of growth factors, and abnormal differentiation.

When DNA transfer to cultured animal cells was first demonstrated (1), the uptake mechanism was unknown. Later it was shown to depend on the formation of a calcium phosphate–DNA coprecipitate, and this was the first of many "chemical transfection" techniques to be described, where cells take up DNA complexed with another molecule by endocytosis. Generally, these techniques result in a significant frequency of transgene mutation due to passage of the DNA through acidic endosomes. Over the years, a number of alternative transfection strategies have been devised (6,20,55) (Fig. 14.4). *Fusion transfection* involves cells taking up DNA by fusion with a natural or artificial lipid membrane containing foreign DNA. *Poration transfection* involves the creation of small pores in the cell membrane through which DNA can be imported. *Physical transfection* involves a mechanical breach of the cell membrane and the direct delivery of DNA either to the cytoplasm or nucleus. All these mechanisms result in direct delivery and avoid endosomal processing of the DNA. By conjugating DNA to a suitable ligand, it can be introduced into specific cell types by receptor-mediated endocytosis (this strategy is particularly applicable for cell targeting in gene therapy). These different transfection mechanisms are summarized in Table 14.5.

The transfection of animal cells in culture is dependent on many parameters such as the quality of the foreign DNA and the health of the target cells. Other parameters are cell-type specific; thus, different cells are transfected with differing efficiencies, and not all cells respond to the same transfection methods. Primary cells are particularly resilient to transfection, using standard methods. Cells that grow as monolayers are easier to transfect than those growing in suspension or as clumps, and quiescent or postmitotic cells are more recalcitrant than rapidly dividing cells. The efficiency of chemical transfection often depends on the composition of the growth medium; the presence of serum tends to inhibit transfection using cationic lipid preparations. Chemical transfection in particular tends to have the most adverse effects. Some cells are badly affected by calcium phosphate transfection because they respond poorly to the precipitate adhering to their surfaces. Conversely, cationic lipids appear to be better tolerated and are suitable for many cells traditionally regarded as difficult to transfect. Transformation protocols have been optimized for the major cell lines used for recombinant protein expression (e.g. CHO, COS-7, HEK 293, and Sf9). Unfortunately, cell lines for transfection cannot always be chosen purely for the ease of DNA transfer. The choice is often made according to other properties, such as the ability of cells to express certain proteins or to use specific regulatory elements efficiently, the ability of cells to differentiate or respond to particular inductive treatments, or because a particular form of posttranslational modification is carried out. Therefore, the first step in a transfection strategy is often to optimize transfection efficiency using a range of protocols and testing the parameters within each transfection method.

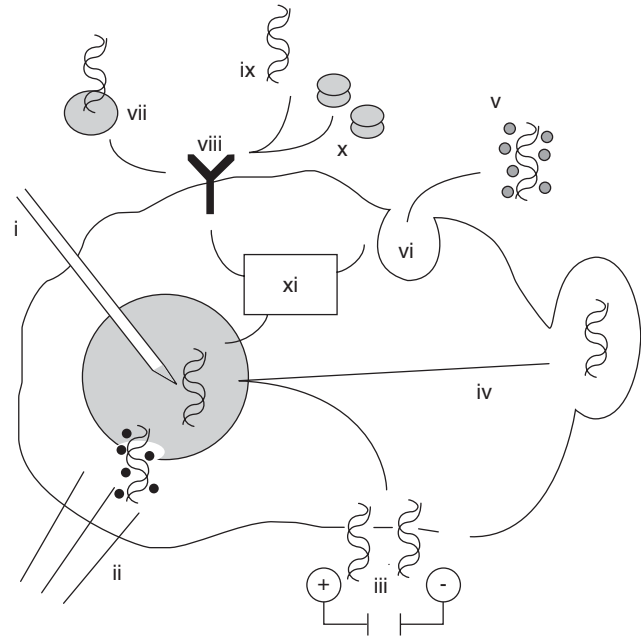

Figure 14.4. Transfection of animal cells and routes to the nucleus. Microinjection (i) or particle bombardment (ii) facilitate the direct delivery of DNA to either the nucleus or cytoplasm. Electroporation (iii) or fusion transfection (e.g. protoplast fusion, liposome fusion (iv)) result in the delivery of DNA to the cytoplasm, and its subsequent transfer to the nucleus. Chemical transfection (v) results in the uptake of DNA–chemical complexes by endocytosis (vi). Ligand-conjugated DNA (vii) is taken up by receptor-mediated endocytosis (viii), which is also thought to be the case for naked DNA (ix) having first interacted with unknown extracellular proteins (x). Following endocytosis, the DNA is transferred to the nucleus through the endosomal pathway (xi). This delivery mechanism is made more efficient using adenoviral capsid proteins, which cause endosomal disruption.

14.6.2 Locally Applied Naked DNA

Naked DNA transfects cultured cells very inefficiently when added to the growth medium, due both to degradation and poor internalization. Similarly, uncomplexed DNA administered intravenously to live animals is rapidly degraded following hepatic uptake (56). The injection of uncomplexed plasmid DNA *in vivo* into muscle results in high efficiency gene transfer and expression (57). This can be exploited to raise a protective immune response against viral and other pathogenic antigens and against tumor proteins (58). The application of naked DNA to other tissues has also resulted in successful transfection (59). DNA has also been injected into the blastocoel cavity of

TABLE 14.5. Properties of the Major Categories of Transfection Methods Used to Introduce DNA into Animal Cells

Category[3]	Examples	Method of Uptake	Route	Transgene Structure
Chemical	Calcium phosphate, DEAE–dextran, polybrene, lipofection	Endocytosis of DNA complexes	Via endosome	Multiple arrays[4]
Poration	Electroporation, laser transfection	Diffusion through transient pores in cell membrane	Directly into cytoplasm	Single transgenes or multiple arrays; highly controllable
Fusion	Liposome/virosome delivery, protoplast fusion	Fusion of DNA-containing lipid vesicle with cell membrane	Directly into cytoplasm	Multiple arrays
Physical	Particle bombardment, microinjection	Mechanical direct transfer of DNA into cell	Directly into cytoplasm or nucleus	Multiple arrays
Receptor mediated	Conjugation to various ligands, naked DNA transfection?	Receptor-mediated endocytosis	Via endosome	?

Note that some methods are suitable for both transient and stable transfection (e.g. calcium phosphate transfection and lipofection), whereas others tend to favor transient transfection (e.g. DEAE–dextran transfection and protoplast fusion) and others tend to favor stable transfection (e.g. nuclear microinjection).

Transgene structure following chemical transfection is dependent on method. Calcium phosphate generates large random arrays if there is carrier DNA, but smaller, concatemeric arrays are generated by other methods. For more details, see the section on Fate of Foreign DNA and Structure of the Transgenome.

mouse embryos, resulting in the generation of transgenic mice, albeit with much lower efficiency than pronuclear microinjection. The mechanism by which naked DNA is taken into muscle cells is entirely unknown. It is thought that the extracellular DNA may become coated with certain extracellular proteins and that these may facilitate receptor-mediated endocytosis.

14.6.3 Calcium Phosphate

Calcium phosphate transfection was first used in 1973 to introduce adenovirus DNA into mammalian cells (60). The first mammalian cell lines stably transfected with nonviral DNA were also produced using this technique (61). Calcium phosphate transfection is probably still the most widely used gene transfer technique because it is inexpensive, highly repeatable, and suitable for both the transient and stable transfection of a wide range of cells (62,63). In transient calcium phosphate-mediated cotransfection, the molar ratio of different plasmids used in the transfection mix appears to be faithfully reproduced in the transfected cell population (64).

There are many variations in the original technique, but all involve mixing DNA, a HEPES-buffered phosphate solution, and calcium chloride, resulting in the immediate formation of a fine DNA/calcium phosphate coprecipitate. This settles onto the cells and is internalized by endocytosis resulting in the transfer of calcium phosphate–DNA complexes to the nucleus (65).

Calcium phosphate transfection is particularly suitable for cells that grow as monolayers, as opposed to cells growing as clumps or in suspension. An alternative technique, using a BES buffer, which allows the precipitate to form gradually over several hours, is up to 100-fold more efficient for stable transfection with high quality plasmid DNA, although equivalent in efficiency to the original HEPES-buffered method for transient transfection or for stable transfection with linear DNA (66,67). The efficiency of transient transfection using the original method may be enhanced by chemical shock; however, this does not increase the efficiency of the BES-buffered method.

14.6.4 Diethylaminoethyl–Dextran

A major disadvantage of the calcium phosphate transfection technique is that certain cell lines are adversely affected by the precipitate, resulting in cell death. A mixture of DNA and diethylaminoethyl (DEAE)–dextran, a *soluble* polycationic carbohydrate, allows the transfection of many cells that respond poorly to calcium phosphate–DNA coprecipitates. The DEAE–dextran technique was originally devised to facilitate the transfer of viral DNA into animal cells and was later adapted as a plasmid transfection method (66,67). DEAE–dextran transfection protocols are based on improved strategies (68,69), which include chemical shock treatments to increase the efficiency of DNA uptake. The DEAE–dextran technique is highly reproducible and simple to carry out. DNA is mixed with 10 mg/mL of DEAE–dextran and added to the cells. The mixture is presumed to contain complexes that

increase the efficiency of endocytosis, and compared with calcium phosphate transfection, a much smaller amount of DNA is required. Plasmid DNA introduced into cells by DEAE–dextran adopts the nucleosome structure typical of endogenous chromosomes, whereas most of the estimated 1 Mbp of DNA entering cells as calcium phosphate coprecipitates remains in an aggregated form (70). Less DNA is introduced into cells using DEAE–dextran, this method is useful only for transient transfection, not for the generation of stably transfected cell lines.

14.6.5 Enhancing Transient Transfection Efficiency

In some transient transfection systems, cotransfection with a plasmid carrying the RNA polymerase III-dependent adenoviral VA_I gene results in an increased efficiency of foreign gene expression (71). VA_I is thought to act at the level of protein synthesis by restoring the activity of the host translational initiation factor eIF2. This factor is inhibited by a protein kinase activated in the presence of double-stranded RNA (dsRNA), which can sometimes arise from dual-strand transcription of transfected plasmid DNA. The adenoviral VA_I gene product is an RNA molecule that specifically interacts with and represses this kinase, the dsRNA-activated inhibitory protein kinase (DAI kinase), and is used to stimulate viral protein synthesis during adenovirus infections. Vectors carrying the adenoviral VA genes are commercially available (e.g. pAdVAntage).

A number of chemical treatments have also been described, which enhance the efficiency of transient transfection. A commonly used procedure is to expose cells to an osmotic shock following transfection, which increases the amount of DNA taken up from the surrounding medium. The shock involves brief exposure of transfected cells to 10–30% solutions of glycerol or dimethylsulfate (68,69). As with other transfection parameters, the optimal concentration and exposure time must be determined empirically. Another transfection enhancer is chloroquine, which inhibits acidification of endosomal vesicles and thus probably protects DNA from degradation (72). Chloroquine is moderately cytotoxic, however, and cells may be exposed to this chemical either during or after transfection, but only for a few hours. Sodium butyrate is also used to increase transfection efficiencies and may be used in conjunction with an osmotic shock (73). The treatment involves adding sodium butyrate (final concentration 10 m*M*) to the growth medium after the shock, leaving cells in contact with it for 24 h.

14.6.6 Electroporation and Laser Transfection

Electroporation is the transfection of cells in culture by exposing them to a transient electric field. This causes nanometer-sized pores to open briefly in the cell membrane, allowing uptake of free DNA from the surrounding medium. This method is ideal for many cells recalcitrant to chemical transfection methods. It is efficient, highly reproducible, and suitable for both stable and transient transfection and has the added advantage that transgene copy number can be controlled (74). Electroporated DNA is transferred directly into the cytoplasm without processing through endocytotic vesicles (75), and the frequency of mutation is much lower than that for chemical transfection methods (76). Electroporation is applicable to most cell types, and once optimal conditions have been determined, it is a very simple procedure—cells are suspended in electroporation buffer in a cuvette and exposed to a brief, high voltage electrical pulse. The exact magnitude and duration of the pulse are the critical parameters, and these must be determined empirically for different cells. Many cells are efficiently electroporated by a brief high voltage pulse (800–1500 V), but others, especially primary cells, may be killed by such treatment and respond better to a longer lasting pulse of 100–300 V. The highest transfection efficiencies typically occur when there is about 50% cell death. The technique was first carried out in 1982 using mouse fibroblasts (77) but was soon adapted to many other cell types (78). Among the few disadvantages of this technique are the requirement for specialized capacitor discharge equipment capable of accurately controlling pulse length and voltage, and the requirement for larger numbers of cells and higher DNA concentrations than that for other procedures (79,80).

Another transfection technology, which has not become widely used, is transfection following laser treatment (81). This technique has been grouped with electroporation because it involves a similar DNA uptake mechanism. Free DNA is taken up directly from the surrounding medium through transient pores created by a finely focused laser beam. Like microinjection, this strategy can be applied only to a small number of cells at a time, but with optimal DNA concentration can result in stable transfection frequencies of $>0.5\%$.

14.6.7 Liposomes, Virosomes, and Lipofection

Gene transfer mediated by liposomes was first described in 1980 (82). *Liposomes* are unilaminar phospholipid vesicles into which DNA can be packaged. When mixed with cells in culture, the vesicles fuse with the cell membrane and deliver DNA directly into the cytoplasm (83). The original liposome transfection techniques were no more efficient than calcium phosphate transfection and suffered the further disadvantage that the preparation of DNA-containing liposomes was complicated and labor intensive. One particular advantage of the method, however, was the ability to transform cells *in vivo* by injecting liposomes into

the bloodstream (84). The efficiency of liposome-mediated gene transfer can be enhanced by incorporating viral proteins that facilitate the active fusion between viral envelopes and cell membranes. Such fusogenic particles have been termed *virosomes*. Virosomes have been prepared from the envelopes of Sendai virus allowing the delivery of DNA to astroglial cultures (85).

A breakthrough came with the development of cationic/neutral lipid mixtures, which spontaneously associate with negatively charged DNA to form complexes (86). Residual positive charge in the complexes then interacts with negatively charged molecules on the cell surface, causing the DNA to be internalized. Technically, this is one of the simplest transfection protocols. Lipid–DNA complexes are prepared by mixing DNA with the lipid preparation in serum-free medium, then the mixture is added to the cells. This facilitates rapid and efficient DNA uptake and is gentle enough to be applicable to both conventional plasmid vectors and YACs (11). The uptake mechanism was originally thought to be similar to liposome fusion (86), but more recent experiments suggest that endocytosis of DNA–lipid complexes occurs (87,88). *Lipofection*, as this technique has become known, is highly reproducible and extremely efficient for both transient and stable transfection. It allows up to 90% of cells in culture to be transiently transfected and demonstrates stable transfection efficiencies up to 20-fold greater than standard chemical transfection methods. One drawback to this approach is that the lipids are very expensive. There are now many different lipid preparations available (89).

14.6.8 Polybrene-Mediated Transfection

Another polycationic chemical, the detergent polybrene, has been used to mediate the transfection of certain cell lines, for example, CHO cells, which resist transfection by calcium phosphate (90). Like DEAE–dextran, polybrene is soluble and may form complexes with DNA to facilitate uptake by endocytosis. For other cell lines, polybrene has been shown to be no more efficient than calcium phosphate as a transfection mediator, and it has not gained widespread use.

14.6.9 Cell or Protoplast Fusion

Polyethylene glycol (PEG) acts as a fusogen causing cell membranes to fuse together. This can be exploited to transfect animal cells by mixing them with other cells containing large amounts of plasmid DNA. Schaffner first successfully used bacterial protoplasts to transfect mammalian cells in culture by treating bacterial cells with chloramphenicol to amplify the plasmid DNA content and lysozyme to remove the cell wall. The protoplasts were then centrifuged onto a layer of mammalian cells and induced to fuse with them, thus delivering the DNA directly into the cytoplasm (91). This is a highly efficient method for transient transfection, but poor for stable transfection and cotransfection. Some investigators have used the hemoglobin-free ghosts of erythrocytes for gene delivery (92). In both the cases, the complexities involved in preparing and delivering the donor cells have hindered the widespread adoption of the method. However, the technique is gentle, allowing it to be applied to the transfection of ES cells with fragile YAC vectors and human chromosome fragments. For YAC delivery, yeast spheroplasts containing recombinant YAC vectors are induced to fuse with ES cells in culture, facilitating the introduction of YAC vector DNA and the eventual generation of YAC transgenic mice. One drawback to this method of YAC transfection is that all the endogenous yeast chromosomes are also introduced into the mouse cells, and these may have unpredictable effects (11). The largest DNA molecules currently transferred to mouse cells are human chromosome fragments, a process involving microcell-mediated gene transfer (93).

14.6.10 Microinjection

The direct microinjection of DNA into the cytoplasm or nuclei of cultured cells is sometimes used as a transfection method, but although highly efficient on an individual cell basis, this procedure is time consuming, and only a small number of cells can be treated. Originally, this technique was used for the transformation of cells that were resistant to any other method of transfection (94). Stable transfection efficiencies are extremely high, in the order of 20%, and very small quantities of DNA are sufficient. Another major advantage of this technique is that direct nuclear delivery avoids exposing the foreign DNA to any cytoplasmic organelle; so it is delivered intact. Microinjected DNA therefore suffers less mutation than DNA delivered by most chemical transfection methods. The most significant use of microinjection is the introduction of DNA into the oocytes and eggs of animals, either for transient expression analysis or to generate transgenic animals. It is suitable for the introduction of YAC vectors into the pronuclei of fertilized mouse eggs, but because DNA delivered in this manner must be very pure, painstaking preparation of the DNA must be carried out to avoid fragmentation. Shearing can also occur in the delivery needle, and YAC DNA is often protected by dissolving it in a high salt buffer and/or mixing it with polyamines.

14.6.11 Particle Bombardment

Particle bombardment (also known as *microballistic* or *microprojectile transfection*) is a relatively recent addition to the range of transfection techniques available to scientists working with animal cells. The procedure

involves coating micrometer-sized gold or tungsten particles with DNA and then accelerating the particles into cells or tissues using a blast of high pressure helium gas or an electrical discharge. The size and total mass of the particles and the force of the bombardment are important parameters that balance efficient penetration against cell damage. The technique was developed for the transformation of maize (95) and is now a method of choice for generating transgenic cereal plants. For animal cells, the technique has been less widely used. The technique has found a role in the transfection of whole organs and tissue slices (96,97) and more recently for the transfer of DNA to surface organs in gene therapy (98). In a variation of the technique, Vahlsing et al. (99) have used a pneumatic gun to drive DNA *solutions* through skin and into muscle. This technique, which is much less efficient than the traditional injection route to *in vivo* muscle transfection, has nevertheless allowed the robust expression of several viral and bacterial antigens, resulting in a particular immune response.

14.6.12 Receptor-Mediated Transfection

A recent development in transfection technology, suitable for gene therapy applications, is the delivery of DNA to particular cells by conjugation to a specific ligand. The ligand interacts with receptors on the cell surface, allowing both it and the attached DNA to be internalized. This strategy was first used to deliver plasmid DNA to liver cells by targeting the liver-specific asialoglycoprotein receptor (100). Plasmid DNA was conjugated to the ligand, asialoorosomucoid protein, using a polylysine bridge. The conjugate was added to cultured cells, and plasmid reporter gene activity was observed in liver cells but not other cell types. Since then, many similar experiments have been performed, and the efficient receptor-mediated transfection of many cell types using various ligands has been reported (58). One problem associated with this technique is that the ligand–DNA complexes are internalized via endocytotic vesicles that generally fuse with lysosomes, resulting in degradation of the DNA and consequent failure of gene expression. Some DNA escapes this fate and finds its way to the nucleus to be expressed. A >1000-fold enhancement of gene expression occurs if the ligand–DNA complexes are joined to adenoviral particles, which are known to disrupt endosomes as part of their infection strategy (101). More recently, adenovirus-derived peptides have been used for the same purpose, because these are less toxic and are less likely to provoke an immune response after *in vivo* delivery. Receptor-mediated transfection is highly efficient in cell culture, resulting in the transfection of up to 90% of cells carrying the appropriate receptor. Less success has been observed for *in vivo* gene transfer, partly because the ligand–DNA complexes are degraded in serum and partly because the size of the particles appears to be a critical parameter for the transfection of different cell types. The attachment of peptides to DNA molecules can serve other purposes in gene delivery. Recently, plasmid DNA has been conjugated to the SV40 T-antigen nuclear localization signal (102), resulting in the accumulation of transfected DNA in the nucleus.

14.7 VIRAL EXPRESSION VECTORS

14.7.1 General Properties

Viruses are natural gene delivery vehicles; so it was inevitable that they should be exploited as vectors for DNA transfer to animal cells, which reflects seven advantageous characteristics of animal viruses:

- They have evolved efficient mechanisms to adsorb to the surface of and gain entry into cells without damaging them.
- They deliver their nucleic acid intact because it is initially packaged in a proteinaceous capsule.
- They tend to block host cell protein synthesis to favor the expression of viral genes (including transduced foreign genes), which simplifies the recovery of recombinant proteins.
- Viral genomes contain strong and promiscuous regulatory elements that drive high level foreign gene expression.
- Many animal viruses have a broad host range and can thus replicate in diverse cell types from a large number of species.
- During lytic infection, viruses replicate to a high copy number and hence facilitate amplification of any foreign gene they carry.
- Many viruses can stably transform cells by integration or latent episomal replication, becoming quiescent in the process and allowing the production of cell lines. The integrated form of a viral genome is a *provirus*.

Many animal viruses have been exploited as vectors, mostly for foreign gene expression in cultured cells, but more recently as gene therapy vectors both *in vitro* and *in vivo*. Four classes of viral vectors—adenovirus, adeno-associated virus (AAV), herpes simplex virus (HSV), and retrovirus—have been used in phase 1 clinical gene therapy trials (103).

Foreign genes inserted into a viral genome are termed *transgenes*. There are three strategies for the incorporation of foreign genes into viral genomes. In two of these strategies, the resulting virus is known as *helper independent* or *replication competent*, meaning that the recombinant virus is able to propagate, even though it carries foreign DNA.

First, foreign DNA can be *added* to the entire viral genome without loss of viral genomic sequences. Vectors designed on this principle are termed *insertion vectors*, and typically, the foreign DNA is inserted between functional viral genes or at the edge of a linear genome. Second, foreign DNA can be used to replace a nonessential viral gene (nonessential, at least, for productive infection in cell culture). Vectors designed on this principle are termed *replacement vectors*, and the wild-type viral DNA fragment that is replaced is termed the *stuffer fragment*. The third strategy also involves replacement, but in this case, one or more *essential* viral genes are replaced with foreign DNA. This renders the recombinant vector *helper dependent* or *replication defective* and missing essential functions must be supplied in *trans*.

Helper-dependent vectors are especially important for gene therapy applications because an obligatory viral infection accompanying gene transfer would be extremely undesirable. The *trans*-functions may be supplied (i) using a *helper virus* (a virus carrying the essential functions, which is cointroduced with the vector) or (ii) using a helper plasmid, which is transfected into the cells infected by the vector. Alternatively, (iii) dedicated cell lines sometimes termed *packaging lines* or *complementary lines* can be used to propagate the vector. These cells are transformed with a deficient viral genome that is itself incapable of replication but supplies helper functions in *trans* to the vector. The extreme form of this strategy uses derivatives that are sometimes termed *amplicons* and sometimes described as *gutted* (or *gutless*): All viral coding sequences are deleted, leaving behind only those *cis*-acting elements required for replication, packaging, and/or proviral integration. The choice of strategy depends on many factors, including genome size, the availability of packaging lines, the number and nature of nonessential genes, and the packaging capacity of the viral capsid. Many viruses (e.g. papovaviruses) package DNA into a preformed capsid and thus have a strictly defined packaging capacity that limits the size of foreign DNA. Others (e.g. the baculoviruses) form the capsid around the genome, and no such limitation exists.

There are a number of techniques for placing foreign DNA into viral genomes. The two most popular are ligation and homologous recombination. In the ligation strategy, restriction enzymes are used to prepare vector and foreign DNA and the two elements are joined *in vitro* using DNA ligase. In the homologous recombination strategy, a plasmid carrying the foreign DNA within a viral homology region is transfected into cells infected with the parental vector, and recombinants are generated by crossing over within the homology region. The homologous recombination strategy is favored for viruses with large genomes, which are difficult to manipulate directly (e.g. baculovirus, herpes virus, and vaccinia virus). In both the cases, various screening and selection strategies may be employed to isolate recombinant vector molecules. The use of helper viruses that are themselves replication defective or that carry mutations allowing counterselection is useful for preparing pure stocks of recombinant vector. Systems are also designed so that two or more entirely independent recombination events are required to generate replication-competent, wild-type virus genomes. Novel strategies involving site-specific recombination and transposition have also been used to generate recombinant viruses.

14.7.2 Adenovirus Vectors

The major advantages of adenoviruses as vectors are the high titer (10^{12}–10^{13} pfu/mL), the efficiency of gene transfer (approaching 100%), the broad species and cellular host range (including postmitotic cells), and the ease of *in vitro* manipulation (104,105). Adenovirus vectors in current use can accommodate up to 8 kbp of foreign DNA, although the theoretical maximum is approximately 30 kbp. One disadvantage of adenoviral vectors is the low efficiency of transformation (10^{-5}). They are therefore useful as transient expression vectors, but not for efficient stable gene transfer. This, together with their tendency to provoke an immune response, may limit their utility for human gene therapy (106,107).

Adenoviruses are, as discussed earlier, exploited in two other areas of gene transfer technology. First, plasmids expressing the adenoviral VA genes may be used to increase foreign gene expression following transient transfection with plasmid vectors. This is because the RNA products of these genes inhibit the activity of DAI protein kinase, an enzyme that blocks protein synthesis in the presence of dsRNA. Second, the presence of adenoviral capsids during receptor-mediated transfection has been shown to increase the efficiency of transgene expression up to 2000-fold. This is because DNA taken up by receptor-mediated endocytosis is delivered to lysosomes, wherein it is degraded, but because the adenovirus disrupts endosomes as a normal part of its infection strategy, the addition of adenovirus particles can increase the survival of internalized DNA and increase foreign gene expression.

14.7.2.1 Adenovirus Molecular Biology. There are approximately 10 transcription units in the linear adenovirus genome, but the number of gene products produced is increased by complex patterns of alternative splicing and protein processing (104,105) (Fig. 14.5). Genes are expressed in two phases, early genes before replication and late genes after replication. E1a proteins are transcriptional regulators. E1b proteins control mRNA export and the inhibition of host cell protein synthesis. E2a and E2b encode proteins for viral DNA replication. E3 proteins help evade the host immune response, and E4 encodes

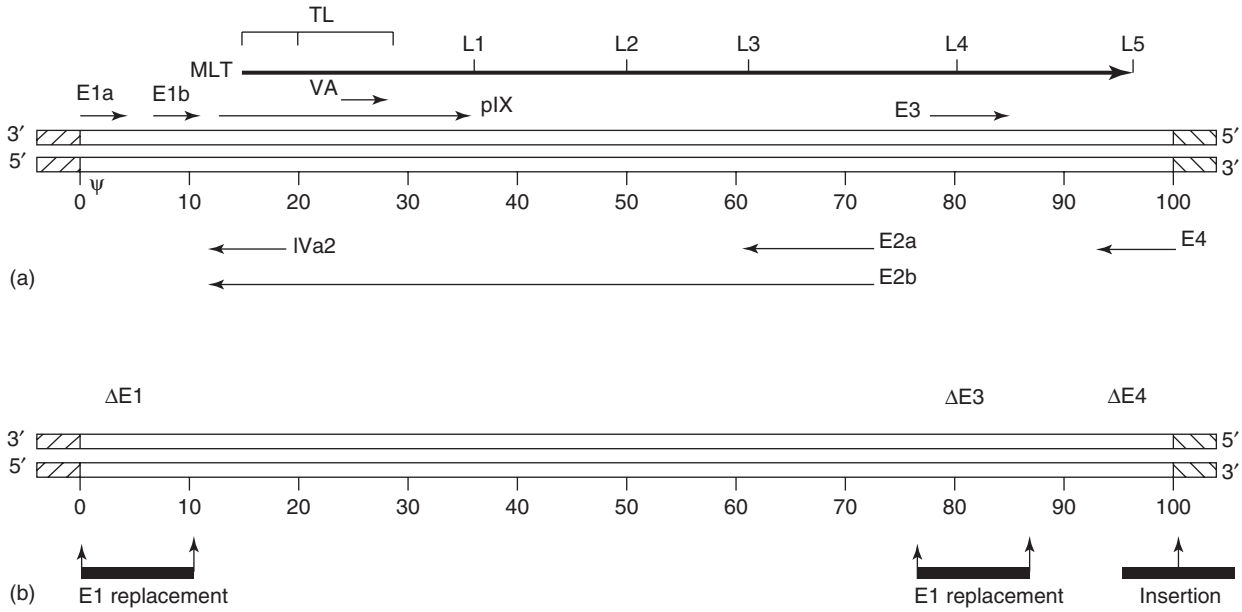

Figure 14.5. (a) The adenovirus 5 (Ad5) genome divided into 100 map units, each representing 360 bp, with inverted terminal repeats (hatched boxes). Arrows represent transcripts, the early transcripts E1–E4, the intermediate transcripts pIX and IVa2, and the major late transcript (MLT). The RNA polymerase III-dependent VA genes are also shown. The MLT is differentially spliced to yield five families of mature transcripts (LI–L5), each beginning with the tripartite leader (TL) and ending where indicated. (b) Strategies for vector development. Foreign genes can be inserted adjacent to the E4 region or used to replace either E1 or E3. E1 replacement vectors are the most widely used, and their capacity may be increased also by deleting the E3 and E4 regions. A further strategy is to delete all internal sequences except the packaging site (ψ), generating an amplicon vector.

further transcriptional regulators. After replication, early gene expression is switched off and transcription initiates from the single *major late promoter*, producing five major families of transcripts. All these late transcripts begin with a *tripartite leader*, an UTR containing two introns, which increases the efficiency of protein synthesis. Late genes encode viral structural proteins and proteins involved in their processing and assembly to form the mature virion.

Although stable integration of adenovirus DNA occurs at low frequency, one of the major reasons for interest in the adenoviruses is their ability to transform cells. The adenoviruses are divided into several subgroups based on their oncogenicity, with subgroup A being the most oncogenic, usually causing tumors when injected into newborn mice. Subgroup B is weakly oncogenic, and subgroups C–F induce tumors only occasionally. All adenoviruses can transform cultured cells; however, this involves stable integration of at least the leftmost 11% of the viral genome. This fragment of the genome contains the E1a and E1b transcription units. Certain products from this region are oncogenic because they inhibit the activity of host cell cycle regulators. E1a inactivates the retinoblastoma protein, whose function is to prevent S-phase transcription, and E1b inhibits the activity of p53, which blocks the cell cycle in response to DNA damage and other signals.

14.7.2.2 Recombinant Adenovirus Vectors. Both replication-competent and replication-deficient adenoviral vectors have been developed (104,105) (Fig. 14.5b). The replication-competent vectors include E3 replacement vectors and insertion vectors (where foreign DNA is added at the right-hand edge of the linear gene map just upstream of the E4 transcription unit). The most widely used adenovirus vectors are replication defective due to deletion of the E1a and E1b transcription units. These E1 replacement vectors are propagated in the complementary human embryonic kidney cell line 293, which is transformed with the leftmost 11% of the adenovirus genome, which supplies the missing functions. E1 replacement vectors may also lack the E3 transcription unit, which increases the maximum capacity of the vector to approximately 8 kbp (108). The further deletion of the E4 region allows foreign DNA of up to 11 kbp to be inserted and has the further advantage of removing adenoviral functions that interfere with host cell physiology. The theoretical maximum capacity of an adenoviral vector is 30 kbp. This

requires the deletion of all adenoviral coding DNA, leaving just the *cis*-acting elements required for packaging and replication—a so-called adenovirus amplicon. Packaging lines such as HEK 293 cannot be prepared for amplicons because the overexpression of adenoviral late proteins is cytotoxic. Current strategies therefore use helper viruses, although there remain problems separating the recombinant vector and helper, and with vector instability. Amplicon vectors have been used successfully to prepare vectors carrying the cystic fibrosis transmembrane receptor cDNA (109) and dystrophin cDNA (110) in 293 cells either cotransfected or coinfected with helper vectors, but yields of the recombinant vector are so far very low.

The production of recombinant adenoviral vectors by homologous recombination is a popular strategy, and a series of plasmid vectors has been produced, containing adenoviral sequences interrupted by a multiple cloning site (104,105). The alternative strategy of recombinant vector production *in vitro* has been facilitated by the development of derivatives of the wild-type adenovirus genome containing unique restriction sites for insertion, or paired sites for excision of E1 or E3 stuffer fragments and their replacement with foreign DNA (104,105). Recombinant adenoviral genomes produced as discussed earlier are infectious and can be introduced into permissive cells by transfection. Evidence of viral infection is seen within a few days, and cell lysates can then be used to infect fresh cells, resulting in the formation of plaques representing viral clones. These can be purified and the DNA analyzed for the presence of the foreign insert by PCR. It is desirable to check for sequence loss and rearrangements, especially if the insert is large and the recombinant genome approaches the maximum packaging size of the virus.

14.7.3 AAV Vectors

The parvovirus family of single-stranded DNA viruses is divided into the autonomous and dependovirus subgroups. The latter includes AAV, which is naturally *defective*, that is, unable to complete its replication cycle in the absence of a helper virus. In this instance, the term *helper virus* does not refer to a replication-competent derivative of the same species. Rather, the dependoviruses require functions supplied by a different virus species for their propagation. Adenovirus is a suitable helper virus; hence, "adeno-associated" but herpes virus is also competent to supply the required functions, and to a lesser extent so is vaccinia virus. The AAV virion is small, with a nonenveloped icosahedral capsid. Either DNA strand is packaged with equal efficiency, and both strands are infectious. AAV has a biphasic infection cycle. In adenovirus-infected cells, it enters the lytic cycle and replicates to a high copy number. In other cells, it enters a latent state where it does not replicate, but instead integrates into the genome. It is this latent state that is currently being exploited for gene transfer, due to the potential for long-term transgene expression. However, if a transformed cell is subsequently infected with adenovirus, the AAV provirus is excised (*rescued*) and lytic infection commences.

AAV has numerous properties that make it a valuable gene transfer and expression vector, particularly for gene therapy (111,112). First, stable integration occurs with great efficiency, and proviral transgenes can be expressed using either AAV or heterologous promoters. Second, the virus has an impressive host range that includes nonproliferating cells. Third, the virus is unusual in that even the wild type does not cause any disease symptom. Fourth, it is very safe to use: Recombinant AAV vectors lacking replication functions require two helper viruses, a helper AAV to supply missing AAV functions, as well as adenovirus. Finally, there is no superinfection immunity; so cells can be transduced with different AAV vectors as many times as necessary. This allows the addition of multiple traits to cells through successive transformations. The host range of AAV has not been fully explored, but it appears to infect and replicate efficiently in all mammalian cell lines if a suitable helper virus is used. The helper virus is the primary determinant of which cells can be productively infected. Integration efficiencies vary from species to species, with human cells the most efficient hosts. This specific targeting could be an advantage in gene therapy, but recombinant AAV vectors tend to integrate randomly, suggesting that the site specificity is conferred by AAV *trans*-functions. AAV has been shown to integrate into the DNA of all human cell lines tested, although the potential of primary cells has not been widely examined. One problem with AAV is the low titer of recombinant viral stocks. Initially, this was as low as 10^4-10^5 transducing units per milliliter, although by careful optimization of preparation methods, this has increased to 10^9.

14.7.3.1 AAV Molecular Biology. The AAV genome is approximately 5 kbp in length. The unique central region of the genome is flanked by 145-bp inverted terminal repeats, which are required for several functions, including replication, gene regulation, and proviral integration (111). The internal region of the genome has been divided into two large sections by genetic analysis (Fig. 14.6a). The *rep* region encodes nonstructural proteins, and mutations within this region generate a replication-deficient phenotype that also lacks certain transcriptional functions. The *cap* region encodes the structural proteins of the capsid, and mutations within this region generate a packaging-deficient phenotype. There are three promoters in the AAV genome (p5, p19, and p40). Rep proteins arise from mRNAs transcribed from the p5 and p19 promoters, while capsid proteins arise from mRNAs transcribed from the p40 promoter.

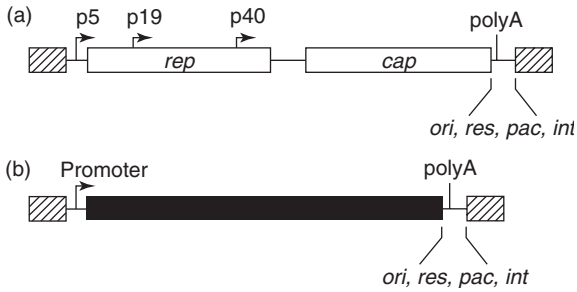

Figure 14.6. (a) Simplified map of the AAV genome showing the *rep* and *cap* regions, the three promoters (p5, p19, and p40), the polyadenylation site, the cluster of *cis*-acting sites (origin of replication, rescue, packaging, and integration), and the inverted terminal repeats (hatched boxes). (b) A recombinant AAV vector. The viral coding sequences have been removed and replaced by a foreign gene under the control of a heterologous promoter. The *cis*-acting sites remain *in situ*.

All transcripts share a common intron and polyadenylation site. The polyadenylation site is adjacent to the origin of replication and *cis*-acting elements required for packaging, integration, and rescue. The regulation of AAV gene expression is complex, involving both helper virus and AAV functions (111).

14.7.3.2 Recombinant AAV Vectors. The first AAV vectors, produced in 1984, were *cap*-replacement vectors. Initially, the *cap* region was replaced with the *E. coli neo* gene. The integrated *neo* gene was expressed at a low level from the endogenous AAV p40 promoter, but levels were sufficient to allow G418 selection of transduced cells. Major improvements to AAV-mediated gene delivery came with the development of vectors where all internal reading frames were deleted, leaving just the polyadenylation site and the *cis*-acting sequences for packaging, integration, and rescue in addition to the terminal repeats (111,112) (Fig. 14.6b). The maximum capacity of the AAV capsid is 110% wild-type genome size; thus, amplicon vectors of this nature allow the insertion of approximately 4.5 kbp of foreign DNA. The removal of the *rep* region provided an additional advantage: AAV Rep proteins control transcription as well as replication and have been shown to interfere with endogenous promoters and enhancers in AAV vectors. However, *rep*$^-$ vectors are not affected in this manner and have been used with several constitutive and inducible eukaryotic promoters, and the patterns of cell type-specific and inducible expression have been faithfully reproduced. Vectors with intact Rep functions are less predictable, although some promoters appear unaffected (e.g. the adenovirus E4 promoter).

One disadvantage of AAV expression vectors is the laborious procedure for producing stocks of recombinant virus. As both a helper virus (adenovirus) and a helper AAV are required to provide missing functions in *trans*, there are two types of contaminants to remove. Wild-type AAV can be used as a helper, but the resulting recombinant stock contains adenovirus and wild-type AAV contaminants, the latter often in great excess to the recombinant virus. Adenovirus can be inactivated by heating (lysates are heated to 60°C for 2 h) and effectively removed by CsCl density centrifugation or other physical methods. Several strategies have been employed to restrict the propagation of wild-type AAV, including the use of packaging-deficient AAV strains, the use of helper plasmids transfected into the cells infected with the parental AAV vector and adenovirus, the use of cell lines with integrated AAV genomes lacking functional rescue sequences, and the use of conditional lethal AAV mutants as helpers. These strategies have reduced the proportion of wild-type virus in the resulting stocks, although the level can still reach 10–50% due to recombination between the recombinant and helper AAV genomes. There is little chance of generating true AAV packaging lines because the overexpression of AAV genes is cytotoxic and so is the overexpression of adenoviral helper functions. The current method for producing essentially pure recombinant AAV is to use two plasmids, one carrying the recombinant AAV genome with all *cis*-acting sites intact, but all *trans*-functions replaced by foreign DNA, and the other carrying the *rep* and *cap* functions, but lacking any *cis*-acting element. These are cotransfected into cells infected with adenovirus. There is no homology between the two plasmids, preventing the production of wild-type AAV by homologous recombination, but with all the required functions supplied in *trans*, the recombinant AAV vector is rescued from the plasmid and packaged. Contaminating adenovirus is then removed as discussed, leaving the recombinant AAV vectors.

AAV vectors are newcomers in the field of gene transfer, and much remains to be learned of their suitability for stable gene expression, especially in gene therapy. In particular, issues that need to be addressed include the nature and efficiency of vector transduction and transgene activity *in vivo*. A number of such studies have been carried out recently (112).

14.7.4 Alphavirus Vectors

The alphaviruses are a group of single-stranded positive-sense RNA viruses with a broad host range, including insects and mammals (113). Alphaviruses have several properties making them suitable as transient expression vectors (113,114). First, they have a broad host range and cell tropism, facilitating gene delivery to many cell types. Second, recombinant alphaviruses deliver their RNA to the cytoplasm, where it is efficiently self-replicated and expressed to yield high levels of recombinant protein

(however, alphavirus genomes can also be cloned as cDNA and expressed from a normal expression vector, resulting in the export of recombinant viral RNA from the nucleus). Third, because the viral structural proteins are encoded on a separate subgenomic RNA, this region can be replaced by foreign DNA without rendering the vector replication defective. Fourth, the delivery of recombinant vector RNA ensures that the virus never integrates into the genome, making this system particularly useful for short-term gene therapy (e.g. cancer therapy). Finally, the two best-characterized alphaviruses—Semliki Forest virus (SFV) and Sindbis virus (SIN)—are transmitted in an asymptomatic manner, so they express foreign DNA in cell culture and *in vivo* without causing cytotoxic effects or disease symptoms. The alphaviruses have been developed as vectors only recently and are so far the only RNA viruses (excluding the retroviruses, which have a DNA stage in their replication cycle) to be commercially exploited as expression vectors. The use of RNA viruses is advantageous because there is no chance of proviral integration, and hence no danger of mutation or transformation. A number of negative-strand RNA viruses have also shown potential for vector development, although at this time, the number of successful gene transfer and expression experiments are limited (115). One potential disadvantage with the use of RNA viruses is the generally low fidelity of the viral replicase enzymes, which results in a higher level of transgene mutation than seen with DNA viruses.

14.7.4.1 Molecular Biology of SFV and SIN. SFV, Sindbis, and other alphaviruses infect cells by receptor-mediated endocytosis. The spike glycoprotein of the virus envelope then causes the viral and endosome vesicles to fuse, releasing the viral nucleocapsid into the cytoplasm. Proteins such as Sindbis spike glycoprotein have been exploited to enhance the efficiency of liposome-mediated transfection by catalyzing the fusion of liposomes and their target cells—such fusogenic DNA-containing particles are known as *virosomes*. Following entry into the cytoplasm, the genomic RNA is released from the nucleocapsid and is immediately translated to yield the viral replicase (Fig. 14.7a). This enzyme produces progeny genomes by first synthesizing a negative-sense antigenomic strand, and then using this as a template to generate positive-sense genomic strands. The replicase also transcribes the subgenomic RNA from an internal promoter, and this encodes a polyprotein containing the viral structural proteins. The polyprotein is cleaved by capsid protein C, which has chymotrypsin-like autoproteolytic activity. The viral proteins associate with naked genomic RNA, and the new nucleocapsids migrate to the cell surface, where they are released by budding, generating new lipid envelopes with spike proteins.

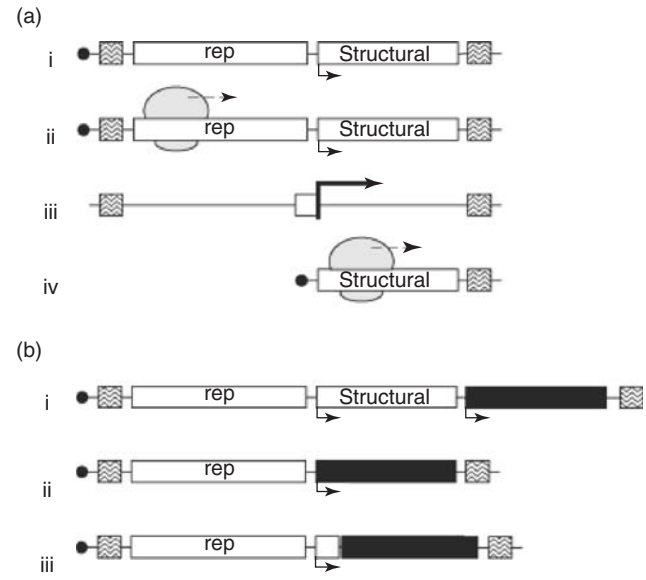

Figure 14.7. (a) Structure and replication of a simplified alphavirus genome. (i) Two genes, one encoding replicase and the other encoding structural proteins. The genome is flanked by replicase binding sequences (wavy lines) and is capped at the 5′ end (black circle). (ii) The 5′ cap allows ribosome binding, resulting in translation of the replicase gene (broken arrow). (iii) Replicase copies the genomic RNA to generate an antigenomic strand. This contains an internal promoter (thick arrow on antigenomic strand, small arrow on genomic strand). (iv) Replicase initiation at the internal promoter facilitates transcription of the subgenomic RNA, which is capped and translated to yield the structural proteins. (b) Alphavirus vectors. (i) Addition vector, where a gene can be added to the full genome under a second internal promoter. (ii) The structural genes can be replaced by foreign DNA. (iii) The foreign DNA can be fused to part of the structural polyprotein gene to take advantage of a translational enhancer.

14.7.4.2 Recombinant SFV and SIN Vectors. One strategy for expressing recombinant proteins from alphavirus vectors is to add a second promoter either upstream or downstream of the structural genes, allowing the insertion of a foreign gene and its expression as an additional subgenomic RNA (113,114). All subgenomic RNAs are capped and can be translated. Alternatively, the insertion of an IRES element between the structural genes and the transgene allows internal translation of the transgene, albeit at a lower efficiency compared with cap-dependent translation. This strategy produces vectors that are not only replication competent but also competent to produce infectious viral progeny. As this is not always desirable, a second strategy is to replace the structural genes with foreign DNA. Such constructs are more efficient than the addition-type vectors, which tend to be unstable (113). Structural gene replacement does not affect replication, but it prevents the formation of infectious virions, and can result in extremely high levels of recombinant protein synthesis, up to 50%

total cellular protein. Foreign DNA can be used to replace the entire structural coding region, but the first 40 amino acid residues include a strong enhancer of protein synthesis, which significantly increases the yield of recombinant protein. In many expression systems, this region is included in the vector, so that the foreign gene is expressed as an N-terminal fusion protein. Alternatively, the entire capsid C protein region can be included. In this case, foreign genes are initially expressed as N-terminal fusion proteins, but autocatalytic cleavage results in the production of native protein (Fig. 14.7b).

As SFV and Sindbis are RNA viruses, *in vitro* manipulation and recombinant vector construction must involve the use of cDNA genome copies (113). These can be used to produce infectious RNA *in vitro*, which can be transfected into cells using many of the methods used for DNA transfection. Sindbis expression vectors are marketed by Invitrogen. The vector pSinRep5 is a plasmid containing bacterial backbone elements, the Sindbis replicase genes and packaging site, and an expression cassette featuring a Sindbis subgenomic promoter, a multiple cloning site, and a polyadenylation site. There is an SP6 promoter upstream of the replicase genes and expression cassette for generating full-length *in vitro* transcripts. There is a second set of restriction sites downstream from the polylinker, allowing the vector to be linearized before *in vitro* transcription. Foreign DNA is cloned in the expression cassette, the vector is linearized and transcribed, and the infectious recombinant Sindbis RNA thus produced is transfected into cells and expressed to generate high levels of recombinant protein. A different approach is to clone the entire alphavirus vector as an expression unit in a conventional plasmid expression vector under the control of a typical mammalian promoter, such as the SV40 promoter. In this case, DNA is transfected into the cell as normal and alphavirus RNA is produced as mRNA and exported to the cytoplasm. Here, it replicates as a virus and produces large amounts of recombinant protein. In both the RNA and DNA transfection strategies, helper functions are not required and recombinant virus particles are not produced.

The introduction of recombinant RNA into cells is unsuitable for gene delivery *in vivo*. In these cases, viral infection of cells is used for gene transfer. The propagation of infectious recombinant viruses requires helper functions (i.e. structural genes) to be supplied in *trans*. A binary approach has been used successfully to produce recombinant viruses. A vector such as that described earlier is used in concert with a second vector carrying the structural genes (113,114). Two *in vitro* transcription reactions are performed and target cells are cotransfected with two RNAs, one expressing replicase and the transgene and the other expressing structural proteins. This facilitates one round of replication and packaging and the production of recombinant viral particles that can be used to infect other cells. There is a risk of replication-competent viruses assembling by promiscuous replication, involving switching between the alternative RNA templates. This has been addressed by developing helper viruses with conditional lethal mutations, but the risks are at present too great for alphaviruses to be considered safe for human gene therapy.

14.7.5 Baculovirus Vectors

The baculoviruses are a diverse group of double-stranded DNA viruses whose productive host range is limited to insects and other arthropods (116). There are no known vertebrate hosts; thus, vectors derived from baculoviruses are among the safest to use. However, baculoviruses are taken up by mammalian cells in culture, and recent studies have shown them to be capable of expressing foreign genes under the control of mammalian viral promoters (117). Baculoviruses are therefore potential vectors for gene therapy.

The main role of baculovirus vectors is the high yield transient expression of foreign proteins in insect cells (118–120). The usefulness of baculoviruses as vectors stems from the unusual infection cycle of one particular subfamily, known as the *nuclear polyhedrosis viruses* (NPVs). The baculoviruses are divided into three subfamilies: the NPVs, the granulosis viruses, and the nonoccluded viruses (116). The NPVs are potentially the most suitable vectors because they produce *nuclear occlusion bodies*, where mature virions are embedded in an abundant proteinaceous matrix. The matrix allows virions to survive in a harsh environment such as the external surface of leaves. The two important features of this system (as concerns vector development) are (i) the matrix consists predominantly of a single virus protein, *polyhedrin*, which is expressed at very high levels, and (ii) the nuclear occlusion stage of the infection cycle is nonessential for viral propagation in insect cell lines. The polyhedrin coding region can therefore be replaced with foreign genes, allowing heterologous gene expression from the polyhedrin promoter, and replacement vectors are replication competent.

Due to the simple procedures involved in laboratory handling and propagation, vector development has concentrated on two species of viruses (119,120). For the production of recombinant proteins in insect cells, the multiple NPV from the alfalfa looper *Autographa californica* has been extensively utilized. This virus [*A. californica* multiple nuclear polyhedrosis virus (AcMNPV)] is propagated in several insect cell lines, the most popular of which are derived from *Spodoptera frugiperda* (e.g. Sf9 and Sf21). Alternative hosts include cell lines derived from *Estigmene acrea, Mamesta brassicae*, and *Trichoplusia ni* (e.g. High Five™). A related virus (BmNPV), which infects the silkworm

Bombyx mori, has been used for the production of recombinant protein in live silkworm larvae.

The baculovirus expression system has two other important advantages in addition to its safety, convenience, and yield. First, the rod-shaped viral capsid is completed after genome packaging, so that the size of the capsid is determined by the length of the genome. This means that any amount of foreign DNA can be accommodated, and multiple genes can be expressed in tandem (121). Second, many types of posttranslational protein modification have been documented in insect cell lines, including proteolytic cleavage, formation of disulfide bonds, N-linked and O-linked glycosylation, and fatty acid acylation (121). Baculoviruses are therefore ideal for overexpressing mammalian proteins, especially those intended for therapeutic use. However, there is some variation in the nature of protein modification, particularly with respect to N-linked glycosylation, between mammalian cells and the baculovirus host cell line Sf9. It has been reported that glycosylation patterns in an alternative cell line derived from *E. acrea* are similar to those in mammalian cells (122). Furthermore, mammalian glycosylation enzymes have been coexpressed with target foreign proteins using baculovirus vectors in Sf9 cells, and this strategy has successfully altered the specificity of the glycosylation pathway to generate correct modifications typical of mammalian proteins (122). For cellular localization studies, it is also notable that most proteins expressed in insect cells using baculovirus vectors are correctly targeted.

14.7.5.1 Molecular Biology of AcMNPV. AcMNPV replicates with a biphasic cycle in susceptible insect cells and produces two distinct forms of viruses (121). The early cycle results in the production of *extracellular budded viruses* (EBVs), single-enveloped virions that are released by budding from the cell membrane and go on to infect other cells. This first phase of the lytic cycle occurs within 20 h following infection and involves the expression of three sets of viral genes. The immediate early (α) genes and the delayed early (β) genes are expressed before DNA replication. The α-genes are expressed immediately after the infecting virus is uncoated, and expression requires no viral gene products; hence, transfected naked AcMNPV genomic DNA is infectious. The β-genes are expressed after the α-genes, and their expression is dependent on α-gene products. The late (γ) genes are expressed after the onset of replication and are thought to encode products involved in ECV structure and assembly. Most of the α-,β-, and γ-genes are essential for productive infection.

After 20-h postinfection, the production of ECVs is dramatically reduced. This corresponds to reduction in the transcription of α-, β-, and γ-genes, and the induction of a fourth set of very late (δ) genes. Importantly, these genes can be regarded as nonessential for productive infection in insect cell lines, although they are essential for the spread of the virus in nature. This establishes a containment system for laboratory-constructed baculovirus vectors.

14.7.5.2 Recombinant Baculovirus Vectors. Most baculovirus vectors involve replacement of the polyhedrin or p10 coding regions (121). The nonessential nature of these δ-gene functions has made them desirable targets for replacement with foreign DNA. There are also vectors that use early promoters, particularly for the production of proteins known to be toxic to insect cells and for baculovirus surface display technology (122).

Polyhedrin replacement vectors are used for prodigious expression of polyhedrin in the late part of the replication cycle (accounting for up to 25% of total cellular protein or 1 mg/10^6 cells). The polyhedrin upstream promoter and 5′ UTR are important for high level foreign gene expression, and these are included in all polyhedrin replacement vectors. Initially, the highest levels of recombinant protein expression were obtained as fusions with at least the first 30 amino acids from the N-terminal region of the polyhedrin protein. This would appear at first to reflect optimization of protein stability, but in fact reflects the presence of additional regulatory elements located downstream of the polyhedrin translation start site. For the production of native proteins, vectors are available where the natural polyhedrin initiation codon is mutated, so that these important "downstream" sequences become part of the 5′ UTR of the foreign gene. However, it has been reported that initiation may still occur at this mutated site; so cloned foreign genes must be trimmed off their own UTRs, and the start codon should be out of frame with respect to the natural polyhedrin start codon.

The major disadvantage of p10 replacement vectors is that p10 mutants are not OB^- and have no easily scorable phenotype. Plaques of both polyhedrin and p10 replacement vectors can be screened for the presence of the insert by hybridization or immunological detection of foreign protein. A number of visual screening strategies have been developed as well as systems for *selecting* recombinant viruses. The *E. coli lacZ* gene has been used to help identify recombinant plaques. The general visibility of plaques is improved by insertion of the *lacZ* gene under an appropriate promoter somewhere in the baculovirus genome, so that *all* plaques turn blue on exposure to X-gal. More refined approaches include exploiting *lacZ* for blue–white selection: By using parental baculovirus strains in which β-galactosidase is expressed from the polyhedrin promoter, recombinants (which replace the *lacZ* gene with the foreign gene to be expressed) form clear plaques, while parental vectors form blue plaques; alternatively, by introducing *lacZ* as a marker alongside the foreign gene, the recombinant vectors form blue plaques, while the wild-type virus

produces clear plaques. Due to the lack of screenable phenotype, p10 expression vectors must incorporate a reporter gene detection system to allow recombinant plaques to be identified. Recently, vectors have been designed with polyhedrin expressed from the p10 promoter, so that the original OB assay can be used.

Baculovirus genomes are large, and although strains have been constructed with unique restriction sites, allowing insertion of foreign DNA by *in vitro* ligation, the favored strategy is homologous recombination using plasmid targeting vectors containing a baculovirus homology region into which foreign DNA has been inserted (119,120). Generally, plasmid and wild-type baculovirus DNAs are cotransfected into the appropriate insect cells by calcium phosphate transfection, lipofection, or electroporation. This strategy generates recombinant vectors at a frequency of 0.5–5%. Linearized baculovirus genomes are noninfectious, but remain recombinogenic, and this can be used to reduce contamination from wild-type virus. The proportion of recombinants can be increased through the use of nonviable deleted derivatives of the wild-type baculovirus genome, which are repaired by homologous recombination with the targeting vector. Derivatives of the wild-type AcMNPV genome, with unique restriction sites added upstream of the polyhedrin gene and within an essential gene found downstream of the polyhedrin locus, can be used to generate linear genome fragments lacking an essential function (e.g. BacPAK6). Compatible targeting vectors span the deletion and provide enough flanking homologous DNA to sponsor recombination between the two elements and generate a viable, recombinant genome. Such approaches result in the production of up to 90% recombinant plaques. Combinatorial approaches using deleted nonviable genomes and targeting vectors incorporating *lacZ* or green fluorescent protein visible screening systems provide very powerful selection for recombinant vectors (122).

Alternative systems, in which the baculovirus genome is maintained and targeted as a low copy-number episome in bacteria (123) or yeast (124), are gaining popularity because they allow the direct isolation of recombinant vectors. Low copy-number maintenance is important to prevent the survival of a background of nonrecombinant vectors. The baculovirus genome can be stably maintained as a low copy-number episome in bacteria if it contains an F-plasmid origin of replication and a bacterial selectable marker such as kanamycin resistance (Bac-to-Bac), which exploits the specificity of the bacterial transposon Tn*7* to introduce foreign genes into the baculovirus/plasmid hybrid, which is called a *bacmid*. The foreign gene is cloned into a bacterial transfer plasmid between two Tn*7* repeats. This is transformed into the appropriate strain of *E. coli*, which contains the bacmid and a helper plasmid supplying Tn*7* transposase. Induction of transposase synthesis results in the site-specific transposition of the transgene into the bacmid, generating a recombinant bacmid that can be cloned and isolated from bacterial culture for transfection into insect cells. The Tn*7* target site in the bacmid is inserted in-frame within the *lacZ* gene, allowing blue–white screening of recombinants.

The baculovirus genome can also be maintained as a low copy-number episome in yeast if it contains a suitable origin of replication, a centromere, and selectable markers: These elements are inserted as a cassette to replace the polyhedrin gene. In the original system, a pair of selectable markers was used, allowing the power of yeast genetics to be applied to vector selection. One marker was used for positive selection of transformed cells, while the other was used for counterselection against nonrecombinant vectors. The *SUP4-o* marker was initially used for counterselection. This is a nonsense suppressor that, in the particular yeast strain used, confers sensitivity to the arginine analog canavanine and the ability to grow in media lacking adenine. Removal of the marker by replacement with homologous DNA confers resistance to canavanine and a requirement for adenine. Plasmid DNA isolated from canavanine-resistant, adenine-requiring yeast cultures was used to transfect insect cells and produce pure recombinant baculovirus. In both bacteria and yeast, the maintenance sequences (origin of replication/centromere and positive selection marker) must stay in the recombinant baculovirus vector. They have been shown to have no effect on baculovirus replication or gene expression in insect cells.

14.7.6 Herpes Virus Vectors

Herpes viruses are large, enveloped viruses with linear, double-stranded DNA genomes varying from 100 to 200 kbp in size. Different herpes viruses differ considerably in their host range and cell tropism. Furthermore, while some cell types undergo only lytic infection, others are also permissive for latent infection, resulting in long-term episomal maintenance of the viral genome. Of the eight known types of human herpesvirus, two have been extensively developed as vectors (51,125). EBV has a narrow host range, and its cell tropism is limited to B-lymphocytes and nasopharyngeal cells displaying the appropriate receptor. Cultured lymphocytes tend to undergo latent viral infection, but many other cell types are also permissive for latent EBV replication following the transfection of naked viral DNA. Hence, the major use of EBV has been the development of episomal plasmid vectors for transfection (51). Conversely, the human HSV-I and HSV-II have a broad host range and cellular tropism because they interact with a near-ubiquitous cell-surface molecule. Many cell types therefore undergo lytic HSV infection, while neurons also undergo latent infection. HSV vectors have thus been developed both

for short-term foreign gene expression in many cell types and for long-term foreign gene expression in neurons (125–128). The vectors show great potential for gene therapy applications, especially genetic intervention in the brain (126). The major advantages of HSV vectors are their broad host range and tropism, their natural ability to cause latent infection of neurons, and their large capacity: Up to 50 kbp of foreign DNA can be incorporated, which may comprise multiple genes.

14.7.6.1 Molecular Biology of HSV-I. HSV-I has a broad host range and cell tropism because it interacts with ubiquitous heparan sulfate molecules on the surface of target cells (129). The viral genome is linear, but after release from the nucleocapsid, it gains entry to the nucleus and immediately circularizes. The capsid also contains a virion host shutoff (VHS) protein that interrupts host protein synthesis and a transcriptional activator termed VP16. During lytic infection, VP16 forms a dimer with the host transcription factor Oct-1 and induces the expression of the five viral immediate early genes: $\alpha 0$, $\alpha 4$, $\alpha 22$, $\alpha 27$, and $\alpha 47$. The immediate early genes are all essential for lytic replication. These encode further regulators that act both on their own genes (in a self-regulatory manner) and on a set of approximately 15 early genes controlling DNA replication. Following replication, approximately 40 late genes are activated, which encode DNA cleavage and packaging proteins and capsid proteins. Progeny genomes are then packaged into virions and transported to the cell surface, where lysis occurs (129).

Lytic infection occurs in many different cell types, but latency is restricted mostly to neurons (129). The switch to latency is thought to reflect the balance of host- and virus-encoded transcriptional regulators in the cell. The immediate early genes are not expressed, and viral activity is restricted to a 152-kbp genomic region that overlaps the $\alpha 0$ immediate early gene in the antisense orientation. This region encodes a set of latency-associated transcripts (LATs). The LATs are also synthesized during lytic infection, although no protein products have been detected (even though LATs are associated with ribosomes). During latency, the LATs remain in the nucleus. The LATs are neither required for the establishment of latency nor its maintenance, but they are required for reactivation of the lytic cycle.

14.7.6.2 HSV Vector Construction. HSV has a large genome, and one simple strategy for generating recombinant HSV vectors is to transfect HSV-infected cells with a targeting vector containing a foreign gene within a viral homology region (103,126). Several HSV genes are nonessential for productive infection and can be replaced with foreign DNA. The resulting viruses are replication competent and infectious. For approaches such as gene therapy, however, HSV vectors must be replication defective. Several derivatives of HSV are now available that carry deletions in one or more of the immediate early genes, and such vectors must be propagated in a complementing cell line or in the presence of a cotransfected helper plasmid. The deletion of immediate early genes is also beneficial because their products are toxic to the host cell. HSV amplicon vectors are also widely used (103,126–128). These comprise the HSV origin of replication and genome packaging site cloned in a plasmid vector along with a mammalian transcription unit. All viral genes are deleted, leaving a vector that can only be packaged in the presence of a helper virus supplying the many missing functions in *trans*. Wild-type HSV-I can be used to supply helper functions, but the wild-type virus often causes lytic infections, resulting in rapid cell death both *in vitro* and in live animals. A number of HSV-I mutants have been developed as helper viruses, as these are nonpermissive for lytic replication (but still induce latent infection when introduced into cultured neurons or injected into the brain). Initially, a temperature-sensitive mutant was used carrying a point mutation in one of the immediate early genes. This was conditionally defective, inducing latent infections in the brain and in cultured neurons at 37°C but lytic infections at 31°C. Unfortunately, its applicability was limited by a significant reversion frequency, resulting in the induction of lytic infections. More recently, defective helper viruses with deletions in one or more of the immediate early genes have been used, providing complementary packaging lines to produce infective recombinant particles. In some cases, the reversion frequency has been reduced to 10^{-7}.

14.7.6.3 HSV Vectors for Prolonged Transgene Expression in Neurons. Due to their ability to cause long-term latent infection of neurons, the major use of HSV-I-derived vectors has been for gene transfer to neurons either *in vitro* or in the central nervous system of living animals (126–128). Neurons have been a difficult gene transfer target because they are postmitotic, and many transfection and viral transduction systems require rapidly dividing cells. The *in vitro* transfection of neurons often yields poor results due to limited uptake as well as the standard problems associated with position and dosage effects. HSV-I vectors possess a number of advantages for gene transfer to neurons, including efficient DNA transfer, a large genome size permitting the transduction of large segments of foreign DNA, and long-term episomal maintenance without viral gene expression. This later property ensures that during latent infection, the host cell physiology is unaffected—in fact, it is thought that most of the human population carries latent herpes virus infections in the absence of disease symptoms. The effect of foreign gene expression can

therefore be studied without considering the background effects of viral gene activity.

Vectors based on pHSVlac have been used to transfer many genes into neurons, including reporter genes, and genes encoding growth factors and their receptors, signal transduction components, and neurotransmitters (127,128). This strategy can be used both for therapeutic intervention and for the experimental study of cell function, for example, through the introduction of novel heterologous genes, the overexpression or constitutive expression of endogenous genes, the expression of dominant negative proteins to generate loss of function effects, and the use of toxins to ablate particular cells. Generally, it has been found that *in vivo* transfer results in relatively long-term foreign gene expression (2 weeks or more) with transformed cells restricted to those surrounding the injection site and more distant cells whose axons project into the site. The duration of transgene expression is strongly influenced by promoter choice. The number of infected cells is influenced by the extent of virion diffusion from the site of injection and the titer of the innoculum. HSV has a broad cell tropism and will infect glia and other nonneuronal cells as well as neurons. There have been a number of successful attempts to restrict the expression of foreign genes carried in HSV vectors using cell type-specific promoters, such as the neurofilament L promoter, which is panneuronal, and the tyrosine hydroxylase promoter, whose activity is restricted to catecholaminergic neurons. Reporter genes driven by IE1, IE3, and IE4/5 promoters have been shown to be active for up to 10 weeks in cultured sensory neurons.

The defective HSV-I vectors described provide a system for therapeutic gene transfer to neurons, which could be used to treat a variety of neurophysiological disorders (126). A number of potentially therapeutic genes have been cloned in this type of vector, including tyrosine hydroxylase for the treatment of Parkinson's disease, nerve growth factor for the treatment of Alzheimer's disease, and brain-derived neurotropic factor for potential repair of neuronal damage. Generally, transgene expression was detected for about 2 weeks following infection under the control of the IE4/5 promoter or other constitutive promoter. The rat brain glucose transporter cDNA has been introduced into the hippocampus of rats by stereotactic injection of HSV amplicon vectors and has successfully reduced neuron loss following kainic acid-induced seizures. However, foreign gene expression was observed for only a few days. Conversely, in a rat Parkinson's disease model, the transfer of tyrosine hydroxylase cDNA in a vector derived from pHSVlac resulted in long-term (>1 year) behavioral recovery.

14.7.6.4 HSV Vectors for Transient Expression in Nonneuronal Cells. The wide cell tropism of HSV provides an opening for its development as a gene delivery and expression vector for many cell types in addition to neurons. Miyanohara et al. (130) carried out successful gene transfer to liver by injecting recombinant herpes virus vectors both directly into the organ and into the portal vein. Although liver cells do not support latent HSV replication, HSV-mediated gene transfer to nonneuronal cells allows short-term recombinant protein expression, which may be sufficient for short-term or repetitive gene therapy, for example, the expression of canine factor IX in liver as a potential therapeutic treatment for hemophilia B. The restriction of HSV-mediated transgene expression to short duration would be an advantage in cancer therapy, as shown by the treatment of experimental glioma by delivering HSV vectors expressing TK, allowing infected dividing cells to be killed by treatment with ganciclovir (131).

14.7.7 Retrovirus Vectors

Retroviruses are RNA viruses whose unusual replication strategy includes reverse transcription of the RNA genome to generate a terminally redundant double-stranded cDNA copy, which integrates into the host genome in a semirandom manner (133). Progeny virions are produced by transcription of the provirus to yield both daughter viral genomes and subgenomic mRNAs encoding enzymes and structural proteins of the viral capsid. The host range and cell specificity of a particular retrovirus species is determined primarily by the envelope proteins, which interact with cell-surface receptors. The envelope proteins of amphotropic murine leukemia virus (MLV) are particularly promiscuous, so this virus has a broad host range and cell tropism and has been extensively developed as a vector for gene transfer to mammalian cells (134–136).

The retroviruses are an obvious choice for vector development, first, because of their natural ability to integrate DNA into the host genome, and second, because some, known as *acute transforming retroviruses*, demonstrate the inherent ability to transduce and express foreign genes. Over 100 acute transforming retroviruses have been described, leading to the discovery of many oncogenes, including those encoding growth factors and their receptors, signal transduction proteins, cell cycle regulators, and transcription factors. In many cases, the viral oncogene is fused to another viral gene so that it is expressed as a fusion protein. If this was an obligatory expression strategy, the construction of recombinant retroviral vectors could be very cumbersome. However, certain retroviruses contain oncogenes whose translation is initiated at a unique start codon (e.g. v-*src* in Rous sarcoma virus), and others carry two oncogenes (e.g. v-*erbA* and the unrelated v-*erbB* in avian erythroblastosis virus), suggesting that a number of alternative transgene integration strategies could be used. Retroviruses are

attractive potential vectors for many reasons (134,135). First, their small genome is no more difficult to manipulate *in vitro* than a standard plasmid vector. Second, they can be propagated to high titers (10^6-10^8 pfu/mL) using appropriate packaging lines. Third, they contain a strong promoter–enhancer complex that can drive high level transgene expression in many cell types. In all naturally occurring acute transforming retroviruses, oncogenes are driven from these LTR promoter–enhancer complexes, but transgenes can also be driven by their own promoters or by heterologous promoters from within the retroviral vector. Fourth, the efficiency of infection *in vitro* can approach 100%. Finally, retroviral integration produces stably transduced cell lines that can express foreign genes on a long-term basis—this makes them particularly suitable for gene therapy (137). The first successful report of human gene therapy, the correction of severe combined immunodeficiency (SCID) by transferring adenosine deaminase (*ADA*) cDNA to cultured hemopoietic stem cells or T-lymphocytes, involved the use of retroviral vectors (138). Similarly, retroviruses can be used for *in vivo* gene transfer simply by injecting recombinant vectors at the appropriate site. A similar concept involves the injection of retroviral vectors into embryos to generate chimeric embryos for the study of cellular interactions during development (139). Retroviral vectors are not used just to generate chimeric animals. Fully transgenic animals can also be produced (140) by retroviral infection of ES cells or preimplantation embryos, followed by the rearing of chimeric animals from which transgenics can be bred. As retroviruses are also transposable elements, retroviral vectors can be used as insertional mutagens. If the appropriate vector components are included, retroviruses can also be used as entrapment vectors and flanking sequences can be isolated by plasmid rescue (14).

14.7.7.1 Molecular Biology of the Retroviruses. Retroviral genome organization is simple and highly conserved between species (133) (Fig. 14.8a). The integrated provirus comprises three major open reading frames (*gag, pol*, and *env*) bracketed by tripartite direct LTRs. A single promoter located in the left LTR is used to transcribe genomic RNA. The *gag* region encodes viral structural proteins (*group antigen*), the *pol* region encodes reverse transcriptase (*polymerase*), integrase and protease, and the *env* region encodes viral *envelope* proteins. The full-length RNA is translated to yield two polypeptides, Gag and Gag-Pol, the latter by occasional programmed read-through of the *gag* termination codon. The full-length RNA also undergoes splicing to eliminate the *gag* and *pol* regions. The splice product is translated to generate the Env polypeptide. The protease encoded by the *pol* region (or occasionally the *gag* region, depending on the virus) cleaves the major gene products to yield approximately 10 mature polypeptides.

The retroviral infection cycle begins by uptake of virions through interaction between virus envelope proteins and the appropriate cell-surface receptors (133). The capsid contains two copies of the RNA genome (i.e. it is diploid) as well as reverse transcriptase. As the packaged RNA genome is transcribed from an integrated proviral cDNA using a promoter within the left LTR and a polyadenylation site within the right LTR, the free genome is truncated at both ends compared with the provirus, and lacks its characteristic LTR structure. Early in the replication cycle, the RNA genome is copied to generate a double-stranded cDNA replica, in a complex process involving two template jumps. It is this process that generates the LTRs. The cDNA genome, complete with redundant LTRs, is integrated into the host DNA using viral integrase. It is then transcribed to generate progeny genomes and mRNAs for translation. Mature viral proteins assemble with the genomic RNAs to form new virions. A specific *cis*-acting packaging site termed ψ is required.

14.7.7.2 Recombinant Retroviral Vectors. Most retroviral vectors are replication defective. Several replication-competent vectors have been developed, but they have a limited insert size and allow the spread of vector DNA throughout the host genome following infection, a consequence that is usually undesirable (134–136). Most naturally occurring acute transforming retroviruses are also replication defective, because the viral oncogene replaces an essential viral function. They require superinfection with a wild-type virus to replicate successfully in the host. An exception is Rous sarcoma virus, which carries the v-*src* oncogene in addition to the entire viral genome. Replication-competent RSV vectors have been developed in which the v-*src* gene is replaced by foreign DNA. These vectors infect avian cells efficiently, but not mammalian cells, unless they have been modified to express the appropriate heterologous receptor. For mammalian cells, replication-competent vectors based on Moloney murine leukemia virus (MoMLV) have also been developed.

Replication-defective vectors are generally amplicons, with most of the viral coding region replaced by foreign DNA (Fig. 14.8b). Such vectors can be propagated only in the presence of helper functions, either using a replication-competent helper virus or a packaging cell line (134–136). The use of helper viruses results in the production of recombinant vector contaminated with the helper virus itself. Packaging cell lines are therefore more suitable for the production of pure, infectious viral particles capable of reverse transcription and integration, but not of further replication. A range of different packaging lines has been developed, differing in the parental virus used to create the line and the extent to which the helper virus genome has been modified and

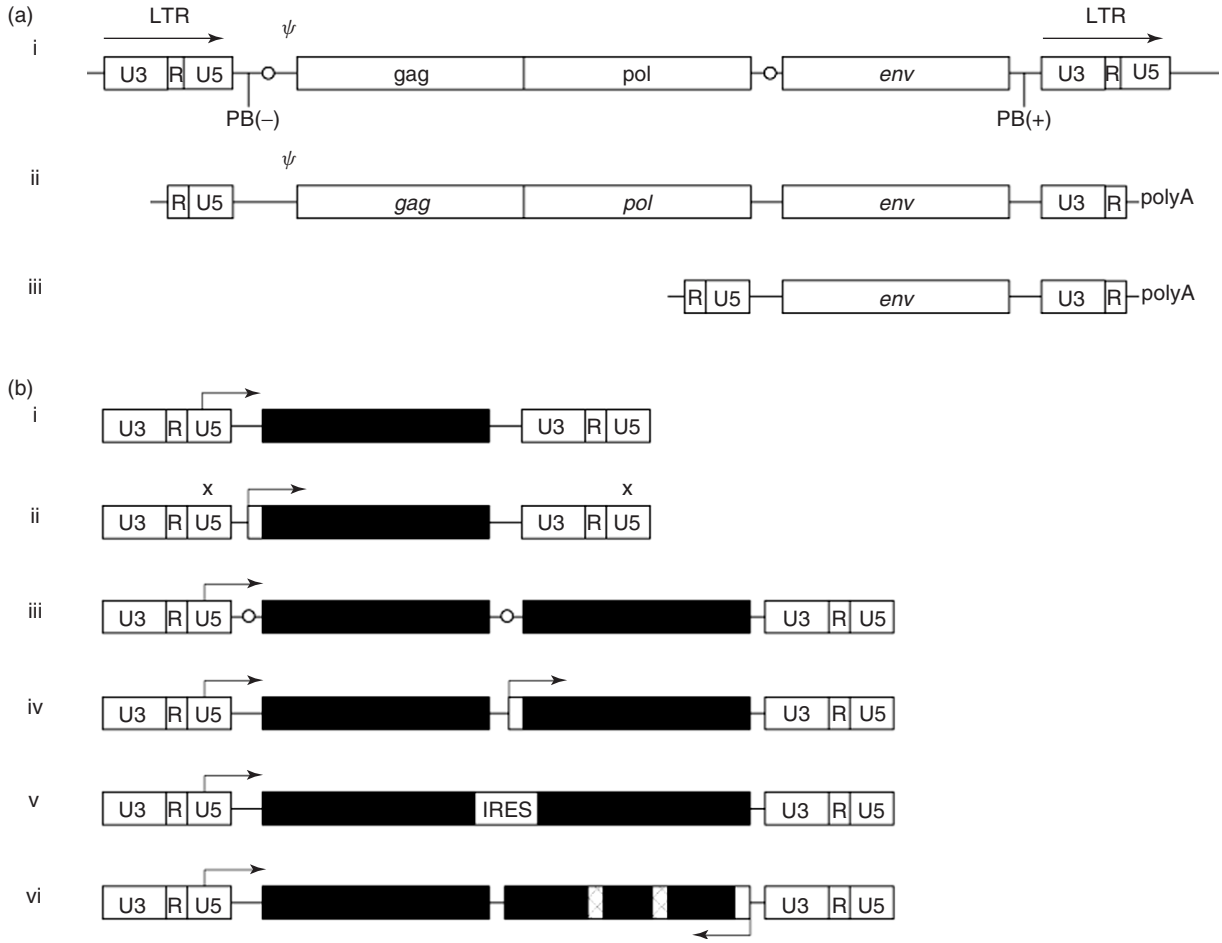

Figure 14.8. (a) Structure of a typical retrovirus genome. (i) Proviral genome is flanked by long terminal direct repeats and with three open reading frames, *gag, pol*, and *env*. The sites marked PB are primer binding sites, where genome replication is initiated. ψ is the packaging site. (ii) The U5 region contains a promoter–enhancer complex that stimulates genomic transcription. The R region contains a polyA site. The maximum transcript thus lacks terminal U3 and U5 elements, which are regenerated during cDNA synthesis. (iii) Splicing between acceptor and donor sites (shown as circles in *1*) generates a subgenomic transcript enabling translation of the *env* coding region. (b) Structure of recombinant retroviral vectors (black bar is foreign gene). (i) Simple vector with transgene driven by LTR promoter. (ii) Vector with transgene driven by an internal heterologous promoter. Such a vector may carry a mutation in the U5 region (x) that abolishes LTR promoter activity. (iii) Double-gene vector where each gene is driven by the LTR promoter by splicing. (iv) Double-gene vector with gene 1 driven by a LTR promoter and gene 2 by its own promoter. (v) Double-gene vector with the downstream gene under the control of an IRES. (vi) Double-gene vector where one transgene contains introns. The intronless transgene is controlled by the LTR promoter, and the other gene is inverted and controlled by an internal promoter.

rearranged. The former property determines the host range of the recombinant vector because it specifies the type of envelope protein inserted into the virion envelope. The most promiscuous vectors are generated using packaging lines derived from amphotropic viruses such as MLV. Many alternative packaging lines are available, which allow the tailoring of vector host range for particular experimental strategies. The latter property determines the extent to which replication-competent viruses are generated by recombination. The most efficient lines contain helper viruses with genomes modified to (i) limit the extent of homologous sequence shared between the helper virus and the vector and (ii) increase the number of independent crossover events required to form a replication-competent genome. One of the most efficient lines in this category is GP + E-86 (141), which contains

split coding regions, point mutations, and deletions, and hence requires three independent recombination events to generate a replication-competent virus.

Various strategies have been used to express foreign genes in retroviral vectors (134,135,138). The simplest strategy is to remove all coding sequences and place the foreign gene between the LTR promoter and the viral polyadenylation site. This results in the high level constitutive production of a single RNA encoding the foreign protein and is useful to synthesize large amounts of protein. However, if a specific expression pattern is required, an internal heterologous promoter can be inserted as part of the transgene. A difficulty with vectors containing internal heterologous promoters (non-LTR promoters) is that the LTR regulatory elements can either positively or negatively affect internal transcription. This problem has been circumvented by the development of *self-inactivating* or *suicide retroviral vectors* (142), with deletions in the 3′ LTR. A mutation in the 3′ LTR is copied to the 5′ LTR during the subsequent round of vector replication, resulting in a virus with inactive LTR promoter and/or enhancer elements, but functional internal promoters.

Selectable markers can be used to identify stably transduced cells to express two genes, the foreign gene and the marker, in the same vector. Many of the selectable markers (Table 14.4) have been used. The dominant markers *neo, hpt, Dhfr*, and *gpt* can be used in any cell, but *Hprt* and *Tk* require gene transfer to $hprt^-$ or tk^- cell lines. The expression of two (or more) genes can be achieved in a number of ways (Fig. 14.8b). An internal promoter can be used so that there are two independent transcription units within the virus. Alternatively, the vector can be modeled on the splicing pattern of a wild-type virus, so that full-length and spliced transcripts are produced. In both the cases, it is essential to allow full-length RNAs to be produced from the recombinant genome in the packaging line; so it is important not to include a polyadenylation site at the end of the first gene, which could terminate (replicative) transcription and result in loss of the second gene. In two-promoter vectors, the lack of a polyadenylation site for the upstream gene can result in read-through transcription and occlusion of the second promoter. This can be alleviated by placing the two genes in opposite orientations, so that the (reversed) polyadenylation site of the transgene is not recognized during full-genome transcription. For alternative splicing vectors, the existence of cryptic splice sites in the upstream gene should be considered. Multiple gene expression with LTR-based, internal promoter-based, and alternative splicing vectors can also be achieved by using IRES. Although the open reading frame downstream of the IRES is usually translated less efficiently than that using the more typical 5′ cap ribosome loading mechanism, it is certainly efficient enough for marker-based selection and reporter-based visible screening.

The interference of introns and polyadenylation signals with the virus replication cycle places certain limitations on the type of sequence that can be expressed in retroviral vectors. cDNAs are the simplest sequences to express because they can be inserted in the same orientation as the viral transcription unit (or they can be reversed with respect to the promoter to generate antisense RNA). Genes are more difficult to express, because the introns and polyadenylation signals may interfere with viral replication and RNA processing. If full, intron-containing genes must be expressed, they need to be placed under the control of an internal promoter, and the whole expression cassette has to be reversed in orientation. This allows intron recognition and splicing (and hence normal translation) from the reversed internal promoter but prevents the introns being spliced during forward, full-genome transcription. The alternative strategy is to remove the introns artificially and insert an intronless minigene into the vector in the forward orientation. Virus titer is reduced by the inclusion of an endogenous polyadenylation site at the end of the intronless minigene, but only by 5- to 10-fold; so infection is still productive.

Recombinant retroviral vectors for mammalian cells are constructed using cloned retrovirus cDNA, containing the essential *cis*-acting sites for the retroviral life cycle but lacking the *gag, pol*, and *env* genes whose products can be supplied in *trans*. The essential elements for high titer virus production are the LTRs, primer binding sites, and the packaging site ψ. Importantly, it has been determined that the ψ site, originally defined as a noncoding sequence 5′ to the *gag* open reading frame, actually extends into the *gag* coding region. Retroviral vectors therefore include this entire sequence (ψ^+) to ensure high titer.

14.7.8 SV40 Vectors

SV40-derived transduction vectors are rarely used these days (132). SV40 is a polyomavirus that infects certain monkey cells. It has a small, icosahedral capsid and a circular, double-stranded DNA genome approximately 5 kbp in size. SV40 was the first animal virus to be characterized in detail at the molecular/genetic level and was hence the first to be developed as a vector.

SV40 lytic infections in monkey cells can be divided into three stages. First, there is a latent stage, where the virus genome is uncoated and transported to the nucleus. This is followed by an "early stage" where early viral genes are expressed and host cell DNA synthesis is stimulated. Finally, in the late stage, the viral genome itself is replicated and progeny genomes are packaged. The host cell is then lysed and progeny virions are released. The SV40 genome has two transcription units known as the *early and late regions*, which have opposite polarities. The transcriptional start sites are located close together, facing outward, and are separated by a complex regulatory

region containing early and late promoters, an enhancer, and the SV40 origin of replication. Both transcription units encode single transcripts that are differentially spliced to yield multiple products. The early transcript produces two mature mRNAs encoding the large T- and small t-antigens (tumor antigens), involved in replication and transcriptional control. The T-antigen is essential for viral replication and must be supplied in *trans* to SV40-derived vectors lacking this function. In addition, the T-antigen also plays a major role in the stimulation of host DNA synthesis by interfering with the regulation of the cell cycle. Hence, cells such as COS-7, which express T-antigen constitutively, are transformed into a continuously proliferating state. The late transcript produces three partially overlapping mRNAs that encode the major coat protein VP1 and the minor coat proteins VP2 and VP3.

In the first SV40 vectors, either the entire early region or the entire late region could be replaced by foreign DNA. As both regions are essential for viral propagation, missing functions had to be supplied in *trans*. This involved coinfection with a helper virus, until the development of the complementary COS cell lines carrying a defective integrated SV40 genome. Such cell lines allowed the propagation of "early replacement" vectors by supplying T-antigen in *trans*. Many recombinant proteins have been produced in CV-1 or COS cells infected with SV40 vectors (132), but they suffer two serious drawbacks, which have limited their use. First, they have a restricted host range (certain permissive monkey cells, such as CV-1 and its derivatives), and most important, the maximum insert size is limited to 2.5 kbp, due to the capacity of the capsid. Such vectors have become obsolete with the discovery that plasmids carrying the SV40 origin of replication can be propagated in just the same way as the virus but without any limit to the insert size.

14.7.9 Vaccinia and Other Poxvirus Vectors

The poxviruses comprise a large family of DNA viruses, with a genome size ranging from 1 to 300 kbp and a host range including vertebrates and invertebrates (143). The most unusual aspect of this DNA virus family is the cytoplasmic site of replication, which means that the virus must encode and package all the enzymes required for replication and transcription. The best-known poxvirus is variola virus, the agent responsible for smallpox. Much interest was therefore generated by the potential use of recombinant vaccinia vectors, carrying genes from other infectious microorganisms, as live vaccines. Vaccinia virus has been used to express several heterologous viral proteins in mammals, including influenza virus hemagglutinin, hepatitis B surface antigen, and HIV envelope protein, and canarypox virus vectors are currently undergoing clinical trials for vaccination of humans (144). Poxviruses represent an advantageous transient expression system due to the wide host range, strong expression levels, and cytoplasmic transcription (145).

14.7.9.1 Molecular Biology of Vaccinia Virus. Vaccinia virus has a complex structure comprising a central core (containing about 100 proteins) and a lipid envelope derived from the Golgi apparatus (containing a further number of unique viral proteins). The envelope is essential for infection and (*in vitro*) plaque formation, and virions containing the envelope are termed *extracellular enveloped viruses* (145). The majority of infectious particles, however, exist as intracellular naked viruses in the cytoplasm. The vaccinia virus genome is double-stranded linear DNA, although the ends of the DNA strands are sealed by hairpins. The genes of the vaccinia virus genome can be divided into four temporal classes: constant, immediate, intermediate, and late. The constant and immediate genes are expressed as infection begins, using the viral RNA polymerase carried in the virion. The immediate genes encode enzymes and other proteins required for replication and exposure of the genome. Expression of most of the immediate and intermediate genes is mutually exclusive; hence, when intermediate gene expression commences after replication, immediate gene expression ceases. The intermediate genes encode, among other products, late gene transcriptional regulators. The constant genes have both early and late promoters and are hence expressed throughout the infection cycle. The late genes encode packaging proteins, capsid components, and enzymes that are carried in the virion and used immediately after infection.

14.7.9.2 Recombinant Vaccinia Virus Expression Vectors. Vaccinia virus is simple to grow because of its broad host range, including both established cell lines and primary cells. However, the efficiency of plating varies according to cell type (145). The genome is too large to manipulate *in vitro*, and because the virus normally carries its own replication and transcription machinery, recombinant genomes introduced into the cell by transfection are not infectious. Although it is now possible to generate infectious recombinant genomes (144), the strategy of choice is to transfect virus-infected cells with targeting vectors carrying a vaccinia promoter/foreign gene expression unit within a vaccinia homology region, allowing the insertion of foreign DNA by homologous recombination (143,145).

As poxviruses encode their own transcriptional apparatus to allow cytoplasmic transcription, endogenous poxvirus promoters must be used to drive the expression of foreign genes. A number of vaccinia promoters have been used, and the gene expression parameters depend on whether early, late, or constant promoters are chosen (143,145). Early expression may be desirable to avoid

the cytopathic effects of the virus, but the highest levels of transcription are provided by late promoters. The P11 promoter is extensively used and can generate over 1μg of protein/10^6 cells. The constant promoter P7.5 is not quite as active as P11 but allows transcription throughout the replication cycle and is widely used. The vaccinia virus early transcriptional apparatus uses a specific transcriptional termination signal with the consensus sequence TTTTTNT; so it is advisable to eliminate such motifs within foreign genes to prevent possible truncation. It is also notable that, due to cytoplasmic transcription, vaccinia virus contains no introns and cannot splice introns present in foreign genes. Therefore, vaccinia vectors must be used to express cDNA sequences or minigenes with introns artificially removed. Higher levels of foreign gene expression can be achieved using a hybrid expression system in which the transgene is driven by the bacteriophage T7 promoter, and the T7 RNA polymerase is expressed from a second vector (146). High level transient expression can be achieved if the T7-expressing vector is a plasmid, transiently present in the cell following transfection. More prolonged expression is achieved by incorporating the T7 gene under the control of a vaccinia promoter in a second recombinant virus vector. For toxic proteins, inducible expression systems have also been designed. One example incorporates a strong vaccinia promoter, such as 4b, combined with the *lac* operator sequence from *E. coli*. The foreign gene is coexpressed with *E. coli lacI*, encoding the Lac repressor, allowing foreign gene expression to be regulated by isopropyl-β-D-thiogalactopyranoside (IPTG).

Vaccinia forms large plaques on permissive cells, and these can be lifted onto nitrocellulose or nylon filters and subjected to hybridization-based screening for the foreign gene. Negative TK selection is used where the foreign gene is inserted into the viral *Tk* locus: tk^- viruses are resistant to the normally lethal effects of 5-bromodeoxyuridine and can be selected on this basis, although naturally occurring tk^- mutants are coselected and true recombinants must still be identified by hybridization. Negative HA selection is used where the foreign gene is inserted into the viral hemagglutinin locus: When chicken erythrocytes are added to the plate, HA plaques are clear, whereas wild-type plaques are red. Selection can also be accomplished by cotransfer of a dominant selectable marker such as *neo* or *gpt* or a visible marker such as *lacZ*. The latter is a popular screening method: Recombinant plaques become blue when incubated in the presence of X-gal, while parental plaques remain clear.

14.7.10 Hybrid Viral Vectors

Individual viruses have certain advantages and disadvantages as vectors, and none is suitable for all applications (103). For instance, herpes virus and adenovirus each has a broad host range, and herpes virus in particular has a large capacity, but neither integrates efficiently into the host genome. Conversely, while AAV integrates with great efficiency, it has a limited capacity. Recently, there has been an effort to design hybrid viral vectors with selected advantageous properties from each of the component viruses. This is one direction in which the field of vector development could expand in the next few years, providing vectors for specific applications, especially for gene therapy (103). Using the example given, a HSV vector carrying inducible AAV *rep* functions could be used to carry recombinant AAV into a broad range of cells, facilitating transfer of the AAV passenger to the genome. The advantage of this strategy is that the AAV genome does not need to be packaged, and there would therefore be no size constraints on the foreign DNA it could carry.

14.8 EXPRESSION PARAMETERS AND OPTIMIZATION—VECTOR AND INSERT SEQUENCES

Sequences in the vector and the insert play a major role in the regulation of foreign gene expression at all levels (transcription, RNA processing, translation, and beyond), and to a large degree, the effect of such sequences is predictable. Much less predicable is the influence of the cellular environment, particularly on integrated transgenes, which are subject to position and dosage effects, and also to variations in the level of DNA methylation.

14.8.1 Transcriptional Initiation: Promoters and Enhancers

Transcriptional initiation is the rate-limiting step in the expression of most higher eukaryotic genes. Control is mediated by *cis*-acting DNA elements that act as binding sites for *trans*-acting regulators termed *transcription factors*. Transcription factors can act positively or negatively and function in one of three ways: (i) by interacting with the transcriptional apparatus to recruit RNA polymerase, and thus influencing the stability of the initiation complex; (ii) by affecting chromatin structure or DNA conformation by displacing a nucleosome or by introducing a kink in the DNA; or (iii) indirectly, by influencing the activity of a second transcription factor.

In animals, many genes are expressed in complex spatial, temporal, and inducible patterns. The manner in which a particular gene is transcribed depends on the combination of *cis*-acting recognition sequences controlling it and the availability of functional transcription factors in the cell (147). Most genes are controlled by at least two functionally distinct elements: a *promoter*, which is located at the 5′ side of the gene and directly interacts with the initiation

complex, and an *enhancer*, which may be located some distance away and interacts with the initiation complex by looping out of the intervening DNA. The promoter is minimally the sequence where RNA polymerase is loaded, and usually consists of an *initiator element* surrounding the transcriptional start site, and/or the *TATA box* located about 25-bp upstream of the start site. The initiator and TATA box are not present in all promoters, but when they are present, they are in the same orientation and on the same strand. Promoters lacking an initiator element typically have multiple start sites because RNA polymerase is not loaded at a unique position. Further motifs are located 5′ to this *basal promoter* and comprise the *upstream promoter elements*. These include (i) the CAAT box, GC-rich boxes, and other elements, which act as binding sites for transcriptional activators; (ii) motifs that bind transcription factors synthesized or activated only in certain cell types and/or at certain developmental stages; and (iii) response elements that bind transcription factors whose activity is inducible or repressible by endogenous and exogenous signals. Enhancers are made up of different motifs, some of which may act generally and some of which may confer cell-type, temporal, or inducible specificity on the gene. Promoters control basal transcription and are therefore orientated so that transcription proceeds only in one direction. Enhancers act to stimulate transcription from a promoter but, because they cannot load RNA polymerase, they have very little promoter activity themselves. Enhancers act in a position-, orientation-, and distance-independent manner and may stimulate transcription up to 1000-fold from a given promoter.

14.8.2 Endogenous and Constitutive Viral Promoters

In the first gene transfer experiments, mammalian transgenes were expressed under the control of their own transcriptional control sequences. As mammalian regulatory elements began to be defined, the use of endogenous promoters continued to impose severe limitations on the range of cells in which foreign genes could be expressed. The rate of recombinant protein expression was wholly dependent on the ability of the cell line chosen to utilize particular promoters and enhancers (20).

The cloning of viral regulatory elements was a breakthrough in gene expression technology. Hence, foreign genes cloned in recombinant viral vectors are often expressed under the control of the most active promoters and enhancers from that viral system, especially as this often represents the most convenient cloning strategy. Examples include the baculovirus polyhedrin and p10 promoters (121), the adenoviral E1 promoter (104), and the vaccinia virus p7.5 promoter (143). Many plasmid overexpression vectors employ the most transcriptionally active promoter/enhancer systems, which maximize the transcription of the cloned gene, and allow expression in a broad range of transfected cells. The most popular systems are the SV40 early promoter and enhancer (148), the Rous sarcoma virus LTR promoter and enhancer (149), and the human cytomegalovirus immediate early promoter (150). These elements function in a broader range of cells because although a virus may not be able to gain entry into all cells due to a lack of appropriate surface receptors, the transcriptional control elements have often evolved to exploit transcription factors present in many cells. While the replication of SV40 is restricted to certain simian cells, the SV40 promoter/enhancer functions in most mammalian cells. Certain cells appear to repress transcription from particular viral promoters; for example, the human embryonic kidney cell line 293, which is widely exploited for propagation of adenoviral vectors, does not support transcription from the SV40 promoter (151).

The advent of transgenic technology and gene transfer to live organisms has resulted in a new requirement for cell- and stage-specific promoters to restrict transgene expression to particular cell types. Examples include the use of cell-specific promoters to ablate particular cell types, the use of milk promoters to obtain high yields of recombinant protein in the milk of transgenic mice and livestock, and the use of neuron-specific promoters to ensure that herpes virus vectors delivered to the brain express transgenes only in neurons and not in glial or epithelial cells.

14.8.3 Inducible Promoters

While high level constitutive protein expression may be suitable for many applications, there are certain situations where the external control of transgene expression is desirable. Where protein overexpression is the aim, external control is required if the recombinant protein is potentially cytotoxic or cytostatic. Furthermore, many experiments require transgenes to be activated at a certain time or for a certain duration.

The earliest experiments involving external transgene regulation took advantage of endogenous inducible systems (152). The best-characterized of these include the heat shock promoter (responsive to elevated temperature) (153), the metallothionein promoter (responsive to the presence of heavy metals such as cadmium and zinc) (154), the mouse mammary tumor virus (MMTV) LTR promoter (responsive to dexamethosone) (155), and the interferon-β promoter (responsive to interferon, viral infection, and dsRNA) (156). A transgene placed under the control of one of these regulatory elements could be stably integrated, and protein expression could be induced by shifting to an elevated temperature or by adding the appropriate inducing substance to the growth medium. These systems suffer from one or more of the following major disadvantages (157): (i) substantial *leakage* (background transgene activity in the noninduced

state); (ii) low *induction ratio* (the ratio of induced to noninduced protein yield); (iii) cytotoxic effects of the inducing agent; and (iv) the concomitant activation of other endogenous genes whose activity may be undesirable or may interfere with the system being studied. For example, activation of the heat shock promoter can induce transgene activity up to 100-fold, but the high temperature causes extensive cell death, blocks protein synthesis, and interferes with protein secretion. Protein synthesis begins when cells are returned to 37°C, but the rate of transcription then drops. Similarly, the metallothionien promoter has a high basal transcription level, an induction ratio of <10, and cadmium is cytotoxic. The glucocorticoid response element of the MMTV LTR promoter provides a more effective system because there is only minimal leakage, but the induction ratio is <10, and other hormone-responsive genes are activated. These promoters have also been used in transgenic animals. In this context, even moderate leakage is unacceptable. A further disadvantage is the unexpected and often undesirable tissue-specific effects of induction, reflecting the tissue-specific distribution of transcription factors or the differential uptake of the inducing agent.

14.8.4 Heterologous, Recombinant, and Artificial Inducible Systems

Many of the problems attributed to the use of endogenous inducible systems can be addressed using systems that are heterologous, recombinant, or totally synthetic. A disadvantage of this approach is that the components of the system (e.g. genes encoding the appropriate *trans*-acting regulators) have to be introduced into the cell along with the target gene and its control sequences. This can be a problem when generating transgenic animals, and for this reason, specific regulator strains of mice have been developed. These can be used to "cross in" heterologous regulatory systems by breeding with transgenic animals carrying the regulatable transgene of interest. Despite this complication, the advantages of nonendogenous systems are manifold (157):

- Transgene induction is specific to exogenously supplied, nontoxic agents.
- Transgene induction does not interfere with any endogenous pathway because no endogenous genes are affected.
- There is no leaking—in the noninduced state, transgene expression is minimal.
- Undesirable cell type–specific effects of induction can be eliminated; alternatively, transgene expression can be induced in specific cell types by design.
- The inducing agent can be chosen to penetrate cells quickly for rapid induction and decay quickly for prompt return to the basal state.

All such systems are designed around a switch principle, where transgene expression is controlled by a heterologous, recombinant, or artificial response element. This is activated (or repressed) by a heterologous, recombinant, or artificial *trans*-acting regulator, whose activity is modulated by a small, exogenously supplied molecule (the inducer). Four major types of system have been exploited (Fig. 14.9): the *E. coli lac* operon (158), the *E. coli tet* operon (159,160), the *Drosophila* molting hormone ecdysone (161), and mammalian steroid hormones (157). Not all inducible switches function at the transcriptional level, and switches at the protein level are discussed later.

The *E. coli lac* system (158) is based on the *lacI* gene, which encodes a transcriptional repressor protein. In the absence of lactose, the LacI repressor binds to operator sites around the transcriptional start site and prevents RNA polymerase initiating transcription. The presence of lactose in the medium results in the synthesis of a metabolic by-product, allolactose. This binds to the repressor, effecting a conformational change that causes it to release the DNA. The same result arises from treatment with a gratuitous inducer, IPTG. Transcription of the genes for lactose catabolism then commences. The strategy for transgene regulation in animal cells is to place a *lac* operator sequence downstream of the transgene transcriptional start site and introduce a second expression construct constitutively expressing the *lacI* gene. Under basal conditions, the transgene is repressed, but if IPTG is added to the medium, the repressor is released from the operator site, allowing transgene expression. This system achieves an induction ratio of about 3–500, up to 100-fold greater than chemical induction systems. However, the number and position of *lac* operator sites in the target gene appears to be critical for correct regulation (159). The original *E. coli tet* system, pioneered in transgenic tobacco plants, was based on a similar principle to the *lac* system. The *tetR* gene encodes a repressor that binds to operator sequences in the *tet* operon when tetracycline is absent. Here, tetracycline itself is the inducer and causes the release of the repressor and induction of the *tet* genes. The operational parameters of the *lac* and *tet* systems in mammalian cells were similar, except that the number and position of *tet* operator sequences was less important for inductive control than the equivalent *lac* operators. The original *lac* and *tet* systems also suffered certain disadvantages. To suppress transgene activity fully, high levels of LacI or TetR proteins were required and were found to be cytotoxic. Furthermore, IPTG and tetracycline levels were slow to decay, resulting in a long time lag before induction.

Some disadvantages of the "repressor"-based systems have been addressed by converting TetR and LacI into activators, by generating fusion proteins in which the repressor is joined to the HSV VP16 transactivator (162,163). In the

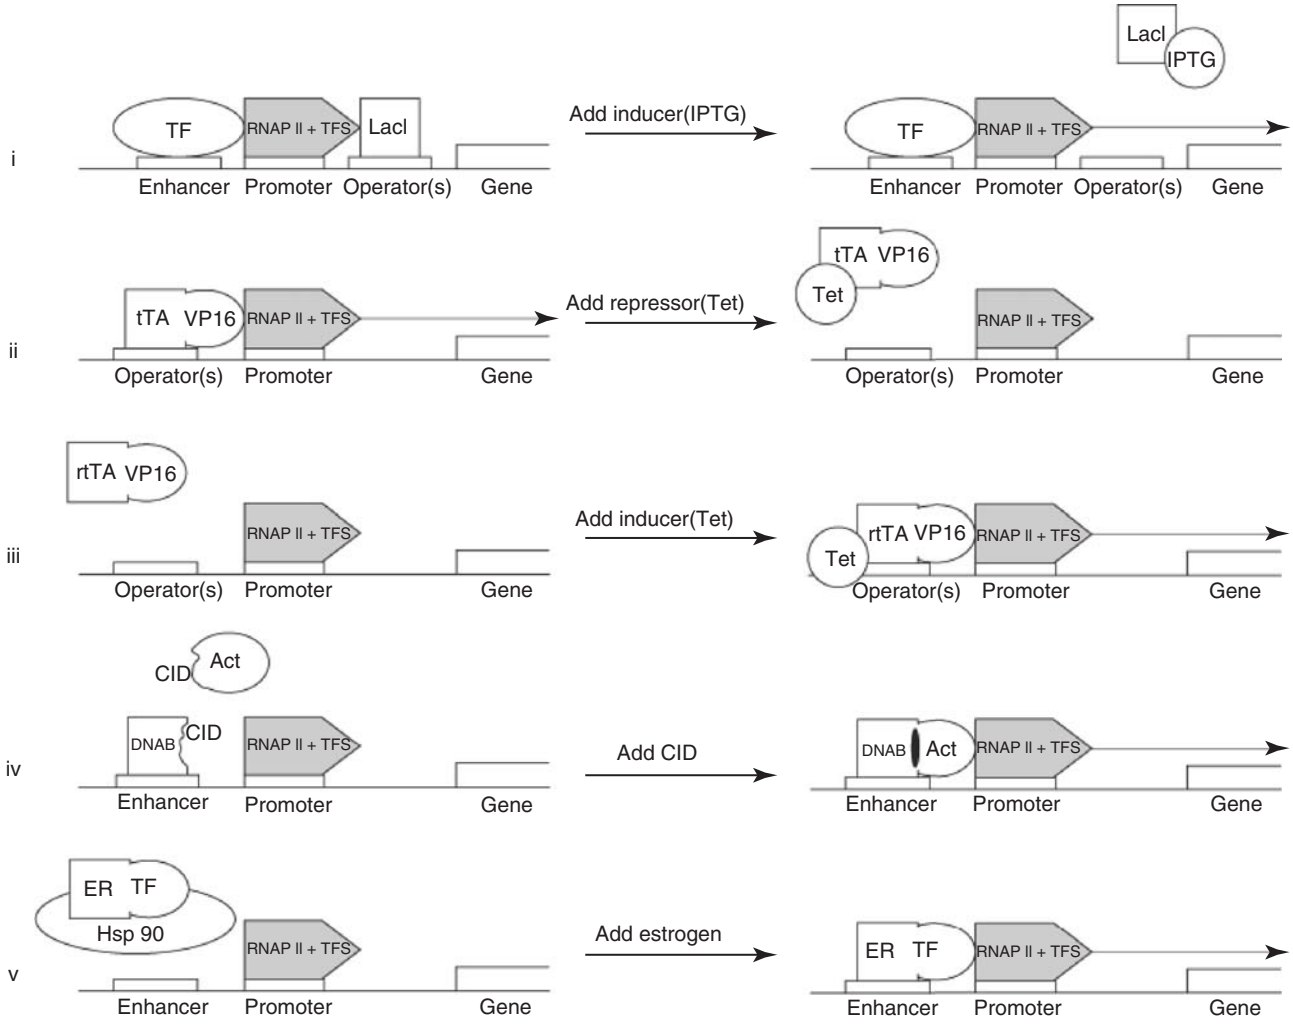

Figure 14.9. Mechanisms of inducible transgene control. (a) Repressor-based system, for example, the Lac switch. The transgene construct contains *lac* operator(s), which bind LacI repressor and prevent transcription. Induction is achieved with IPTG, which binds to and inactivates the repressor, causing it to release the DNA. (b) Activator-based system, for example, tTA. The *E. coli* Tet repressor is fused to a transcriptional activation domain, for example, VP16. The transgene contains *tet* operators that now function as enhancers. Introducing tetracycline into the system inactivates tTA causing transgene repression. (c) Reverse activator-based system, utilizing a mutated Tet repressor–VP16 fusion, which binds to DNA in the presence of tetracycline and releases DNA in its absence. (d) CID system. A transcription factor is expressed as separate DNA-binding and activation domains, each including a binding site for a bivalent ligand such as FKBP12. Introducing the ligand into the system causes dimerization and transcription factor activity. (e) Steroid-based system. A transcription factor is expressed as an estrogen receptor fusion protein. In the absence of estrogen, the fusion protein is sequestered into an inactive complex by Hsp90. Introducing estrogen to the system releases, and hence activates, the transcription factor. *Abbreviations:* TF, transcription factor; RNAP, RNA polymerase; IPTG, isopropyl-β-D-thiogalactopyranoside; Tet, tetracycline; Act, activator domain; DNAB, DNA-binding domain; ER, estrogen receptor.

case of the *tet* system, the fusion product (termed *tTA*) confers constitutive transgene activity in the absence of tetracycline and is suppressible by tetracycline (or its derivative deoxycycline). These systems have a reduced basal transcription level because a eukaryotic enhancer is not required (the operator now provides the enhancer activity) and high levels of repressor protein are unnecessary. This provides an induction ratio in the order of 10^5. One disadvantage, however, is the constant requirement for tetracycline in the growth medium (for cells) or drinking water (for transgenic

animals) to maintain the basal state. This is toxic in many experimental systems, and the unequal distribution of tetracycline results in fluctuation in the basal level of transgene activity, which is intolerable for the regulated expression of some proteins. Furthermore, as induction requires the absence of tetracycline, it is dependent on the rate at which tetracycline can be eliminated. The tTA protein has also proven to be toxic when expressed at high levels, although autoregulatory systems have been designed to optimize tTA expression levels. These problems have been addressed by generating a mutated form of the tTA activator whose DNA-binding activity is improved rather than abolished by tetracycline (164). This protein (termed *rtTA*, reverse tTA) is thus an activator in the presence of tetracycline, removing the requirement for long-term exposure to the inducer. Numerous plasmid- and viral-based delivery vectors have been constructed (157).

The *Drosophila* ecdysone system (161) exploits a steroid hormone signaling pathway endogenous to insect cells but absent from mammalian cells. The steroid hormone ecdysone is responsible for the extensive morphological changes that occur during molting in *Drosophila*. The hormone acts through a heterodimeric transcription factor of the nuclear receptor family, comprising the products of the genes *ecr* (ecdysone receptor) and *usp* (ultraspiracle). This system can be used for transgene regulation by including an ecdysone response element upstream of the transgene and cotransfecting cells with constructs carrying the two *Drosophila* genes encoding the receptor. Transgene induction is achieved by treating cells with either ecdysone or its analog muristerone A. As both the receptor and its response element are insect specific, neither the ligand nor its receptor has any toxic or other physiological effects on mammalian cells. Ecdysone and muristerone A appear to be harmless when injected into mice and are totally eliminated within a few hours. Despite its advantages, the original ecdysone system had a poor induction ratio. This problem has been addressed by introducing mammalian components into the system to generate hybrid receptors recognizing totally artificial response elements. A systems has recently been described in which the Ecr protein is expressed as a fusion with the HSV transactivator protein VP16 and the mammalian glucocorticoid receptor (157). The Usp protein is replaced by its mammalian homolog, the retinoid X receptor. The resulting hybrid recombinant receptor responds to ecdysone and muristerone A and binds to an artificial response element recognized by no other receptor of mammalian or insect origin. This powerful system has minimal background activity and an induction ratio of up to 1000. In addition, because the hormones are eliminated rapidly from cells and animals, this system enables rapid induction and return to the basal state. Perhaps the most promising approach is the construction of a recombinant progesterone receptor carrying the yeast GAL4 DNA-binding domain and the HSV transactivator VP16 (165,166). This receptor is unable to bind progesterone, but can bind the progesterone antagonist RU486, also known as *mifepristone*. Transgenes driven by the yeast GAL4 recognition site are induced by RU486, apparently at levels low enough not to affect endogenous progesterone activity. However, these systems suffer from leakage, low induction ratio, and undesirable physiological effects.

A recently described system of transgene regulation exploits the yeast two-hybrid system. This technique, known as *chemically induced dimerization* (CID), uses a divalent ligand simultaneously to bind and hence aggregate separate DNA-binding and transactivation domains to generate a hybrid transcription factor. This facilitates very tight transgene regulation and shows minimal background effects. The initial system exploited the immunophilin-binding domain of the immunosuppressant drug FK-506. A divalent homodimer of this drug, FK-1012, binds to two immunophilin domains and promotes dimerization (167). A problem with this system is that homodimer transactivators and homodimer DNA-binding domains are generated at high frequency. More recent systems have used heterodimers of FK-506 and rifamycin, so that only two different proteins are able to dimerize, thus preventing such undesirable interactions (168). Unfortunately, while these CIDs penetrate and decay rapidly, they are only active at concentrations causing immunosuppressive side effects.

14.8.5 Transcriptional Termination and RNA Processing

In eukaryotic cells, the primary transcripts of protein-encoding genes are extensively processed before export from the nucleus for translation. The processing steps include the addition of an inverted 7-methylguanosine cap to the 5′ end, the removal of introns by splicing, the cleavage and polyadenylation of the 3′ end, and the methylation of certain internal bases (169). The function of internal methylation is not understood, but the other modification steps are essential for message stability, nuclear export, and efficient translation. These factors must therefore be taken into account when designing expression vectors.

14.8.5.1 Capping. All eukaryotic mRNAs are capped. The capping process occurs immediately following transcriptional initiation, probably because the enzyme responsible (mRNA guanyltransferase) is associated with the initiation complex. Most animal cell mRNAs have a type 1 cap, which is methylated at position G^7 of the cap itself and at position $O^{2'}$ on the ribose moiety of the next residue. The capping reaction occurs automatically;

hence, no special precautions are needed to ensure that vector-encoded transcripts are capped. The cap serves a number of functions—it appears to be required for nuclear export, it prevents 5′ end degradation, and it serves as a recognition site for the factors that initiate translation.

14.8.5.2 Intron Splicing. Most genes in animal cells are interrupted by one or more noncoding segments of DNA, known as *introns*. These are removed from the primary transcript by the recognition of 5′ and 3′ splice sites by a large, *trans*-acting spliceosome assembly. The activities of the spliceosome result in a transesterification reaction that joins the upstream and downstream exons and eliminates the intron. Many vertebrate genes contain large and numerous introns, and the majority of mammalian genes comprise more intron material than exon material, in some cases exceeding 95% of the transcription unit. However, due to the size constraints of many expression vectors, the simplicity of *in vitro* manipulation, the genes are often expressed as cDNAs or as artificial minigenes with all introns removed (20,6,170).

Splicing might be required for efficient mRNA synthesis, prompting the inclusion of an intron in the transcription unit. Many investigators have independently confirmed that cDNA expression is either intron dependent or significantly improved in the presence of an intron, in some cases up to 500-fold (170). However, there have also been numerous reports of cDNAs that are efficiently expressed without an intron. Furthermore, there are a number of mammalian genes that lack introns, and the vast majority of bacterial genes lack introns yet are still efficiently expressed in mammalian cells. However, the presence of an intron has rarely been shown to have adverse effects. Genuine introns include the SV40 small t-antigen intron (used, e.g. in vectors marketed by Invitrogen) and the human growth hormone intron. Improved expression has been documented using hybrid introns, for example, comprising a 5′ splice site from the β-globin gene and a 3′ splice site from an immunoglobulin gene. These are particularly close to the ideal splice signal consensus. In some cases, point mutations have been introduced so that introns match the splice consensus perfectly. The requirement for introns in transgenic animals is more widely accepted, and genomic constructs are generally more efficiently expressed than cDNAs (171).

Early investigations showed that the presence or absence of an intron could control gene expression by affecting the resultant levels of mRNA. The role of introns in the regulation of foreign gene expression has been investigated recently, and a posttranscriptional regulatory mechanism has been identified (172). Primary transcripts are associated with proteins during synthesis, processing, and export from the nucleus to form heterogenous ribonucleoproteins (hnRNPs). It appears that intron-containing and intronless genes expressed in the nucleus end up associated with different sets of proteins and that this ribonucleoprotein architecture may affect translational efficiency. The absence of an intron resulted in a significant amount of posttranscriptional silencing, presumably due to repression by hnRNP structure. An intron placed at the 5′ end of the transcript could alleviate this silencing, but a 3′ intron increased the silencing effect. Although these data were obtained using *Xenopus* oocytes rather than mammalian cells, the study provides evidence that the nature of the transcription unit can affect subsequent levels of gene expression by stimulating the recruitment of particular regulatory proteins. While the evidence from mammalian systems is in some cases contradictory, the presence of a 5′ intron is also favored and may indicate that a similar mechanism is in operation.

Another consideration is the nature of the splice signals and the presence of cryptic splice sites. Generally, eukaryotic primary transcripts are spliced in a predictable fashion, even though all introns carry the same consensus splice signals, which are short enough to occur by chance. The sequence context of the splice sites, the distance between them, and the secondary structure adopted by the nascent transcript or completed primary transcript may dictate how the splicing apparatus and RNA interact to define the introns to be removed. If a normal splice site is mutated, one or more local cryptic splice sites may become active, and these are used efficiently even if there is no "leaky" cryptic splice site usage in the wild-type transcript. This readiness to utilize alternative splice sites should be considered when designing recombinant genes with hybrid introns, as they may not be spliced in a predictable fashion and may produce aberrant transcripts that are not translated.

Finally, the requirement for introns should be considered carefully if a viral gene delivery strategy is favored. The inclusion of sense-orientation introns in retroviral vectors can interfere with the viral replication cycle (134,135). If a cDNA or intronless minigene cannot be expressed efficiently, the intron-containing genes must be inserted in the reverse orientation so that the introns are not recognized during the transcription phase of the replication cycle. Poxviruses are unusual DNA viruses that replicate in the cytoplasm, and no viral genes contain introns because the virus does not have access to the nuclear splicing machinery. Therefore, foreign genes cloned in poxvirus vectors such as vaccinia virus must also lack introns (143).

14.8.5.3 Transcriptional Termination and Polyadenylation. The mechanism of transcriptional termination is thought to occur downstream of the mature 3′ end of the transcript, which is generated by endonucleolytic cleavage of the nascent RNA (169). The cleavage reaction is followed by polyadenylation, the addition of a variable number (approximately 200) of adenylate residues to

generate the so-called poly(A) tail. This occurs 10–30 nucleotides downstream of a highly conserved polyadenylation site, with the consensus sequence AAUAAA. A GU-rich sequence downstream of the polyadenylation site may influence the actual position of cleavage. Cleavage and polyadenylation are carried out by a multimeric complex comprising recognition factors that bind to the polyadenylation site, a dimeric cleavage enzyme, and the enzyme polyadenylate polymerase. Although the precise function of polyadenylation is not known, it appears to increase mRNA stability and control mRNA export. If the polyadenylation site is mutated, the level of protein synthesis can drop by as much as 90%. It is therefore essential to include an authentic polyadenylation site and terminator region in expression vectors, downstream of the foreign gene. A number of polyadenylation sites are commonly used, including those from the SV40 early transcription unit and the mouse β-globin gene. The inclusion of a polyadenylation site within the vector removes any reliance on endogenous polyadenylation sites supplied with foreign genes and cDNAs. This is particularly advantageous for the expression of genes and cDNAs with large 3′ UTRs, because these can be trimmed off, an operation that may also improve transgene expression by increasing mRNA stability (170).

14.8.5.4 Polyadenylation Sites in Cointegrate Vectors. Many gene transfer experiments involve the use of cointegrate vectors, that is, vectors containing multiple genes. A cointegrate vector is usually defined as one where linked genes are under separate transcriptional control and gene transfer experiments involving two or three genes linked on the same vector. In such vectors, it is particularly important to include termination/polyadenylation sequences at the end of each transcription unit. If this is not carried out, it is possible for gene expression to be limited at three levels. First, where transcription from one gene reads through into a second downstream gene, *promoter occlusion* can occur. This involves transcription through the promoter of the downstream gene, preventing the assembly of the transcription complex and blocking gene expression (173). Promoter occlusion occurs if two adjacent genes are in the same orientation. If adjacent genes are in opposite orientation, read-through transcription from one gene generates antisense RNA that can block the expression of the second gene at the posttranscriptional level, a phenomenon termed *antisense suppression*. If both promoters are active, both sense and antisense RNA can be generated. These may associate to generate dsRNA, activating the DAI protein kinase, which phosphorylates and inactivates eIF2, a critical translation initiation factor (71). These problems can be alleviated by preventing read-through transcription, through the inclusion of a terminator and polyadenylation site after each gene.

14.8.6 Protein Synthesis

14.8.6.1 Kozak Consensus. The requirements for high efficiency translation of foreign genes in mammalian cells have been studied in great detail (174,175) and reflect three important properties of the foreign gene: (i) the nucleotide sequence surrounding the translational start site, (ii) codon choice throughout the coding region, and (iii) the structure of the 5′ and 3′ UTRs.

The optimal translational start site sequence was defined by Kozak as 5′ CCRCC*AUG*G 3′, with the italicized sequence representing the initiation codon (R is any purine). The adenosine residue of the initiation codon is defined as position +1 of the coding region and the residue immediately 5′ to that is defined as position −1 (there is no position 0). The two most important residues appear to be the purine at position −3 and the guanosine at position +4. Most expression vectors contain the Kozak sequence, although only proteins with valine, alanine, glutamine, glycine, or aspartate as their second residue can be specified by a coding region with guanosine at position +4. Mutations deviating from the Kozak consensus can reduce protein expression levels by up to 90%.

14.8.6.2 Codon Choice. The genetic code is degenerate; hence, most amino acids are encoded by a family of codons. Some codon families (e.g. those encoding leucine and serine) have as many as six members. The analysis of many gene sequences obtained from different organisms has revealed two important principles of codon usage. First, there is codon bias; that is, particular codons within a family are used more often than others. Second, the codon bias differs from species to species, so that a codon favored in one animal might be different to that favored in another (176). Codon bias can reflect several underlying factors. Degeneracy at first and second base positions is caused by the presence of isoaccepting tRNAs, alternative tRNAs that are charged with the same amino acid but recognize distinct codons. Third base degeneracy reflects the relaxed base pairing rules (the so-called wobble rules) at the third base of the codon and the first base of the anticodon, which reflects the modification of tRNA bases. A further reason for codon bias involves bulk properties of the genome. In GC-rich genomes, guanine- or cytosine-containing codons might be favored over adenine- or thymine-containing codons, while in AT-rich genomes, the opposite bias might apply. Codon choice can influence transgene expression at several levels. The progress of translation can be inhibited if a particular codon is favored in the source organism, but not in the host to which the foreign gene is transferred. The translation machinery may pause at a rare codon. This may reduce the rate of protein synthesis, resulting in a lower yield, or it may cause misincorporation, frameshifting, or truncation. This can be addressed by attempts to match codon preference in the

transgene to that of the host, by introducing translationally neutral mutations into the coding region. However, this can sometimes have unpredictable effects by influencing the stability of the mRNA. It should also be borne in mind that rare codons are occasionally used in a regulatory capacity and that under some special circumstances, they may even misread in a programmed fashion. Examples include frameshifting during the translation of retroviral *gag* and *pol* genes and insertion of the rare amino acid selenocysteine (169).

14.8.6.3 Structure of Noncoding Regions. The structure of the 5′ UTR influences translational efficiency by affecting ribosome assembly and scanning (174,175). Ribosomes comprise two subunits, and initial binding involves only the small subunit, which interacts with proteins assembled at the 5′,7-methylguanosine cap, and scans along the mRNA until the first AUG codon is encountered. If the 5′ UTR contains a significant amount of secondary structure, assembly and scanning can be inhibited. The presence of false AUG codons upstream of the genuine start site is also deleterious, especially if they are followed by in-frame termination codons. Most expression vectors are therefore designed to incorporate minimal *processed* 5′ UTR sequences (there may be an intron in the 5′ UTR, but this would not be represented in the processed mRNA) or a 5′ UTR known to function efficiently in concert with the appropriate promoter–enhancer system. The sensitivity of transgene expression to sequences upstream of the initiation codon means that it is important to ensure that sequences at the 5′ end of the insert do not generate secondary structure or additional start codons when integrated into the vector.

A 3′ UTR is not usually included in expression vectors because it serves no function essential for translation. Endogenous 3′ UTRs may contain regulatory elements, such as AU-rich elements conferring instability on the message resulting in rapid turnover (177). Typically, the entire 3′ UTR is removed from cloned genes or cDNAs before insertion, so that the termination codon of the transgene is more or less adjacent to the polyadenylation site (170).

14.8.6.4 IRESs and Polycistronic Vectors. Multiple genes may be expressed on the same cointegrate vector as independent transcription units, by placing each under the control of an independent promoter and polyadenylation site. Another way to express multiple genes on a single vector is to include several coding regions in the same polycistronic message. The discovery of IRES elements provided a useful strategy for transgene coexpression and selection for high level foreign gene expression (178). A reporter gene such as *lacZ* can be placed downstream of an IRES in the same transcription unit as a given foreign gene. This allows cells expressing the foreign gene to be identified through coexpression of β-galactosidase. This is particularly useful in transgenic animals where expression patterns can be mapped and the effect of heterologous protein expression determined in the same animals (179). In knockout mice, the insertion of an IRES–*lacZ* construct into an endogenous gene facilitates both knockout by insertional mutagenesis and the identification of cells that now lack the targeted gene product (179). The expression of genes downstream of an IRES is much less efficient than normal 5′ cap-dependent genes. This can be exploited to isolate cells expressing foreign genes at high levels. If a selectable marker is placed in the downstream position, only cells with high levels of marker expression will survive, and this will identify cells with elevated levels of foreign gene expression (170).

14.8.7 Posttranslational Events

During or following synthesis, all polypeptides undergo some form of covalent modification before folding to form functional proteins. Such modifications may involve minor chemical changes to specific amino acid side chains or the addition of major chemical adducts such as complex oligosaccharides or lipids. Other proteins are modified by endo- or exoproteolytic cleavage. In some cases, protein modification may be reversible and can be used as a means to regulate protein activity (e.g. phosphorylation of serine, threonine, and tyrosine residues) or can be permanent (e.g. glycosylation and proteolytic cleavage). Certain forms of modification are required for the protein to adopt its correct tertiary or quaternary structure (e.g. the formation of disulfide bonds) or are characteristic of particular protein sorting pathways in the cell; for example, N-linked glycosylation occurs in the endoplasmic reticulum (ER) lumen and O-linked glycosylation occurs in the Golgi network. In some cases, particular modifications are required for protein sorting (e.g. the addition of mannose-6-phosphate groups targets proteins to lysosomes and the cleavage of signal peptides may be required to reveal further targeting motifs, e.g. in mitochondrial import). Finally, some forms of protein modification are involved in the regulation of protein degradation (e.g. ubiquitination of lysine residues).

The secretion of proteins from mammalian cells involves a series of modifications that take place in the ER and Golgi (180,181). Such proteins generally carry an N-terminal signal peptide that causes the ribosome to associate with the ER membrane. The protein is then cotranslationally translocated into the ER lumen, a process termed *vectorial discharge*. In the lumen, the signal peptide is cleaved, and a preformed high mannose oligosaccharide is added to asparagine residues in the "sequon" element with the consensus sequence Asn–Xaa–Ser/Thr (Xaa is any residue except proline). Terminal glucose residues and

probably a single mannose residue are removed, and fatty acylation may also occur, before the part-modified protein is transported to the Golgi network. In the Golgi, further modifications occur to the N-linked glycosyl groups, including the hydrolysis of more mannose residues, and the addition of distinct oilgosaccharide groups such as fucose, galactose, *N*-acetylglucosamine, and sialic acid. De novo O-linked glycosylation may also occur by the transfer of *N*-acetylglucosamine groups to serine and threonine residues. In addition to glycosylation and acylation, other forms of modification also occur in the secretory pathway, such as the O^4-sulfation of tyrosine residues, and various forms of proteolytic processing.

14.8.7.1 Factors Affecting the Processing of Recombinant Proteins. Three major factors affect the processing of recombinant proteins: (i) correct targeting of the protein, (ii) the ability of the protein to fold and undergo proper modification, and (iii) the availability of appropriate enzymes in the host cell. A protein that requires a particular form of posttranslational modification needs to be targeted to the correct intracellular compartment for that processing to occur. Hence, a normally secreted protein whose coding region is truncated so that the signal peptide is no longer translated will likely accumulate in the cytoplasm in a biologically inactive form. Many vectors are available with integral secretory signals to target expressed proteins to the secretory network. Other targeting motifs, such as mitochondrial entry sequences and nuclear localization signals, are also terminal, and the same precautions need to be taken when expressing proteins containing these signals.

The modification of a protein is dependent on the presence of appropriate targeting sequences, the presence of modification consensus sequences (such as the N-linked glycosylation sequon), the sequence context surrounding this motif, and the overall tertiary conformation of the protein. Modification relies not just on the presence of particular motifs in the polypeptide primary structure, but also on the tertiary structural context in which this motif is presented to the processing enzymes and the enzyme positioning (e.g. in the Golgi). Furthermore, where modification occurs in a series of successive steps, each modification may cause the tertiary structure of the protein to change to make it more accessible to the next processing enzyme. Hence, any alteration to the primary structure of a polypeptide may cause a critical deviation from the optimum tertiary conformation, resulting in the failure of a particular modification reaction (182). This is demonstrated by the alteration of, for example, glycosylation patterns following mutations causing nonconservative amino acid changes or following the incorporation of amino acid analogs.

Finally, it has been observed that recombinant proteins may be processed differently in alternative expression hosts, probably reflecting the absence or differential abundance of processing enzymes. Some differences in glycosylation patterns have been observed between alternative mammalian hosts; for example, secreted proteins produced in CHO cells tend to have more terminal sialic acid residues than those produced in COS cells (183,184). Insect cells use a distinct N-linked glycosylation pathway to that found in mammals (185). Proteins expressed in the popular Sf9 cell line cannot produce certain glycosylation intermediates, such as side chains ending in galactose–sialic acid residues, and this is thought to reflect the absence of a key processing enzyme synthesized in mammalian cells, *N*-acetyl-β-glucosidase. However, cell lines derived from the alternative host *E. acrea* do synthesize *N*-acetyl-β-glucosidase and are hence more likely to produce authentic mammalian glycoproteins. Recently, the ability of the baculovirus expression system to coexpress two or more proteins simultaneously has been exploited to alter the endogenous glycosylation pathway of Sf9 cells (186).

14.8.7.2 Many endogenous proteins are processed by cleavage. Some are autoproteolytic, while others, including inactive proenzymes (zymogens), growth factors, and a large number of hormones and neuropeptides (e.g. proinsulin, proglucagon, prorenin, proenkephalin, prodynorphin) require modification in *trans*. The overexpression of such recombinant proteins is often hampered by the low level of endogenous proteases, termed *proprotein convertases*. Recently, a family of proprotein convertases has been extensively characterized and several members have been cloned (187). Several groups have successfully coexpressed the precursor and its cognate proprotein convertase in an attempt to generate high yields of mature recombinant protein, such as insulin in insect cells (188), von Willebrand factor in CHO cells (189), and coagulation factor C in transgenic pigs (190).

14.8.7.3 Inducible Protein Activity. Two promising approaches are the use of steroid-binding fusion proteins (191) and the exploitation of CID (167). The estrogen receptor exists in an inert state in the absence of estrogen because the hormone-binding domain interacts with heat shock protein 90 (Hsp90) to form an inactive complex. When estrogen is present, however, a conformational change causes the release of the receptor, which is then free to dimerize and interact with DNA. The principle of the steroid-based posttranslational switch is that any protein expressed as a fusion with a hormone-binding domain will similarly interact with Hsp90 and form an inactive complex (191). A given heterologous protein can thus be expressed at high levels in an inactive state and can be activated by feeding cells or transgenic animals with estrogen (reviewed in Ref. 192). The kinetics of the switch are rapid, on the order of seconds rather than hours, and can therefore be used to study rapid cellular events

such as those occurring in signal transduction pathways. A more recently developed version of this system uses a modified estrogen receptor, which is highly specific for the ligand 4-hydroxytamoxifen, thus removing many of the pleiotropic effects of estrogen administration (193).

The CID system takes advantage of the ability of ligands to facilitate the dimerization of proteins carrying ligand-binding domains (167). The CID system has already been described as a transcriptional switch, in which separate DNA-binding and transactivation domains expressed as ligand-binding fusion proteins are conditionally dimerized by supplying a divalent ligand. The same idea can be exploited to activate proteins whose normal activation requires a dimerization step or the separately expressed domains of monomeric proteins. CID has been successfully used to regulate the activity of a range of transmembrane receptors and intracellular signaling proteins by conditional activation. It is also possible to use inhibitory proteins to facilitate conditional gene silencing.

14.9 EXPRESSION PARAMETEROPTIMIZATION—CONSEQUENCES OF TRANSGENE INTEGRATION

The integration of foreign DNA into the genome of a host cell is a chaotic and typically random process (194). Certain viral vectors display various degrees of regional specificity, for example, retroviruses may preferentially integrate into actively transcribed DNA (134,135) and wild-type AAV shows definite preference for a particular region of the human genome (111). The existence of preferential integration sites for plasmid DNA transfected into animal cells has been suggested (195). The integration of foreign genes into animal genomes is highly variable among cell lines or transgenic animals generated by independent transformation events. Transgene integration may cause unexpected changes in phenotype. Conversely, transgene expression within a clone of transformed cells, or within a line of transgenic animals, is more likely to be comparable.

As DNA integration is both chaotic and random, several molecular parameters can vary between clones but would be expected to remain the same within clones (194). First, the position of integration can vary, giving rise to the so-called position effects that reflect the influence of the local molecular environment. Second, the number of integrated transgene copies can vary, giving rise to gene *dosage effects*. Third, transgene structure and organization can vary, including factors such as the internal mutation, rearrangement, or truncation of single transgenes and the orientation and arrangement of adjacent transgenes. Finally, transgenes can become de novo methylated, which often causes transgene silencing and may represent a genomic defense mechanism.

14.9.1 Timing of Integration

When DNA is introduced into cultured cells, individual cells are selected on the basis of their ability to express the foreign DNA on a long-term basis, which is an evidence for stable integration. For transgenic animals, however, the timing of integration may play an important role in the behavior of transgenes in different cells and hence determine the characteristics of the whole animal. In mice, DNA introduced into the fertilized egg by pronuclear microinjection often integrates after DNA replication, or after one or more cell divisions, and the resulting embryo may thus be mosaic for transgene insertion. This means that a transgene has to be transmitted through the germline before it is stably inherited.

Mice, and mammals generally, undergo a characteristic form of development where very little material is stored in the egg, and zygotic transcription begins at the two-cell stage. Conversely, animals such as fish and amphibians have large eggs with a stockpile of proteins and RNA. The early embryo undergoes a rapid series of synchronous cleavage divisions followed by an event termed the *mid-blastula transition*, where division becomes asynchronous and zygotic transcription begins. This event is thought to reflect the titration of DNA packaging proteins such as histones. It is the initial surplus of these DNA packaging proteins that may be responsible for the unique behavior of DNA introduced into fish and amphibian eggs. Unlike mammalian systems, where the DNA is soon integrated, exogenous DNA in fish and frog eggs is rapidly concatemerized and subject to extrachromosomal replication (196). As the embryo cleaves, the distribution of transgene copies is arbitrary, resulting in mosaic and variable expression levels between equivalent cells. Although mosaic transgene expression is widely attributed to differential *distribution* of the transgene in cells of the early embryo, there may also be factors causing differential transgene *expression*: This applies to fish, frogs, and mammals (197). Eventually, exogenous DNA is degraded, but at some point, integration may occur. While this is an early event in mouse development, with fish and frogs, integration occurs much later, and the resulting mosaics may contain only a low percentage of transformed cells (reflecting integration after perhaps 12 rounds of cleavage). Consequently, there are different position and dosage effects in different cells of the same animal, and it may also be more difficult to obtain fully transgenic animals.

14.9.2 The Fate of Foreign DNA and the Structure of the Transgenome

Exogenous DNA introduced into animal cells rapidly becomes covalently joined to form larger arrays. The size and structure of the arrays depends on the amount, conformation, and complexity of the source DNA. In

techniques such as calcium phosphate transfection, a large amount of DNA enters the cell. In many cases, at least two independent transgenes are introduced (a selectable marker and one or more nonselected genes) and carrier DNA is used to bring the DNA concentration to optimal levels for coprecipitate formation. Carrier DNA is often sheared or sonicated genomic DNA from a convenient source, such as salmon sperm, and is thus linear and of high complexity. Shortly after transfection, the transgenes and carrier DNA form large, randomly arranged arrays reflecting the arbitrary ligation of DNA fragments. This structure, termed the *transgenome*, usually integrates at a single site. It is sometimes unstable and may be subject to full or partial excision, probably reflecting intrachromosomal recombination events (19,198).

In other transfection methods, and in microinjection, carrier DNA is not used. Less DNA therefore enters the cell and the DNA that does reach the nucleus is relatively simple (and hence repetitive) in its sequence. There are two consequences of using smaller amounts of less complex DNA. First, the transgenome is smaller; hence, the number of integrated transgene copies is reduced. Single or multiple copies can integrate, but rarely more than 30 copies are present at a single site. There may be several sites of integration, and a degree of control can be exercised over transgene copy number by varying the amount of DNA introduced into the cell. Second, smaller amounts of DNA are likely to favor the generation of head-to-tail concatemers rather than randomly arranged arrays. This is because larger amounts of DNA (especially carrier DNA) increase the concentration of free DNA ends, and this can stimulate the synthesis of DNA ligase (199). Large amounts of high complexity DNA thus favor random ligation, while small amounts of low complexity DNA favor homologous recombination. In mammals, linear DNA is integrated five times more efficiently than supercoiled plasmid DNA because it provides a substrate for DNA ligase (78). Supercoiled plasmids presumably have to undergo homologous recombination with each other, or become randomly broken, to generate free ends. Although both linear and circular DNA is concatermerized by homologous recombination in mammals, only circular DNA tends to promote concatemerization in frogs and fish, while linear DNA is more likely to form random arrays. This is presumed to reflect the accumulation of stored DNA ligase in the precleavage embryo, which can use linear but not circular DNA as a substrate (200,201). In fish and frogs, the random ligation of linear DNA is much more rapid than the concatemerization of circular DNA, thus linear DNA is more effective for transient expression, episomal replication, and integration (202).

14.9.3 Position Effects

Position effect is a catch-all term used to describe variability in transgene expression conferred by the position of integration. As the earliest transformation experiments, it has been known that the chromosomal locus of a transgene can influence its expression. For example, when a transgene isolated from an anomalously expressing transgenic mouse is microinjected back into eggs, the secondary transgenic mice may express the transgene in the normal manner (203). This suggests that the anomalous expression profile of the primary transgene was due to the site of transgene integration. Position effects are a major cause of differential transgene expression levels among independently derived transformed cell lines or transgenic animals, and they are also thought to reduce or eliminate copy-number dependence in transgene expression. The position of integration can influence transgene expression through at least three mechanisms (Fig. 14.10): the activity of local regulatory elements, the local chromatin structure, and the local state of DNA methylation. These factors may be interdependent.

A transgene may come under the influence of a local regulatory element, and this causes the most specific position effects (16). If a transgene integrates near an endogenous enhancer, it may come under that enhancer's influence, resulting either in the elevation or depression of transcriptional activity, or in transgenic animals, an altered spatial or temporal expression pattern. The effect of local regulatory elements is succinctly demonstrated by the success of entrapment vectors (16). An enhancer trap consists of a reporter gene linked to a minimal promoter. If this integrates near an endogenous enhancer element, the reporter gene expression pattern reveals the properties of the enhancer. In this case, the position effects are desirable and indeed useful—they can lead to the identification and cloning of a novel gene. Transgenes with weak promoters and enhancers are the most susceptible to such position effects, but local enhancers (and silencers) will affect any transgene construct, even those with strong and specific promoters and enhancers of their own.

Transgenes can also integrate within endogenous genes, in which case they may be influenced by local promoter elements or splice signals (12). Again, there are entrapment vectors that exploit this phenomenon. Such vectors contain either a "naked" reporter gene (i.e. one driven simply by a translational start codon that can respond to adjacent promoter elements) or a splice acceptor site, which enables the vector to function as an ectopic exon when it integrates into an endogenous intron. Transgenes integrating at the 5′ end of a gene may come under the control of the endogenous promoter, or the endogenous and transgene promoter elements may combine in a novel and unexpected manner. Transgenes that integrate into the body of an endogenous gene may be expressed either from their own promoter or as an aberrant hybrid mRNA under the control of the endogenous gene promoter.

Not all position effects result from such specific influences. Gene expression is dependent not only on

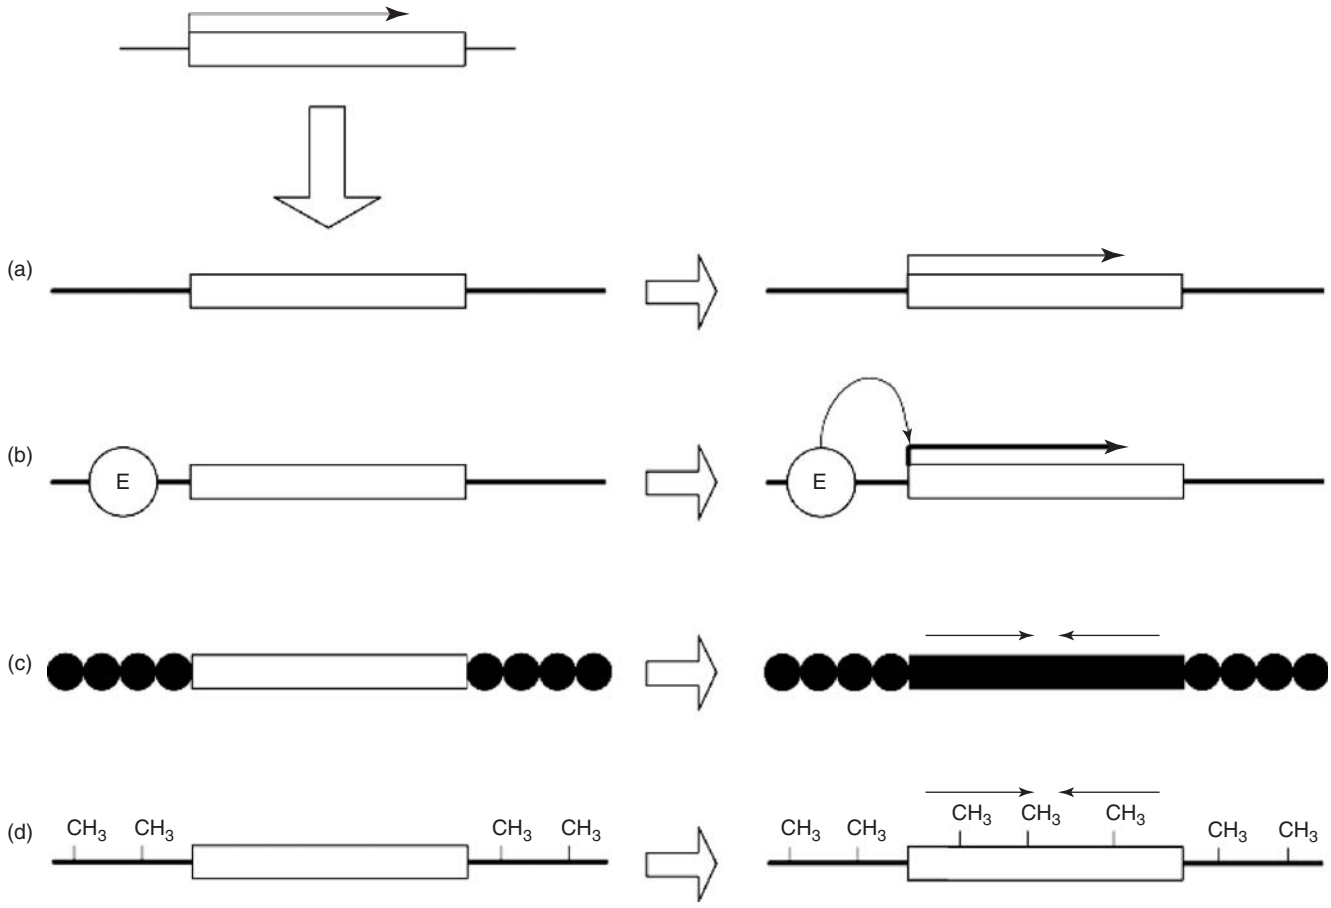

Figure 14.10. Causes of position effects. A transgene under the control of its own promoter (top of figure) integrates into the host genome (left). In (a), there are minimal local influences and the transgene is expressed as expected. In (b), the transgene happens to integrate near an endogenous enhancer; so its expression may be modified by the enhancer. In (c), the transgene integrates into repressed chromatin, while in (d), it integrates into hypermethylated DNA. In either case, the epigenetic structure can spread across the transgene causing silencing.

the availability of specific *cis*-acting sites but also on the local chromatin structure, which may be "open" and transcriptionally active or "closed" and transcriptionally repressed (204). Open and closed chromatin differs in the degree of histone acetylation, the degree of DNA methylation, the presence of certain types of nonhistone protein, and the sensitivity of the DNA to nuclease digestion. A transgene integrating into a region of closed, inactive chromatin (heterochromatin) is often silenced by the spreading of transcriptional repression across the transgene (205). Similarly, if a transgene integrates into hypermethylated DNA, the DNA methylation may also spread across the transgene causing transcriptional silencing. Chromatin structure and DNA methylation are often linked in vertebrates, and indeed, it has been shown recently that methylcytosine-binding proteins exist in a complex with histone deacetylase (206). Certain regions of the genome (e.g. centromeric DNA and the Y chromosome in mammals) consist predominantly of heterochromatin, and transgenes integrating there are likely to be subject to position-dependent silencing. Conversely, other regions of the genome, such as the subtelomeric areas, are highly transcriptionally active, and transgenes integrating there are likely to be efficiently expressed.

Position effects also occur naturally, and in humans, they are often responsible for cancer. If an oncogene is transferred to a new chromosomal locus by a translocation, it may come under the influence of a novel regulatory element, it may fuse with a different gene, or it may find itself integrated into active chromatin, all of which can increase its transcriptional activity, resulting in uncontrolled cell proliferation. In *Drosophila*, a phenomenon often associated with chromosome translocations is *position-effect variegation* (PEV) (207). This occurs when active and repressed chromatin become juxtaposed by a translocation and the transcriptional repression spreads

from the heterochromatin into the active chromatin, but to a different extent in different cells. This reflects the mechanism of heterochromatinization, which is thought to involve the addition of heterochromatin proteins to preexisting heterochromatin. Usually, this occurs until a boundary is reached, but when such a boundary is removed by chromosome rearrangement, the spreading is limited only by the amount of free heterochromatin protein in each cell. Hence, genes near the translocation breakpoint may be inactivated in some cells but remain active in others. This epigenetic state is clonally heritable, causing a variegated pattern resulting from patches of cells with the gene either active or repressed. Similar phenomena occur in transgenic mammals through inconsistent spreading of transcriptional repression from heterochromatin into a transgene. This may cause mosaic transgene activity and is further complicated where there are multiple transgene copies because different numbers of transgenes can be active in different cells. Position effects may therefore cause variable levels of transgene expression, either between individual transgenic animals within a given line or between transgenic lines. For example, discrete patches of transgene-expressing cells surrounded by nonexpressing cells in the mammary gland of transgenic mice expressing β-lactoglobulin transgenes have been observed. It has been proposed that patchy or variegated silencing may be a consequence of the proximity of the transgene array to centromeric heterochromatin (208) or that multicopy transgene arrays may themselves act as the focus for heterochromatin formation (209).

14.9.4 Integration Effects

Position effects describe the influence of the local molecular environment on transgene activity, but the effect may also be reciprocal (2). Transgene integration can generate unexpected phenotypes by influencing the expression of adjacent or even distant genes. The most overt integration effect is insertional mutagenesis, where a transgene integrates into an endogenous gene and generates a mutant phenotype. The phenotype may be apparent immediately if there is only one functional copy of the host gene, if the locus is haploinsufficient, or if the integration event happens to generate a dominant mutant allele. Otherwise, a phenotype may only be observed if the transgene is bred to homozygosity. The effect may be due to simple insertional disruption or through the deletion of cellular DNA surrounding the integration site. This appears to be a totally random process: In some cases, the integration site remains intact; in others, up to 80 kbp of DNA can be deleted. In many cases, insertional mutagenesis by transgene integration has led to the serendipitous isolation of novel interesting genes (14). For example, transgenic mice carrying a tyrosinase transgene were shown to have situs inversus (mirror-image reversal of the left–right axis). This has nothing to do with tyrosinase activity but reveals the functional mutation of a new locus controlling left–right axis specification (210).

More subtle integration effects can also occur. A transgene may cause ectopic activation of a nearby gene that comes under the influence of transgene regulatory elements. This often occurs with retroviral vectors, which carry a strong enhancer–promoter complex in the right-hand LTR. Wild-type retroviruses also show this activity and can occasionally activate an adjacent proto-oncogene causing it to be overexpressed. Specialized "suicide" retroviral vectors have been designed to limit this effect: They have a mutated LTR promoter–enhancer, with transgene expression driven by an internal promoter (142). Another consequence of transgene integration is the alteration of cellular methylation patterns. Surprisingly, the integration of certain sequences can cause the alteration of cellular methylation patterns at sites located a great distance from the integration locus (2).

14.9.5 Copy-Number and Dosage Effects

Foreign DNA may integrate either as a single transgene copy or as multiple copies, and the copy number depends on the transfection method and the amount of DNA used. For conventional transgenes, there appears to be no correlation between transgene copy number and expression. Copy-number dependence may be blocked by position effects. If position effects are abolished, transgene expression often becomes copy number related, if not perfectly correlated. The discrepancy may reflect interaction in *trans* between transgene copies or the unaccounted presence of nonfunctional transgenes in the cluster. The effects of transgene dosage can best be observed where a single gene causes a dose-dependent phenotype in a transgenic animal. Hence, when the *Pax-6* gene was expressed in YAC transgenic mice, a range of eye phenotypes was observed, reflecting varying dosage of this transcription factor (211). Gene amplification strategies, which produce thousands of transgene copies, eventually maximize transgene expression by saturating the protein synthesis machinery, but provide little information concerning the effect of transgene dosage on protein expression levels in a nonsaturated system.

14.9.6 Organization

Several aspects of transgene organization could potentially affect transgene activity, resulting in the production of mutant or aberrant proteins or in the failure of transgene expression (2). Foreign DNA often undergoes point mutation due to damage in transit. This applies especially to transfected DNA, less so to virally transduced DNA and DNA injected directly into the nucleus. Furthermore, the integration event itself is often destructive, resulting in

the deletion of terminal regions of the transgene, internal rearrangement, and transgene fusion. This can result in the production of aberrant, compound, and truncated transcripts.

Transgenes are generally integrated at a single site in pseudotandem arrays (arrays where fragments of host DNA and transgene DNA may be interposed between neighboring transgenes). In cotransfer experiments (i.e. where two or more discrete transgenes are introduced into the cell at the same time), both transgenes tend to integrate at the same site, whether the two genes were originally linked on the same, cointegrate vector or were cotransfected using separate vectors. For cointegrate vectors, the copy number of each transgene is approximately the same within individual cell clones, and the numbers covary between clones. For separate transgenes, the copy numbers of each transgene appear to vary independently between clones, although if one transgene is a selectable marker, there is often less cross-clone variability for that transgene due to selective constraints. Transgenes may integrate at more than one locus, and occasionally, cotransfected transgenes may integrate separately. Adjacent transgenes may also influence each other's expression. Tandem transgenes may cause promoter occlusion by transcriptional read-through, while inverted transgenes may cause antisense suppression. However, while adenoviral VA_I RNA can improve episomal foreign gene expression following transient transfection, stable transgene expression appears not to be affected, suggesting that significant amounts of dsRNA are not synthesized. Some bacterial sequences in transgenic animals have been shown to exert specific negative transcriptional effects in *cis*. Most problems are caused by vector backbone sequences, which can be efficiently separated from the transgene before gene transfer (29). However, the selectable marker *neo* has also been shown to exert undesirable negative effects on adjacent promoters (212), and strategies for generating transgenic animals often incorporate a recombination step, allowing the removal of this marker.

14.9.7 DNA Methylation and Homology-Dependent Gene Silencing

In vertebrate genomes, approximately 10% of cytosine residues in the dinucleotide motif 5′-CG−3′ are methylated. DNA methylation is often correlated with gene silencing (213,214), and transgenes methylated *in vitro* before gene transfer also tend to be silent, in contrast to nonmethylated transgenes of identical sequence. It has been proposed that DNA methylation may be widely used as a form of gene regulation in mammals. The analysis of methylation sites in mammalian DNA suggests that the primary role of DNA methylation may be the silencing of invasive DNA, such as that of viruses and transposable elements. Most naturally occurring methylated cytosine residues in human DNA have been found to lie within *Alu* and LINE elements, two abundant classes of dispersed repetitive DNA corresponding to active and "ghost" (inactivated by mutation) transposable elements (215).

DNA methylation is relevant to animal cell genetic engineering in several ways. First, transgenes introduced into cells and transgenic animals are frequently de novo methylated (2,216), either immediately on integration, or within a few cell generations (in cell lines) or after passing through the germline (in transgenic animals). This type of methylation is different to the methylation spreading phenomenon discussed previously. For example, de novo methylation is position independent and may affect transgenes integrated at known active chromosomal sites. The mechanism of de novo methylation is poorly understood, but the targeting of many unrelated transgenes suggests that a specific sequence is not responsible for initiating methylation (217). The de novo methylation apparatus may scan the genome for unusual structure, such as uncharacteristic chromatin conformation following an integration event. It has also been suggested that transgenes may be identified on the basis of their atypical base composition. Vertebrate genomes are divided into the so-called isochore regions, each with a specific base composition (average % GC content). The different isochores are also characterized by differences in gene density, gene structure, chromatin conformation, replication timing, recombination frequency, and the presence of specific classes of transposable element (218). The base composition is maintained in the genes and the surrounding nontranscribed DNA, and isochore regions are separated by relatively distinct borders containing clusters of repetitive elements. In plants, it has been suggested that the tendency for some transgenes to be consistently expressed and for others to be consistently silenced in a particular host species reflects the degree of cross-species isochore similarity (219). It may therefore be possible to protect transgenes from de novo methylation by matching their base composition to that of the integration site.

A second methylation effect in gene transfer experiments was observed when cells were transformed with either adenoviral or bacteriophage λ DNA (2). Integrated transgenes (in this case the viral genome) often undergo de novo methylation. A more surprising consequence of transgene integration, however, is the alteration of cellular DNA methylation patterns at loci very distant from the integration site, including endogenous genes. DNA hypermethylation generally corresponds to transcriptional repression, so it is possible that the integration of a transgene at one site in the genome can alter endogenous gene expression patterns by causing some genes to be methylated and repressed and others to be demethylated and activated.

In certain plants, multicopy transgene integration often leads to transgene silencing, whereas single copy insertion

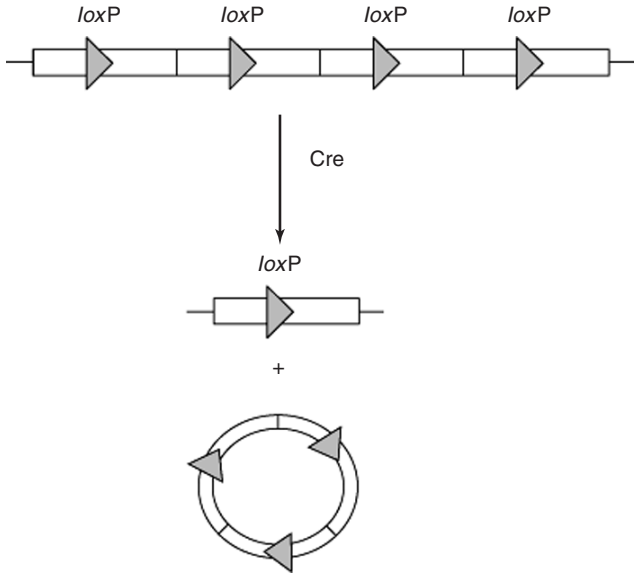

Figure 14.11. Repeat-induced gene silencing by Cre recombinase. If transgenes carry a single Cre recombinase recognition site (*loxP*), the activation of Cre recombinase in a multicopy transgenic animal results in copy number reduction, from four to one. The excised copies are rapidly degraded, and the single-copy transgene is expressed at a much higher level.

results in high level transgene expression (219). This phenomenon is position independent but may be copy number related, and often involves DNA hypermethylation. Homology-dependent silencing occurs at two levels. At the transcriptional level, silencing often occurs if there is homology in the promoter region, and is thought to result from ectopic DNA pairing, which initiates de novo methylation. Cre recombinase (discussed in the following section) has been instrumental in demonstrating that this phenomenon of *repeat-induced silencing*, which has been extensively reported in both plants and *Drosophila*, also occurs in mammals (Fig. 14.11) (220). Silencing can also occur at the posttranscriptional level, requiring homology in the coding region, and may involve the production of aberrant or antisense RNA molecules. Alternatively, a threshold system may be in operation, where a certain mRNA dosage stimulates RNA degradation. A remarkable consequence of posttranscriptional silencing is *cosuppression*: If a transgene is homologous to an endogenous gene, multicopy integration can silence not only the transgene but also the endogenous gene, generating an apparent null phenotype (219). The first cases of cosuppression-like silencing in animals were observed in *Drosophila* (221).

14.9.8 Stability and Transmission

It is also important to consider how transgenes are maintained and transmitted through successive cell divisions following integration. In cells transfected using calcium phosphate, it is not uncommon to see complete or partial transgene excision, resulting in reversion to the nontransformed phenotype. Other forms of transformation are more stable because the transgenome is smaller, but where there are multiple transgene copies, copy number expansion or reduction can occur through unequal crossing over or sister chromatid exchange between tandem repeats. This mechanism is thought to be responsible for generating the large transgene arrays that accompany gene amplification. The maintenance of selection ensures that any cell undergoing reversion is counterselected, and increasing selection pressure selects for those cells with copy number expansions. Integrated transgene arrays and amplified units are often pseudotandemly arranged, containing fragments of host DNA between transgene copies. They also appear to contain unlinked DNA, which may originate a great distance away from the amplification site. It is unknown how this DNA is cointegrated and coamplified, but is presumed to represent chromosomal recombination events resulting from the interaction of distant loci in *trans*.

In transgenic animals, spontaneous transgene loss is also observed. In species such as fish and frogs, the tendency for foreign DNA to be replicated and episomally expressed means that it is not always possible to confirm that integration has occurred. This can be checked by various experimental approaches, including Southern hybridization to genomic DNA, analysis of Mendelian segregation ratios, *in situ* hybridization to chromosomes, and sequencing across integration junctions (196). Only rarely has sustained episomal maintenance been observed in transgenic mice. Very occasionally, the loss of a transgene phenotype may be caused by transgene excision or mutation early in development, so that the resulting mouse is phenotypically and genotypically wild type. More often, the genotype of the animal is unchanged, and changes in phenotype result from transgene silencing through de novo transgene methylation. This may occur after one or more generations and is subject to various controlling factors, including the influence of different genetic backgrounds and the parental route of transgene transmission (222). Transgenes, such as endogenous genes, may be subject to parental imprinting effects. Hence, the offspring of a transgenic male and wild-type female may show a different phenotype to that of a wild-type male and transgenic female, through sex-specific transgene methylation during gametogenesis (223). In mice, particular strains are associated with different forms of transgene behavior. BALB/c and C57BL/6 backgrounds are thought to promote de novo methylation, while inbred lines such as DBA/2 are thought to promote demethylation (224). Hence, crossing a founder transgenic mouse with a BALB/c wild-type mouse may cause transgene silencing in the mixed genetic background. Conversely, crossing to a

DBA/2 mouse often results in continued transgene activity and can also erase transgene parental imprinting effects. Strain-specific methylation, transgene cluster mosaic methylation, cellular mosaicism for transgene methylation, and imprinting may be largely position dependent (222).

14.9.9 Design of Transgenes for Transgenic Animals

With the information presented previously concerning transgene behavior, and the time and expense required for the generation of transgenic animals, it is beneficial to give careful consideration to transgene design. The ability to modify transgene constructs *in vitro* means that sequences from diverse sources can be combined, and completely synthetic genes can be constructed. This is extremely useful when the intention is the ectopic expression of a protein. For example, a protein normally found in blood can be targeted to milk by linking the regulatory DNA elements from a gene normally expressed in the mammary gland to the protein coding sequences of the gene of interest (225). This type of construct is termed a *hybrid transgene*, and the strategy is being exploited to develop transgenic livestock as animal bioreactors for the commercial production of human pharmaceuticals.

Unfortunately, for the majority of genes, the exact location of the regulatory elements required for efficient expression is still unknown. Consequently, for many studies, the sequences included in the transgene and their organization have been determined on an empirical basis. First, all prokaryotic vector sequences should be removed before microinjection (194). Second, transgene design should be as simple as possible. Where hybrid transgenes are used, the sequences from different sources are linked to generate a novel gene, and it is best to keep the number of different sequence fragments as small as possible. A third consideration is whether to use genomic or cDNA sequences. In general, genomic sequences are expressed more efficiently. Many studies have demonstrated that introns facilitate cDNA transgene expression and that intron removal reduces genomic transgene activity (Fig. 14.12), although the mechanisms involved remain to be identified (226). Fourth, if precise transcriptional control elements have not been defined, it is best to use as large a promoter region as feasible. This has been facilitated by the development of methods to introduce large genomic fragments (e.g. YACs) into the mouse germline. Finally, inclusion of dominantly acting

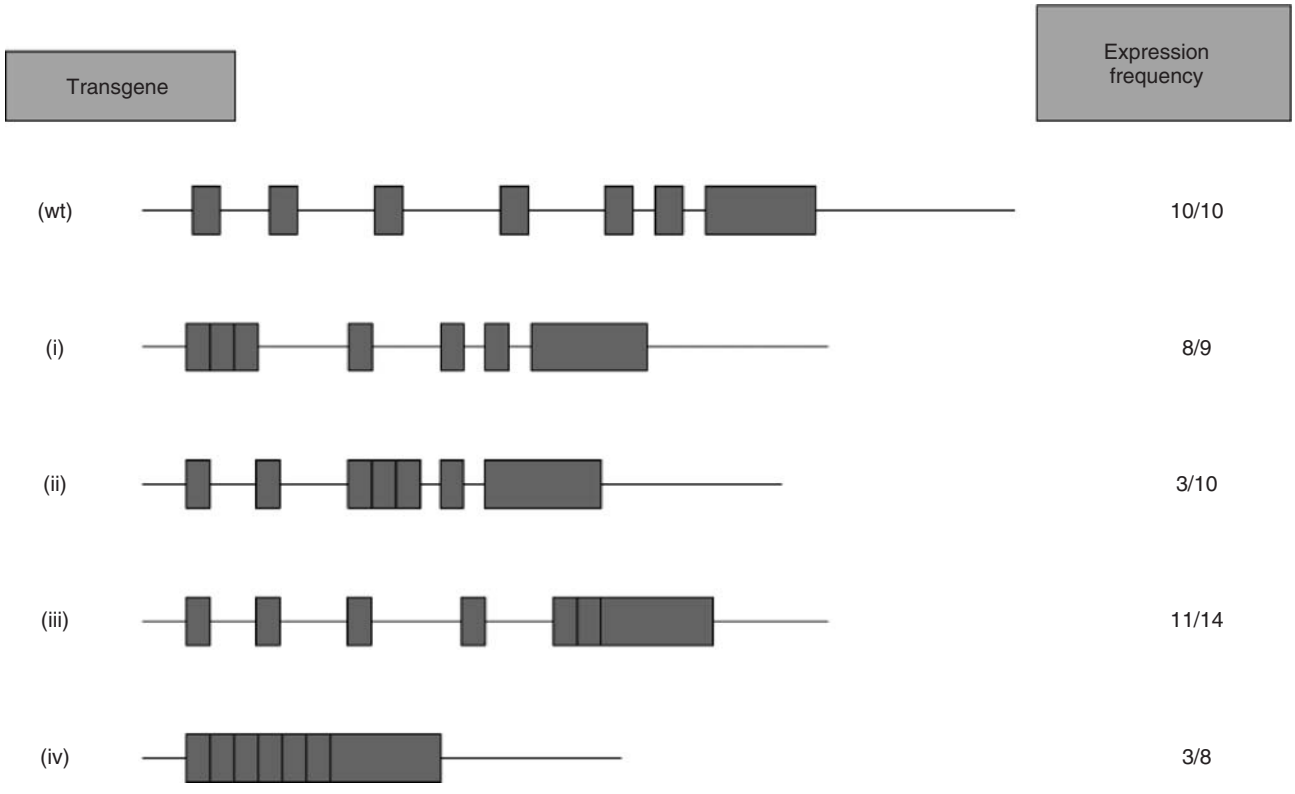

Figure 14.12. Reduction in transgene activity by intron removal. Wild-type (wt) genomic β-lactoglobulin transgenes are expressed in all transgenic lines generated. The removal of any pair of introns reduces the expression frequency (i, ii, and iii), and a construct containing no introns (iv) was expressed in only 30% of transgenic lines.

control elements, such as locus control regions (LCRs), should be considered (227). Unfortunately, this type of element has been identified for only a few genes.

Conventional transgenes have traditionally been small in size. If the desired gene covers a large genomic region, or if several genes (perhaps part of a gene cluster) are to be transferred, larger vectors are required. In this regard, transgenic animals have been produced that carry transgenes derived from bacteriophage P1 vectors and bacterial or YACs (PACs, BACs, and YACs). P1 clones carry inserts of 80–90 kbp, YACs can carry inserts over 1 Mbp, while BACs carry an intermediate insert size (11). The aim now is to generate MAC vectors with the recent description of a YAC-based MAC (228). Alternative approaches have been developed that rely on recombination between two injected fragments to generate a large integrated transgene. The use of these large transgenes is not limited to mice, because transgenic rabbits carrying YACs have also been produced (229). The main use of these large clone transgenes is in positional cloning, specifically in relation to adding functional information to the genetic maps currently being generated for most livestock species. Recently, the potential for introducing even larger genomic fragments has been demonstrated by the generation of transgenic mice carrying human chromosome fragments. This was accomplished by microcell-mediated chromosome transfer (MMCT) into ES cells (93).

14.9.10 Overcoming Position Effects

Position effects can reduce or silence transgene expression or generate ectopic expression patterns. There are four ways to deal with position effects: (i) increase transgene copy number so that the rate of mRNA synthesis is no longer the limiting factor in recombinant protein synthesis, (ii) ensure that the transgene integrates at a site that is not subject to undesirable position effects, (iii) protect the transgene from position effects, and (iv) import positive position effects along with the transgene.

One way to overcome position effects is to amplify the transgene to such a high copy number that even if each transgene copy is transcribed minimally, enough mRNA is produced to ensure that transcription is no longer the limiting step in foreign gene expression (40,41). This is achieved by cotransfecting cells with the experimental transgene and an amplifiable marker such as *Dhfr*, followed by subjecting the transfected cells to stepwise increments in the concentration of the selective drug, in this case methotrexate. This approach is only useful where the aim of the experiment is to maximize yields of recombinant protein and cannot be used for the precise control of transgene expression either in cells or transgenic animals.

The alternative approaches each allow a degree of control over transgene expression and can be used in more refined experiments. The use of site-specific recombination and gene targeting systems to introduce transgenes at specific loci chosen for their favorable position effects has been proposed to avoid transgene silencing and expression variability (230). Such approaches would also be advantageous because isogenic cell clones and transgenic animals could be produced on demand. Transgene targeting to a specific gene locus in transgenic mice has thus been the focus of attempts to identify permissive sites within the genome (231). The existence of position effects suggests that certain sites within the genome may prove more permissive for expression than others for a given transgene. One strategy is to identify lines of mice that efficiently express a transgene and clone the entire transgenic locus, including as much chromosomal flanking sequences as possible. This assumes that sequences relatively close to the site of insertion mediate the effect. Alternatively, neutral sites within the genome, which shield the transgene, can be identified using the appropriate gene targeting construct in ES cells.

A promising approach for overcoming position effects is to protect transgenes from surrounding chromatin in the same way that the cell is thought to isolate active and repressed chromatin domains by using *cis*-dominant boundary elements. It has been observed that genes *in situ* reside within large chromatin domains, which extend many kilobases either side of the transcription unit. Active chromatin domains are biochemically defined by the extent of nuclease sensitivity, and transcription per se is not required for a domain to remain in the open configuration (232). There are several ways to exploit these observations. First, DNA sequences found at the domain borders can be used as artificial insulator elements. Such elements have been isolated, for example, from the chicken lysozyme A gene locus and have been shown to insulate transgenes from the activity of local enhancers and to protect transgenes from position effects in cell lines (233) and transgenic animals (234). Such elements are thought to act by attaching to the nuclear matrix and isolating the transgene as a topologically defined chromatin loop. In animals, it has generally been observed that when such boundary elements protect transgenes from position effects, transgene expression also becomes copy number dependent.

Second, susceptibility to position effects can be suppressed through the incorporation of dominantly acting transcriptional control elements in the transgene (227). The best-studied element is from the human β-globin locus and comprises a set of DNase I hypersensitive sites normally located several kilobases upstream of the β-globin gene. This chromatin element is called the *LCR*. For those β-globin transgenes that harbor the LCR, expression is seen in all transgenic lines and at a level that corresponds to the transgene copy number. Conversely, β-globin transgenes lacking the LCR are often silenced, and where expression occurs, it does so at a low level.

Although a vast literature has accumulated concerning the various protein factor interactions within this region, there is no clear understanding of LCR-mediated transgene regulation (235).

Third, the use of large vectors, such as YACs and chromosome fragments, can also protect transgenes from position effects. YAC transgenes are rarely subject to position effects and tend to show dose-dependent activity, presumably reflecting the inclusion of native dominant transcriptional control elements (LCRs) and/or boundary elements within the construct.

A final strategy for overcoming position effects is termed *transgene rescue*. In this approach, which is particularly suited to cDNA transgenes, the experimental transgene is cotransfected with a second transgene renowned for its strong expression, such as the β-lactoglobulin (*BLG*) gene (236). The *BLG* transgene cointegrates with the experimental transgene, and high level expression of both transgenes is observed. The basis of the "rescue" is thought to reflect a favorable chromatin configuration in the *BLG* transgene spreading into the surrounding chromatin and keeping it in an active state, a phenomenon that can be regarded as an "antiposition effect."

14.10 RECOMBINATION-BASED METHODOLOGY AND GENE INHIBITION STRATEGY

14.10.1 Recombination and Its Use in Genetic Engineering

The term *recombination* refers to the creation of new combinations of preexisting DNA sequences. Two major forms of recombination can be recognized: intergenic recombination (also called *independent assortment*), which refers to the mixing of discrete DNA elements such as complete chromosomes, and intragenic recombination, where DNA fragments are covalently joined together. There are five different classes of intragenic recombination (Table 14.6) (237). Illegitimate recombination, which is responsible for random transgene integration, and homologous recombination, which is exploited for gene targeting, are general recombination mechanisms occurring in all cells. Conversely, site-specific recombination and transposition are controlled by enzymes encoded by particular DNA elements, such as plasmids, viruses, and transposons. As such recombination systems are not ubiquitous, they can be exploited to carry out specific tasks in genetic engineering by transferring them into

TABLE 14.6. Categories of Intramolecular Recombination and Their Use in Genetic Engineering[a]

Category	Properties	Relevance to Genetic Engineering
Illegitimate	Ubiquitous and neither homology nor sequence dependent, although regions of microhomology may be involved. End-joining is a form of illegitimate recombination	Random joining of multiple transgene copies. Transgene integration at random sites
Homologous	Ubiquitous and homology dependent. Not sequence dependent. Often involves long regions of homology	Transgene concatemerization. Gene targeting strategies. Construction of recombinant viral vectors. YAC mutation and retrofitting in yeast
Site-specific	Encoded by specific genetic elements, for example, plasmids and viruses. Dependent on proteins (recombinases) that recognize short consensus sequences in donor and target molecules	Site-specific transgene integration and excision. Transgene engineering *in vivo*. Tissue- and stage-specific transgene (in) activation. Chromosome engineering
Transposition	Encoded by specific genetic elements (transposons). Dependent on proteins (transposases) that recognize short consensus sequences in donor, although target site is relatively nonspecific	Retrovirus integration. Insertional mutagenesis and cloning by tagging or plasmid rescue. Insertion of foreign DNA into viral vectors (e.g. Tn*7* transposase targeting of Bac-to-Bac vectors)
Artificial	Joining DNA molecules with DNA ligase *in vitro*	Preparation of recombinant vectors for gene transfer

[a] Site-specific and homologous recombination are discussed in more detail in the current text. See earlier section on mechanisms and consequences of transgene integration for a discussion of illegitimate recombination, and earlier sections on insertional mutagenesis and entrapment vectors, and construction of recombinant baculovirus vectors for discussion of transposition. Note that Tn*7* transposase is unusual in its preference for particular target sequences, allowing its use for site-specific transgene integration, while insertional mutagenesis and trap vector integration exploit the lower specificity of, for example, P elements and retroviruses.

new host cells. The use of cloned recombination systems from heterologous sources has facilitated *in vivo* transgene manipulation and chromosome engineering.

14.10.2 Inhibition of Endogenous Genes

The major thrust of genetic engineering in animal cells has been to optimize and regulate the expression of recombinant proteins; however, there is now an interest in using the same gene transfer technology to silence endogenous genes and alter the endogenous genome to generate functional mutants (192). With the advent of recombinant DNA technology, it became possible to address gene function by first cloning the gene, then mutating it *in vitro*, and reintroducing it into the source organism to study its function. Until a few years ago, the scope of this so-called reverse genetics approach was limited to the transfer of *in vitro* mutated genes into cells and later transgenic animals to study their effects. Only recently has it become possible to directly modify the genotype of a cell or animal by altering endogenous genes. Silencing is not only useful experimentally to generate mutants for functional studies but also in applied fields to knock out undesirable traits and to correct dominant genetic disorders (a form of gene therapy known as *gene inhibition therapy*).

14.10.3 Homologous Recombination

Homologous recombination in mammals occurs predominantly during meiosis and in some types of DNA repair. Exogenous DNA involved in homologous recombination events is probably used as a substrate by these DNA repair enzymes. Mechanistic parallels between DNA replication, recombination, and transcription are evident (238). There are three possible outcomes of a homologous recombination event (Fig. 14.13). In most cases, the choice is between reciprocal exchange (usually termed a *crossover event*) and nonreciprocal exchange (usually termed *gene conversion*). In the former case, a recombination event occurring between two heterozygous loci will result in the exchange of markers between recombination partners (Fig. 14.13, panel I). In the latter case, recombination results in the unidirectional transfer of information, so that one allele appears to have been converted into the other. This can occur both in the absence (Fig. 14.13, panel II) and in the presence (Fig. 14.13, panel III) of a crossover event involving a third marker. Both crossing over and gene conversion involve the invasion of double-stranded DNA by a single strand, a process often initiated by a single- or double-strand chromosome break in the donor DNA molecule (or the free end of a linearized targeting construct). Homologous recombination then proceeds in a conservative manner with a preponderance of gene conversion over reciprocal recombination. The third possibility is extrachromosomal recombination (Fig. 14.13, panel IV), which occurs nonconservatively and results in the loss of the sequences at the opposite end of the two molecules.

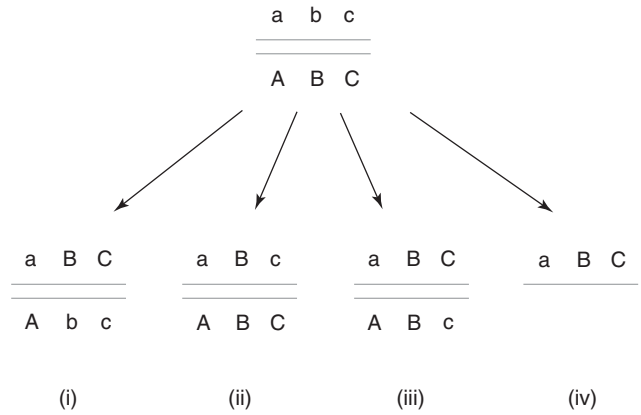

Figure 14.13. Possible outcomes following homologous recombination. The bars represent homologous DNA molecules, and the letters represent three genetic loci, with upper and lower cases indicating different alleles: (i) reciprocal recombination, (ii) gene conversion, (iii) gene conversion with crossover, and (iv) nonconservative recombination.

14.10.4 Development of Homologous Recombination as a Genetic Tool

The development of engineering strategies based on homologous recombination in mammalian cells was preceded by the demonstration that exogenous DNA could participate in extrachromosomal recombination. The mechanism of extrachromosomal recombination differs from that of homologous recombination between exogenous DNA and chromosomal DNA, which is loosely termed *gene targeting*. Extrachromosomal recombination involves a nonconservative recombination event where one of the substrates is lost, while gene targeting usually involves sequence conservation, unless the targeting strategy is specifically designed to remove sequences.

Homologous recombination between similar or identical DNA sequences allows the introduction of any sequence modification into a living cell. Initially, the technology was used to interrupt target genes, a gene silencing strategy popularly, if inaccurately, known as *gene knockout*. However, precise single-base-pair changes can also be generated (239). Alternatively, large-scale genomic rearrangements are possible, including chromosomal translocations (240). A novel exploitation of this technique is to replace one gene with an entirely different gene, a strategy termed *gene knock in*. In each case, the desired mutation is generated in a cloned and *in vitro* modified DNA fragment, while the target homologous sequence representing the gene of

interest resides within a chromosome of the host cell (241). The recombination event is catalyzed by the endogenous general recombination machinery of the cell.

Homologous recombination is a rare event in mammalian cells, with nonhomologous (illegitimate) recombination occurring three to five orders of magnitude more frequently (242). Therefore, it is necessary to incorporate a selectable marker system that will enrich for the targeted integration event. The design of an appropriate targeting construct is a critical step for successful gene targeting. In 1985, a mutation was generated in the human β-globin gene using an insertion vector (243). A targeting frequency of 10^{-3} clones was achieved, but this still represented an inefficient targeting event. The procedure was refined through use of the endogenous *Hprt* marker gene, which could be selectively inactivated by homologous recombination (244). As discussed earlier (Table 14.4), cells *lacking* HPRT activity can be selected by culturing them in the presence of the toxic base analog 6-thioguanine (6-TG) and counterselected in the presence hypoxanthine, aminopterin, and thymidine (using HAT medium). This system allowed studies concerning the variables associated with homologous recombination to be addressed, such as the size of the homology region required and the effects of terminal homology (245).

Homologous recombination strategies in genetic engineering rely on the detection of very rare molecular events, so it is important to optimize the targeting efficiency. The targeting frequency depends on a number of factors (246). First, better targeting efficiencies are achieved with a larger *homology region* (the region of shared homology between the targeting vector and the target itself). Targeting efficiency increases exponentially with the size of the homology region up to about 10–14 kbp, where a plateau is reached. In addition, the degree of similarity between the sequences in the targeting construct and the endogenous locus has a major effect on the recombination efficiency. For example, the frequency of the recombination event can be increased three- to fivefold if the DNA used is from an identical (isogenic) source rather than a different strain of animal (247). Another factor is the actual targeted locus. For as yet unknown reasons (but presumably due to either the specific overall sequence composition or higher order chromosomal structure), some genomic targets are highly resistant to recombination and are thus recalcitrant to gene targeting. Finally, the design of the targeting vector also determines the outcome of the experiment, with targeting strategies reflecting the use of either insertion or replacement vectors (248,249).

14.10.5 Gene Silencing—Targeting Vector Design

There are two classes of targeting vector, termed *insertion vectors* and *replacement* (or *transplacement*) *vectors*. Insertion vectors are linearized *within* the homology region, resulting in the insertion of the entire vector into the target locus (250). This type of vector disrupts the target gene but leads to a duplication of the sequences adjacent to the selectable marker (Fig. 14.14a). This is not always a desirable configuration (251). First, duplication of the target sequences can lead to a leaky phenotype (e.g. if the intention is to disrupt the target gene, the duplicated region can undergo variable splicing event leading to production of wild-type transcript). Second, a subsequent homologous recombination event can occur between the duplicated regions, removing the selectable marker and causing reversion to the wild-type genotype (Fig. 14.14c).

Replacement vectors are designed so that the homology region is collinear with the endogenous target. The vector is linearized *outside* the homology region before transfection, resulting in crossover events in which the endogenous DNA is replaced by the incoming DNA (Fig. 14.14b). With this type of vector, plasmid backbone sequences are not inserted, only sequences within the homology region. Insertional inactivation is thus achieved by interrupting the vector homology region with extra DNA so that it is no longer functional (Fig. 14.14b). To allow identification of targeted cell clones, the homology region is interrupted by a selectable marker such as *neo*. Insertion or replacement thus introduces the selectable marker at the target site, and growing the cells under selection (e.g. neomycin or its more widely used analog, G418) will kill all those cells that do not harbor the appropriate allele, representing the integration event. This strategy produces a disrupted target gene (252) and is termed *positive selection*.

The use of a single selectable marker, although allowing selection for integration events, does not discriminate between targeted events due to homologous recombination and random, nontargeted integrations. What is needed is an enrichment procedure. The most widely used system requires the inclusion of a second, counterselectable marker and is the basis of *positive–negative selection* (Fig. 14.15) (253). The most commonly used system involves inclusion of the HSV TK (*tk*) gene, which will kill transfected cells in the presence of ganciclovir. The counterselectable marker is positioned at one end of the vector, outside the homology region, and will not be inserted by homologous recombination, allowing correctly targeted cells to survive. However, the marker is inserted by random integration, allowing cells carrying randomly integrated constructs to be counterselected with ganciclovir.

Variations on positive–negative selection are available, including a highly efficient system involving a promoterless construct (254). In this case, the selectable marker lacks the sequences required to initiate transcription, and its expression is therefore dependent on insertion into the target gene by homologous recombination. Modifications on this approach include using an IRES, which generates a

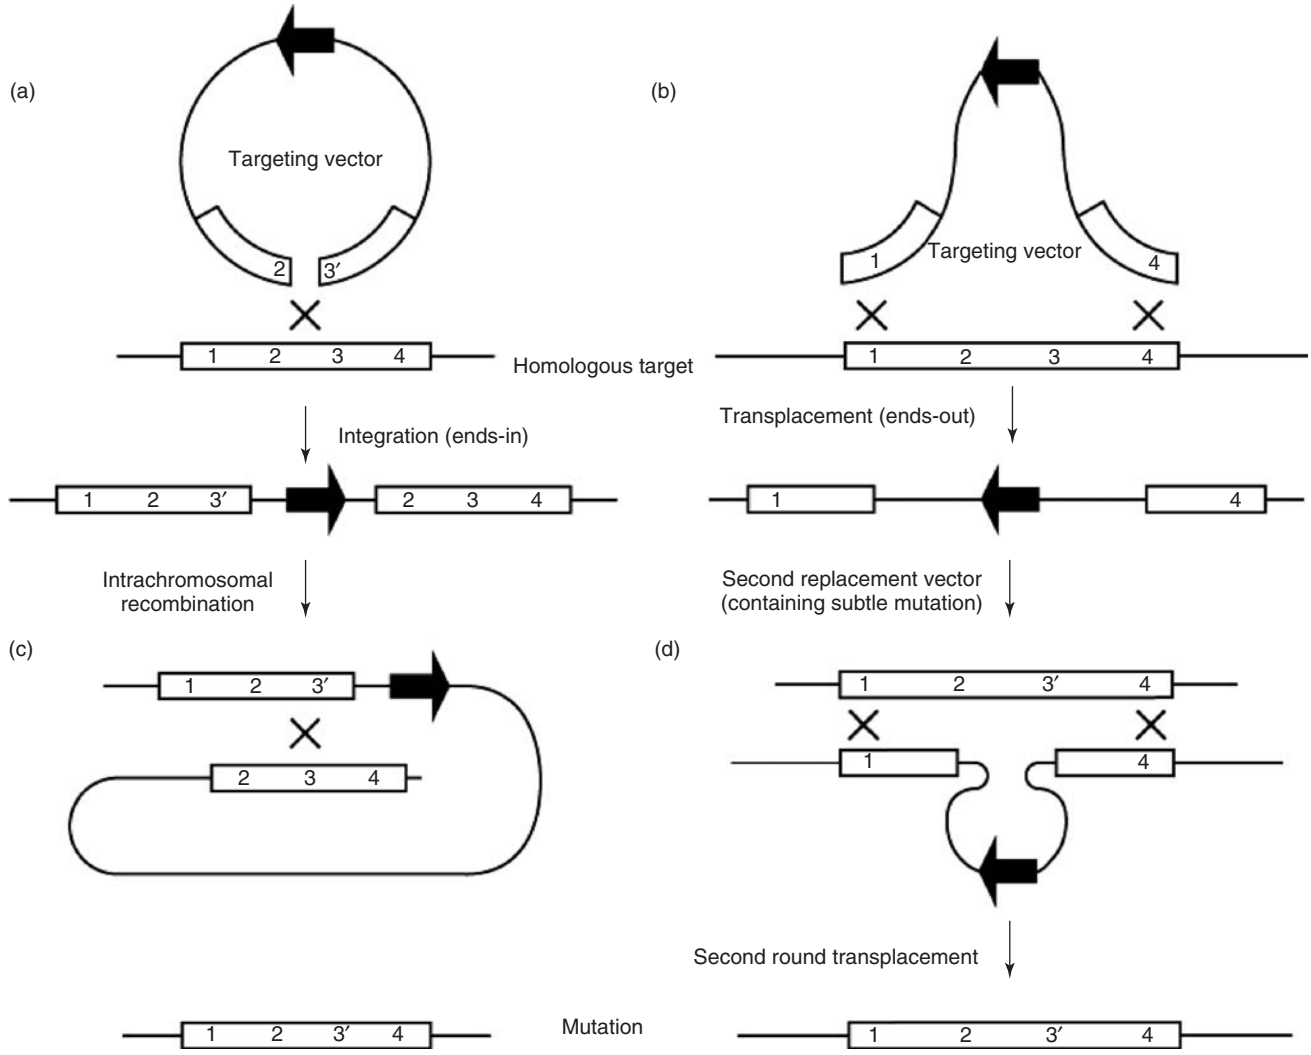

Figure 14.14. Design of targeting vectors and their use for gene knockout and allele replacement. (a) Insertion vector, linearized in the homology region. This undergoes "ends-in" recombination with a single crossover; inserts the entire vector into the targeted locus. (b) Replacement (or transplacement) vector, linearized outside the homology region. This undergoes "ends-out" recombination with a double crossover or gene conversion; replaces the targeted locus with the homologous region of the vector. Gene knockout is achieved by interrupting the vector homology region. (c) Subtle mutation using an insertion vector (hit and run). The first integration generates the hit and inserts the marker(s) (black arrow), which are used for positive selection. The vector homology region carries the desired mutation. Subsequently, intrachromosomal recombination between the tandem homology regions replaces the endogenous gene with the mutant allele with no further intervention from the experimenter. The mutation is represented by (′). Targeted clones can be identified by negative selection, because the second recombination event removes the counterselectable marker. (d) Subtle mutation by transplacement requires two vectors. The first vector is the tag, interrupting the gene and leaving the selectable markers. The second vector carries the desired mutation and facilitates the exchange, replacing the interrupted allele with the desired mutation and removing the counterselctable marker.

bicistronic messenger RNA (179). In addition to providing a very efficient targeting strategy, the IRES also considerably simplifies construction of the vector, because the selectable marker does not have to be inserted in-frame.

14.10.6 Introducing Subtle Mutations

While gene targeting has traditionally been used to disrupt and hence silence specific endogenous genes by introducing large insertions, more refined approaches are now

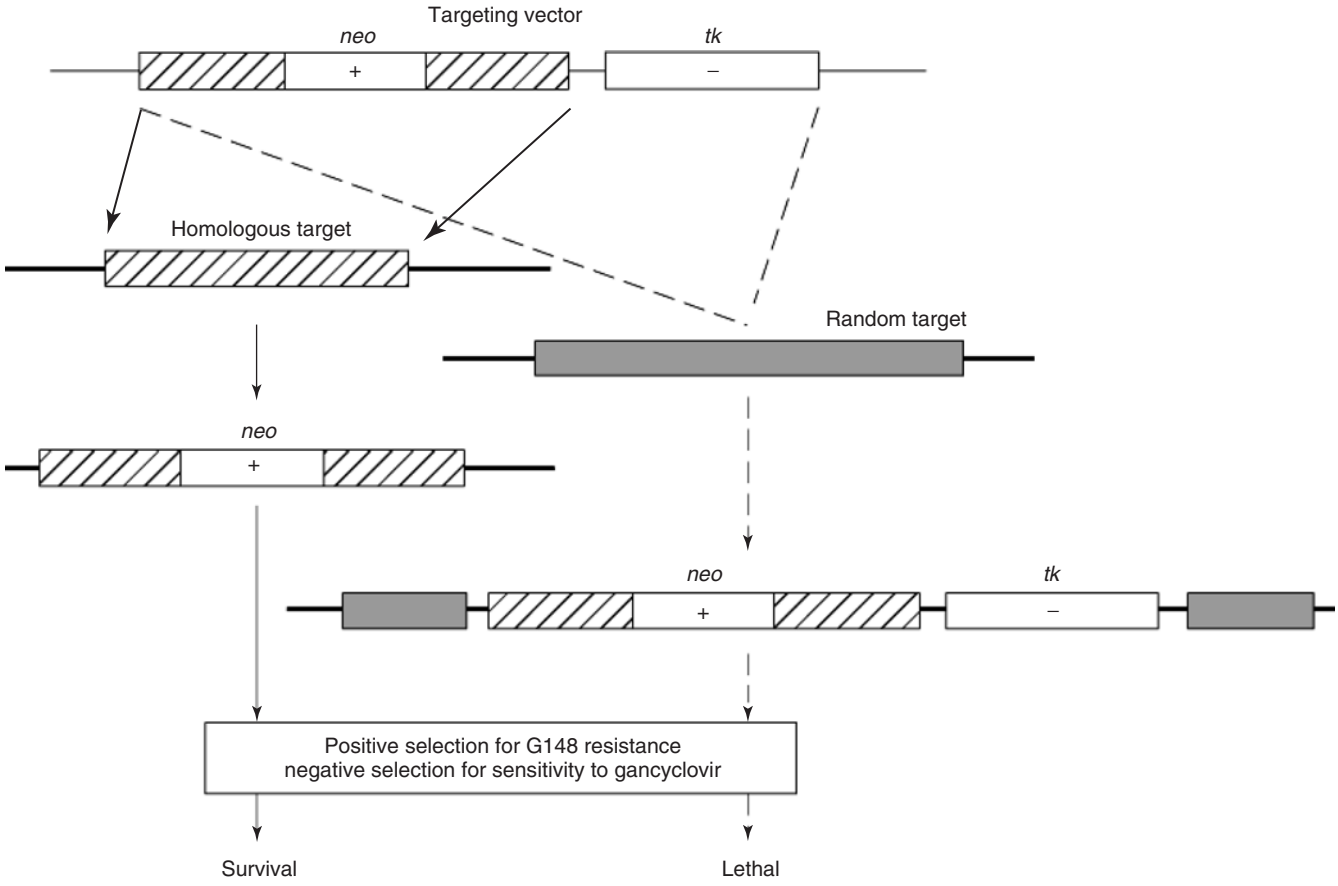

Figure 14.15. Positive–negative selection. Random integration occurs several orders of magnitude more frequently than homologous recombination in mammals, and a single selectable marker cannot discriminate between the two events. Positive–negative selection employs two markers, a selectable marker within the homology region, which is integrated by both recombination and random end-joining, and a counterselectable marker outside the homology region, which is only integrated by random end-joining, not by homologous recombination. Only targeted clones are therefore resistant to both G418 (conferred by *neo*) *and* ganciclovir (conferred by the *absence* of *Tk*).

being used to generate subtle mutations. The precise effects of minor deletions or point mutations cannot be assessed through simple targeting strategies, which necessarily leave the selectable marker, and in some cases the entire targeting vector, integrated at the target site. Two major strategies for introducing *clean mutations* (subtle mutations without markers or foreign sequences) have been devised, each involving two rounds of homologous recombination. These are the "hit-and-run" strategy (Fig. 14.14c), involving a single insertion vector, and the "tag-and-exchange" strategy (Fig. 14.14d) involving two replacement vectors. In each case, the first targeting event introduces a marker or markers for positive–negative selection—this event is identified by positive selection. The second targeting event introduces the mutation and removes the marker(s)—this event is identified by negative selection.

The *hit-and-run* or "in–out" strategy (239,255) involves the use of an insertion vector carrying two selectable markers, such as *neo* and *Tk* (Fig. 14.14c). The insertion event is positively selected by culturing the cells in the presence of G418. As an insertion vector is used, the entire vector is integrated and the homology region is duplicated in the targeted clone. One of these duplicated regions, the one derived from the insertion vector, harbors the desired subtle mutation. The success of this approach relies on a second intrachromosomal homologous recombination event between the duplicated homology regions, which first replaces the endogenous allele with the mutant and second deletes the markers allowing negative selection for ganciclovir resistance. Pending the resolution of this second event, the desired mutation may be left at the target locus. Although elegant in conception, this technique

suffers from one disadvantage, which is that the second homologous recombination event is inefficient.

The *tag-and-exchange* strategy is similar in that it also requires two homologous recombination events, but differs in that it requires two replacement-type vectors (256). The first "tag" vector is designed to mutate the target gene and insert the selectable marker(s). The second vector facilitates the exchange reaction by reintroducing the desired mutation into the target gene, while eliminating the selectable marker(s). Selection for the two events is analogous to that for the hit-and-run approach when two markers such as *neo* and *Tk* are used (Fig. 14.14d). Variations include strategies using a single selectable marker such as *Hgprt*, which can be positively selected or counterselected as appropriate (257).

14.10.7 Target Cells for Homologous Recombination

In theory, any mammalian cell can provide the target for homologous recombination. However, gene targeting in the majority of cells is very inefficient, with ES cells being a notable exception (246). Indeed, the general inefficiency of homologous recombination in mammalian cells remains one of the central limiting factors in the exploitation of this powerful technique. *ES cells* have therefore been used in most gene targeting experiments (Fig. 14.16) (258,259). Furthermore, when handled appropriately, ES cells are pluripotent: They can differentiate into any (all) somatic cell type (241). This means that a genetic modification introduced into ES cells can be incorporated into the germline of an animal. To date, the only animal that has been genetically modified through homologous recombination is mice. This is because only mouse ES cells are currently available (260,261). ES cells are also a valuable cell culture-based resource for studying gene function, especially in development, because they can be induced to differentiate into specific cell lineages in culture (262).

DNA can be introduced into ES cells by a variety of routes, the choice depending on the intended use of the cells. If germline transmission is the desired outcome, the effect of the protocol on the integrity of the ES cell genotype and phenotype must be considered. For example, cells that have undergone chromosomal rearrangements or cells that have differentiated will not contribute to the germline. ES cell transformation was first achieved by retroviral transduction and calcium phosphate-mediated transfection, but electroporation has now replaced these as the method of choice. Electroporation gives a higher transfection efficiency, is relatively simple and reproducible, and is compatible with germline transmission. Alternative methods to introduce DNA into ES cells include microinjection (which is technically very demanding) and lipofection, perhaps best suited for the delivery of large fragments of DNA.

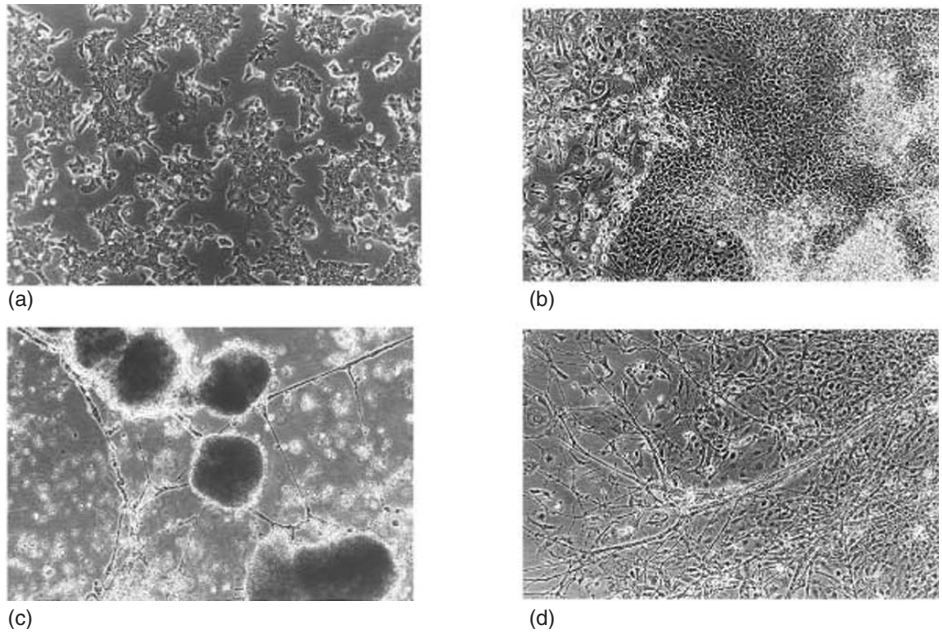

Figure 14.16. ES cells. (a) Recently plated mouse ES cells from strain 129 (note the small cytoplasmic volume relative to nuclear size). (b) In culture, the cells will develop three-dimensional growth characteristics. In the absence of the growth factor LIF, embryoid bodies will be formed. Alternatively, ES cells will differentiate into a variety of cell types, including (c) epithelial and fibroblastoid or (d) neuronal filament-like. Photographs courtesy of Jim McWhir and Ray Ansell (Roslin Institute).

Recently, there has been considerable interest in the potential of primary cells for gene targeting, at least in part due to the development of nuclear transfer techniques in mammalian species. Gene targeting is an inefficient process with individual targeting events in primary and established somatic cells occurring at low frequencies, typically $<10^{-4}$. At this efficiency, thousands of stably transfected clones must be screened to isolate a single homologous recombinant, and this requirement severely limits the use of primary somatic cells as the target for homologous recombination. Primary cells are usually isolated in only small numbers and are capable of only a few rounds of cell division before senescence or crisis. In attempts to overcome this limitation, various enrichment strategies have been developed, including the positive–negative selection system discussed, which can achieve a 30% targeting efficiency. As more experiments have been documented, however, the promoterless vectors have emerged as the most successful. Using these approaches for gene knockout in human primary cells, human gene function can be addressed. For example, disruption of the $p21^{CIP1/WAF1}$ gene in normal diploid human fibroblasts demonstrated its pivotal role in cell senescence (263).

There is also considerable interest in the use of somatic cells for gene targeting. For example, as the means to propagate human somatic cells in the form of lineage-specific stem cells becomes available, gene targeting could be used to correct or remedy genetic defects by interrupting dominant mutant alleles or replacing them with the wild-type allele. The somatic cells could then be used to replace the mutant cells *in vivo*, a form of somatic gene therapy. Alternatively, gene targeting in somatic cells could provide a basis for the genetic modification of animals when used in conjunction with nuclear transfer technology. Gene targeting in the majority of cell lines is an inefficient process compared with ES cells, and the basis of the amenability of ES cells for homologous recombination is unclear. One example is the chicken pre-B cell line DT40. The characterization of the high targeting efficiency of DT40 cells is not understood. Importantly, these cells can be used to direct genetic modification of human cells. For example, by combining gene targeting in DT40 cells and microcell fusion (which allows chromosome shuttling between cells), specific mutations can be introduced into human gene sequences before their functional testing in human cells. Other genetic tricks are possible in these cells, including telomerase-directed truncation, allowing gross modifications of target chromosomes (264).

14.10.8 Site-Specific Recombination Systems

Site-specific recombination involves the recognition of short consensus sequences by specific enzymes (recombinases) that catalyze strand exchange and resolution within small regions of DNA homology. They are encoded by individual bacteria, plasmids, viruses, and transposons and serve many purposes (237). The most extensively used systems are Cre recombinase from bacteriophage P1 (265) and FLP recombinase (flippase) from the *Saccharomyces cerevisiae* 2-μm plasmid (266). These have been shown to function in many heterologous eukaryotic systems, including mammalian cells and transgenic animals. Both recombinases recognize 34-bp sites (termed *loxP* and *FRP*, respectively) comprising a pair of 13-bp inverted repeats surrounding an 8-bp central element. *FRP* possesses an additional copy of the 13-bp repeat sequence, although this is nonessential for recombination. The introduction of these sequences into animal genomes, along with expression constructs driving expression of the recombinase protein, can therefore induce site-specific recombination events in mammals. The activity of Cre recombinase is shown in Fig. 14.17.

14.10.9 Site-Specific Recombination

If two recombination sites are integrated in the same orientation, site-specific recombination between them will excise the intervening DNA. Transgenes flanked by such sites can therefore be introduced into the genome as normal, but excised by supplying the recombinase in *trans*. This "site-specific excision" strategy has many applications (230), including the excision of unwanted sequences from the transgene (e.g. selectable markers and plasmid backbone sequences) and deletion of blocking sequences to allow transgene activation. This last strategy, known as *recombination activation of gene expression* (RAGE), involves the insertion of a blocking element (such as a polyadenylation site) between the transgene and its promoter. RAGE can be used to excise the blocking element, bringing the transgene and promoter into juxtaposition, resulting in transgene activation. Site-specific recombination, in concert with gene targeting, can also be used for endogenous gene silencing. In one strategy, sometimes termed *floxing*, gene targeting is used to introduce recombinase sites flanking an endogenous gene. The term *floxing* is derived from the term *flanking loxP*, but other recombinases are used in an analogous manner. Once the targeting strategy is complete, the introduction of recombinase into the system causes site-specific gene deletion or inversion (as appropriate), resulting in gene silencing. Similar strategies can be used to facilitate the deletion, inversion, or transposition of particular chromosome segments, an approach often used to model human diseases caused by chromosome rearrangements.

Site-specific recombination can also be used for transgene integration. In this strategy, a single recombination site is introduced into a particular chromosomal locus by gene

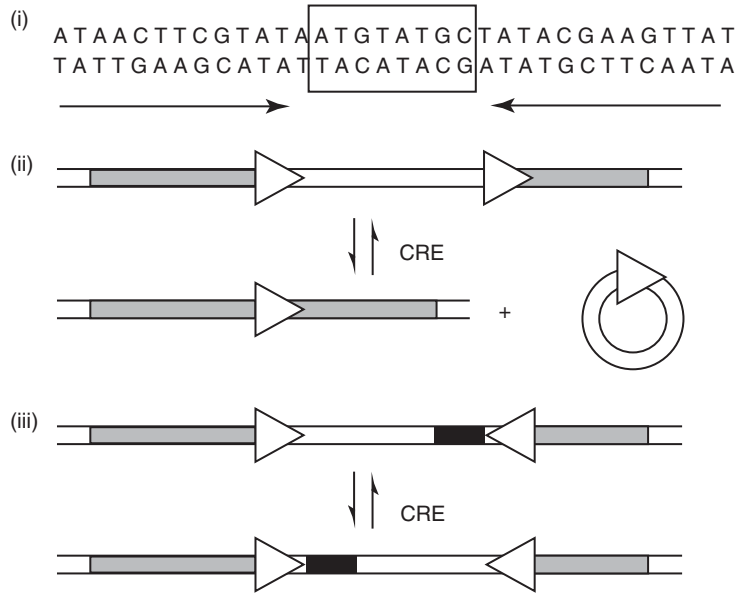

Figure 14.17. Characteristics of Cre recombinase. (a) The *loxP* site recognized by Cre recombinase, comprising 13-bp palindromic sequences (arrows) surrounding an 8-bp core (boxed). (b) Cre recombinase deletes the sequence between two *loxP* sites in the same orientation, and such a sequence is said to be "floxed." (c) When *loxP* sites are inverted with respect to each other, Cre recombinase inverts the DNA sequence between them. In both the cases, the reaction is reversible, but the circular excision product in (b) is quickly degraded, making the reaction effectively irreversible. Floxed linear DNA can integrate at a single *loxP* site in the presence of Cre, but because integration and excision occur with equal frequency, the degradation of the excision product drives the equilibrium of the reaction toward excision. Cre-mediated DNA integration is currently as inefficient as random integration.

targeting, and if recombinase is supplied in *trans*, transgene constructs flanked by recombination sites can be transfected into the cell and persuaded to integrate by site-specific recombination. However, while the constitutive expression of recombinase is sufficient for site-specific excision strategies, a transient burst of recombinase is required for integration because the reaction is easily reversible. The availability of recombinase is difficult to control precisely; thus, site-specific integration is currently only just as efficient as random transgene integration by illegitimate recombination.

14.10.10 Gene Silencing Using Antisense RNA Constructs

Gene targeting and site-specific recombination-based strategies are now well-established technologies for gene silencing. However, the activity of an endogenous gene may also be suppressed if antisense RNA is introduced into a cell. Antisense RNA has a complementary sequence to mRNA and can bind to the sense transcript either in the nucleus or cytoplasm to form a duplex. The mechanism of gene inhibition is unclear and may act at several levels. Protein synthesis is a likely target, either through the prevention of productive pre-mRNA processing and export, or duplex-induced mRNA degradation, or by direct inhibition of ribosome binding, scanning, or translocation. In addition, the presence of dsRNA induces DAI protein kinase, causing a general reduction in the rate of protein synthesis. The effects of injecting or transfecting antisense RNA into a cell are transient because the RNA cannot replicate and is rapidly degraded. However, long-term gene inhibition can be achieved simply by reversing the orientation of a transgene with respect to its promoter and introducing such a construct into cells or transgenic animals through the normal routes. If such a construct integrates and is expressed, the cell has a constant supply of antisense RNA sufficient for long-term gene inhibition. This strategy has been achieved using both transfected plasmid DNA and retroviral vectors. Antisense inhibition has been used in many cell culture experiments and in ES cells to generate transgenic animals. The results have been variable, with mRNA levels reduced by 20% to almost 100% (267). It is not necessary to express full-length antisense RNA for "knockdown" effects to occur. The expression of an approximately 5-kbp antisense RNA corresponding to the *Wnt-1* transcript resulted in 98% reduction, while just 40 bp of antisense RNA corresponding to the mouse $G_{\alpha i}$ transcript resulted in 95% reduction.

Additional sequences can be added to antisense transcription units to increase the inhibitory activity of the molecule. In a few cases, targeting sequences have been used to direct antisense RNA to particular subcellular locations. A popular strategy is to exploit the ability of ribozymes linked to antisense RNA to cleave mRNA in a sequence-dependent manner. Ribozymes are catalytic RNA molecules whose complex tertiary structure allows them to adopt the molecular configurations characteristic of (protein) enzymes and hence to catalyze biochemical reactions. The self-splicing introns found in organelle genomes are autocatalytic (i.e. the RNA facilitates its own excision), whereas other ribozymes are catalytic in the strict sense, because they act in *trans* on a distinct substrate. Ribozymes have a bipartite structure, including a targeting sequence and a catalytic core. The targeting sequence is an antisense RNA that forms base pairs with a specific RNA substrate and holds the catalytic core in the correct position, allowing cleavage of a phosphodiester bond. If the ribozyme catalytic core is fused *in vitro* to a given antisense RNA (268), the ribozyme can be targeted to the mRNA, which will be cleaved. Cleavage destroys the function of the mRNA, and the 3′ fragment (lacking a cap) is rapidly degraded. Critical comparisons of ribozyme constructs and related antisense constructs containing no catalytic core have often revealed similar levels of inhibitory activity (267). This suggests that some ribosome constructs may work simply through their antisense effects rather than by cleaving mRNA.

14.10.11 Gene Silencing Using Inhibitory Proteins

Genetic engineering can be used to interfere with endogenous gene expression at the protein level, as well as at the RNA level. The specificity and affinity of antibodies for their complementary antigens has been widely exploited for identifying, localizing, and purifying proteins (269). Antibodies microinjected into cells have also been used to inactivate proteins (270), but such effects are only transient and cannot readily be applied to whole organisms. A new approach is to stably transform animal cells with antibody-encoding genes. This strategy results in the long-term expression of "intracellular antibodies" known as *intrabodies*, which can be targeted to particular cellular compartments and used to abolish the activity of specific proteins. Intrabodies have been used to generate functional knockouts of important molecules such as growth factor receptors, and their potential role in gene therapy has been explored by targeting oncogenic proteins and the gp120 HIV envelope protein (271). The strategy for expressing intrabodies is complex. Immunoglobulin genes cannot be used for transfection due to their size and the absence of V(D)J recombinase and switch recombinase in most cells. In addition, because *specific* antibodies are required, DNA sequences corresponding to particular mature (rearranged) immunoglobulins must be used. However, the native immunoglobulin assembly pathway occurs very inefficiently in the cytoplasm and attempts to reassemble functional immunoglobulins from distinct heavy and light chains have not succeeded. One strategy is to synthesize single-chain antibodies carrying the antigen-binding domains of both heavy and light chains on a single polypeptide with a flexible intervening linker chain. Such molecules are capable of folding in the cytoplasm and interact with their targets, but they have shorter half-lives than secreted immunoglobulins.

An alternative strategy for gene inhibition at the protein level is to transfect cells with constructs encoding dominant inhibitory proteins. Proteins that function as oligomeric complexes possess domains for interaction with other subunits. It is often possible to identify dominant loss of function alleles (*dominant negatives*) for the genes encoding such proteins. These encode nonfunctional subunits that form stable complexes with the functional wild-type subunits, sequestering them into inactive oligomers. Dominant negative alleles may be generated by point mutations or truncations, and the overexpression of such alleles is useful for generating functional knockout phenotypes. This strategy has been used to inactivate many different types of protein, including receptor tyrosine kinases and cytokine receptors, transcription factors, and other oncoproteins. More recently, dominant negative overexpression has been combined with techniques for conditional gene expression to generate conditional silencing systems for the study of signal transduction, cell cycle, apoptosis, and the function of telomerase (192). The major therapeutic application of dominant negative gene expression has been blocking the HIV replication cycle by interfering with capsid assembly (272).

14.10.12 Transient Gene Silencing with Oligonucleotides

Gene silencing strategies based on the integration and long-term expression of inhibitory transgenes are designed to permanently block the expression of a given endogenous gene. However, a similar but transient effect can be achieved by introducing the inhibitory gene product directly into the cell, such as antisense RNA or antibodies active against specific gene products. Another approach to transient gene silencing is the introduction of short oligonucleotides (15–30 nucleotides) into the cell. Depending on their design, oligonucleotides can block the expression of specific genes at the levels of transcription, RNA processing, translation, or protein function. Pyrimidine-rich oligonucleotides can interact with duplex DNA if there is pronounced pyrimidine/purine strand asymmetry. The oligonucleotide can interact

with the duplex using Hoogsteen pairing. The resulting triple helix is stable and blocks transcription, allowing gene-specific silencing (273). Oligonucleotides for triple-helix gene silencing can be sense or antisense with respect to the target gene, but their use is limited by the stringent pyrimidine-rich sequence requirements. A more general approach is to use antisense oligonucleotides in the same way as antisense RNA. However, because the oligonucleotides are DNA, they are generally more stable than the RNA, and they also form DNA:RNA hybrids that act as substrates for RNaseH and, hence, induce the degradation of the target mRNAs. Antisense oligonucleotides for gene therapy have been validated in animal disease models and are now undergoing clinical trials for human diseases (274). Finally, improvement in oligonucleotide synthesis technology has allowed the production of sets of degenerate oligonucleotides that can be screened for their ability to bind specific proteins. An oligonucleotide binding in such a specific manner is termed an *aptamer*. Current problems with oligonucleotide-mediated gene inhibition include stability and delivery. Oligonucleotides are linear and prone to exonuclease attack, but this can be alleviated by chemical modification of the terminal residues. Cellular uptake of naked oligonucleotides is poor because they are large hydrophilic molecules, and transfection may require cell permeabilization or the use of a gene delivery system such as liposomes or lipofection.

14.10.13 Conditional Gene Silencing

Constitutive and permanent gene silencing are useful techniques, but cannot address complex questions such as the effect of withholding the product of a gene for a specific duration and the function of pleiotropic genes with embryonic lethal null phenotypes. In the latter case, it should be stressed that many genes active in early development also have roles in later development or the adult, and these roles cannot be studied with constitutive knockouts if the animal dies in early development due to loss of an early gene function. Traditional methods for studying such genes include conditional mutants, usually temperature-sensitive mutants, which can be maintained under permissive conditions and then shifted to restrictive conditions at the appropriate time. However, more sophisticated and regulatable strategies for conditional gene silencing can be devised by combining the silencing strategies discussed with the inducible gene expression systems discussed earlier in this chapter.

Gene targeting and site-specific recombination can be used in a number of related strategies to bring endogenous gene expression under exogenous control. In the first strategy, gene targeting is used to flox the endogenous gene, but the recombinase enzyme gene is expressed under a tissue-specific or inducible promoter, or the recombinase enzyme is expressed as, for example, a steroid receptor fusion that can be activated in a ligand-dependent manner. This allows the generation of somatic knockouts, where an endogenous gene present in all cells can be selectively deleted in particular cells or at particular stages of development. It also allows the generation of inducible knockouts, so that the timing of deletion can be controlled by the experimenter. An alternative strategy is to use gene targeting to replace the endogenous gene with a homologous copy containing a blocking element flanked by *loxP* sites. In this case, the supply of recombinase catalyzes the removal of the blocking element, leading to conditional gene activation, a strategy termed *infloxing*. In all conditionally silenced mice generated to date, either inducible or cell type-specific Cre recombinase has been used. The general strategy is to use two strains of mice, a responder carrying the floxed target and a regulator carrying a *cre* gene either under inducible or cell type-specific control. Conditional gene silencing is observed when the two strains of mice are interbred. Although site-specific recombinases offer exciting possibilities for transgene engineering *in vivo*, their activity in transgenic animals is not 100% efficient. There is a low level of background recombination, leading to leaky (in)activation. There is also pronounced and undesirable tissue specificity, resulting in the production of mosaics, and unexpected cell type-preferred transgene (in)activation.

Strategies for conditional gene silencing that do not rely on Cre recombinase have been used most frequently in cell lines as opposed to transgenic animals (conversely, Cre-mediated silencing has not been used for conditional silencing in cell lines). Gene targeting strategies include the replacement of endogenous promoters with inducible ones (192). Conditional silencing can be achieved by the inducible transcription of antisense RNA, and the inducible expression of dominant negative proteins. A final strategy is the conditional expression of a toxic transgene, such as the ricin toxin A chain gene or the diphtheria toxin A chain gene. This strategy has been reported in mammals but has been extensively used in *Drosophila* (275).

14.11 THE PRODUCTION OF TRANSGENIC MAMMALS FROM MANIPULATED CELLS

A *transgenic* animal is one in which every cell carries a fragment of foreign DNA. Initially, the term *transgenic* specifically applied to animals (and plants) carrying genes from a heterologous species. In many cases, the scope of the term can be broadened to include animals carrying, for example, extra or modified copies of endogenous genes, but most researchers stop short of using the term to describe any form of genome modification, because this would include animals carrying subtle mutations (e.g. point mutations)

generated by two rounds of replacement. In the majority of cases, the foreign DNA represents a gene (a *transgene*) or set of transgenes (194). The transgene integrates into one of the host chromosomes, becomes part of that animal's genetic repertoire, and is usually inherited by subsequent generations as a Mendelian trait. The transgene can be derived from any conceivable source, that is, the same species (e.g. an extra copy of an endogenous gene controlled by a heterologous promoter), a related species (e.g. human growth hormone expressed in mice), or an evolutionary distant species (such as bacterial transgenes in sheep). In addition, a hybrid gene may be generated from a variety of sources or a synthetic gene may be produced de novo. Integrated transgenes are often expressed correctly and can have profound phenotypic effects as shown by the greatly increased size of transgenic mice carrying growth hormone transgenes. The abnormal growth resulted from the elevated levels of growth hormone in their serum (276).

A variety of methods have been developed for the production of transgenic animals. All are based on the introduction of the DNA into a single cell that contributes to the development of the animal. In most cases, the cell is a fertilized egg, although cell culture-based approaches (using ES cells or nuclear transfer) are more sophisticated. The advantage of transgenic animals over cell culture studies lies in their ability to show the function of a gene in its normal physiological environment, that of the whole organism (241,246). Transgenic animals permit the study of developmental and physiological events in the context of the natural processes occurring in the animal.

In mammals, the vast majority of transgenic experiments have been performed using mice. Nevertheless, studies have been performed in a number of other mammals (277). Transgenic rats are well suited for experiments involving multiple analyses (e.g. blood sampling) and have been successfully used in studies addressing blood pressure. Transgenic rabbits offer an intermediate between a laboratory species and a farm animal and display a similar lipid metabolism to man and may provide useful models for the study of fat-related diseases (e.g. athersclerosis). However, excluding mice, it has been the generation of transgenic farm animals—pigs, sheep, goats, and cattle—which has received most attention. Certainly, transgenic livestock have provided the incentive for substantial commercial involvement in the discipline of animal genetic engineering.

14.11.1 Pronuclear Microinjection

The most widely used method for introducing genes into the germline of mammals is the direct microinjection of DNA into the pronuclei of fertilized eggs (278). Pronuclear microinjection is a fine needle used to pierce the pronucleus and the DNA is injected (Fig. 14.18). This requires special equipment and a considerable amount of technical expertise and dexterity from the operator. Nevertheless, the majority of research laboratories around the world now have access to such transgenic mouse facilities. By adapting the techniques employed for gene transfer to mice, pronuclear microinjection has been used to generate transgenic farm animals (279).

Figure 14.18. Pronuclear microinjection of a fertilized mouse egg. The two pronuclei are visible within the egg, which is being held by a suction pipette. The DNA is introduced through a fine glass needle. Photograph courtesy of Roberta Wallace (Roslin Institute).

Pronuclear microinjection is relatively inefficient, with only 20–30% of the mice derived from microinjected eggs carrying the transgene. This efficiency drops to 1% for domestic farm animals. It is generally accepted that the DNA integrates at or after the first round of chromosomal DNA replication. This means that the founder embryo is mosaic with regard to transgene status (280), resulting in founder animals with different integration positions and transgene copy numbers in different tissues, due to the mixing and allocation of cells during early embryogenesis. Once transmitted through the germline, however, the transgene copy number is usually stable, and the transgene is then inherited in a Mendelian fashion. There have been a few reports of transgenes undergoing rearrangement, deletion, or amplification, but these appear to be exceptions to the rule. Also, with a few obscure exceptions, the transgene does not appear to be retained extrachromosomally in mammalian species.

Although pronuclear microinjection has provided the main route for the generation of transgenic animals, a variety of other approaches are available. Integration has been observed following cytoplasmic injection or injection into the blastocoel cavity. Both routes proved to be substantially less efficient than pronuclear injection. Attempts to improve the efficiency of these approaches (e.g. using poly-L-lysine) have shown some promise, but remain unreliable (281). Retroviral infection of

preimplantation embryos has been successful, but this method is now used only rarely to generate transgenic animals (140). It has been proposed that adenovirus vectors may be used for germline transformation in the future (282). However, viral transduction as a method for generating transgenic animals suffers from several drawbacks, including the limited amount of foreign DNA that can be incorporated into integrating viral vectors, the effect of viral sequences both on transgene expression and the expression of endogenous genes located near to the transgene insertion site, and the susceptibility of transgenes carried in recombinant proviruses to de novo DNA methylation.

There have also been reports that transgenic animals can be produced using a simple technique in which DNA is mixed with spermatozoa before *in vitro* fertilization. However, a reliable sperm-mediated gene transfer technique in mammals remains to be developed (283).

14.11.2 ES Cells

Mouse ES cells have revolutionized mammalian genetics by providing a route for the directed and sequence-specific alteration of the mouse genome (241,246). ES cells possess a unique combination of useful properties: They are pluripotent (and hence compatible with germline modification), they are amenable to *in vitro* cell culture, and they possess an inherent capacity for homologous recombination (Fig. 14.19). First, the DNA transfected into cultured ES cells integrates into the genome (either randomly or by homologous recombination—gene targeting). Then, the genetically modified cells are introduced into preimplantation stage embryos, either by blastocyst injection or by morula aggregation, to produce chimeras. In some of these chimeric animals, the ES cells will have contributed to the germline, thus providing a source of fully transgenic offspring. One strategy is to use ES cells and preimplantation embryos from mouse strains with different coat color markers. The ES cells often carry a dominant marker such as agouti, while the recipient embryos carry a recessive black coat color. The chimeric founder mice have patchwork black/agouti coats representing cell clones derived from the two genotypes that contributed to the embryo, because the markers are cell autonomous. Chimeric males are then mated to black females, and transgenic offspring are identified by their agouti coats, showing they are entirely derived from the ES cells. This germline modification is then inherited as a Mendelian trait. This simple strategy saves performing Southern blot hybridization or PCR analysis on all offspring to determine their genotype. ES cells offer an attractive route to germline modification when compared with pronuclear injection because DNA alterations can be carried out in cell culture and verified before being introduced into the embryo. The limitations associated with pronuclear injection (technical requirements for working with pronuclear eggs and the lack of preimplantation screening so that transgenic status has to be verified after birth) do not apply to ES cells. ES cells may therefore facilitate more precise genome modifications, especially by exploiting the versatility of gene targeting strategies (239,240).

The injection of ES cells into blastocysts has been developed to improved strategies for ES cell delivery into the embryo. Morula injections are easier and give better results in terms of germline transmission but suffer from very high embryo mortality rates. Alternatively, coculturing ES cells with eight-cell-stage embryos generates blastocysts with an inner cell mass containing ES cells. The *in vitro* derived blastocysts are then reimplanted. This is an appealing method due to its simplicity and has proven effective. However, the resulting animals are still chimeras, and germline transmission is not always achieved. It is also possible to make aggregates between tetraploid morula cells (obtained by electrofusion) and ES cells. As tetraploid cells cannot support development, the postimplantation embryos developing from these aggregates give rise to mice derived entirely from ES cells (284). Under these conditions, chimeric diploid/tetraploid embryos implant and develop to midgestation at high frequency, but the efficiency drops off during later development and few embryos survive to term. However, this *tetraploid rescue* technique is becoming more robust (285).

14.11.3 Primoridal Germ Cells

Nonmurine ES cells are currently available only for mice. The application of the recently developed selection protocol for embryonic cells, which kills differentiated cells while leaving the undifferentiated (and pluripotent) cells to grow, may now provide a route to generate ruminant ES cells (261). The failure to derive ES cells from other species has been the driving force to discover alternative strategies. One alternative approach would introduce the genetic change directly into the germline by gene targeting of primordial germ cells (PGCs) (Fig. 14.20). There have been claims that embryonic germ (EG) cells may be analogous to ES cells. Unfortunately, it has proven difficult to persuade PGCs to contribute to the germline (286), and the technique is not yet routine.

14.12 USES FOR TRANSGENIC ANIMALS

Since the first transgenic mice produced by pronuclear injection in the early 1980s (287), a vast literature has been amassed concerning genetically modified mammals (277). The majority of transgenic mammals are mice. The use of

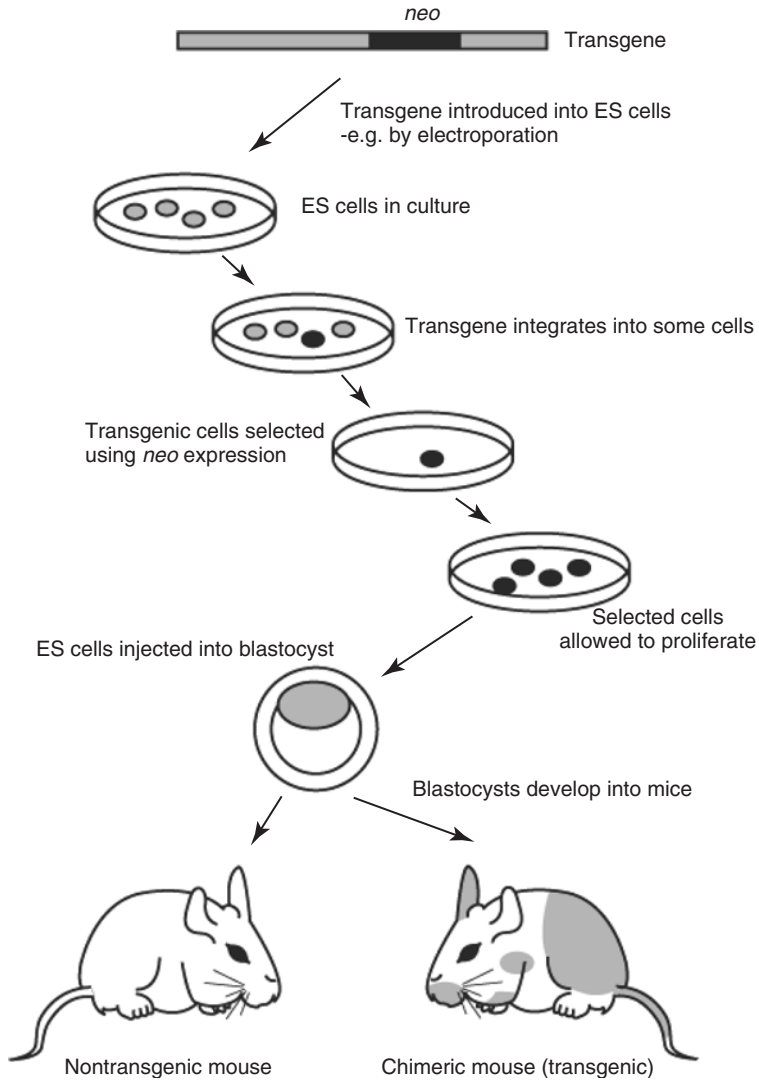

Figure 14.19. Generation of transgenic mice from ES cells modified in culture by transfection or retroviral transduction. Transformants are selected and injected into wild-type blastocysts. A proportion of the mice developing from ES cell-injected blastocysts will be normal, and a proportion will be chimeric for donor- and ES cell-derived tissue. In some of the latter category, the germline will be ES cell derived, and any progeny of these "germline-transformed" mice will be transgenic. The identification of chimeric and transgenic mice is simplified by using donor blastocysts and ES cells carrying different coat color markers and of different sexes. Chimeric mice therefore possess a variegated coat, but transgenic mice will carry the ES coat color marker.

other species has been restricted by technical limitations, cost, the time involved in breeding, and welfare issues. The recent development of nuclear transfer techniques in livestock (288) provides new openings for animal breeding and animal biotechnology (289).

14.12.1 Gene Function Studies

There are two basic expression strategies for studying gene function in transgenic mice. The first involves a gain-of-function by overexpression of the protein of interest. All that is required is the appropriate transcriptional control elements and the coding region of the gene of interest. The gene can be expressed according to its normal cellular parameters or deliberately expressed in an ectopic fashion. In addition, the incorporation of inducible promoters allows overexpression at a defined developmental stage. The transgene can be in the form of either a genomic fragment or a cDNA, although, in general, genomic constructs are the more efficient. An alternative use of this approach has been to facilitate the production

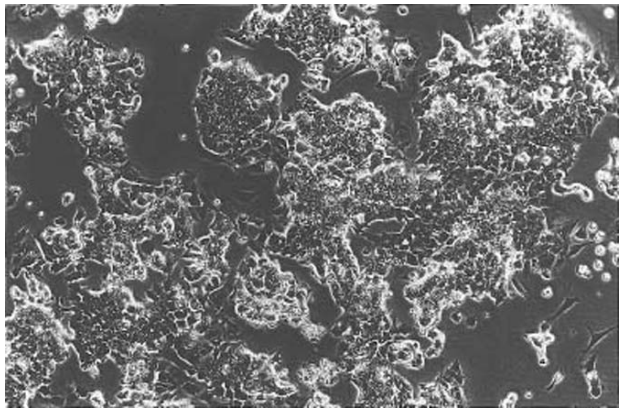

Figure 14.20. Mouse embryonic germ (EG) cells, strikingly similar to ES cells. Photograph courtesy of Ed Gallacher and Jim McWhir (Roslin Institute).

of immortalized cell lines. To do this, a transgene is constructed consisting of the desired promoter linked to a gene capable of immortalizing cells, most commonly the SV40 viral T-antigen (290). Transgenes can be expressed in atypical tissues/stages of development, which can result in inappropriate but informative phenotypes (e.g. mice expressing the HSV *Tk* gene) that are sterile due to the ectopic expression of TK gene in the testes (291). Ectopic expression can be due to influences of the adjacent cellular DNA or to unforeseen interactions between *cis*-acting sequences in hybrid transgenes.

The alternative strategy results in a loss of function. This can be achieved by either gene targeting approaches to generate a knockout (see the following) or directing expression of a transgenes encoding cytotoxic proteins (292). More recent efforts have utilized genes encoding enzymes that convert an inactive prodrug into a cytotoxin. This approach is being developed as a strategy for cancer treatment, termed *gene-directed enzyme prodrug therapy* (GDEPT). One of the most promising examples of this approach is the *E. coli* nitroreductase gene, which offers a number of advantages over the more commonly used HSV *Tk* gene (293). Variations of this strategy include suppressing gene expression through the use of transgenes generating antisense RNA molecules or the overexpression of a dominant negative form of the protein (192).

Another way to use a transgene to study gene function is to use it as a tracer. This can be in the form of a physical genetic marker, because multicopy transgenes can be easily detected by chromosomal *in situ* techniques. Alternatively, transgene expression can be used to trace cell lineages, particularly during development (16).

14.12.2 Knockout (Null) Mice

The most powerful approach used to interfere with the function of a gene is to disrupt one allele by gene targeting in ES cells (241). In conjunction with the established positive–negative selection systems, precise genetic changes can be produced. However, this approach has also revealed the high degree of redundancy in the mammalian genome. In attempts to get around this problem, a variety of spatial and temporal expression vectors have been developed.

Gene targeting has been used successfully to define the function of a number of genes, including many proto-oncogenes (e.g. c-*Myb* and *Wnt*-1) (246). Gene targeting has also made valuable contributions to the understanding of the immune system. Nevertheless, the greatest use of gene targeting has been to identify and characterize developmentally regulated genes. This has been most clearly demonstrated for the *Hox* genes and the transcription factors involved in muscle cell development (294).

The first step in generating a knockout mouse is to introduce the appropriately designed targeting vector into ES cells. In a few cells, the vector is inserted, by homologous integration, into the target gene. This event is identified by positive–negative selection. Subsequent clonal expansion of the target cell then generates an isogenic population of genetically modified cells. These are injected into the blastocoel cavity of a preimplantation mouse embryo. The blastocyst is surgically transferred into the uterus of a foster mother, where development is allowed to continue to term. The resulting offspring are chimeric, and these can be bred to produce transgenic knockout mice in the subsequent generation.

14.12.3 Gene Regulation Studies

Transgenic studies specifically designed to localize and characterize gene regulatory elements have provided important information regarding transcription regulation. The use of enhancer trap and gene trap mice falls into this category. Indeed, gene regulatory elements have been identified *in vivo* through transgenic studies that were not apparent in cell culture studies.

Two classes of transcriptional control elements have been identified by transgenic studies. Both act dominantly to facilitate transgene expression. The first is the human β-globin LCR that overcomes position effects. LCRs enable position-independent, copy-related expression of most genes (227). However, there are genes that even LCRs cannot drive efficiently in transgenic animals (e.g. the *lacZ* reporter gene) (295). The second element is the boundary or insulator element. These loosely characterized sequences appear to protect the transgene from *cis*-acting influences at the site of transgene integration (296). Other aspects of gene regulation have become apparent through transgenic studies. For example, several studies have clearly demonstrated that intronic sequences facilitate gene

expression *in vivo*. Indeed, it has been argued that intron removal per se increases the sensitivity of transgenes to position effects *in vivo* (226).

Transgenes can also provide a valuable tool to look at the mechanisms involved in gene suppression or silencing (297). These include bacterial genes, such as the routinely used *cat* reporter gene encoding chloramphenicol acetyltransferase, and the intronless versions of genomic genes, which are regularly used in expression systems. No robust route to express this type of sequence has been developed, although LCRs and transgene rescue have proved useful. There are now several examples of variegated or patchy transgene expression within a given cell type; that is, not all cells within a given population efficiently express the transgene. This phenomenon is both position and dosage effects (208). It has also been proposed that transgenes present as a multicopy array may themselves direct the formation of heterochromatin (209).

14.12.4 Disease Models

Considerable effort has been directed to the development of transgenic animals as suitable models for human diseases, and there have been a number of successes that should now allow the development of novel therapies. The majority of these animals have been generated using the pronuclear injection method. Such transgenic mice have played a particularly important role in unraveling the consequence of oncogene expression in tumorigenesis. The pronuclear injection technique, however, suffers from the limitations that foreign DNA can only be added, not deleted or altered. The use of homologous recombination in ES cells overcomes this limitation (246,298).

The desire and ability to produce mouse models is clearly demonstrated by the generation of a variety of cystic fibrosis models within 3 years of the isolation of the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This example also shows the limitation of the mouse model, as none of the cystic fibrosis mice clearly reflected the human disease phenotype (i.e. no lung pathology). Although not showing the relevant disease phenotype, these mice do lack CFTR gene activity and therefore are valuable as a model to develop gene therapy strategies to restore the CFTR mRNA levels and hence protein function (299).

To date, all genetically engineered animal disease models have been mice, although it has been suggested that alternative species might be more appropriate models for certain diseases (300). The recent development of nuclear transfer methodology may now allow the development of large animal models of human disease (e.g. sheep genetically modified to provide a model for cystic fibrosis).

14.12.5 Nonmammalian Species as Heterologous Systems

Gene transfer has been accomplished in many nonmammalian animals, including the model invertebrates *D. melanogaster* and the nematode *Caenorhabditis elegans* (275,277), model vertebrates such as the chicken (301), and more recently *X. laevis* (302) and many species of fish (196). In all the cases, DNA transfer is achieved by the microinjection of DNA into oocytes, eggs, or early embryos. In addition to providing valuable information concerning gene function in these species, information relevant to mammalian genes can be generated. For instance, the use of recombinant P elements has facilitated the study of vertebrate regulatory elements such as the β-globin LCR and the chicken lysozyme A boundary elements in *Drosophila* (303). Some nonmammalian species have commercial applications, such as fish, with regard to accelerating growth (304), and birds, with regard to enhanced disease resistance. The latter was brought a step closer with the development of microinjection techniques for chickens (301).

14.12.6 Expression Modeling

Gene regulatory elements not apparent in cell culture have been identified *in vivo* through transgenic studies (305). Furthermore, a comparison of the effect of various regulatory elements showed examples of high efficiency expression *in vitro* and only moderately efficient expression *in vivo*.

These differences can relate to specific transcriptional control elements or more generic differences. For example, molecular analysis of the distal enhancer of the mouse α-fetoprotein gene has shown that mutations affecting specific transcription factor-binding sites caused a 10-fold reduction in enhancer function *in vitro*, whereas in transgenic mice, the same mutation resulted in sporadic tissue-specific expression of the transgene, dependent on the site of integration. In contrast, mutations in the glucocorticoid receptor element of the ovine β-lactoglobulin promoter all abolished expression in transfected cells but had no effect on expression in transgenic mice, as compared with wild-type constructs. The same contrast between *in vitro* and *in vivo* experiments is also observed for the basal transcription machinery. Mutagenesis of the αB-crystallin TATA-box sequence had no effect on promoter activity in transfected lens cells but preferentially reduced promoter activity in the lenses of transgenic mice. Therefore, when comparing cell transfection and transgenic mice, it would seem that regulation of transcription differs *in vitro* from *in vivo* at the levels of both the basal transcription machinery and upstream regulatory elements. There is also considerable evidence to support the hypothesis that a more stringent requirement for

introns exists in transgenic mice than in cell culture. For example, while introns increase transcriptional efficiency of metallothionein-I promoter-driven rat growth hormone gene constructs in transgenic mice, expression in cultured cells seems to be insensitive to the presence of introns (306). This observation led to the proposal that introns facilitate gene expression, but only once the target genes have passed through the germline.

Transcriptional control mechanisms observed *in vivo* are often not consistent with those acting *in vitro*. However, pre-mRNA processing mechanisms observed in cell culture have been shown to correlate with the posttranscriptional modifications observed in transgenic mice. For example, β-lactoglobulin minigene constructs were inefficiently spliced, with the frequency of intron retention similar *in vitro* and *in vivo* (307). This similarity may prove distinctly useful by allowing transgene constructs to be tested for efficient posttranscriptional processing *in vitro* before their use in transgenic livestock.

14.12.7 Transgenic Livestock

Classical animal breeding regimes rely on gene import by cross-breeding and are therefore limited to the improvement of those traits already present in a given species. Transgenic animal technology can overcome these limitations because the exogenous DNA can be derived from a heterologous species and it can be modified *in vitro* before being introduced into the germline.

Working with domestic animals poses a number of technical problems (277). The recovery of adequate numbers of pronuclear eggs, and their successful transfer following microinjection, requires a large number of donor and recipient animals. In addition, the pronuclear eggs of livestock species are delicate and relatively opaque. In pigs and cattle, centrifugation is often necessary before injection to visualize the pronuclei. In sheep, eggs must be observed using a differential interference optics (DIC) microscope to see the pronuclei clearly. These technical hurdles add to the constraints of dealing with large animals with generation intervals of several years.

It has been proposed that transgenesis may allow the generation of farm animals with improved traits, animal models for research, and animal bioreactors. This includes the production of animals with modified growth characteristics and carcass compositions, novel properties of the digestive system, enhanced wool yields, and the production of novel proteins. It is this last opportunity that has seen the most progress over the past decade, with the expression of a variety of proteins targeted to the milk of sheep, cattle, pigs, goats, and rabbits (225). Indeed, this application of gene transfer in livestock is fast approaching commercial success, with the first products currently undergoing clinical trials.

14.12.8 Modulation of Production Traits

The ability to transfer genes into the germline of livestock may well be instrumental in providing an alternative route to satisfying the ever-increasing demand for animal food and products. Productivity traits that may be amenable to modification by transgenesis include growth rate, nutrient composition of food products, quality of wool, and resistance to disease. Initial experiments concentrated on the transfer of growth-related genes (308). These studies were on the whole unsuccessful due to undesirable side effects. The problem was identified as a lack of stringent control over the expression of the transgene. Encouraging results have been obtained with attempts to improve wool production (309). Perhaps the greatest progress has been made in projects aiming to modulate milk composition through the generation of transgenic animal bioreactors (225). In the near future, most progress will perhaps be seen in the area of engineering disease resistance. However, while several strategies addressing disease management have potential, additional research is still required before these approaches can be applied (310).

14.12.9 Animal Bioreactors

To date, the most successful application of gene transfer technology in livestock has been to target the expression of commercially and medically valuable proteins to milk. In the early 1980s, it was speculated that transgenic animals could be used to produce important human proteins for medical use. It was perceived that transgenic animal bioreactors would overcome the limitations of the other recombinant protein production systems and provide proteins with appropriate posttranslational modifications in large amounts (225,311). The first step involves the generation of a hybrid transgene, comprising DNA control elements from a gene normally expressed in the mammary gland linked to the coding region of a valuable gene that is normally expressed in a different tissue, such as the liver.

Clark et al. (312) provided the first demonstration of the feasibility of this approach in large animals. In this study, transgenic sheep were generated that expressed a transgene encoding human clotting factor IX. Unfortunately, in this early experiment, the level of product detected in the milk was very low (25 mg/L). The problem of low yield has now been solved for many proteins, and this general approach has been applied to several animal species, including rabbits, goats, sheep, pigs, and cattle (225). Many different proteins have now been produced in the milk of transgenic animals, although these predominantly reflect model studies in the mouse. These range from relatively simple proteins, such as albumin, to highly complex proteins such as monoclonal IgA antibodies and hexameric fibrinogen (313). The successes in large animals include tissue plasminogen activator in rabbits and goats, antithrombin III in goats,

α-1-antitrypsin and clotting factor IX in sheep, and protein C in pigs. In one of these studies, very high level production was obtained (Fig. 14.21). Tracy, the transgenic ewe, produced human α-1-antitrypsin in her milk at 30 g/L, which approaches half that of the total protein content (314).

It may be that certain species are more appropriate bioreactors for the synthesis of specific proteins. For example, rabbits have been proposed to be appropriate for those products required in small quantities, while the generation of transgenic birds using a DNA microinjection approach opens up the possibility of producing pharmaceuticals in chicken eggs (301). Different tissues may also have particular advantages, for example, because they carry out a specific form of posttranslational modification.

14.13 NUCLEAR TRANSFER TECHNOLOGY

Although to date all gene transfer experiments in livestock have involved the *addition* of genetic material, there is an understandable desire to develop gene targeting strategies. This would open up a vast range of applications in livestock. For example, gene targeting techniques could allow disruption of the prion-related protein gene (*Prp-1*) in cattle and sheep, which could facilitate the production of bovine spongiform encephalopathy (BSE)- and scrapie-resistant animals. In addition, the removal of certain histocompatibility genes would allow the production of animals (pigs) as a source of xenograft organs for transplantation surgery. Furthermore, the ability

to derive live animals from cultured cells would provide a more efficient way to produce superior farm animals. Before such strategies become feasible, however, cell lines that can contribute to the germline must be derived from livestock (260,289).

Nuclear transfer was the first cell culture-based procedure used to produce livestock and was achieved by Campbell and colleagues at the Roslin Institute in 1995 with the generation of the cloned sheep Megan and Morag (288) (Fig. 14.22). Two years later, the same group announced the generation of Dolly (Fig. 14.23), who was derived from an adult cell by nuclear transfer (289). Variations on this procedure, including the generation of ruminant ES or EG cells, are being explored and encouraged by the recent demonstration of live births following nuclear transfer in mice (315). Whatever the route to gene targeting in livestock, the inevitable experimental timescale and the unavoidable financial costs will mean that only those projects likely to yield profitable biotechnological or agricultural applications will be undertaken. At present, there would be little public support for the production of genetically modified livestock for the food chain, though this might well change if it could be shown the animals would benefit (e.g. by having improved resistance to disease). Therefore, the first applications of this second-generation transgenic technology will almost certainly concern biotechnology and medicine (e.g. xenotransplantation or the production of therapeutic proteins in milk).

14.13.1 Advantages of Cell-Based Gene Transfer Procedures

There are two driving forces behind the development of cell-based gene transfer procedures in livestock. First, the desire to overcome position and dosage effects (316), and second, the desire to overcome the laborious techniques involved in the production of transgenic livestock by pronuclear microinjection (primarily reflecting the large number of animals required). In addition, microinjection can only add genes. A cell-based method to produce transgenic livestock allows single-copy transgene integrants to be generated at predetermined sites, which should limit problems such as variegated transgene expression. Future transgenic livestock will probably have the transgene integrated into a permissive site, and although such an appropriate genomic site remains to be determined, this approach has been evaluated in the mouse model. The outcome is likely to be more predictable in terms of generating the anticipated transgene expression profile. Expression levels from these single-copy transgenes may need to be enhanced, because multiple-copy transgene loci can generate very high levels of expression. It is likely that many of these issues can be evaluated in cells before generating a transgenic animal.

Targeted integration has been possible in the mouse model through ES cell technology (241). Although there has been considerable effort to generate ruminant ES cells, to date all attempts have been unsuccessful. An alternative approach involves the transfer of nuclear genetic material from cells grown in culture into an unfertilized egg (317). Now, rather than merely evaluating a transgene construct in cell culture, the actual cell is the genetic material from which the transgenic animal is generated. The gateway has been opened for the production of a variety of livestock for both agricultural and biomedical applications. There are many advantages to this technology; for example, all founder animals are transgenic, mosaic founders are not produced, the sex of the founder can be selected, and a flock/herd of clonal animals can be produced within one generation. More important, many aspects of the

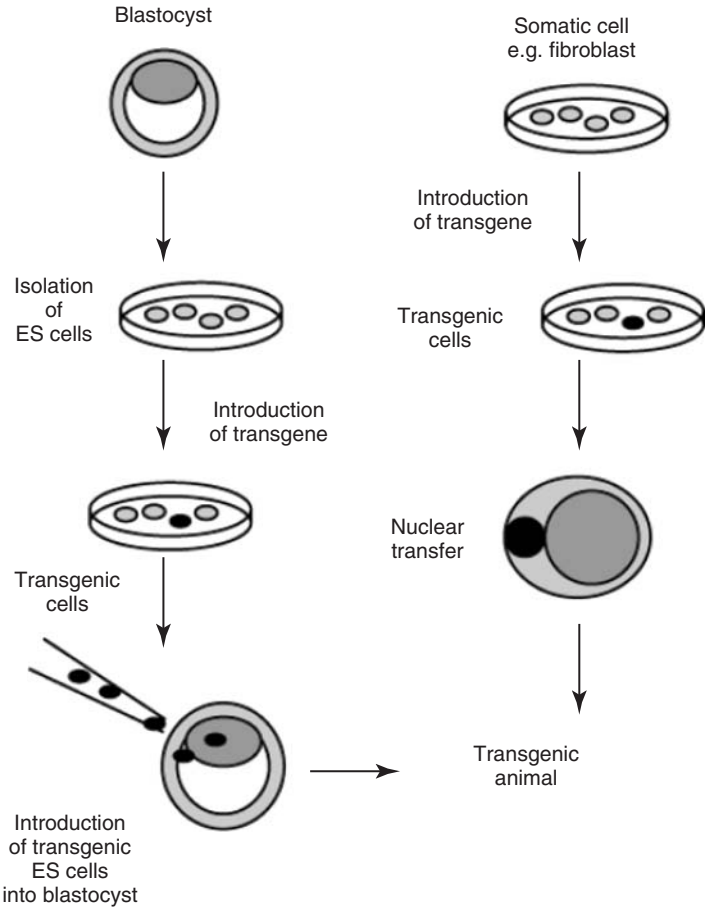

Figure 14.24. A comparison of the ES cell and nuclear transfer routes to generate transgenic livestock. Either procedure is amenable to gene targeting strategies, following introduction of DNA by microinjection, electroporation, or other forms of transfection.

transgene can be analyzed *in vitro* before the generation of an animal. The integrity of the transgene locus can be evaluated, which may be particularly important when large transgenes such as YACs are used. Furthermore, it will be possible to check the expression potential of a transgene before going through the cost of producing the animal. Expression strategies could, for example, involve the transient production of an appropriate transcriptional activator, which could mediate *trans*-induction of transgene expression. The most important point, however, is that it is possible to select for site-specific integration events generated by gene targeting, thus allowing strategies involving gene knockout or replacement to be performed as shown in Fig. 14.24.

14.13.2 Ruminant Embryonic Cells

No ruminant ES or EG cells are currently available. In this regard, there is an ongoing debate about which *in vitro*, environmental, and genetic factors could be responsible for the differences between mice and other mammalian species (261). The rationale behind this approach is that ES cells can be isolated from some mouse strains more efficiently than others. It was proposed that this may reflect the differences in the control of ES progenitor cells by other lineages within the embryo (318). Thus, if these other lineages were removed, the ES cell progenitors might survive. This is indeed the case, at least for some mouse strains nonpermissive for ES cells (Fig. 14.25). This approach is currently being tried in pigs and rabbits. Although encouraging, the selection method is limited by the initial requirement of the appropriate transgenic line. In an attempt to overcome this limitation, transient expression strategies are being developed.

An alternative cell type is the EG cell derived from PGCs. There is some considerable progress in the development of this cell type, and recent advances in PGC isolation and culture, and hence the culture of EG cells, have provided the impetus to develop this approach.

Figure 14.25. Selective ablation of differentiated cells permits isolation of ES cell lines from nonpermissive strains. The photograph shows a germline chimera derived from line 39/1, its albino MF1 mate, together with germline (agouti) and nongermline (albino) littermates. Courtesy of Jim McWhir and Helen Wallace (Roslin Institute).

14.13.3 Nuclear Transfer

Xenopus nuclear transfer was first reported in 1952. Since then, it has been widely used in amphibians, primarily for experiments addressing early development (319). In 1977, a mouse was generated by nuclear transfer using a cell from a very early embryo. The procedure in mice proved to be very difficult. Since then, most research has concentrated on farm animals, driven by the prospect of large financial benefits derived from cloning elite and/or transgenic embryos. In the 1980s, cloned sheep and cattle were generated using early embryo cells as donors. Furthermore, some experiments in the United States showed that live calves could be derived by nuclear transfer using cells from the late blastocyst stage. At this stage of mammalian development, primitive cell types are distinguishable; therefore, this was the first suggestion that nuclear transfer in mammals was possible from at least partially differentiated cells. The major breakthrough came in 1995, when Ian Wilmut and Keith Campbell produced two live lambs—Megan and Morag—by nuclear transfer of embryonic cells grown in culture (288). Within a year, a lamb had been produced from an adult cell (289). This lamb was called *Dolly*. Since then, a number of lambs and calves have been generated using this technology, some of which are transgenic (260,317). The objective is now to expand the number of species where nuclear transfer can be applied. In this regard, the recent demonstration of nuclear transfer in mice should dramatically accelerate the development of this technology (315).

Embryo reconstruction by nuclear transfer involves the transfer of a single nucleus to an unfertilized oocyte or one-cell zygote from which the genetic material has been removed. For livestock, the recipient cell of choice is usually an unfertilized oocyte that has been arrested at metaphase of the second meiotic division. The first step is to enucleate the recipient oocyte. The genetic material is removed using a small glass pipette, a highly skilled procedure. The genetic material from the donor cell is then introduced into the enucleated oocyte, usually by cell fusion using a short electrical pulse, although treatment with PEG or Sendai virus is also possible. The next phase involves the activation of the reconstructed embryo. In nature, this is achieved by fertilization and involves calcium mobilization. Activation can be mimicked by a variety of chemical agents, such as phorbol esters or calcium ionophores. In practice, this step is often simplified, because the electric pulse used to fuse the cells can also activate the embryo. Finally, the embryo is cultured to a stage at which it can be transferred to a synchronized recipient animal for development to term. Some livestock generated by nuclear transfer are shown in Fig. 14.26.

14.13.4 Source of Donor Nuclei

The highly publicized generation of Dolly demonstrated that the donor cell for nuclear transfer could be derived from a differentiated cell. In this case, the source was a cultured mammary cell line, the cells being derived originally from a 6-year-old ewe. However, this experiment was very inefficient with only one animal being produced from about 250 cultured cells (289). The donor cell must be neither aneuploid nor contain any other chromosomal damage. In addition, for technical reasons, it must be easy to handle and manipulate in culture. The most commonly used cell

Figure 14.26. Livestock generated by nuclear transfer. (a) Mr Jefferson, a Holstein calf produced by nuclear transfer from a fetal fibroblast cell line in 1998. (b) Dolly, the first transgenic lamb produced by nuclear transfer, born in 1997. Photographs courtesy of Ian Garner and April D'Arcy (PPL Therapeutics plc).

type is the fetal fibroblast (317). Obviously, if ruminant ES or EG cells become available, they would provide ideal donor cells (260).

One of the main requirements for successful nuclear transfer using ruminant cells is the synchronization of the cell cycle between donor and recipient cells. The outcome of these studies demonstrated that cell cycle arrest in G_0 phase was crucial for the procedure to work. This can be accomplished simply by reducing serum levels in the culture medium, although whether this is the best strategy remains to be investigated. The suitability of the quiescent donor nuclei may reflect a number of factors, such as reduced transcription and translation, low metabolic activity, and condensed chromatin. Presumably these changes render the nucleus and cytoplasm more compatible with the mechanisms of reprogramming.

14.13.5 Reprogramming

Reprogramming refers to the change in differentiation state associated with nuclear transfer. The donor cell is differentiated, to varying degrees, while the egg is not. Before transfer, a variety of cell type-specific genes would be active in the donor nucleus. These must be repressed, and the appropriate genes required for early embryonic development must be activated; that is, the nucleus has to "forget" its history (whether it was taken from a fibroblast, mammary cell, etc.) and take instructions from the cytoplasm of the recipient cell. Reprogramming is anticipated to depend on a large number of factors, the majority of which are undefined and not understood at present. In addition to differences in the levels of various transcription factors, the nucleus itself also changes during development, through chromatin remodeling and DNA methylation, resulting in the silencing of many genes. Such changes also need to be erased before development can be recapitulated by nucleus transferred to a reconstituted embryo. Another important factor is the age of the donor nucleus. The cell used to generate Dolly was derived from a 6-year-old ewe, raising the question of whether Dolly would show signs of premature aging. One anticipated effect is that the telomeres, which protect the chromosome ends, become progressively shorter. A recent study (320) showed that Dolly's telomeres were indeed shorter than expected for a sheep her age. However, this does not appear to have affected the health or reproductive ability of Dolly or any other cloned animal—indeed, Dolly has already had two successful pregnancies. This finding does have important implications for some nuclear transfer strategies, such as sequential cloning.

14.13.6 Xenotransplantation

Over the past few decades, transplantation has become the preferred treatment for human organ failure. However, there is a chronic shortage of donor organs, so that only half of the potential operations are actually performed. If animal organs could be used instead of human organs (xenotransplantation), this shortage would be overcome (321). The major limitation to the use of nonprimate organs in human patients is tissue rejection. As the immune system plays such a critical role in the host defense, there is considerable interest in engineering tissue compatibility into the xenograft donor as opposed to suppressing the patients' immune response. Transgenic animals offer a route to overcome this limitation.

The hyperacute rejection of organs reflects the activity of the host's complement system. One proposed strategy involves the generation of animals that carry transgenes, allowing evasion of the complement system. For example, transgenic pigs have been produced carrying a transgene encoding a complement inhibitory factor that coats the cells (322). At present, further developments are required, including modulation of the antibody response induced by xenotransplantation (323). Here, the ability to remove genes could have a major impact on the success of xenotransplants. Surprisingly, most of the antibodies in our blood that would react against a pig organ recognize a single carbohydrate linkage present on pig cells (324). This disaccharide, Gal-$\alpha 1-3-$Gal, is synthesized by α1,3-galactosyltransferase. Primates do not have a functional α1,3-galactosyltransferase gene and therefore do not recognize this carbohydrate. Elimination of this enzyme in pigs by gene knockout could therefore reduce hyperacute rejection of transplanted organs. This strategy requires the ability to perform germline gene targeting experiments in pigs. This may now be possible with the development of nuclear transfer technology (260,289).

The first experimental transfer of a genetically modified pig's heart was into cynomolgus monkeys (325). None of the 10 hearts was rejected, and the monkeys survived for an average of 40 days. Conversely, hearts from control pigs were rejected within hours. This is encouraging, but the routine use of xenotransplantation by the surgeon will require equally challenging approaches to overcome delayed rejection, such as cellular rejection. Currently, this type of rejection is controlled by immunosuppressive drugs, but here again gene transfer technology may hold the answer. Notwithstanding the technical hurdles required to generate transgenic pigs with the appropriate genetic modifications, there are many ethical issues that need to be debated. In addition, xenotransplantation may well bring novel disease problems, and the potential severity of these issues remains to be examined. For example, the transplantation of a pig heart into a human patient may expose that individual to infection from endogenous retroviruses present in the pig cells (321).

14.13.7 Nuclear Transfer and Somatic Cell Therapy

An alternative approach to *in vivo* gene therapy is to modify cells genetically *ex vivo* and then reintroduce them into the patient. This route overcomes many of the serious problems associated with efficient gene delivery but has been restricted by the ability to isolate the appropriate cells. The development of nuclear transfer using somatic cells grown in culture has provided an new impetus to these studies (289). These pioneering nuclear transfer experiments have demonstrated that a differentiated cell can be programmed to restart development. Once the mechanisms behind this process are understood, it may be possible to reprogram animal cells without resorting to the use of an egg. In the future, this may well allow a patient's own cells to be used for personal gene therapy. This would avoid the expense and uncertainty of tissue matching. In this scenario, cells would be removed from the patient, converted into the desired cell type in the laboratory by nuclear reprogramming, and then reintroduced into the same patient.

14.13.8 Animal Cloning

The cloning of animals provides immediate advantages for both animal breeding and basic research. The main advantage in breeding would not be in the selection programs and in the rapid dissemination of the genetic progress from elite herds to the commercial farmer. There is a risk attached, that of loss of genetic diversity, but this could be avoided, for example, by systems to ensure that breeding companies produce a limited number of clones of each type. Alternatively, nuclear transfer from cultured cells could be of use for species where repeated breeding is impractical or prohibitively expensive. It may also prove useful in providing new approaches for genetic conservation. In the context of research, genetic variation between individuals tends to confound the often subtle responses to test diets or drugs. The advantages of genetic uniformity has been demonstrated in studies with inbred lines of mice and exploited to some extent with the numerous back crosses that provide the basis for many animal genome mapping schemes.

INOCULUM EXPANSION METHODS, ANIMAL CELL LINES

Claudia Kloth, Glenn Maclsaac, Haile Ghebremariam, and Alahari Arunakumari
Medarex, Inc., Bloomssbury, New Jersey

15.1 INTRODUCTION

Genetically engineered mammalian cell lines are the main production systems used for therapeutics as well as diagnostics (1). For such manufacturing processes, the initial process steps of inoculum expansion contribute greatly to the success of the subsequent manufacturing steps, overall process efficiency, and product consistency. Common therapeutic protein products such as Epogen®, Rituxan®, Herceptin®, Avastin®, Humira®, and Vectibix® are manufactured in immortalized Chinese hamster ovary (CHO) cells (1). Other commonly used cell lines for the production of recombinant products are derived from baby hamster kidney (BHK), mouse myeloma (NS0, SP2/0), mouse mammary (C127), human embryonic kidney (HEK-239) and more recently, human primary embryonic retinoblasts (PER.C6®) (2–5).

Hence, in this chapter previous practices as well as state-of-the-art inoculum expansion methods for recombinant mammalian cell lines are summarized. Suspension cell lines are the main focus due to their predominant current and potential usage in large-scale biomanufacturing. Conventional inoculum expansion process operations are discussed including both, small-scale flask expansion and seed bioreactor. In addition, the trend toward applying current disposable technologies in the inoculum trains is also highlighted. This review also covers strategies to reduce the duration of the inoculum expansion process since it can be one of the most time-consuming phases of large-scale manufacturing. In addition, technology transfer of the inoculum expansion and the influence of cell bank quality on a successful vial thaw and inoculum process are addressed.

15.2 INOCULUM EXPANSION PROCESSES

A consistent and robust inoculum expansion method is crucial to initiate a successful manufacturing run. The main objective is to generate large volumes of highly viable cells in the shortest possible time period, for inoculation of the production bioreactor. This is achieved by maintaining the cells in an actively growing state, known as the *exponential phase*, throughout the inoculum expansion.

Conventional inoculum expansion procedures start with thawing the cryopreserved cells, commonly one vial of the Master Cell Bank (MCB) or Working Cell Bank (WCB), followed by cell expansion through multiple cell passages (Fig. 15.1). During expansion, culture medium is added to replenish nutrients and increase cell inoculum volume. Shaker flasks (available in 125 mL to 3 L sizes), T-flasks (T25 to T175), spinner flasks (100 mL to 5 L) and/or roller bottles (500 mL to 2 L) are mostly used for the initial expansion steps. In these flasks, cell inoculum of 10–20 L volume is commonly generated, and can be used to inoculate 40–100 L bioreactors. Beyond this volume, the workload of passaging cells under aseptic conditions and the increased incubator demand renders the flask process laborious and impractical. For larger inoculum volumes, seed bioreactors or seed bioreactor trains are used (refer

Step		Description	Duration (days)	Final volume
Vial thaw		Thaw one vial (a) Seed T-flask (b)	0 0	1 mL 50 mL
Inoculum expansion (passages)	P#1	Count cell density/viability Seed spinner flask (c)		150 mL
	P#2	Count cell density/ viability Seed spinner flask (d)	5	600 mL
	P#3	Count cell density/ viability Seed spinner flask (e)	8	3 L
	P#4	Count cell density/ viability Seed spinner flask (f)	11	10 L
Seed bioreactor		Inoculate reactor in perfusion (g) or batch mode	14	35 L
Production bioreactor		Inoculate reactor (s)	19	250 L

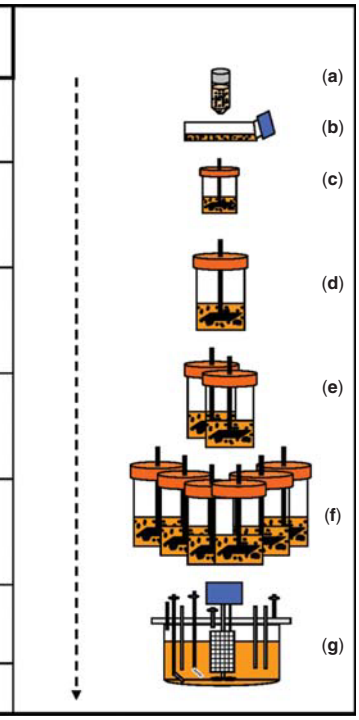

Figure 15.1. Example of inoculum expansion process for a large-scale production bioreactor. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

to section titled "Expansion in Seed Bioreactors"). The expansion steps in flasks require routine opening of culture flasks which present a significant risk of contamination. As a result, the dedicated inoculum preparation room for cGMP manufacturing is segregated and controlled as a Class 10,000 (ISO Class 7) area. Within this room, activities related to cell culture, like sampling and passaging, are conducted in a Class 100 (ISO Class 5) biosafety cabinet. Examples for vial thaw and inoculum expansion processes, also used in cGMP production, are described in the following sections. Contamination risks can be minimized by direct inoculation of bioreactors without the flask expansion process (refer to section titled "Time Reduction").

15.2.1 Vial Thaw

The vial thaw is the first step to commence cell inoculum from cell banks. Cryopreserved cells are removed from vapor phase liquid nitrogen used for long-term storage and are thawed at controlled temperature. Depending on the product development stage, the cells for the inoculum may originate from the MCB or manufacturer's WCBs. The MCB is generally used for early clinical phases of cGMP production, while vials from the WCB are used to initiate commercial manufacturing runs.

All cell banks are prepared from a homogeneous cell source and aliquoted into cryogenic containers, typically vials. The cell bank is frozen slowly using a controlled rate freezing process at around 1–3°C/min, and subsequently stored in the vapor phase of liquid nitrogen (6,7). To protect the cells from freezing related damage such as intracellular ice crystallization and cell lysis during freezing, long-term storage, and cell recovery (8), cryoprotectants such as DMSO are used in the freezing mixture (8). Historically, freezing mixtures have contained a defined amount of heat inactivated serum, like fetal bovine serum (FBS) of 10–95% (v/v) final concentration, along with cryoprotectants like dimethyl sulfoxide (DMSO), glycerol or polyethylene glycol (PEG), sucrose, and conditioned culture medium (9,10). Due to regulatory preferences and the shift to animal component–free processes, FBS is generally avoided in current banking procedures for production of cell lines. Freezing mixtures containing solely DMSO and animal component–free or chemically defined media are successfully used for preparing cell banks.

For highest viable cell recovery during cell revival, literature recommends a rapid thaw above 20°C/min (8), commonly performed in a 37°C water bath. Slow warming should be avoided since it may result in intracellular crystallization which damages fragile cell membranes (11) and may expose the cells to hyperosmotic concentrations of external and internal solutes (12).

Once thawed, cells are immediately re-suspended in culture medium and generally centrifuged to remove the freezing mixture. Centrifugation removes the majority of DMSO, FBS, or other media components in the freezing mixture, and the cell pellet is re-suspended in new culture medium for the first passage at predetermined cell density. The centrifugation step, however, may lead to stress-related loss of cell viability and cells (13). To avoid this loss as well as to ease the thaw process operation, the most desirable thawing procedure appears to be seeding of the cells directly into the culture without centrifugation. This can be easily incorporated when the freezing and inoculum expansion medium are identical or comparable. It is further recommended to sufficiently dilute the thawed cells with culture medium to reduce DMSO below cell inhibitory concentrations. For example, freshly thawed CHO-S cells tolerate up to 0.4% DMSO in the culture medium while maintaining their original doubling time (12), whereas in a case study for a frozen fragile recombinant CHO DG-44 cell line, additional dilution of the DMSO was required; for example to concentrations as low as 0.1% (13).

15.2.2 Cell Expansion for Suspension Cell Cultures

Expansion of cell cultures in a small scale, also referred as passaging, subculturing or splitting the culture, involves transferring a defined number of cells into a new vessel and adding culture medium for further cell propagation. When passaged at well-defined intervals, cells are maintained in a healthy condition for a long period of time. For the biomanufacturing of recombinant proteins in mammalian cell lines, both suspension and adherent cells have been used, though suspension cell cultures are far more common. During inoculum expansion, the suspension cells are maintained in static or agitated cultures or a combination of both. The cultures are generally split using a ratio of cell culture to medium volumes from as low as 1:2 up to 1:10 depending on cell line and culture medium.

15.2.2.1 Static Cultures. In static cultures, cells are grown in flasks without agitation. Here, the shear stress–free environment may be advantageous immediately after thaw. However, even suspension cells tend to attach to plastic surfaces in static conditions, leading to potential cell loss. In addition, cell growth in static culture allows only a limited volume to surface ratio due to ineffective gas diffusion requiring large surface area. Therefore, the inoculum is expanded using either multiple T-flasks or larger systems like Nunc Cell Factories, which provide increased surface areas from 632 cm^2 (one tray) up to 25,280 cm^2 (40 trays, www.nuncbrand.com). Since each tray can handle 200 mL of culture, up to 8 L of cell culture inoculum can be generated using a 40 tray factory. Each Cell Factory is filled and harvested in a single operation which minimizes culture manipulations. Although the 40 tray factory has been described as a challenge to operate manually (14), it can successfully be automated with a manipulator and robot (www.nuncbrand.com).

Most static processes lead to cell aggregation. When these cannot be separated solely by tapping or pipetting, obtaining accurate cell counts remains challenging. Precise cell counts facilitate the specified seeding cell densities for each passage, and are essential for robustness and predictability of the entire cell expansion phase. To limit operator variances due to subjectivity in counting aggregates, the representative cell sample can be pretreated with proteases such as porcine trypsin, or enzyme containing mixtures such as Accumax™ (www.innovativecelltech.com). These agents separate cell aggregates into single cells without altering cell viabilities (www.innovativecelltech.com, 13). For use in cGMP manufacturing, animal component–free agents like Accumax™ are preferred. Reduced cell aggregates are generally observed in agitated systems in comparison to static growth cell cultures.

15.2.2.2 Agitated Cultures. Agitated systems are mainly used in inoculum expansion for clinical and commercial processes. They are superior to static flask cultures through active mixing of the cell culture, maintaining homogenous temperature, improved mixing of nutrients, as well as better gas diffusion. The agitation speed is a crucial process parameter to be optimized for each flask size and culture volume and also includes roller speed, speed of magnetic stir plates, as well as speed and angle of rotation for orbital moving shaker flasks. Though most agitated systems provide sufficient gas transfer through surface aeration, it is also common practice to aerate by active sparging to accommodate increased inoculum volumes in the culture vessels. Adherent cells fixed on porous carriers can also be cultured in agitated cultures, similar to suspension cells (refer to section titled “Cell Expansion for Adherent Cell Cultures”).

15.2.2.3 Process Parameters. For a robust manufacturing process, operational ranges for process parameters need to be established prior to process transfer from process development to clinical and commercial manufacturing. Both static and agitated systems require the maintenance of temperature and carbon dioxide concentration within a defined range to promote optimum cell growth. Incubators are maintained at a physiological temperature of around 37°C at which mammalian cells grow optimally. Lower temperatures reduce cell growth, which in turn prolongs the inoculum expansion time. On the other hand, elevated temperatures may also lead to heat shock and cell death (15,16).

Similarly, culture medium pH plays a crucial role in cell growth. Values of pH between 6.7 to 7.9 support cell growth of most animal cells, though the optimum range depends

upon the specific cell line (17,18). In most cases, buffering components in the medium, such as sodium bicarbonate ($NaHCO_3$) in combination with carbon dioxide (CO_2) in the incubator, are used to control the culture pH. Other media components, like amino acids or HEPES, may also modify the culture medium pH. To establish growth-supporting pH conditions in the cell culture, the amount of selected buffering agents and corresponding CO_2 concentration need to be optimized for each culture medium. The CO_2 gas is introduced into the culture by either pre-gassing a CO_2–air mixture into the flask prior to cap closure or by continuous gas transfer using vented flasks. During vented flask operation, flask caps with integrated filters are used and the flasks are maintained in the humidified incubator chamber with desired CO_2 concentration, which is commonly between 5% and 10%. The most effective way to add CO_2 gas to the cell culture is by actively gassing the CO_2 –air mixture into the culture medium.

For healthy cell cultures, sufficient oxygen supply is required. Agitated systems effectively enhance gas exchange through active mixing, which allows increased working volumes. Even though agitated systems increase the rate of oxygen transfer into the culture, it is still often limited through low agitation speeds used to protect cells from shear forces. As a consequence, flasks still operate with a diminished working volume. To overcome this limitation, agitated systems can be actively sparged using dip tubes, porous spargers, or internal gas permeable membranes to significantly enhance gas transfer. As a result, greatly increased culture volumes can be maintained in these actively sparged flasks (19). In the case of a 3-L spinner flask, up to 1.5 L of cell culture can be supported when maintained in conventional spinner flask operation, and up to 3 L of culture volumes when actively sparged. Advanced designs of disposable flasks such as SuperSpinner (www.sartorius.com) result in even more effective gas transfer using active bubble-free addition of gas mixture through a permeable internal membrane. For this system, a 3.5 times increased volumetric transfer coefficient ($k_L a$) was reported in contrast to other agitated systems (20). This may support growth to higher cell densities than conventional surface-aerated spinners which lead to economically enhanced inoculum expansion processes through decreased flask usage and culture handling (21).

15.2.3 Cell Expansion for Adherent Cell Cultures

Suspension cultures are passaged by diluting cell culture with new medium, whereas for adherent cultures, the cells first need to be detached from the matrix surface before seeding a new culture. Adherent cell cultures, also known as anchorage-dependent cultures, are seeded either in static flasks (e.g. T-flasks), or more commonly, in agitated systems like roller bottles where the cells attach to the flask surface thereby covering greater surface area during cell growth. For inoculum expansion, minimum seed cell densities for around 10% flask confluence are recommended to avoid initial lags in growth. The cell culture should be split prior to reaching confluence to maintain rapidly growing adherent cells. The routine subculturing is performed according to a strict schedule to ensure a reproducible growth pattern. A recommended routine may follow subculturing once a week with a medium change in-between the splits (22). Roller bottles are inoculated with 5–30% of overall volume and slowly rotated. The rotation promotes nutrient and gas supply for the adherent cells. Between the middle of the logarithmic growth phase and the time before entering the plateau phase (confluence), cell passaging commonly occurs. The excess culture medium is typically removed and the cells are detached from the matrix with enzyme mixtures. Historically, a porcine trypsin–EDTA mixture (23) was used, although animal component–free enzyme mixtures such as Accustase™ (www.innovativecelltech.com), Detachin™ (www.genlantis.com) are currently available, and preferably used in cGMP operation. The detached cells are diluted with new culture medium and new flasks are inoculated until sufficient cells are generated to either start the production stage in roller bottles, or inoculate a seed or production bioreactor. The production in roller bottles was successfully automated as shown in the production of erythropoietin (EPO) (24). Here, most of the critical manufacturing steps of bottle handling are performed by robots, including cell seeding, media fill, and harvesting of supernatant. For conventional bioreactor operations, adherent cells are seeded onto microcarriers or porous microspheres and can be maintained in agitated culture (6,25,26), fixed/packed or fluidized bed operations. Cells adhering to microcarriers grow within pores and possibly in multiple layers, which may result in difficulties during the cell removal process and in significant loss of cells during the seed bioreactor phase.

Adherent cells can be transitioned into suspension cells by changing culture conditions and medium composition, such as reducing Ca^{2+} concentration. This transition is often time-consuming, involving the screening of various media and requiring multiple cell passages before the cells have adapted to single-cell suspension. Institutions have generated suspension-based host cells in chosen culture medium to eliminate this adaptation process and to reduce developmental timelines significantly (27). Many of these cell lines are commercially available and can be used immediately for the transfection step to generate the recombinant cell line.

In contrast, suspension cells may convert back to adherent cells, mainly through the choice of culture medium and carrier material. Alternatively, cells can also be entrapped

in fibrous material such as that used in the iCellis™ technology (www.artelis.be), where the perfusion in the fibrous bed relies on cell attachment to the three-dimensional structure. Some of the advantages of the so-called 3D cultures are higher cell densities and higher productivities (28), although the monitoring of cell growth and viability may still be challenging.

15.2.4 Expansion in Seed Bioreactors

For large-scale production of suspension cells at 200 to 20,000 L bioreactor scale, the initial inoculum expansion process continues in seed bioreactors to bridge the gap between culture flasks and production bioreactors. Seed bioreactors of successively larger volumes are used, and their number and scale depends on the final production scale and volume split ratio. Most commonly, the seed reactors in biopharmaceutical production are operated in batch or perfusion mode.

15.2.4.1 Batch Process. The batch process is a simple operation that requires the least amount of culture medium compared to a perfusion process. Once the culture is inoculated, cell growth and viability is monitored for several days until the transfer cell density is reached. Here, the batch process provides only a narrow time window for the transfer of exponentially growing cells with a limited split ratio. Batch-to-batch transfers from small to subsequently larger size bioreactors commonly have split ratios from 1:5 to 1:10. As an example, a 40-L cell inoculum can seed a 200- to 400-L bioreactor. These split ratios are considered during the design of seed bioreactor trains in commercial facilities.

A special case of batch operation is the "feed and bleed process", which is a semicontinuous process. In this case, the cell inoculum is grown to the transfer cell density in the seed bioreactor, and then around 80–90% of the cell culture is removed to inoculate the production bioreactors (29). The remaining 10–20% of cell culture in the seed reactor is replenished with new culture medium to continue the cell expansion and to serve again as cell inoculum for the future production reactors. This cycle can continue until either the maximum population doubling level (PDL) of the cell line is reached, or sufficient production bioreactors are inoculated.

If a cell line in basal medium cannot achieve adequate transfer cell densities in batch operation, the cell culture can be enriched with nutrients to increase overall cell densities. Table 15.1 shows an example where seed reactors were cultured in batch mode as well as with nutrient supplementation on day 0 or day 3. The maximum transfer cell density was set to not exceed 75% of the measured peak cell density. As a result, an approximately 60% increase in peak viable cell density was observed with supplement-enriched conditions in comparison to the batch process independent of the time of supplementation. With the increased peak cell density, the transfer range to the next larger bioreactor was widened, providing additional operational flexibility.

15.2.4.2 Perfusion Process. In comparison to batch operation, a seed bioreactor in perfusion mode is extremely flexible in allowing an extended window of inoculation. Here, the cell culture can be maintained at high cell density and viability for a long period of time, due to continuous perfusion of culture medium and possible cell purge. Since higher cell densities can be achieved in the perfusion mode relative to batch mode, a perfusion seed reactor can inoculate larger reactor volumes or multiple bioreactors simultaneously.

Inoculation ratios up to 1:20 are commonly being reached in perfusion application for example, a 10-L perfusion seed bioreactor can inoculate a 200-L production bioreactor (8). The inoculation ratio can be even extended up to 1:250 by using a novel gravity settling device to achieve high cell density and viability seed cultures (30). In this condition, as little as 0.8 L of cell culture would be sufficient to inoculate a 200-L bioreactor. Although such a perfusion system demonstrates future potential for inoculum expansion, such a device is currently not implemented in large-scale production.

Staggered inoculation of multiple production bioreactors from perfusion seed bioreactors were demonstrated in 5-L

TABLE 15.1. Seed Bioreactor Operation in Batch, Fed-Batch with Nutrient Addition on Days 0 and 3 and Perfusion Mode in 5-L Bioreactor Scale

Mode of Operation	Peak Cell Density ($\times 10^6$ vc/mL)	Maximum Transfer Cell Density ($\times$106 vc/mL)	Maximum Production Bioreactor Volume (L) using 5-L Seed Reactor
Batch Mode			
Basal medium = Control + Feed addition (day 0) + Feed addition (day 3)	2.1	1.6	40
	3.5	2.6	65
	3.4	2.6	65
Perfusion mode			
With basal medium (1RV/d)	4.6	3.5	90

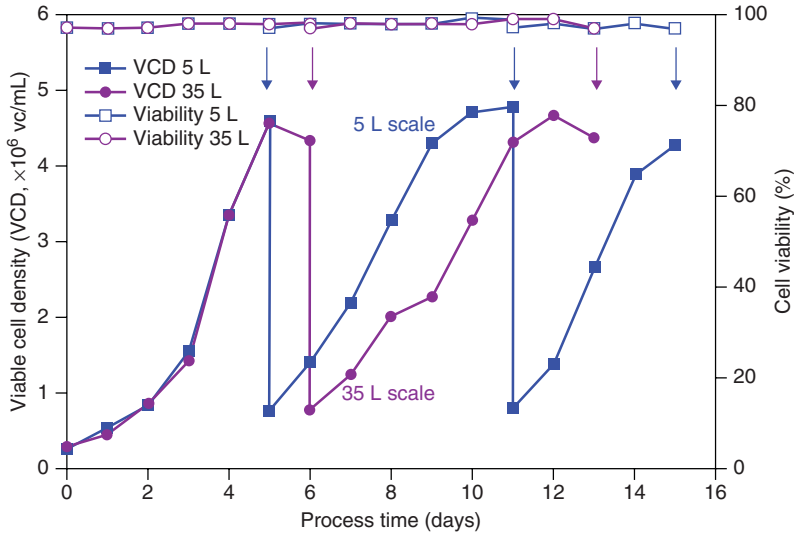

Figure 15.2. Operational flexibility of seed bioreactor in perfusion mode. Perfusion seed bioreactors in 5-L (blue) and 35-L (red) scale. Multiple production bioreactors were inoculated in a staggered fashion as indicated by arrows. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

development and 35-L manufacturing scales (Fig. 15.2). In a staggered fashion, each perfusion bioreactor could inoculate two or three production bioreactors. In both scales, the recommended transfer cell densities were reached on day 5 for a 1:15 to 1:20 inoculation ratio and partial seed culture volumes were sufficient to inoculate the production bioreactors. After inoculation, the seed bioreactor working volume can be replenished with new medium and the perfusion operation continues until additional production bioreactors require inoculattion. All sets of production bioreactors can be inoculated based on the manufacturing schedule since the perfusion operation can easily be modified, that is, maintaining a certain cell density through initiation of cell purge. Clearly, seed bioreactor operations in perfusion mode provide manufacturing flexibility. The inoculation cycle can be repeated multiple times as long as the cell line is stable, resulting in consistent and robust production bioreactor performance in terms of cell growth, product concentration, and quality. On the other hand, the major disadvantages of perfusion are the increased volume of medium usage and the relative complexity of operation (31). In comparison to batch processes, operation in perfusion mode requires additional characterizations of process parameters like cell retention device–related settings, perfusion or biomass removal rates.

Selecting the most appropriate seed bioreactor mode is mainly based on equipment availability, operational knowledge, cell line, and medium-specific performance. Table 15.1 summarizes a study where the seed bioreactor operation was tested in baseline batch mode, batch mode with nutrient supplementation, and perfusion mode. In perfusion mode, the transfer cell densities increased 120% relative to batch performance using one reactor volume per day (1 RV/d) perfusion rate. Here, the peak cell density could be further enhanced by either increasing perfusion rate or supplementing the basal medium with nutrients. In this case study, both modes of seed bioreactor operation, fed-batch and perfusion, fulfilled the inoculation requirements and delivered healthy seeds.

15.2.4.3 Process Parameters. Different seed reactor designs and operations, such as stirred tank and air lift bioreactors, are found in large-scale manufacturing of suspension cells. In recent years, disposable systems including single-use stirred tank bioreactors or wave-mixed bioreactors have been increasingly utilized due to their operational ease and reduced validation requirements (see section titled "Disposable Systems"). Seed bioreactors are operated with process controls analogous to production bioreactors, including dissolved oxygen (DO), pH, temperature, agitation, and aeration besides cell density and cell viability. The latter two are the most crucial expansion parameters and can be monitored regularly through automated sampling systems (e.g. www.grotonbiosystems.com, www.innovatis.com) connected to automated cell counters (e.g. Cedex, www.innovatis.com). Continuous, *in situ* monitoring of these key parameters in a nondisruptive fashion is also enabled using new sensor technologies such as capacitance-based probes monitoring viable biomass (e.g. www.aber-instruments.com, www.fogalebiotech.com). Recent developments in noninvasive optical sensors provide means of

monitoring cell culture performance in disposable systems with single-use sensors (32,33). Such sensors commonly measure DO, pH, and various nutrients although cell density monitoring is also commercially available (e.g. www.aberinstruments.com, www.fogalebiotech.com). Such sensors allow real-time monitoring, resulting in better process understanding and controls and may increasingly be integrated in future production processes. These improvements can lead to successful implementation of process analytical technologies (PAT) in the manufacturing process and support quality by design (QbD) process concepts (34,35).

15.2.5 Inoculum Cell Density and Cell Physiology

Since the main goal of inoculum expansion is to generate healthy and rapidly growing cell cultures, cells should be maintained in exponential growth phase to minimize lag phases. Generally, for the first passage after vial thaw, increased seed cell densities ensure a smooth transition into typical growth pattern. In the case of CHO and HEK293 cell lines, seeding cell densities of $0.3–2.0 \times 10^6$ c/mL supported growth directly out of vial thaw, without lag phase (12). For each individual project, minimum seeding and maximum transfer cell densities are established to avoid lag and stationary phases (36). These ranges can be determined experimentally in a small scale by performing growth studies with various initial seeding cell densities such as 0.1×10^6 vc/mL to 0.8×10^6 vc/mL (Fig. 15.3). By plotting the viable cell densities, the logarithmic growth phase in this case study ranges from 0.25×10^6 vc/mL to maximum transfer cell densities of 2.8×10^6 vc/mL. This range ensures the fastest cell growth rate and the shortest inoculum expansion time.

15.3 IMPACT OF CELL BANKS ON INOCULUM EXPANSION

The quality of cell banks significantly influences the consistency of inoculum expansion. Many factors contribute to the success of the expansion including the physiological state of the cells prior to freezing, the type of freezing mixture, the freezing procedure, storage, and vial transport. Its overall impact can be detected during small-scale characterization studies of MCB and WCB. Growth and productivity profiles over multiple cell generations (37) can reflect on long-term cell culture expansion for large-scale manufacturing.

15.3.1 Influence of Culture Medium

Cell cultures in the exponential growth phase show the best potential to sustain freezing and thawing procedures and to recover them with high cell viability. A bank with a prematurely adapted cell line, or a cell line frozen in a medium different from the medium for inoculum expansion, may lead to inconsistent growth profiles during initial passages, prolonging the already time-consuming inoculation process even further. Therefore, it is recommended to fully adapt the cell cultures to the inoculum expansion medium prior to freezing the banks.

A case study is given in Fig. 15.4 demonstrating the significance of cell adaptation. From Bank #1 two cell banks were prepared, designated as Bank #2 and #3. During bank preparation the cell culture medium was shifted from medium A of Bank #1 to B; medium B also being used during the inoculum expansion phase. Bank #2 was prepared after expanding the cells for limited passages (five passages)

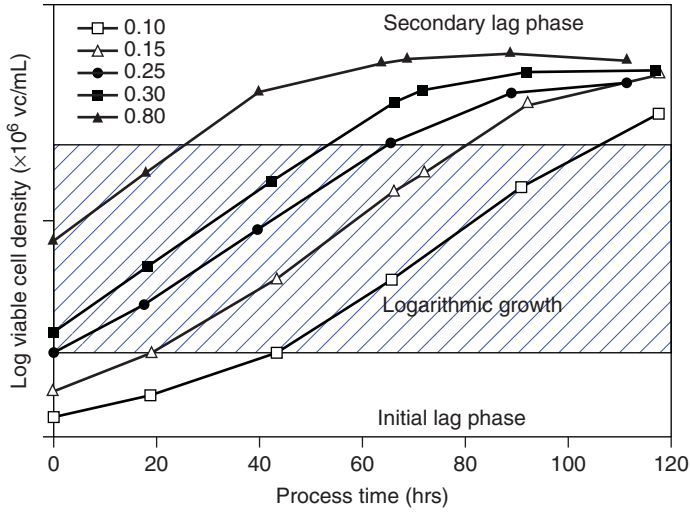

Figure 15.3. Optimization of seeding and transfer cell densities to reduce the inoculum expansion period. The optimum is shown in blue, indicating the exponential growth phase. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

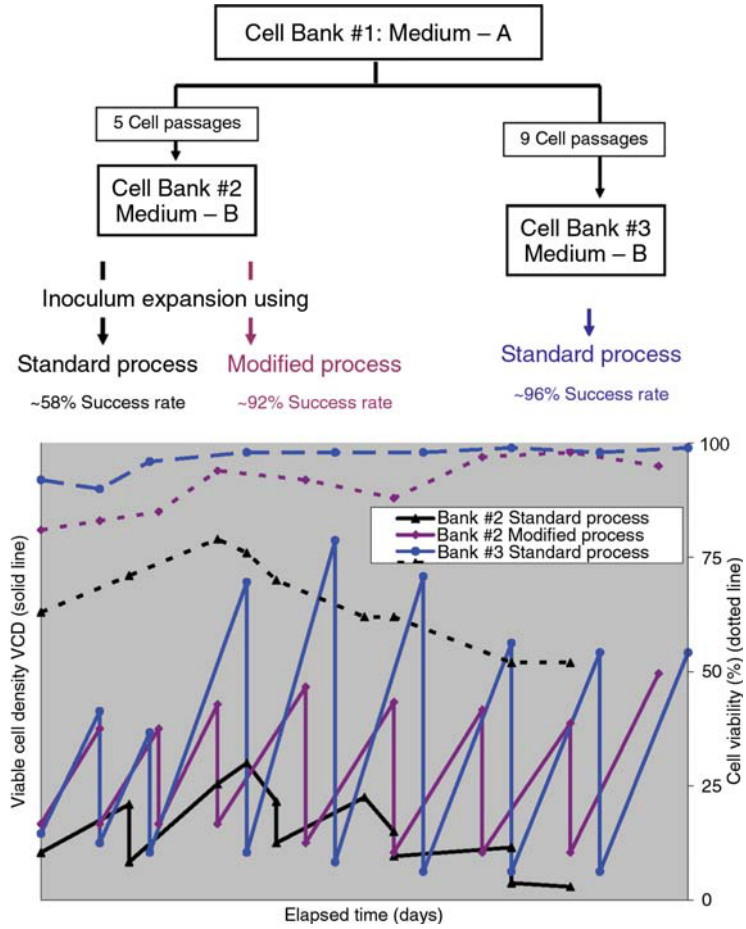

Figure 15.4. Impact of cell adaptation on inoculum expansion. Cell Banks #2 and #3 were prepared from Bank #1 in different medium. Bank #2 was prepared after five passages. The inoculum expansion required further optimization for robust process. Bank #3 was adapted for four additional passages (nine passages) prior cell banking resulting in successful inoculum expansion by standard procedure. Success rate is defined as number of vials reaching seed bioreactor stage. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

in medium B, whereas for Bank #3 it was extended to four additional passages (nine passages). During vial thaw and initial cell expansion, cells from Bank #2 did not recover consistently with high cell viabilities. The low success rate and unpredictable growth pattern of this cell expansion were not practical for a manufacturing process. Therefore, multiple modifications were incorporated for a consistent inoculum expansion using Bank #2. To avoid cell stress during the vial thawing procedure, the cells were settled instead of centrifuged; this increased overall cell recovery and viability. The pH buffering strategy for the culture medium was also changed which resulted in far better cell growth. Medium exchanges were introduced in the beginning phase of the inoculum where the most inconsistent cell growth was observed. Overall, the optimized process led to a robust inoculum expansion with improved success rate (13). In contrast, the vials from Bank #3 were revived and expanded with a very high success rate even using a standard thaw and inoculum expansion process. Therefore, cell adaptation to the appropriate culture medium prior to cell banking is a factor that contributes significantly to successful vial thaw and cell expansion.

The use of one basal medium throughout production cell line generation, selection, banking, and production process is preferable since it minimizes media shifts and cell line adaptation periods (38). Besides reducing cell line developmental timelines, this developmental process generates fully adapted, healthy cells for a robust inoculum expansion.

15.3.2 Maintaining Cell Banks

Frozen cell bank aliquots are preferably stored in the vapor phase of liquid nitrogen (around $-150^{\circ}C$) or at equivalent low temperatures. Maintaining low temperature during

the frozen vial storage is extremely important to guarantee highly viable cells after vial thaw. Temperature variations during short term vial handling and transport should be kept to a minimum. Once vials are removed from storage and exposed to room temperature, the vials warm at a rate of ~10–20°C/min and remaining below −50°C is critical to avoid cell deterioration (22). Sufficient care needs to be employed during frozen vial shipment among different facilities as well as during delivery from the cryostorage area to the inoculum expansion suite prior to vial thaw (39). A common practice in the biotech industry is the extensive validation of cryo-shippers for cell bank transport to ensure a successful transfer under well-defined temperature conditions. To provide evidence of adequate storage, cell bank stability needs to be investigated at predetermined intervals to ensure sufficient cell recovery and viability after thaw (37). These data can be generated every time a vial is thawed that is, during manufacturing campaigns, WCB preparation, or at otherwise predetermined intervals.

15.3.3 Genetic Stability of Cell Lines

The cell line development process is geared toward selecting stable production cell lines. Only stable cell lines can ensure process consistency as well as biochemical equivalency which are directly linked to drug safety, efficacy, and process economics. For fed-batch processes, 60 to 100 cell generations are commonly analyzed to cover cell line stability for up to 20,000-L manufacturing scale. However, for production bioreactors in perfusion mode, additional generations may be required depending on process scale and duration.

The advantage of testing a large number of cell generations is to provide sufficient room for successful manufacturing processes despite unforeseen interruptions. A maximum cell generation number is preferably allocated to the inoculum expansion phase as compared to the production bioreactor in batch or fed-batch operation. For seed bioreactors in perfusion mode, a larger number of PDLs need to be reserved to accommodate multiple staggered inoculations of production bioreactors from one single perfusion bioreactor.

In many cases, it is recommended to maintain the selective pressure during the inoculum expansion phase, to ensure the stability of cell lines in the production process. In the case of CHO dhfr$^-$ cells, significant gene copy losses (40) and decrease in productivity were reported after removal of the selective agent methotrexate (MTX) (41). In these situations, the addition of MTX throughout parts of the manufacturing process might be advantageous to maintain gene stability and avoid significant productivity loss. In the case of the GS expression system, the selective agent methionine sulphoximine (MSX) is added in some instances throughout the inoculum phase in order to maintain cell line stability (42). Upon MSX removal CHO-GS cell lines have shown more cell instability than NSO-GS cell lines (43).

Under special circumstances, titering the concentration of selective agent may add value in maintaining stability in the inoculum expansion process and therefore, the entire production process. It was observed however, that with elevated selection pressure, the cell doubling time may also increase, further prolonging the already time-consuming inoculum expansion (5).

By considering cell line stability as part of the selection and banking process, issues involving cell line instability can be resolved early in the development phase. This is a key to avoid subsequent situations jeopardizing clinical or even commercial manufacturing (44).

15.4 CURRENT TRENDS IN INOCULUM EXPANSION

15.4.1 Disposable Systems

Disposable T-flasks, shaker flasks, and roller bottles are established culture flasks for early inocuum expansion, and disposable spinner flasks have also become available (Fig. 15.5). For seed reactor operation, disposable bioreactors such as single-use stirred bioreactors (STR), for example XDR™ (www.xcellerex.com), BIOSTAT® CultiBag STR (www.sartorius.com) or SUB (http://www.thermo.com), and wave-mixed bioreactors are increasingly used. Several models of wave-mixed bioreactors are commercially available, including BioWAVE® (www.sartorius.com), WAVE Bioreactor™ (www5.gelifesciences.com), BIOSTAT® CultiBag RM (www.sartorius.com), AppliFlex (www.applikon.com), and CELL-tainer® (www.lonzabiologics.com). All have the general principle of waving operation in common which is provided by a rocking platform. Since most of these disposable systems come in sizes between 0.5–1000 L working volume, they are able to completely cover the inoculum expansion phase, starting with vial thaw up to the production bioreactor (21). Other disposable reactor systems, such as hollow-fiber reactors, are used in recombinant protein production in smaller scale (45) but they are not a good fit for the inoculum expansion phase due to their limited predictability of cell density and cell viability, and difficulties in cell harvesting.

Using the wave-mixed bioreactors, the entire inoculum expansion process can be performed in disposable reactors by direct inoculation of a 2-L disposable bag with 0.5-L working volume after cell thaw. The initial culture volume is steadily increased by adding culture medium, and is transferred into the next larger seed reactor once the maximum volume in the bag is reached. Direct inoculation of a disposable reactor after cell thaw simplifies the process

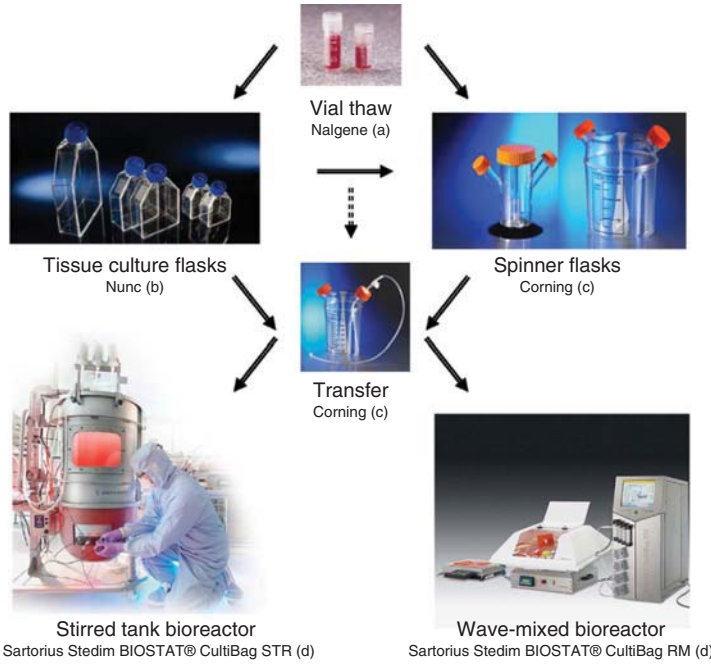

Figure 15.5. Examples of commercially available disposable systems for a complete inoculum expansion process. [Pictures sourced from (a) www.nalgenelabware.com, (b) www.nuncbrand.com, (c) www.corning.com/lifesciences, (d) www.sartorius.com.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

by carrying only one inoculum pool instead of multiple flasks while generating a homogeneous inoculum. It also decreases the risk of contamination through the use of a closed bioreactor system in comparison to the open operation in the biosafety hood required during conventional inoculum expansion in flasks.

Similar growth performance has been demonstrated in disposable systems relative to glass containers, although sometimes, small adjustments may be required in the operation of disposables including increased inoculum cell density to avoid lag in cell growth (28). Figure 15.6 shows a cell expansion in disposable containers compared to conventional glass spinners and seed bioreactors. Equivalent cell growth and cell densities were achieved in all container operations and seed reactors, and the cells were used to finally inoculate production bioreactors. Here, cell growth and viability profiles as well as final product concentration were comparable, providing evidence for a feasible switch to disposable technologies for the inoculum expansion.

The very first models of disposable WAVE bioreactor™ were not provided with feedback control for pH and DO, and instead, values were manually adjusted. In most cases, even these simple operations were superior relative to a flask inoculum expansion process (28). However, newer disposable systems are equipped with feedback controls to support robust processes throughout cell expansion stages (46). The advancements and sophistication of single-use systems support the paradigm shift to completely disposable solutions in the biomanufacturing industry, and may include production as well as support activities (47). Currently, various vendors (www.sartorius.com, www.xcellerex.com, www.pall.com, and www.millipore.com) offer partial or complete disposable solutions like the FlexFactory™ (www.xcellerex.com). The main advantages of disposable systems are low capital investment, increased flexibility through reduced downtime, reduced validation expense, and up to 87% reduced water usage due to reduced equipment washing and flushing (48,49). The main disadvantages are increased amounts of solid waste and higher material costs. These are commonly outweighed by the overall advantages and it is generally expected that the use of disposables, particularly for inoculum expansion, will continue to increase in the future. Economic models help to determine the benefits of disposable technologies and may vary for each company, product, and process (50).

15.4.2 Automation

During inoculum expansion, the labor-intensive cell maintenance in flasks is an optimal target for automation. Various automated systems are available and include roller bottle operation (www.synthecon.com) as well as T-flask and shake flask scale-up (www.auto-

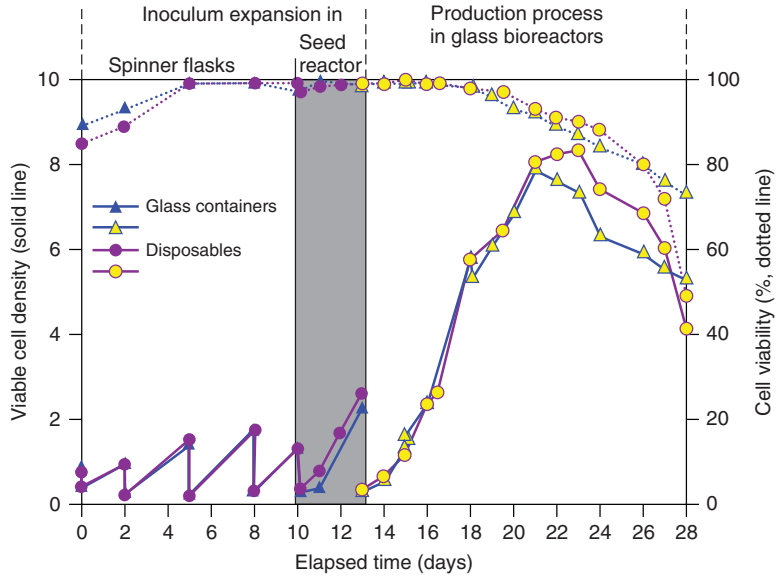

Figure 15.6. Equivalent performances of disposable versus conventional glass equipment during inoculum expansion. Cells were expanded in disposable (disposable spinners and 10-L WAVE reactor) and glass containers (glass spinners and 5-L glass STR). The cells from both systems inoculated glass production bioreactors. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

mationpartnership.com, 51). Due to the complexity and operational specifics, automated systems often require custom-built solutions. Automation of the inoculum expansion, therefore, seems cost-effective for commercial production processes and frequent usage of these systems such as multiple campaigns of the same process or campaigns of similarly operating inoculum processes. In special cases, cell culture handling is feasible only by incorporating robots, that is for the 40-tray Nunc Cell Factory (www.nuncbrand.com, refer to section titled "Static Cultures") and for excessive amounts of roller bottles (as given in "Cell Expansion for Adherent Cell Cultures"). Accuracy, sterility, and round-the-clock operation are the biggest advantages for automating the inoculum expansion. As with all cGMP systems, automated systems and software require 21 CFR Part 11 compliance and validation.

15.4.3 Time Reduction

Generating sufficient biomass from vial thaw to the initiation of the production bioreactor remains a time-consuming process which can take from as little as 1 week up to 6 weeks depending on scale, cell line characteristics, and process (8). A lengthy inoculum expansion process increases manufacturing costs significantly, through additional facility occupancy. Efforts to reduce timelines include the use of multiple cryovials for culture initiation as well as freezing cells at higher cell densities and/or higher volumes in vials or disposable bags to generate frozen seeds. For CHO, BHK, and HEK cells, freezing and thawing conditions were optimized for 50 and 100 mL cell volumes in bags with cell densities between $2-5\times10^7$ c/mL (8,12). Frozen cells from these large volume seed bags enabled direct inoculation of a bioreactor with initial 2-L working volume right after thaw of the frozen cell bulk. This "one-step" inoculum process reduced valuable facility time by 60–70% leading to a more cost-effective and streamlined inoculum expansion process (8). Such high cell density and high volume cell banks are mostly effective and appropriate for the preparation of WCBs used to initiate large-scale production campaigns and commercial production.

Incorporating the high volume bag banks into an existing cGMP cell banking area requires new procedures and equipment for controlled freezing, storage, and thawing of the frozen bags. However, significant process improvements are still attainable without drastically changing the banking procedure and storage equipment (52). Increased volumes and cell densities could be obtained by freezing 9-mL cell volume in 10-mL Nunc vials at higher freezing cell densities, which can directly inoculate 3-L spinner flasks or small disposable bags. Therefore with minimum changes, the inoculum volume was increased 10–30 fold, reducing the expansion time by over 50% (Fig. 15.7).

15.5 TECHNOLOGY TRANSFER

Vial thaw and inoculum expansion is an important part of the process technology transfer which is for the most part

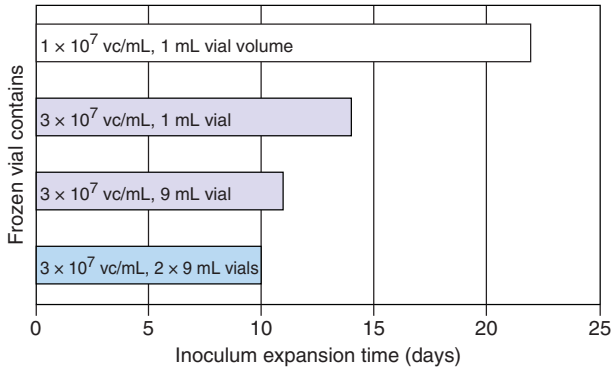

Figure 15.7. Time reduction in inoculum expansion through high cell density and large volume banks. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

quite straightforward in comparison to other process steps. The transfer package includes a detailed description of the expansion process, along with knowledge transfer on cell line stability and characteristics. For a successful technology transfer, the description should contain general parameters like equipment settings, media preparation, media and supplement storage, and expiry. In addition, the maximum number of cell generations for the inoculum expansion and seed bioreactor phase is transferred, to ensure manufacturing within the stability-assessed period (refer to section titled "Genetic Stability of Cell Lines"). Transfer parameters for the flask expansion phase may include container usage, volume ranges, splitting schedule as well as ranges for seeding and transfer cell densities. For seed bioreactor operation in batch mode, the transfer includes process parameter settings, seeding, and transfer cell densities. In comparison, perfusion seed bioreactors need more attention and description of additional process parameters including perfusion rate, specific perfusion rate, and cell retention device–specific settings.

During transfer, limited process modifications might be necessary to adapt to the new facility. In the past, it was observed that different incubator brands may vary in their performance which can result in changed cell growth characteristics mainly due to different pH profiles. Therefore, a proactive approach could include a pH screening in the dedicated incubators during technology transfer (13). This procedure may help to normalize incubator variances between facilities, and CO_2 concentration adjustments can be applied when necessary.

Incorporating a medium-exchange step might be beneficial in the early inoculum expansion phase for certain cell lines. Added as preventative measure, the cells regain vigor and cell growth is restored in case of a slow or halted growth pattern. This method is practical for the expansion robustness of fragile cell lines and can reduce inoculum expansion failures (13).

15.6 CONCLUSION

During the inoculum expansion phases, batch, fed-batch, and perfusion process modes can be used to generate sufficient cells for the inoculation of production bioreactors. Cell line–specific knowledge to maintain the exponential growth phase leads to a rapid and streamlined inoculum expansion process with predetermined cell passaging schedule. In addition, much attention needs to be given at the cell banking process, vial storage, and shipment conditions to ensure healthy cells from the thawed vials.

Process simplification is achieved through the preparation of large volume and high cell density cell banks. This allows the immediate inoculation of seed bioreactors from the frozen bag or vials and may in fact reduce a significant portion or even eliminate the flask inoculum expansion phase in the future. It not only reduces cell handling of multiple flasks but may possibly convert all steps to disposable bioreactor systems. Building the expansion process as a completely disposable train enables the integration of flexible inoculum expansion methods into current manufacturing facilities. Such processes will generally be straightforward and relatively easy to transfer among different facilities.

16.1 INTRODUCTION

Owing to their potential as biopesticides in agriculture, substantial knowledge has been obtained over past decades concerning the structure and function of insect viruses. This knowledge has been used to alter the genetic content of these insect-specific viruses in order to incorporate heterologous genes for production of recombinant proteins. Baculoviruses such as the *Autographica californica* nuclear polyhedrosis virus (AcMNPV or AcNPV) have been modified to incorporate foreign genes from a number of other organisms. Insect cells or insect larvae are then infected with these altered viruses in the baculovirus expression vector system (BEVS or BES), which includes both a cell growth and infection stage, to generate recombinant proteins for vaccines, biopharmaceuticals, diagnostics, biopesticides, and structure and function studies. Various insect cell hosts, viral vectors, and expression methodologies are being explored along with alternative media formulations and bioreactors. Fed-batch, semibatch, and continuous processes are available to scale-up production for cells such as *Spodoptera frugiperda* (Sf-9) and *Trichoplusia ni* (High Five™). Alternatively, larval systems with their lower capital costs are also finding wide-spread use. These processes are now being optimized by evaluating insect metabolism using sophisticated analytical techniques in concert with control methods based on complex mathematical models. Metabolic engineering of glycosylation and other posttranslational events are being applied to improve product yields and generate proteins applicable as human therapeutics. Indeed, the future application areas and prospects of BEVS will continue to expand thanks to significant advances in the biology, biochemistry, and engineering of insect cells and insect-culture processes.

16.2 INSECT CELL LINES

Insect cell lines have been established from nearly 100 different species within the following seven orders of Arthropoda: Lepidoptera, Diptera, Homoptera, Hymenoptera, Orthoptera, Hemiptera, and Coleoptera. These lines are isolated from eggs or embryonic, larval, or adult tissues such as hemocytes, ovaries, imaginal discs, testes, midgut, and fat body using methods that are now well known (1). The procedures typically involve the lysis of tissue followed by suspension in a rich serum-containing medium in tissue culture flasks. The nutrients are replaced periodically, and the cultures are monitored until cell division is observed. The cells are then subcultured after one to several weeks to obtain a new cell line. Eventually, the cell lines are screened for desired properties such as

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

short doubling times, virus susceptibility, recombinant gene expression, or posttranslational processing. Clonal isolates can be obtained that have better growth or gene expression properties, as was the case in the development of the Sf-9 clone from the established cell line (IPLB-Sf-21) of the fall armyworm, *S. frugiperda*. Both of these cell lines are now widely used for the replication of AcMNPV and production of recombinant proteins.

The screening of established cell lines led to the identification of a *T. ni* (cabbage looper) cell line (BTI-TN5B1-4), with the trade name High Five™ (Invitrogen, Inc.), which often provides recombinant protein yields on a per cell basis that are superior to those of Sf-9 and Sf-21(2). Originally, an attachment-dependent cell line, High Five cells have been adapted to suspension growth in many laboratories. Adaptation to suspension is aided by the addition of 50–2000 U/cm^3 heparin to prevent clumping, but the heparin should be removed prior to viral infection and expression of products (3,4). Shown in Fig. 16.1 is a micrograph of healthy and AcMNPV-infected Sf-9 and High Five cells. Commercial serum-free media has been developed for High Five, Sf-21, and Sf-9 cell lines. Because the Sf-9 cell line produces higher levels of the extracellular virus (EV), this cell line is often used for virus production, whereas the High Five are used for heterologous gene expression. Although, High Five and Sf-9 are the cell lines of choice for many applications, recombinant protein production from AcMNPV has been achieved in a number of other cell lines such as those isolated from *Heliothis, Lymantria, Plutella*, and *Trichoplusia* (5,6). A smaller variety of cell lines from *Bombyx mori* (silkworm) and *Lymantria dispar* (gypsy moth) are available for infection with *Bombyx mori* nuclear polyhedrosis virus (BmNPV) and *Lymantria dispar* nuclear polyhedrosis virus (LdNPV), respectively.

Cell lines are usually cultured at the laboratory scale in polystyrene culture flasks or roller bottles. Those cell lines that are not anchorage dependent can be grown in shaker flasks or small suspension culture flasks. Cells are monitored for number density and passaged one to two times per week by subculturing into fresh medium. Attachment-dependent cells must be dislodged by agitation, scraping, or enzymatic treatment. Following a lag phase, the cells grow logarithmically with doubling times between 0.5 and 2 days. Maximum cell densities in shake flask cultures are typically in the range of 2–10 million cells/mL. Cell size is in the range of 8–20 μm, and culture temperatures are typically between 25 and 30°C. Stocks of cells can be cryopreserved in liquid nitrogen using medium and dimethylsulfoxide (DMSO). Recovery is achieved by a rapid thaw and can be enhanced by using a serum-bearing medium prior to freezing the cells.

16.3 VIRUSES

The most widely studied and utilized insect viruses are the baculoviruses, a helper-independent eukaryotic DNA vector that can infect a wide range of lepidopteran (butterflies and moths) insects and insect cells. *Baculo* refers to the rod-shaped capsid that is characteristic of these viruses, which are 40–50 nm in diameter and 200–400 nm in length. The two most widely studied baculoviruses, AcMNPV and BmNPV, contain DNAs that are approximately 130 kb in length. The relatively large size of the virus allows for the encapsulation of large pieces of foreign DNA in addition to the essential viral DNA.

The infection of a single cell by the baculovirus is illustrated in Fig. 16.2. Baculoviruses are deposited in two forms, budded and occluded, in the infected cells (7,8). During the initial stages of infection (10–14 h postinfection), membrane-enveloped viruses bud from the plasma membrane of an infected host in a form commonly referred to as *extracellular virus (EV)*, *nonoccluded virus* (NOV), or *budded virus* (BV). A second form of the virus, the occluded virus (OV), forms in the nucleus of an infected cell beginning at 20–24 h postinfection. This intracellular virus is enveloped and encased within a crystalline viral protein matrix called *polyhedrin*. These protein crystals, called *occlusion bodies*, *polyhedra*, or *polyhedral inclusion bodies* (*PIB*s), may be as large as 5 μm in diameter and contain many virions as shown in (Fig. 16.3). The OV encased within the polyhedrin protein matrix may contain multiple nucleocapsids within a single envelope for multiple embedded nuclear polyhedrosis viruses (MNPVs), or a single nucleocapsid per envelope for single nuclear polyhedrosis viruses (SNPVs). In addition to nuclear polyhedrosis virus (NPV), a second type of occluded baculovirus, the granulosis virus (GV), includes one or, very rarely, two virions embedded in a much smaller protein matrix called a *capsule* or *granule*. Most baculoviruses used as biopesticides and all baculoviruses used in biotechnology are NPVs, although, a few GVs have shown potential for future applications.

It is the OV that is responsible for transmission of the virus from insect to insect, as shown in the baculovirus life cycle depicted in Fig. 16.4 (8). After death and decomposition of an infected insect, the polyhedra are deposited on vegetation where they are ingested by other feeding insect larvae. Transported with food to the midgut, the

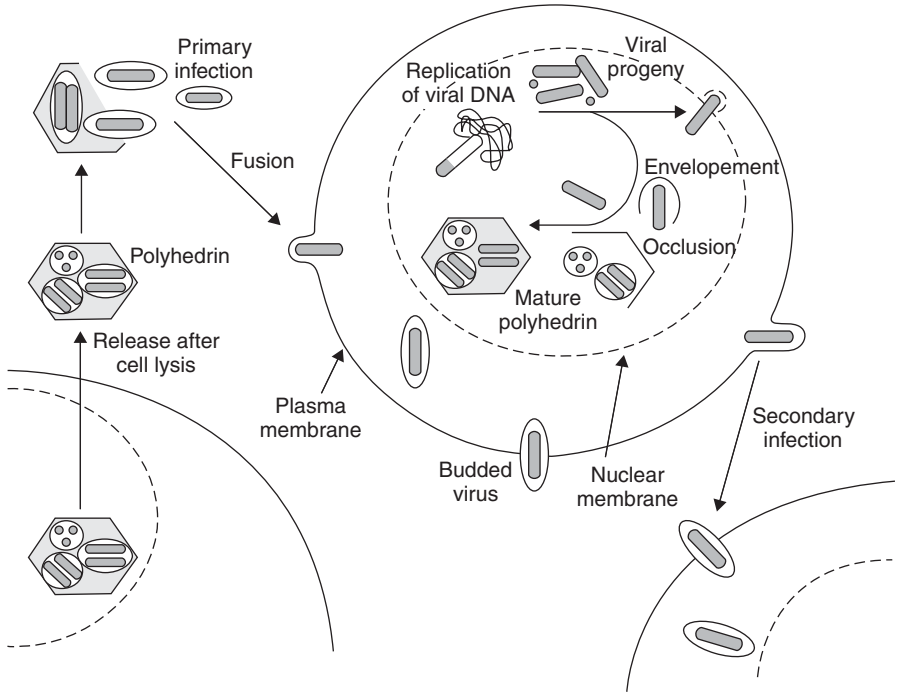

Figure 16.2. Single-cell replication life cycle of the natural baculovirus, AcMNPV. Primary infection by occluded virus occurs upon disintegration of the polyhedrin matrix and subsequent fusion to the plasma membrane. Budded virus produced within the cell proceed to initiate the secondary infection process. Adapted from figure appearing in *Baculovirus Expression Systems and Biopesticides*, M.L. Shuler, H.A. Wood, R.R. Granados, and D.A. Hammer, Wiley-Liss, 1995. Reprinted by permission of John Wiley & Sons, Inc.

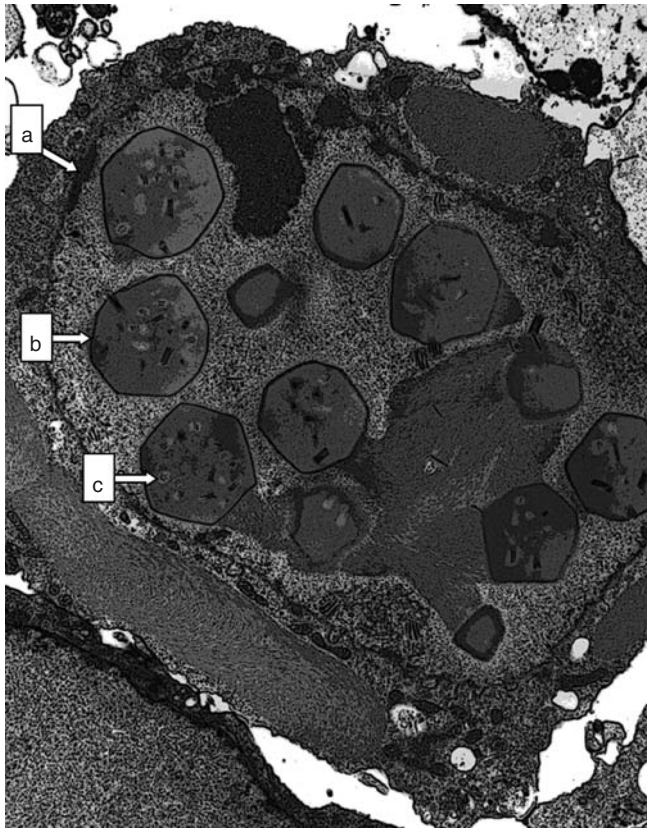

Figure 16.3. Electron micrograph of AcMNPV infection in *S. frugiperda*. (a) Nuclear membrane, (b) polyhedrin inclusion bodies, and (c) virions at 48 h postinfection. Micrograph courtesy of G. Williams.

polyhedra are dissolved in the alkaline environment, subsequently, releasing virions into the lumen of the midgut. These viruses then fuse to the epithelial cells where they cause an infection in the midgut tissue. The infected cells then release BV, which are responsible for secondary infection of other tissues by spreading through the hemolymph and trachea. The infected larva continues to feed for 5–7 days until it becomes listless. The larval cuticle melanizes, and the muscular structure dissolves in a process called *melting* or *wilting*. The larva eventually ruptures, releasing about 25% of its dry weight in the form of PIBs, which are spread over vegetation for consumption by other insects and reinitiation of the infection cycle.

16.4 BACULOVIRUS GENE EXPRESSION

Baculovirus gene expression of viruses such as AcMNPV occurs over four phases: immediate early (α), early (β), late (γ), and very late (δ). During the immediate early phase, viral genes are expressed using host cell factors. The immediate early gene products then control the expression of the early genes, whose products are responsible for cytoskeletal rearrangement and nucleus enlargement. Extensive viral DNA replication occurs about 5–7 h after infection, followed by expression of the late genes. The late phase extends from 6 until 20–24 h postinfection and involves the assembly of nucleocapsids, the transport and release of BV, and the degradation of the host genome. The formation of OV occurs during the very late phase, beginning at about 20–24 h postinfection. The occluded viral particles can accumulate for 3–5 days until the infected cells lyse.

Two genes abundantly expressed during the very late phase are the polyhedrin and p10 genes. The product of the polyhedrin gene (*polh)* is the 29-kDa protein that forms the crystalline matrix of the occlusion particles protecting encased virus nucleocapsids. The product of the p10 gene is a 10-kDa protein that forms large fibrous arrays in the nucleus and, occasionally, in the cytoplasm. In 1983, it was observed that viruses containing deletions in the polyhedrin gene were stable and could be replicated in cells in culture (9). Though, the cells infected with these viruses lack the characteristic occlusion particles, production of BV was unaffected. Furthermore, these BV could be collected from the cell culture media and used to infect other cells in order to passage the altered virus. Because the polyhedrin gene is nonessential for BV infection and propagation in cell culture, the construction of a recombinant baculovirus can be accomplished by replacing the polyhedrin gene with a foreign gene such as interferon β (10). In this way, the foreign gene, now under the control of the very strong polyhedrin promoter, is expressed, instead of the polyhedrin gene at the very late phase of AcMNPV infection. Similarly, it was observed that the disruption of the p10 gene resulted in the disruption of the fibrous matrix, but the formation of BV was not affected. Subsequently, recombinant baculovirus constructs containing foreign genes inserted under the control of the p10 promoter were used to produce heterologous proteins in place of the p10 protein (11). Because the polyhedrin and p10 are very strong late promoters, with as much as 50% of the total stained protein consisting of polyhedrin (12), these promoters have the potential for very high rates of foreign gene expression. One disadvantage of this system is that the production of heterologous protein is accomplished late in the viral infection, at the time when host cell function is deteriorating. Furthermore, the insect host eventually succumbs to the infection, thus, requiring a new batch of insect cells to be grown and infected each time recombinant protein is to be produced.

In an effort to avoid the problems associated with insect cell death because of virus infection, a number of vectors have been developed that allow the stable integration of foreign DNA into insect cell hosts. Stable expression of heterologous proteins using these integrated vectors

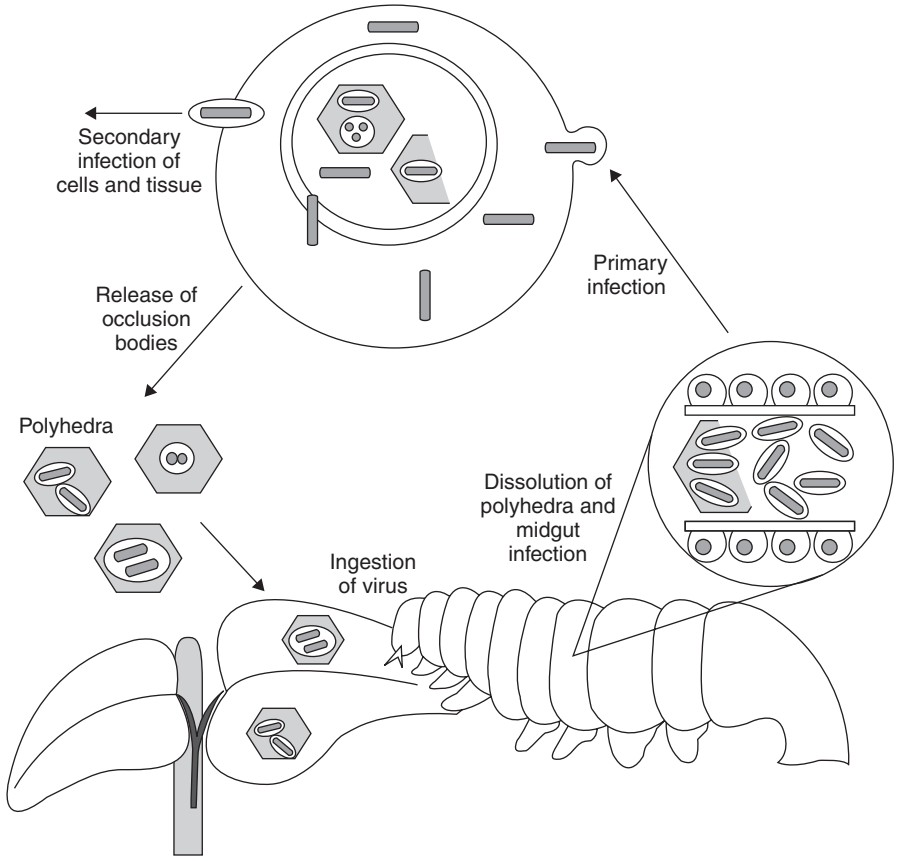

Figure 16.4. Life cycle of the natural baculovirus, AcMNPV. Adapted from figure appearing in *Baculovirus Expression Systems and Biopesticides*, M.L. Shuler, H.A. Wood, R.R. Granados, and D.A. Hammer, Wiley-Liss, 1995. Reprinted by permission of John Wiley & Sons, Inc.

has been achieved in several insect cell lines including Sf-9, *Drosophila* S2, *B. mori, T. ni*, and *Aedes albopictus* (13,14). However, expression levels in most cases are many times lower than baculovirus, so these systems are yet to approach the popularity of BEVS. Stable expression systems are likely to find niche applications when lower expression is acceptable in return for desirable host processing functions.

16.5 CONSTRUCTION OF RECOMBINANT BACULOVIRUSES

More than 500 different baculoviruses of the Baculoviridae family are currently known. For use as a vector to deliver foreign genes into insect cells, the most extensively used is AcMNPV (15). BmNPV (16), LdMNPV (17), and granulosis viruses (18) have also been considered as vectors, but to a much lesser extent. Techniques for manipulating AcMNPV to generate recombinant baculoviruses is discussed here because this subtype is the most widely investigated and the procedures are similar for many other baculoviruses. AcMNPV is a large, double-stranded, circular DNA virus for which the complete nucleotide sequence has been determined (19). Because of the large size of the baculovirus capsid, very large genes (>20 kb) can be inserted into the viral genome, making it a favorable expression system for a wide variety of proteins including huge virus like particles (VLPs). However, the large size of the baculovirus DNA prohibits the typical recombinant DNA manipulations used for cloning with bacterial plasmids. Consequently, an alternative approach involving plasmid transfer vectors and allelic replacement (homologous recombination) was developed and remains the most popular method for foreign gene insertion into the baculovirus. Many improvements have been made for generating recombinant baculoviruses, but almost all are based on homologous recombination.

The first step in allelic replacement involves the manipulation of a transfer plasmid in *Escherichia coli* by cloning the foreign gene downstream from a baculovirus promoter, typically those for polyhedrin or p10. The promoter and gene are also flanked by baculovirus DNA derived from a nonessential locus such as polyhedrin

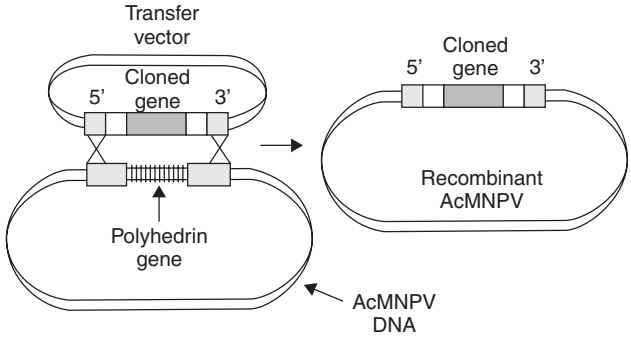

Figure 16.5. Homologous recombination. A baculovirus gene locus (usually p10 or polyhedrin) is targeted for homologous recombination using a transfer vector that includes flanking homologous sequences and, in some cases, encoding a selectable marker. The recombination event (represented here by X's) results in the replacement of sequences flanked by the homologous areas with the sequence of the foreign gene.

or p10 genes. The recombinant transfer plasmid is then mixed with native baculovirus DNA, and the mixture is transfected into insect cells using calcium phosphate or cationic lipids. A small fraction of the baculoviruses will undergo homologous recombination with the transfer plasmid to create a recombinant baculovirus containing a heterologous gene under the control of the appropriate promoter (Fig. 16.5). The recombinant baculovirus constructs may be identified by examining for the absence or presence of a particular baculovirus or plasmid function because of the insertion of the foreign gene.

The initial screening technique involved the identification of plaques of insect cells containing occlusion-minus (*occ*−) infections as a result of the deletion of the polyhedrin gene from the original baculovirus DNA. Occlusion-positive plaques include an opaque light refractile characteristic that can be visually distinguished from the characteristics of *occ*− plaques under the microscope. However, picking an *occ*− clone is a formidable task for inexperienced researchers because young nonrecombinant plaques often show no sign of "occlusion," and recombination frequencies can be as low as 0.1%. These difficulties resulted in the time consuming and tedious isolation of recombinant baculovirus through multiple rounds of plaque purification. The first modification of the system was the use of the bacterial gene *lacZ* (β-galactosidase) to produce chromogenic recombinant plaques that enhance plaque purification (20,21). Significant progress in isolating recombinant baculovirus was achieved by derivatizing the circular, double-stranded wild-type baculovirus into a linear form through the introduction of a unique restriction site (*Bsu36I*) at the polyhedrin locus (22). A higher proportion of recombinant viruses were obtained when the linearized baculovirus genome was cotransfected with a transfer vector, because the infectivity of the linearized virus alone was substantially reduced below wild-type levels. Later, aβ-galactosidase gene flanked with restriction sites (*Bsu36I*) was inserted in the AcMNPV under the polyhedron promoter such that linearizing the viral DNA using the restriction enzyme also removed a part of another essential viral gene (ORF 1629). The missing part of the viral gene was then provided via the transfer vector along with the recombinant gene of interest. As a result, the recircularized AcMNPV DNA without homologous recombination was unable to infect and any nonlinearized parent AcMNPV could be detected using X-Gal because of the expression of β-galactosidase. Conversely, commercial systems are also available that turn on expression of β-galactosidase expression under a second promoter as a positive marker for homologous recombination in combination with reconstruction of ORF 1629 gene needed for viral replication.

A more rapid approach to generate pure recombinant baculovirus in 7–10 days has also been reported (23). This technique uses a baculovirus shuttle vector (bacmid) that can replicate in *E. coli* and infect susceptible lepidopteran insects. The homologous recombination event is performed using site-specific transposition by transforming the gene of interest in recombinant *E. coli* engineered to express the parent bacmid and transposase. The successfully cloned candidates are visually screened (e.g. based on *lacZ* gene) and the high molecular weight bacmid DNA is isolated from the colonies. A recombinant baculovirus is then generated by introducing the composite bacmid into insect cells in culture and harvesting the virus from the medium. This approach eliminates the need for plaque purification because only the recombinant baculovirus is generated during the initial infection.

Other expression vectors are available that provide for the expression of up to four genes in the same baculovirus construct (e.g. pBAC4x-1). These constructs may include one or more polyhedrin, p10, or heat shock promoters to control expression of the foreign genes. Infection of insect cells with several viruses, each containing multiple genes, can provide simultaneous expression of numerous proteins in one insect cell. Constructs containing baculovirus promoters such as IE1 and core that are activated earlier in the infection are also available (24). Specialized vectors that include histidine tags, that help facilitate protein purification, as well as gp64 or melittin fusions, for enhancing protein secretion, are also available. Commercial vectors have also been developed to aid surface display of recombinant proteins on baculovirus particles. A modified baculovirus system, BacMam, has also been developed to enable the use of baculovirus technology to deliver genes or to express recombinant proteins in mammalian cells (25). This is done by either adding a mammalian expression cassette or by

replacing the viral expression cassette with a mammalian expression cassette in the viral DNA.

For a laboratory not experienced with BEVS, it is advisable to employ the linear baculovirus genome with a lethal deletion and selectable marker or the *E. coli* bacmid shuttle vector as the initial method for generating recombinants. Many kits are now commercially available that include the transfer vectors and baculovirus DNA for rapidly generating recombinant baculovirus constructs.

16.6 POSTTRANSLATIONAL PROCESSING

Because insects are eukaryotic organisms, the derived cell lines are capable of performing many of the posttranslational processes including secretion, folding, and glycosylation observed in higher organisms. In fact, insect cells are often the expression system of choice for the rapid generation of functional eukaryotic proteins. However, the posttranslational processing may not be identical to that performed in the native environment. It may be worthwhile to compare the protein expressed in the insect cells with the native protein to determine if significant differences in posttranslational processing exist that will detract from subsequent structural or functional analysis. Some of the posttranslational processing events that are observed in insect cells are described in the following sections.

16.6.1 Glycosylation

A majority of secreted and membrane proteins are glycosylated, and the attached oligosaccharides can play critical roles in cellular targeting, structural stability, resistance to proteolysis, immunogenicity, and circulatory half-life. The oligosaccharide residues are added to the protein at specific amino acids during processing in the endoplasmic reticulum (ER). Subsequently, these oligosaccharides are trimmed and modified during processing in the ER and Golgi compartments. Both N-linked and O-linked glycosylation have been observed in insect cells.

During N-glycosylation in both insect and mammalian cells an initial $Glc_3Man_9GlcNAc_2$ group is added to the Asn residue of the Asn-X-Ser/Thr sequence of a nascently translated protein. Glucose and mannose residues are then trimmed from the $Glc_3Man_9GlcNAc_2$ group. However, the level of trimming and subsequent modifications are likely to be different in insect cells than those observed in mammalian cells. Recent evidence indicates that these differences may depend significantly on the particular insect cell line used. Many initial studies of *N*-glycans from heterologous glycoproteins obtained from Sf-9 or Sf-21 cells indicated the presence of only high mannose type ($Man_{9\text{-}5}GlcNAc_2$) or short, truncated, paucimannosidic ($Man_{3\text{-}2}GlcNAc_2$) oligosaccharides, sometimes including an α(1,6)-linked fucose (26,27).

A comparison of the *N*-glycans of IgG from High Five cells (28) with those attached to an IgG3a from the mammalian NS/0 cells reveals significant similarities and some differences in the glycosylation properties of the two cell lines. A typical endogenous oligosaccharide processing pathway observed in many insect cell lines is shown in Fig. 16.6 (29). The initial mammalian ER pathway, including trimming of the terminal glucose and mannose residues, is operative. Insect cell processing diverges from mammalian cell processing in the pathways leading to the paucimannosidic structures, with the critical step being the cleavage of GlcNAc from the α-(1,3) branch by a hexosaminidase (30–32). Other significant differences in insect cell processing are the α-(1–3)-linked addition of fucose, also observed in the processing pathway of plants, and the absence of any attached sialic acids (28,33,34). Glycoprotein processing in insect cells has now been engineered by expressing mammalian glycosylation enzymes in insect cells in order to generate glycoforms similar to those produced by mammalian cells (24,35). This has been achieved by expressing various glycosyltransferases as well as expressing the cytidine monophosphate (CMP)-sialic acid synthesis pathway enzymes (Fig. 16.6) (36,37).

Several studies on heterologous glycoproteins have indicated that certain insect cell lines can synthesize hybrid and complex oligosaccharides (28,34,36,38,39). For example, analysis of *N*-glycans of heterologous interferon-γ secreted from *Estigmena acrea* (Ea-4) confirmed the presence of complex, hybrid, paucimannosidic, and high mannose N-linked oligosaccharides (34). In contrast, *S. frugiperda* (Sf-9) cells were observed to produce only hybrid, paucimannosidic, and high mannose *N*-glycans. Alternatively, the insect cell line *Danaus plexippus* (DpN1) was observed to produce a combination of *N*-glycans including 26% complex structures, some of which terminated in sialic acid (38).

O-glycosylation, which involves the addition of carbohydrates to hydroxylated amino acids such as serine or threonine residues, has been observed for several recombinant proteins produced by baculovirus-infected insect cells. A pseudorabies viral glycoprotein, gp50, and extracellular domains of the respiratory syncytial virus protein were found to contain the attached monosaccharide GalNAc and lesser amounts of the disaccharide Galβ1-3GalNAc (40). In mammalian cells, only the disaccharide form was observed in the presence or absence of attached sialic acids. Activity levels of the relevant glycosyltransferases in the insect cells and mammalian cells supported the particular distribution patterns observed.

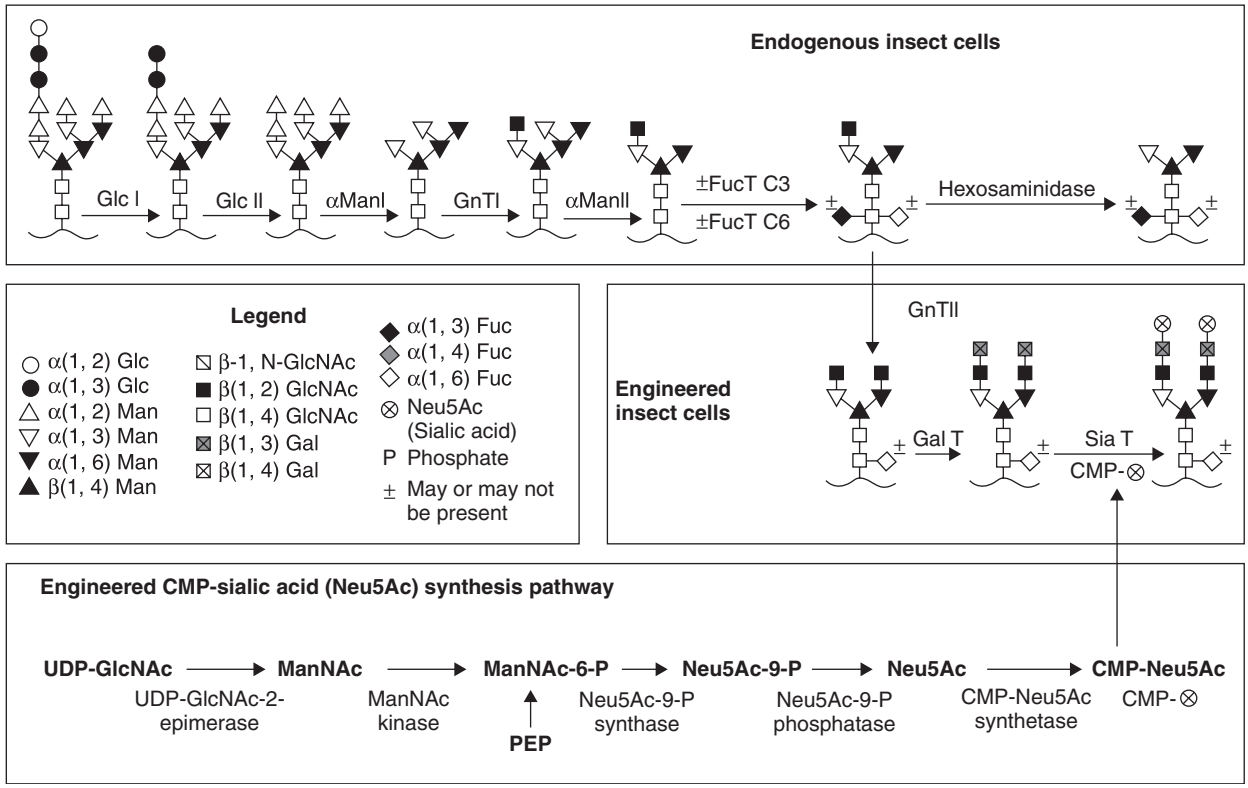

Figure 16.6. Endogenous *N*-glycan processing pathway in insect cells together with efforts to engineer glycosylation and CMP-sialic acid synthesis pathways. Enzymes involved in processing are noted with abbreviated titles.

16.6.2 Other Posttranslational Processes

Many proteins expressed in insect cells are directed to the appropriate cellular compartment including the nucleus, cytoplasm, organelles, plasma membrane, or extracellular space. For secreted proteins, a short (15–40 amino acids) signal peptide is present for translocating polypeptide from the cytoplasm into the ER. This signal peptide, whether from mammalian, plant, or yeast sources, is usually cleaved correctly by the signal peptidases in insect cells. However, signal peptide processing is not always efficient, especially for peptides from plants or other distant eukaryotes. In fact, a complete absence of processing has been observed in at least one case (40). Replacement of the original signal peptide with another signal peptide from a protein such as melittin of honeybee venom (41) or the gp67 and ecdysteroid UDP-glucosyltransferase (EGT) proteins (7) from AcMNPV can help to alleviate this limitation in some cases. Alternatively, the expression of recombinant signal peptidase can also overcome a limitation in the processing capacity of insect cells (42). Sometimes, a substantial fraction of proteins destined for secretion will be retained intracellularly in incorrectly folded forms or as aggregates. Coexpression of chaperones or folding enzymes can reduce aggregation and enhance secretion of recombinant proteins that rely on such folding assistance factors (43,44). Another, undesirable posttranslational processing event that often occurs with insect cell-derived proteins is proteolysis, that releases cellular and baculovirus proteases that can degrade target recombinant proteins. Protein degradation can be minimized through control of culture conditions to limit cell lysis or by addition of protease inhibitors to the medium (45–47). Another approach to limit proteolysis is to delete the proteases genes from the virus (48) or inhibit protease activity in the virus or cells using RNA inhibition (49). Other posttranslational processing steps including phosphorylation, fatty acid acylation, α-amidation, and N-terminal amidation have also been observed in insect cells or insect larvae.

16.7 APPLICATIONS

Baculovirus-infected insect cells often provide high levels of expression of heterologous proteins, leading to the use of this system across a broad spectrum of applications and fields. BEVS has been used for the production of proteins for structure and function studies, vaccines, VLPs, multisubunit assemblies, and diagnostic reagents (50). The

application of BEVS products as human and animal therapeutics and vaccines is also under active development.

The ability to generate vaccines rapidly using this system, makes this a favorable candidate, particularly for producing influenza vaccine in which new variants are generated each year. FluBlok, a trivalent influenza vaccine being developed by Protein Sciences Corp. and UMN Pharma Inc., is one example using the insect cell-baculovirus expression system. This technology will enable production of this vaccine in less than 2 months, and the vaccine is currently under Phase III clinical trails (51). Another approach to generate the influenza vaccine is by using VLPs produced by coexpressing the core matrix protein M1 and various combinations of hemagglutinin, neuraminidase and/or M2 proteins of the influenza virus. Novavax has initiated clinical trials for seasonal influenza VLP vaccine (52) and for a pandemic VLP vaccine (53). In 2007, the European and Australian approval of GlaxoSmithKline's human papillomavirus (HPV) vaccine, Cervarix, produced using the baculovirus expression system reinforced the commercial potential of insect cell-baculovirus technology. In addition, a promising vector for human gene therapy, recombinant adeno-associated virus (rAAV) vectors was produced in large-scale bioreactors using baculovirus expression vectors in insect cell cultures (54).

The use of baculoviruses as biopesticides, the original motivation for studying these viruses, represents another thrust of the technology (4,55). Wild-type baculoviruses have been used as efficacious pest control agents for many years but have a limited host range and can take between 5 and 10 days to debilitate insect larvae. A number of genetic modifications, mostly centered on replacement of polyhedrin or p10 genes with heterologous insect toxins, have been implemented to lower viral killing time and reduce the duration of pest feeding. Some of the heterologous genes that have been considered are listed in Table 16.1. A major concern in the development of baculovirus pesticides is the potential safety of these agents. However, extensive studies have concluded that baculoviruses have a very low range of infectivity and will not infect beneficial insects or mammals. Inclusion of a foreign gene under the control of a baculovirus promoter appears to present little danger as well. Finally, insect cell expression system has been exploited as tools for examining the role of proteins in physiological processes.

16.8 LARGE-SCALE PROCESSING: CELL CULTURE OR LARVAL PRODUCTION

Structural and functional characterization studies, diagnostic reagents, and vaccine production often require product levels beyond the scale of shaker flasks. Biopesticides will require huge amounts of the final product for use in field trials. The production of these large quantities of heterologous proteins or baculoviruses will require the use of large-scale cell culture or insect larvae. Insect cell culture provides an environment in which the process parameters can be carefully controlled and monitored (4,7). It also allows for the utilization of a single-cell line with more uniform posttranslational processing than can be achieved in larvae. Chemically defined animal protein free medium can be used to grow the cells, although, care must me taken to successfully remove any toxic compounds from cell culture medium. Also, the cost of commercial media used in cell culture can become prohibitive for large volumes, and a significant capital investment is required for purchasing large bioreactors. These considerations may warrant the consideration of insect larvae as an alternative method for the production of recombinant proteins. The use of larvae can provide substantial cost advantages and easy scale-up for the production of recombinant proteins and the yields may even be higher. Some posttranslational processing events such as glycosylation, secretion, and carboxy-terminal amidation also may be more efficient in larvae (56). However, larvae may include significant levels of other insect proteins including larval proteases that can degrade the final product. Also, larval purification will require an additional solids handling step for separating the hemolymph from the insect carcass but this step can be automated.

16.8.1 Cell Culture Processes

Increasing the volume and mass of production from a small 100 mL spinner flask to a large 100-L bioreactor is not a simple linear process (13). Many of the process parameters, especially, the delivery of O_2 and mixing, change when production is moved to a large bioreactor. Even so, large-scale production of proteins in BEVS has been achieved in 100-L bioreactors while maintaining cell growth kinetics and productivity. Issues that are relevant to cell culture scale-up are addressed next.

16.8.2 Bioreactors

A number of bioreactor configurations and processing conditions have been applied to the culture of insect cells including both airlift and agitated–sparged (stirred-tank) bioreactors. Stirred-tank bioreactors typically consist of glass, carbonate, or stainless steel vessels containing a marine or paddle impeller driven by an overhead motor. Temperature, oxygen, and pH can be controlled. Temperature control can be maintained by immersion in a water jacket, using circulating cooling and heating coils, or by enclosure in a controlled incubator. Stirred-tank bioreactors typically require the injection of air or oxygen into the bioreactor at a position below the impeller.

TABLE 16.1. Genes Utilized to Increase the Insecticidal Effects of Recombinant Baculoviruses

Name of gene	Effect(s) of expressed gene on host insect	Percentage increase in insect killing
Diuretic hormone	Reduction of hemolymph volume	20
Juvenile hormone esterase	Feeding cessation and blackening	—
Bacillus thuringiensis toxin	Feeding cessation	$(2 \times LD_{50})^a$
Scorpion toxin (AaIT)	Paralysis, body tremors, and dorsal arching	30–40
Mite toxin (Txp-1)	Paralysis	30–40
Wasp toxin (antigen 5)	Premature melanization and low weight gain	—
AcNPV deletion mutant lacking ecdysteroid UDP-glucosyltransferase gene (egt)	Reduces larval feeding times	20% reduction in $ST_{50}{}^b$

[a] LD_{50}, the dose necessary to kill 50% of the larval population.
[b] ST_{50}, the time necessary to kill 50% of the larval population.

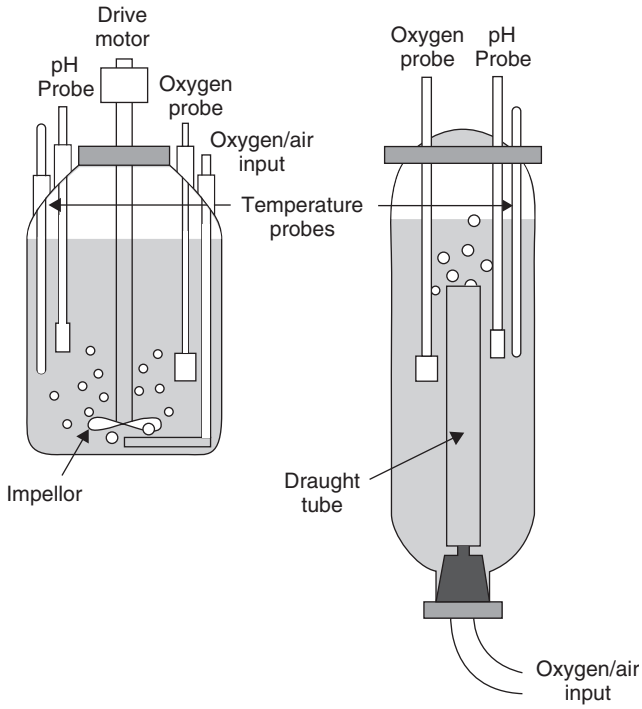

Figure 16.7. Configuration of stirred-tank and airlift reactors.

Air can also be supplied to the headspace in order to limit the amount of oxygen sparged directly into the bioreactor. An alternative to the stirred-tank bioreactor is the airlift bioreactor in which liquid circulation through the bioreactor is driven by the lifting force created by injection of air or oxygen through the bottom of the bioreactor (Fig. 16.7). This bioreactor includes an inner draft tube that carries the air/oxygen and liquid medium up through the bioreactor to the surface of the medium in order to set up circular flow of the medium within the bioreactor.

A side-by-side comparison of a 6-L airlift vessel and an 8-L stirred-tank vessel (5.5-L working volume) containing Sf-9 cells in serum-free medium showed similar growth rates, cell viabilities, and cell densities throughout the cell growth period (57). The stirred-tank fermentation system can be implemented without a commercial vendor, if necessary, by purchasing a large motor and vessel, whereas an airlift system is usually purchased as a single unit from a commercial source.

A number of other bioreactor configurations have also been considered. The NASA designed rotating-wall vessel, which limits shear effects, has been used to culture both Sf-9 and High Five for the production of recombinant proteins and found to be superior to shake flask cultures (58,59). Wave bioreactors have also been used up to the 40-L scale with production yields of rAAV particles equivalent to those obtained in stirred-tank bioreactors (60). Hollow fiber configurations have also been applied for the high density cultivation of *Drosophila* S2 cells for several months allowing the production of multimilligram amounts of recombinant protein with minimal culture maintenance (61).

Clumping of attachment-dependent cell lines in suspension, such as with High Five, is common, so bioreactor configurations that allow attachment-dependent cell growth and infection have also been developed (3,62). These attached cell lines are typically grown in roller bottles or on supporting particles such as glass beads or microcarriers. The supporting particles are then incorporated into immobilized perfusion or airlift bioreactor configurations. In addition, bioreactors in which oxygen is supplied through membrane tubing have been utilized, although not extensively for large-scale cell culture (63).

16.8.3 Process Monitoring Techniques

Cell growth and infection in insect cell bioreactors are usually monitored by following total and viable cell numbers by means of trypan blue staining and counting with a hemacytometer. Cell viability typically drops after several days after baculovirus infection of an insect cell culture. Given the labor-intensive and invasive nature of this assay, other

techniques have been considered for monitoring cell growth and infection, both off-line and on-line (63). Coulter™ particle counters and optical density (OD) measurements taken using a fiber optic probe can speed the cell counting process considerably during the cell growth period. Alternatively, growth can be monitored online through indirect measurements of cellular respiration such as oxygen uptake rate (OUR) using dissolved oxygen probes or carbon dioxide evolution rates (CERs) using infrared detectors (64). Near infrared (NIR) absorption spectroscopy can also be applied as a means to monitor the glucose and glutamine concentrations in bioreactors using noninvasive methods (65).

Monitoring the infection process is much more challenging, although, several techniques are used to supplement trypan blue staining. OUR can track the infection process because an increase in oxygen consumption occurs during the initial stages of the baculovirus infection (66). The CER is also observed to increase up to 24 h postinfection followed by a decline as the virus is released. Relative permittivity (ε), has been also used as an on-line monitor of the different phases of infection in which a plateau is observed between 18 and 24 h postinfection and a peak detected at 48 h postinfection corresponding to active cell lysis (67).

Other tools that have been used to monitor the infection process include epifluorescence microscopy of live and dead cells using fluorescence stains as well as flow cytometry, in which the side scatter parameter can be used to differentiate between infected and noninfected cells (68). The amount of recombinant protein generated during baculovirus infections can be followed by tracking the levels of a secondary protein such as green fluorescent protein (GFP) coexpressed along with the target protein of interest either in bioreactors or in larvae (69–71). The use of a GFP marker will assist in monitoring and optimizing infection conditions and identifying optimal harvesting time for the target protein.

16.8.4 Oxygen Supply

One of the critical nutrients that must be supplied to an insect cell culture during the growth and infection stages is oxygen. Oxygen consumption rates per cell range from 10^{-17} to 10^{-18} mol/cell-s and can increase up to 40% or more during the initial stages of infection (72). Absence of sufficient aeration and oxygen supply during the infection stage can inhibit the viral infection and lower recombinant protein yields several fold (73). Consequently, it is important to monitor the dissolved oxygen level in large-scale insect cell bioreactors using commercially available probes. Some researchers have suggested that dissolved oxygen tension (DOT) be maintained at about 50% saturation to reduce the oxygen sparging that is potentially lethal to insect cells (74). Aeration rates greater than 0.04 vol/vol-min can be inhibitory to cell growth (75). The production of VLPs during the infection stage was reported to be optimal when the oxygen concentration was maintained at 25% saturation with significant declines in productivity observed when dissolved oxygen decreased to 10% or increased above 50% (75).

16.8.5 Cell Damage during Sparging

Oxygen supply to the bioreactors is typically provided through sparging of oxygen or air into the bottom of a stirred-tank or airlift bioreactor. The oxygen is transferred from the gas to the liquid as the bubbles rise up the bioreactor. In order to provide sufficient mass transfer area, the air is bubbled through small openings. Impeller rotation can enhance bubble breakup further to increase the surface area available for mass transfer. The resulting bubble size is typically 1–5 mm in diameter, and the Reynolds number of a rising bubble can vary from 100 to 1000 in conventional bioreactors (76). It is now known that the sparging of oxygen or air can cause significant damage to insect cells as well as mammalian cells in suspension (77–79). This cell damage is principally because of the adhesion of cells to bursting gas bubbles at the gas–liquid interface. In contrast, agitation is likely to be less of a factor in causing cell damage in many sparged bioreactor environments. Suspended cells can often tolerate high agitation rates as long as the gas–liquid interface is removed (80,81). Cell damage from agitation may occur in some cases because of the formation of Kolmogorov eddies on a length scale comparable to the size of a cell (80,81).

High speed video microscopy studies have been used to observe directly cell–bubble interactions during the bubble rise through an insect cell culture medium (78,79). Cells attach independently or in clumps to a rising bubble and are carried upward through the fluid (Fig. 16.8). These cells then accumulate in high concentrations in the foam layer at the surface of the medium. The rupture of bubbles at the gas–liquid interface leads to the formation of upward and downward liquid jets that generate large shear stresses sufficient to damage or kill insect cells attached to the bubbles. The cell concentration in the jets is higher than in the medium, and more than 75% of these cells are killed by bubble rupture and jet formation. Approximately, 1,200 Sf-9 cells can be killed per bubble rupture (76).

Much of the cell damage because of bubble rupture can be prevented by the addition of surfactant polymers such as Pluronic F-68 at concentrations in the range of 0.1–0.2% (78,82–84). The addition of Pluronic F-68 prevents the adhesion of cells to bubbles and eliminates the damage to cells caused by bubble breakup at the liquid surface. The polymeric surfactants may prevent cell adherence to bubbles by lowering the interfacial tension at the

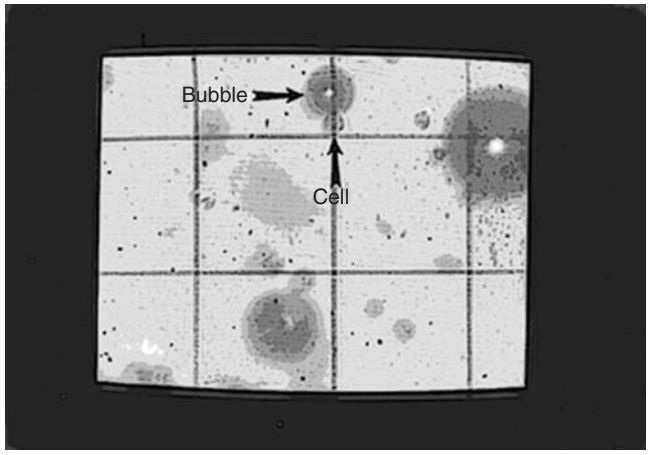

Figure 16.8. Insect cell attachment to bubbles rising through culture medium. Grid spacing is 100 μm. Photograph courtesy of J. Chalmers.

gas–liquid interface. Most commercial serum-free cell culture media for insect and mammalian cells include Pluronic F-68, although, other surfactants such as methylcellulose, serum, carboxymethylcellulose, bovine serum albumin, and dextrans have been considered as well. Unfortunately, only a limited selection of surfactants can be used because the interaction of the surfactants with the cells may affect membrane permeability and cause cell lysis (76).

16.8.6 Media Formulation

Media formulations are derived from elements originally identified in the insect hemolymph and include salts, vitamins, amino acids, sugars, organic acids, and trace elements (85,86). A number of proprietary commercial serum-free media are available for insect cell growth, including HyClone SFX-Insect™, Express Five®, Drosophila-SFM, and Sf-900 III™ from Invitrogen, and EX-CELL® 405 and 420 from Sigma-Aldrich. These media are derivations of noncommercial media such as Grace's, TNM-FH, TC-100, and IPL-41 that were supplemented with 5–20% fetal calf serum and used for many years in the cultivation of insect cells. The serum-free media are supplemented with lipids (cholesterol, α-tocopherol acetate, cod liver oil fatty acid methyl esters, β-sitosterol, and stigmasterol), yeast extract (yeastolate), and Pluronic F-68 in addition to other proprietary alterations (87,88). Antibiotics such as penicillin G and streptomycin are often added to the medium during cell culture.

Media sugars, including glucose, maltose, and fructose, can be partially or completely consumed during insect cell growth and recombinant protein production. Also, a significant fraction of the amino acids, including glutamine, glutamate, serine, asparagine, threonine, aspartate, and arginine, can be consumed during insect cell growth. However, much of this consumption may be devoted to energy use by the cells rather than the production of biomass (86,87).

Because the level of amino acids present in IPL-41 medium is sometimes in excess of that required for biomass production, media alterations that reduce these amino acid levels may lead to more efficient nutrient utilization (88). Furthermore, the amino acids utilized may vary depending on the cell line with some cell lines utilizing more glutamine and other consuming more asparagine (89). Supplementary components such as yeastolate or Primatone RL were observed to improve cell growth and the length of the stationary phases (90). A more detailed characterization of the yeast extract components critical to cell growth may eventually result in the development of a truly defined medium for insect cell culture (85,88). The consumption rates of these nutrient components may change following baculovirus infection (74).

16.8.7 Cell Culture By-Products

A significant amount of carbon dioxide is exhausted because of nutrient oxidation. Metabolites including lactate and other organic acids (pyruvate, α-ketoglutarate, fumarate) can also accumulate during growth and infection. The production of lactate from Sf-9 cells is generally lower than that observed with mammalian cells and poses no significant inhibitory effect on growth, although, lactate levels can increase significantly following dissolved oxygen (DO) limitations (91). The metabolites secreted and nutrients consumed in cell culture may change significantly depending on the cell line and even the specific medium considered.

For example, much higher levels of lactate and/or ammonia are generated by *T. ni* and *B. mori* cells when compared to Sf-9 cells (74,89,92). Likewise the glucose utilization rates and lactate and alanine production rates were found to vary significantly depending on particular commercial medium used for High Five cells (89). Different cell lines will also utilize the cellular energetic pathways in different ratios. Sf-9 cells channel slightly more glucose into the tricarboxylic acid (TCA) cycle than High Five cells (2.7% vs 0.6%) but the High Five cells direct nearly five times more glutamine into the TCA cycle than Sf-9, perhaps explaining the accumulation of higher ammonia and lactate in the High Five cells. In both cell lines, approximately 15% of the remaining glucose is directed to the pentose phosphate (PP) pathway with the bulk of the glucose (83% in both cell lines) metabolized into by-products including lactate, alanine, and others (93). Metabolic engineering can be used to alter the ratios of a substrate devoted to these different energetic pathways (93).

Most insect-culture media are not buffered with carbon dioxide, so there is no need for a CO_2 environment for growth. The optimal pH for growth of most insect cells is

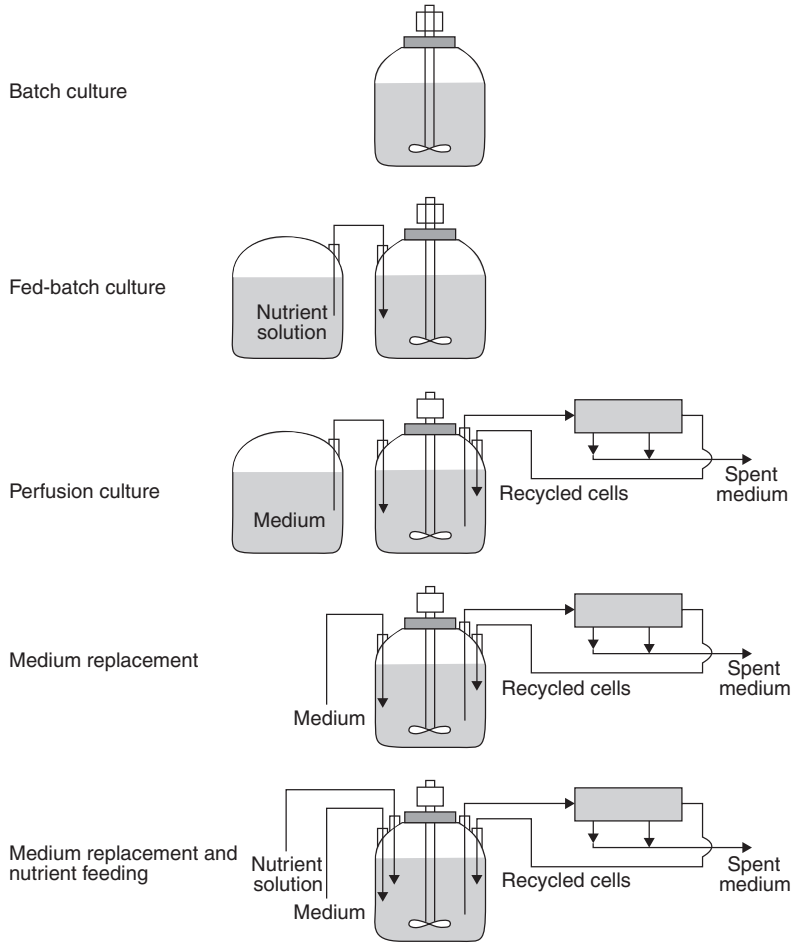

Figure 16.9. Various reactor configurations for batch and fed-batch production strategies.

between 6.2 and 6.3, though the pH of Sf-9 cultures in an uncontrolled medium can reach a minimum value between 5.9 and 6 (63). Because pH variations in the medium will affect both the growth and infection stages (94), pH control is suggested for optimal productivity in large-scale cell cultures. Osmolarity is another variable that should be considered, although, varying the osmolarity from 350 to 385 mOsm/kg did not alter the insect cell growth rate more than 10% (95). Most media osmolarities range from 320 to 375 mOsm/kg.

16.8.8 Batch Production Techniques

Recombinant baculovirus and heterologous proteins have been produced using batch, fed-batch, and continuous production modes. Typical processing of insect cells involves the batch cultivation of cells in a small suspension vessel, followed by a gradual scale-up of the cultures into progressively larger bioreactors. The cells are grown to a maximum cell density in one vessel and then pumped through steam-sterilized lines to increasingly larger vessels containing fresh medium. The optimal growth temperature is usually between 27 and 29°C, with cell doubling times between 17 and 24 h, depending on the cell line and medium utilized. High Five cells typically have a shorter doubling time (13–17 h) than Sf-9 cells (20–24 h) (92). In the final production-scale vessel, the cells are infected with virus during the exponential growth phase, and the virus or recombinant protein is collected at the conclusion of the infection stage (typically, between 48 and 100 h postinfection).

16.8.9 Fed-Batch, Perfusion, and Semibatch/Semicontinuous Production

It is desirable to grow the cells to a high cell density to maximize the productive capacity of the bioreactor. Supplementation of glucose, amino acids, yeastolate, lipids, or a concentrate of multiple nutrients can be used to increase the maximum cell density up to 5×10^7 cells/mL and enhance recombinant productivity (96). These nutrients can be added continuously in a fed-batch mode or added as one or multiple pulse feeds over the growth and infection

stages (97) (Fig. 16.9). As an alternative, fresh medium can be fed continuously in a perfusion mode to replace the spent medium exiting through a hollow fiber or other device (0.4–0.6 vol/day) to provide cell densities up to 3×10^7 cells/mL of bioreactor volume (98). Another approach that has been used to increase cell density is the replacement of 80% of the medium for several consecutive days near the end of the growth stage. Using the same hollow fiber technology (0.2 μm pore size), most of the spent media is removed, and then fresh medium is added to the bioreactor. Similar nutrient supplementation strategies are used to enhance the yields of recombinant proteins during the infection stage because the recombinant product yield is highly dependent on the nutrient levels. One approach that is used to ensure high product yields is to resuspend the cells in fresh medium prior to the infection, or else to add fresh medium to the bioreactor at the beginning and/or during the infection stage (73). Supplementation of limiting nutrients such as glucose, glutamine, and yeastolate can also be used to enhance the infection process (4,99–101), eliminating the costly replacement of the entire medium. Another feeding alternative during the infection stage is to perfuse the bioreactor with fresh medium which will generate a larger volume of spent medium compared with nutrient supplementation but ensure high recombinant protein yields throughout the infection phase (102).

A semibatch operating strategy used for production of recombinant baculoviruses and heterologous proteins can also utilize separate growth and infection reactors (Fig. 16.10) (103). An initial cell growth reactor is followed by single or multiple sequential infection vessels in series. After each cycle, the contents from one infection vessel are pumped to a following infection vessel, while the contents of the final infection vessel are harvested for product. The first infection vessel is then filled with medium and cells from the growth reactor and inoculated with virus. The cell growth reactor is provided with fresh medium, and the growth cycle repeated. Some of the cells from the growth stage may remain in the reactor to serve as an inoculum for the next growth cycle (104,105), and a portion of the contents of the first infection reactor can be left to infect a new batch of cells. However, modeling studies have indicated that the productivity of this sequential system may decline after a number of cycles because of the buildup of mutant viruses known as *defective interfering particles* (DIPs) (see later section) (106). The formation of these mutants is because of the "passage" effect. The recombinant protein productivity of the second and subsequent infection stages must be monitored closely for the buildup of these particles, and the second infection stage must be completely emptied and inoculated with a fresh sample of virus in order to eliminate the DIPs. Semicontinuous operation has been achieved by maintaining a first-growth reactor in a

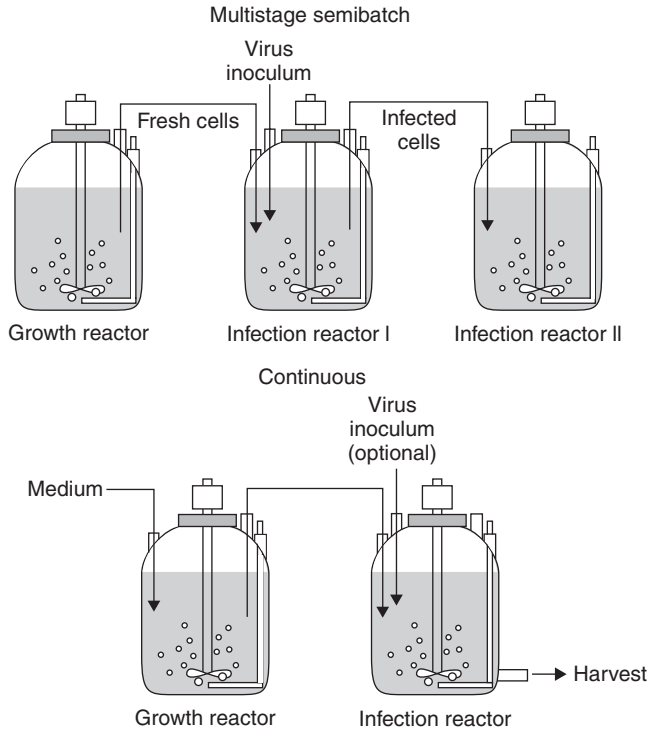

Figure 16.10. Multistage reactor systems. Multistage reactor systems used for the semibatch, semicontinuous, and continuous production of recombinant proteins in insect cell culture using AcMNPV. The initial reactor is primarily used for cell growth, whereas subsequent reactors contain the insect cells infected with the virus.

continuous operating mode and then gradually filling a second reactor (107). Following the filling of the second reactor, virus is added to initiate a batch infection in the second stage. At the end of the infection process, the second stage is emptied in part or completely, and the filling and infection cycle repeated. The medium in the infection reactors may also be supplemented or replaced by separating the cells from spent medium by settling, membrane filtration, or ultracentrifugation. Since the nutrients are often not consumed completely in the infection stage(s), it may not be necessary to replace all the spent media. These semibatch/semicontinuous processes can be achieved with processing times dictated by the exhaustion of nutrients, decline of cell viability, and accumulation of recombinant proteins.

16.8.10 Continuous Production Systems

The release of BV from infected insect cells into the cell culture medium has led to the design and evaluation of continuous-flow stirred-tank reactors for the production of polyhedra and recombinant proteins. The utilization of a continuous system could reduce production costs by 50% when compared with a batch system (108). Batch

systems have the disadvantage of long downtimes as a result of cleaning and sterilization after each run. Continuous systems typically consist of sequential two-stage continuous-flow bioreactors in which the first stage is used for cell growth and the second stage is used for virus production and heterologous gene expression (Fig. 16.10). The effluent of cells from the first stage feeds the second infection stage, and the effluent of the second stage includes the infected cells and associated baculoviruses and/or recombinant product. The BV generated in the second stage are used to infect the feed from the first reactor. In one study (109), a 60 h mean residence time was maintained in each stage, and production of polyhedra and recombinant protein was sustained for approximately, 4 weeks. Because about 200 BVs are produced per cell, there is a gradual accumulation of virus in the second reactor, followed by a severe decline in productivity after 4 weeks because of the formation of DIPs. A model that considers the presence of infectious virus (I-BV), defective virus (DIP), and abortive virus (A-BV) effectively predicted the accumulation of DIPs and the decline of recombinant protein production for a two-stage continuous-infection process (106).

Thus, a continuous reactor system may be problematic for extended production of baculovirus and recombinant protein. However, such a setup may be used for production over shorter periods such as a 30-day cycle prior to the accumulation of DIPs (106). This reactor setup would be analogous to a continuous catalytic reactor that experiences gradual catalyst deactivation during its operation and has to be periodically recharged with new catalyst. This could be accomplished by a complete shut down and restart with fresh virus or else by providing a secondary feed of fresh virus to the second infection reactor. A continuous setup provides for larger processing volumes of insect cell culture and recombinant product than does batch operation, although, the yield of recombinant protein in the effluent may be low compared with batch or fed-batch operation. Another innovation in the continuous culture process has been the sequential combination of a continuous stirred-tank reactor (CSTR) for growth, followed by a tubular reactor for infection. The tubular reactor provides for the continuous introduction of baculovirus at higher multiplicity of infection (MOI) without the negative passage effects present in a two-stage CSTR system (110).

16.8.11 Virus Stocks, Multiplicity of Infection, and Time of Infection

To initiate the infection, an aliquot of virus is added to the cell culture broth. Virus stocks are made from a single viral isolate obtained by plaque assay or end-point dilution. The plaque assay involves the infection of a monolayer of cells with a low concentration of virus, followed by an overlay of agarose-containing medium. Eventually, an isolated region of infected cells, called a *plaque*, is identified, and an agarose plug is collected at this plaque location for generating viral stocks. With the end-point dilution method, the tissue culture medium is diluted to the point at which any infection must result from a single infectious virus. Large stocks of the virus are obtained by infecting a monolayer or suspension cell culture with the agarose plug (from a plaque) or tissue culture medium (from the end-point dilution). The cell culture medium is then collected after 4–5 days, however, it may be necessary to repeat the infection several times in order to generate a viral stock of sufficient titer. The viral titer can determined by several methods, such as, plaque assay method, end-point dilution method, anti-gp64 antibody method or by using flow cytometry.

The viral titer obtained by determining the number of plaque-forming units (PFUs) per milliliter, using the plaque assay, or by finding the 50% tissue culture–infectious dose ($TCID_{50}$) per milliliter using end-point dilution are more commonly used as they selectively provide the concentration of the infectious baculovirus particles. The $TCID_{50}$ dose per milliliter is then multiplied by 0.69 to determine the number of plaque-forming units per milliliter. Staining of baculovirus with a highly fluorescent nucleic acid specific dye such as SYBR Green I combined with flow cytometry can be used as a rapid method to estimate viral titers in as little as 2 h, and the technique may also ascertain baculovirus aggregation in stored viral stocks (111,112). Several master viral stocks are frozen at $-70^{\circ}C$ for long-term storage, with one master stock kept at $4^{\circ}C$ in order to generate working viral stocks. Cells are then infected at a desired MOI, which represents the number of plaque-forming units per viable cell, from the working viral stock. In small shaker-flask cultures, cells are typically infected at an MOI greater than three during the mid to late exponential phase of growth in order to generate a synchronous infection. The Poisson distribution predicts that approximately 9.5, 63.2, and 99.995% of the cells will be infected at MOI of 0.1, 1, and 10 respectively. Infecting the cells at the highest possible cell density and cell viability while still in the exponential growth phase provides high volumetric productivities. However, an efficient infection is also dependent on the presence of adequate nutrient levels in the medium. If the cells are infected at a point near the end of the exponential phase or during the stationary phase, insufficient substrates may be available for the viral infection, and low recombinant product yields will result (73).

In larger bioreactors, infection at a high MOI (>1) may not be feasible or desirable because of the requirements for large amounts of virus stock. If cells are infected at a lower MOI, then the infection of the cells will not be synchronous, and some insect cell growth will occur prior to secondary infection by BV generated during the initial infection (95). If the MOI is too low or cell density too

high, the cells will grow to the late exponential or stationary phase prior to complete infection, and product yields will be lower. Consequently, it is important to optimize both the time of infection (TOI) and MOI to ensure that all cells are infected by virus and that sufficient substrates remain for virus and/or protein production (113). This optimization is facilitated by the use of mathematical models that consider both cell growth and viral infection stages as well as substrate consumption, recombinant protein production, and cell death (114–116), These models are often probabilistic in nature and consider the infection of cells as a Poisson distribution or a stochastic event in which the MOI or another variable is varied in order to maximize production of heterologous proteins (114,117,118). According to some models, high protein yields can be achieved even using very low MOIs although this approach may be difficult to implement in practice because of inaccuracies in viral titers and other parameters (113). Furthermore, infections at low MOI and low cell density may be effective for cell lines such as Sf-9, but the approach may not be as successful for cell lines such as TN-5-B1-4, which produce much lower levels of EV.

16.8.12 Passage Effects and Mutant Virus Formation

The continuous passage of viruses in cell culture often leads to the formation of mutant viruses such as DIPs (119,120). The DIPs will replicate more rapidly than the normal-size viruses, and the concentration of DIPs can rise to as high as 60% of the total virus stock (119,120). These DIPs average about 200–230 nm in size, as compared with the standard 330 nm sized virions (120), and can lack up to 40% of the baculovirus genome because of spontaneous deletions during passaging (119). The deleted segment often includes the polyhedrin gene and at least one other gene necessary for virus replication. Consequently, DIP mutants cannot be plaque purified because they replicate only in cells that are also infected by a normal virus. To avoid the passage effect, viral passage number should be monitored, and a low passage master viral titer stock used to generate working viral titer stocks since DIP mutants can accumulate within two passages of the original viral isolation (121). If contamination with DIPs is suspected, then a plaque assay can be performed to reisolate the infectious virus. Also, low MOI infections can be used to minimize DIP formation, but this approach results in asynchronous infections. Alternatively, baculovirus homologous repeat regions (hours) may be inserted to increase the stability of baculoviral vectors since deletions in the virus are observed to correlate with a low density of hours (122).

Other mutant viruses, such as ones that result in the generation of a few polyhedra (FP), have also been observed. The FP mutants substantially lower the number of polyhedra produced per infected cell and reduce the number of occluded viruses generated (123). These FP mutants may have a selective advantage in cell culture by producing more BV at the expense of polyhedra. Unlike DIPs, FP mutants can be plaque purified. Once again, formation of FP mutants can be minimized by working with low passage viral titers and utilizing a master viral titer stock. Because FP mutants do not include significant virus levels in the polyhedra, insect-to-insect transmission will not include FP mutants, which are not capable of spreading through polyhedra infections.

16.8.13 Larval Production Systems

On the basis of productivity comparisons with polyhedra, approximately, 100–200 larvae will provide a final protein yield approximately equal to 1 L of cells for an intracellular recombinant protein (7). The use of larvae eliminates the need for high capital investments in large-scale bioreactors, but requires the development of systems for insect rearing and infection. Furthermore, purification strategies must be implemented to isolate the proteins from insect parts or hemolymph. Typical species considered include *S. frugiperda*, *T. ni*, *Heliothis virescens*, *Manduca sexta*, and *Hyalaphora cecropia* for AcMNPV infections, and *B*. for BmNPV infections (7,56). Lepidopteran eggs are available from commercial suppliers and hatch 5 days to 1 week after incubation at 25–27°C in a humidified environment under a controlled light cycle. Artificial diets are also available from commercial sources or may be prepared from components in the laboratory. Constituents typically include pinto beans, Brewer's yeast, ascorbic acid, wheat germ, sorbic acid, 14% auromycin, and a vitamin mix. The ingredients are combined with agar and then provided to larvae with periodic replacement to ensure a moist supply of nutrients. It is important to infect the insects at the appropriate developmental stage to provide the maximum yield of baculovirus or heterologous protein. The insects typically molt five or six times as larvae with the last stage being the larval–pupal molt. The intermolt period is the stadium or instar. Optimal infections are typically achieved 1 or 2 days after molting into the last larval instar. Infections are accomplished by feeding the insects with PIBs or by injecting BV directly into the hemolymph. For recombinant baculoviruses that are occlusion negative, injection of the BV is the required method of infection. A small number of mock-infected insects should also be maintained to check for possible contamination problems and to provide a comparison of infected and uninfected larvae. The expression of fluorescent proteins such as GFP in larvae can be used in order to identify optimal infection and harvesting conditions (69,124). Shown in Fig. 16.11a is a photograph of an infected *T. ni* larva expressing GFP as compared with an uninfected larva (69). Fig. 16.11b shows massive

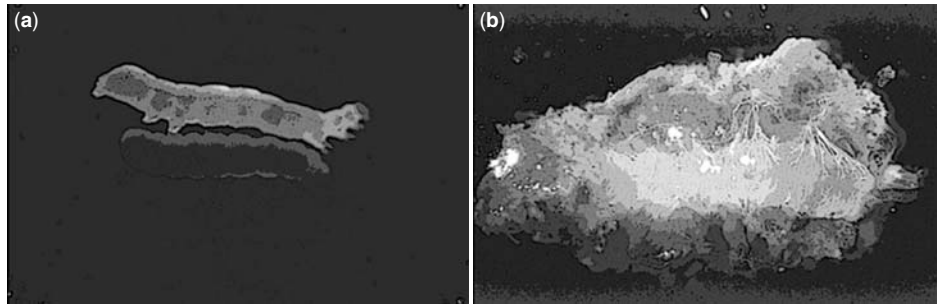

Figure 16.11. (a) Photo of *T. ni* larvae sitting on top of a laboratory UV transilluminator table. The upper larva has been infected (72 h) with a recombinant AcMNPV baculovirus that contains the gene for green fluorescent protein (GFPuv) placed under control of the polyhedrin promoter. The brightness is because of the massive overexpression of GFPuv, which has been shown to reach 26% of the total larvae protein. The lower larva (nonglowing) is the uninfected control. Photograph courtesy of W. Bentley. (b) Micrograph showing AcMNPV-β-galactosidase infection of *T. ni* insect larva at 60 h postinfection. Staining represents β-galactosidase expressed in insect cell tissues. Infection has cleared the midgut and spread to the fat body. Micrograph courtesy of G. Williams.

expression of β-galactosidase in a *T. ni* larva when infected with AcMNPV containing the heterologous *lacZ* gene under the control of the p10 promoter. At 60 h postinfection, the infection has cleared the midgut and entered the fat body. The best time to collect product from infected insects is generally prior to death. For secreted proteins, the product is collected by bleeding the insects to collect hemolymph, whereas nonsecreted proteins are isolated by homogenization of whole insects. Unfortunately, homogenization can result in the release of proteases; these can be minimized by the removal of the insect gut before processing (7,56). Alternatively, a particular metabolically active tissue such as the fat body can be removed from the insect and used as a source of the desired protein (7,56). The number of recombinant proteins expressed in larvae continues to grow because of the low cost and convenience of this method. Furthermore, production has recently been automated and is linearly scaleable with the rearing of more insect larvae giving more recombinant protein (125). Examples of secreted proteins produced and purified from larvae include monoclonal antibody Fab fragments and human granulocyte-macrophage colony-stimulating factor with yields up to 1.1 g/kg larvae (125,126).

16.9 CONCLUSION

The use of the baculovirus–insect cell system for heterologous gene expression and recombinant biopesticides has grown dramatically since its first application in 1983. Commercially available vectors that provide for the rapid selection and screening of recombinant viruses have made this technology accessible in most biotechnological laboratories. The development of serum-free media, the isolation of alternative insect cell lines, and the implementation of efficient bioreactor operating strategies have increased productivities and lowered costs. As a result, insect cells are often the method of choice for rapid and high level production of functional eukaryotic proteins. The use of BEVS is likely to increase even more with the growth of genomics and its associated need for functional characterization of unknown proteins. The use of insect cell-derived proteins as vaccines and pharmaceuticals is now beginning to emerge as another important application of BEVS as a number of clinical approvals are in progress. The future growth of the insect cell culture systems will also be assisted by the modification of posttranslational processing including glycosylation using metabolic engineering approaches. Other promising areas include the use of insect larvae and the development of stable expression systems for *T. ni*, *B. mori*, Sf-9, and *Drosophila* S2 cells (127). With these advances, insects and insect cells are likely to remain a popular choice for the manufacture of recombinant DNA products.

KINETICS OF MICROBIAL GROWTH

NICOLAI S. PANIKOV
Northeastern University, Department of Biology, Boston, Massachusetts

17.1 INTRODUCTION

Kinetics (Greek $\kappa\iota\nu\varepsilon\tau\iota\kappa o\sigma$, forcing to move) is a branch of natural science that deals with *the rates and mechanisms* of any processes—physical, chemical or biological. Kinetic studies in microbiology cover all dynamic manifestations of microbial life: growth itself, survival and death, product formation, adaptations, mutations, cell cycles, environmental effects and biological interactions. Kinetics provides a theoretical framework for optimal design in biotechnologies based on fermentation and enzyme catalysis, as well as on employment of outdoor activity of natural microbial populations (wastewater treatment, soil bioremediation, etc.)

Contrary to simple rates measurements, kinetic studies require the perception of the underlying basic *mechanisms* of studied processes. We will define mechanistic studies as those that interpret some complex process as an interplay of several simpler reactions, for example, cell growth can be explained through activity of enzymes and microbial community dynamics can be interpreted—through behavior of individual cells and populations. Ideally, mechanistic studies infer the coupling of experimental measurements with analysis of simulating mathematical models. The models formalize postulated mechanisms, so that the comparison of observations and the model's predictions allows one to discard an incorrect hypotheses.

The quantitative studies in microbiology often involve the assessment of *growth stoichiometry*. Stoichiometry (Greek $\sigma\tau\omega\iota\kappa\eta\varepsilon\iota o\nu$, element) is the quantitative relationship between reactants and products in a chemical reaction. In microbiology, stoichiometry stands for a quantitative relationship between substrates and products of microbial processes, including biomass formation (the consequence of complying with mass and energy conservation laws). In practical terms, kinetic and stoichiometry are tightly linked to each other, but stoichiometry mainly addresses problems of a static nature (how much? in what proportion?), whereas kinetics considers the dynamics questions (at what rate? by which mechanism?).

17.2 GROWTH STOICHIOMETRY

17.2.1 Macrostoichiometry of Microbial Growth

By analogy to simple chemical reactions we can represent growth as a conversion of a number of substrates (medium components) into cell mass and products. Growth of aerobic heterotrophic microorganisms can be approximated by the following stoichiometric equation (1,2):

$$\underset{\text{substrates}}{\mathrm{CH_mO_l} + a_1\mathrm{NH_3} + a_2\mathrm{HPO_4}^{2-} + a_3\mathrm{K}^{+} + \ldots + b\mathrm{O_2}} = \underset{\text{biomass}}{Y\mathrm{CH_pO_nN_qP_oK_v}\ldots} + \underset{\text{products}}{a_4\mathrm{CO_2} + a_5\mathrm{H_2O}} \qquad (17.1)$$

Here, microbial biomass is empirically expressed by the gross formula $\mathrm{CH_pO_nN_qP_oK_v}\ldots$, for example, if

TABLE 17.1. Selected Macrostoichiometric Equations Describing Growth of Microorganisms with Different Types of Energy Generation

Microbial Process	Substrates		Biomass		Products	Stoichiometric Parameters
Heterotrophic growth and product formation	$CH_mO_1 + a_1O_2 + a_2\ NH_3$	=	$YCH_pO_nN_q$	+	$Y_pCH_rO_sN_t + a_3CO_2 + a_4H_2O$	$a_1 = 0.5(Yn + Y's - l + a_4) + a_3$, $a_2 = Yq + Y't, a_3 = 1 - Y - Y'$, $a_4 = 0.5[m + Y(3q - p) + Y'(3t - r)]$
Phototrophic growth (algae or plant cells)	$CO_2 + a_1H_2O + a_2\ NH_3$	=	$YCH_pO_nN_q$	+	$a_3CH_rO_sN_t + a_4O_2$	$a_1 = 0.5[Y(p - 3n) + (r - 3t)(1 - Y)]$, $a_2 = Y(n - t) + t, a_3 = 1 - Y$, $a_4 = 0.5(2 + a_1 - Y_n - a_3s)$
Hydrogenotrophic methanogenesis	$CO_2 + a_1H_2 + a_2\ NH_3$	=	$YCH_pO_nN_q$	+	$a_3CH_4 + a_4H_2O$	$a_1 = 4 - 0.5Y(4 + 2n + 3q - p)$, $a_2 = Yq, a_3 = 1 - Y$, $a_4 = 2 - Yn$
Nitrification	$YCO_2 + a_1O_2 + a_2NH_4^+$	=	$YCH_pO_nN_q$	+	$a_3NO_3^- + a_4H^+ + a_5H_2O$	$a_1 = 2Y^{-1} - Y[1 + 0.25(p - 2n - 3q)]$, $a_2 = Y^{-1} + Yq, a_3 = Y^{-1}$, $a_4 = 2Y^{-1} + Yq, a_5 = Y^{-1} - 0.5Y(p - 3q)$

some average microbial cell contains per dry cell weight (%) C, 46; H, 7.5; O, 31; N, 11; and P, 1.3, then the biomass formula $CH_{1.9}O_{0.5}N_{0.2}P_{0.01}$. The stoichiometric quotients $a_1 - a_5 \ldots, b$ and Y (biomass yield) specify quantities of substrate and products of microbial growth. If we know biomass yield and gross formulas of all substrates and products, then quotients a_1-$a_6 \ldots$ are easily calculated from conservation conditions. There are at least two such conditions. First, the mass of each element (C, H, O, N, P, K, ...) on the left side of Equation 17.1 should be equal to that on the right side (mass balance). Second, if ionized substances are involved, we should take into account the balance of charges to satisfy the condition of electroneutrality. Table 17.1 demonstrates some examples of stoichiometric growth reactions relevant to biotechnology.

Described formalism is useful as a first step in biotechnological studies aimed at planning and optimizing microbial growth. It estimates how much nutrient should be supplied to the fermentor to obtain the required amount of biomass or target product. However, it should be absolutely clear that stoichiometric equations like Equation 17.1 are no more than an approximation to reality. The most severe deviation stems from the fact that unlike chemical reagents, microbial cells are characterized by changeable composition, and stoichiometric coefficients are not true constants. One task of contemporary microbial stoichiometry is to find out the functional relationships between stoichiometric parameters and internal (physiological) and external (environmental) factors.

17.2.2 Growth Yield: Catabolic and Conserved Substrates

The growth yield is one of the main stoichiometric parameters. It is defined as follows:

$$Y = -\frac{\delta x}{\delta s} \approx -\frac{\Delta x}{\Delta s} \tag{17.2}$$

where Δx is the increase in microbial biomass consequent on utilization of the amount Δs of substrate, and δx and δs are respective infinitely small increments. Rigorous definition of Y as derivative $\delta x/\delta s$ stems from the fact that Y can vary in time, the negative sign being introduced because of x and s vary in opposite senses. Sometimes, it is used as the reciprocal of $Y : \alpha = 1/Y$ which is called *the economic coefficient*. It expresses explicitly the nutrient requirements for growth: how many mass units of a particular substrate should be consumed to produce one unit mass of cell material.

The growth efficiency depends generally on the partitioning of consumed element between new cell biomass and extracellular products. The mass balance is as follows:

total element consumed		incorporated into cell	+	incorporated into extracellular products	
δE_s	=	δE_x	+	δE_p	(17.3)

There are two groups of substrates for microbial growth: (i) *catabolic substrates*, which are sources of energy; and (ii) *anabolic* or *conserved substrates*, which are sources of biogenic elements forming cellular material. Catabolic substrates include H_2 for lithotrophic hydrogen bacteria, NH_4^+ and NO_2^- for nitrifying bacteria, S^0 for sulfur-oxidizing bacteria, oxidizable or fermentable organic substances for heterotrophic bacteria and fungi, and so on. Their consumption is accompanied by oxidation and dissipation of chemical substances into extracellular waste products that are no longer reusable as an energy source ($H_2O, NO_3^-, SO_4^{2-}, CO_2$, etc.) The anabolic substrates after uptake are incorporated into *de novo* synthesized cell components, being conserved in biomass (that is why they are called conserved). Contrary to catabolic substrates, they can be reused (e.g. after cell lysis to be taken up by survived cells). The conserved substrates include nearly all the noncarbon sources of biogenic elements (N, P, K, Mg, Fe, and trace elements), CO_2 for autotrophs, and the indispensable amino acids and growth factors. Most catabolic substrates are used also as a source of biogenic elements. We can assess both these components separately in terms of respective yields Y_E (biomass yield/mass unit of oxidized substrate) and Y_A (biomass yield/mass unit of assimilated substrate), from the experimentally measured yield, Y. For C substrate, Equation 17.4 can be specified as follows:

Total carbon consumed		C incorporated into cell		C oxidized to CO_2 to provide energy		C incorporated into by-products	
δC_s	=	δC_x	+	δC_{CO2}	+	δC_P	(17.4)

Let us neglect the last term δC_P (by assuming that extracellular by-products can be reused and functionally are equivalent to C substrate) and divide the substrate balance by δC_x, which is the amount of biomass C produced, then:

$$\frac{1}{Y} = 1 + \frac{1}{Y_E}, \tag{17.5}$$

where Y = gram of biomass of C/gram substrate of C and $Y_E = gram$ of biomass of C/gram $CO_2 - C$

$$\frac{1}{Y} = \frac{\sigma_x}{\sigma_s} + \frac{12}{Y_E \sigma_s}, \tag{17.6}$$

where Y = grams of CDW/gram substrate, $Y_E = gram$ of CDW/mmol of CO_2, σ_x and σ_s are fractions of carbon in biomass and substrate, respectively. For example, if total measurable yield Y is 0.6 g biomass C/g glucose C, it means that from each gram of consumed C, 0.6 g is incorporated into biomass (assimilated), and 0.4 g is dissimilated (oxidized to CO_2), then $Y_E = 0.6/0.4 = 1.5$. To calculate oxygen demand for aerobic growth (or biomass yield on O_2) we have a balance:

oxygen required to produce 1 g CDW		oxygen required to burn substrate consumed to produce 1 g CDW		oxygen required to burn 1 g CDW	
$1/Y_{x/o}$	=	A/Y	−	B	(17.7)

where A and B are constants estimated from stoichiometry of their respective combustion reactions (see Eq. 17.10 later), for example, the value of A is 33.33 mmol O_2g glucose and B is about 42 mmol O_2/g CDW. The relationship between biomass yields on O_2 and CO_2 is derived from comparison of Equations 17.6 and 17.7:

$$\frac{Y_{x/CO_2}}{Y_{x/o}} = \frac{A - BY}{\sigma_s - \sigma_x Y} \tag{17.8}$$

Now we will go back to the general substrate balance (Eq. 17.3) and derive an expression for conserved substrate. Again, we neglect term δE_P (because extracellular products are assumed to be reusable) and divide the balance by δx, which is the amount of biomass produced:

$$\frac{1}{Y} = \frac{\delta E_x}{\delta x} \approx \sigma_x \tag{17.9}$$

where σ_x is the intracellular content of element incorporated into biomass from consumed substrate. Sometimes σ_x is called the *cell quota*. The values $1/Y$ and σ_x are not identical although they have the same dimension (e.g. milligram N/gram biomass) and very close numeric value. The reciprocal $1/Y$ is characterizing the *process* (the expenditure of conserved substrate to synthesize biomass unit), whereas σ_x is an index of cell composition (the content of intracellular N/biomass unit). Formally $1/Y$ is equal to σ_x value of an infinitely small increment of cell biomass, and σ_x is the averaged value for entire cell. Notice that although σ_x is a slow and $1/Y$ is a rapid variable, their numerical values are exactly the same for balanced steady-state growth and can differ considerably during transients.

17.2.3 Yield Variation as Dependent on the Chemical Nature of Organic Substrates

In this section, we will discuss why biomass yield varies when microorganisms are grown on different C substrates. This problem was best solved within the framework of the *theory of mass and energy balance* (TMEB) (3,4). Evidently, the fraction of C in dry biomass is almost constant. By contrast, the content of carbon in utilized substrates, σ_s, and energetic quality of substrate vary over a broad range (e.g. compare methane vs oxalic acid). To characterize substrate and biomass by a single common measure, TMEB

uses an index of *degree of carbon reduction*, γ related to the internal energy of organic compounds. The heat liberated by biological or chemical oxidation is proportional to oxygen uptake or equally to the number of electrons gained by oxygen from oxidized substrates, according to Payne's term *available electrons* (*ae*) (5). The heat production from an oxidation reaction averages at 27 kcal/*ae* equivalent. A carbon reduction degree, γ is defined as the number of *ae*/carbon atom. Its numeric value can be determined from the stoichiometry of the oxidation reaction:

$$CH_pO_nN_q + bO_2 = CO_2 + 0.5(p\text{-}3q)H_2O + qNH_3, \quad (17.10)$$

$$\gamma = 4b = 4 + p - 2n - 3q \quad (17.11)$$

The *ae* balance for Equation 17.1 can be written as

$$\gamma_s + b(-4) = Y\gamma_x + Y_P\gamma_p \quad (17.12)$$

where γ_s, γ_x, and γ_p are the carbon reduction degree of respectively substrate, biomass, and extracellular product. Dividing both sides of Equation 17.12 by γ_s we obtain the relationship delineating the *ae* distribution between oxygen (*ae* used for respiration), biomass, and the intracellular product:

$$\underset{\text{oxygen}}{\frac{4b}{\gamma_s}} + \underset{\text{biomass}}{\frac{Y\gamma_x}{\gamma_s}} + \underset{\text{product}}{\frac{Y_P\gamma_p}{\gamma_s}} = 1 \quad (17.13)$$

The second term in this equation is the fraction of *ae* transferred to biomass from utilized substrate, termed the *energetic growth yield*.

$$\eta = Y_C\gamma_x/\gamma_s \quad (17.14)$$

The third term designates that fraction of total substrate internal energy that is transferred to the product. It is called the *energetic product yield*.

$$\xi = Y_P\gamma_p/\gamma_s \quad (17.15)$$

Energetic yield η is related to other stoichiometric parameters as follows:

$$\eta = Y_{x/s}\sigma x\ \gamma x/(\sigma s\gamma s)$$
$$\eta = Y_{x/C}\gamma_x/\gamma_s$$

where $Y_{x/s}$ is gram of CDW/gram of substrate and $Y_{x/C}$ is gram of CDW-C/gram of substrate C.

The advantage of using η is that it varies within a much smaller range than other yield expressions. At one and the same efficiency of energy utilization (η), the conventional biomass C yield $Y_{x/C}$ is proportional to substrate reduction degree γ_s and, for example, it is 4 times higher on glucose ($\gamma_s = 4$) than on oxalate ($\gamma_s = 1$), 0.48 and 0.12 g C/g C, respectively (assuming $\eta = 0.5$ and $\gamma_x = 4.2$). The energetic growth yield η is more or less constant (0.5–0.7) for substrates with $\gamma_s \leq 4.2$ (4.2 corresponds to average reduction degree of microbial biomass), and it declines at higher γ_s.

The attractiveness of macrostoichiometry and TMEB is that all growth coefficients are interrelated and could be measured from any available components of the culture mass balance. For example, if you cannot record microbial growth by conventional routine as dry weight biomass (because of presence of solids in broth liquid), you may still calculate it from N or O_2 uptake, CO_2 evolution, pH titration rate, and so on.

17.2.4 Variations in Yield from Energy Source, Maintenance Requirements

To multiply and grow cells require energy, but the opposite is not true: cells do not require growth to spend energy. Sometimes catabolic machinery is entirely wasteful (respiration without cell growth) and always at least some minor part of energy consumption is diverted from growth. To account for this phenomenon, it was postulated that microbes and cells require energy not only for growth but also for other *maintenance purposes*. Certain specific maintenance functions recognized now are turnover of cell material, osmotic work to maintain concentration gradients between the cell and its exterior, and cell motility.

According to conventional definition of maintenance (6), the balance of energy source is

$$\underset{\text{source consumed}}{\text{total energy}} \quad \underset{\text{for cell growth}}{\text{consumption}} \quad \underset{\text{maintenance}}{\text{consumption for}}$$
$$\delta S_E = \delta S_G + \delta S_M \quad (17.16)$$

Let us divide it by δx, the amount of biomass produced, then:

$$\frac{1}{Y} = \frac{\delta S_G}{\delta x} + \frac{\delta S_M}{\delta x} = \frac{1}{Y^{\max}} + \frac{m}{\mu} \quad (17.17)$$

Here $Y^{\max} = \delta x/\delta S_G$ is "true" growth yield, that is, yield under imaginary conditions of maintenance being zero. The maintenance coefficient, m is introduced as the specific (i.e. expressed per unit of biomass) rate of energy consumption for maintenance functions: $m = (1/x)(\delta S_M/\delta t)$. The ratio m/μ on the right side of Equation 17.17 was derived as follows: $m/\mu = [(1/x)(\delta S_M/\delta t)]/[(1/x)(\delta x/\delta t)] = \delta S_M/\delta_x$.

If we divide Equation 17.16 by $x\delta t$ (note that the second term is $\delta S_G/(x\delta t) = [\delta x/(x\delta t)]/[\delta x/\delta S_G] = \mu/Y^{\max}$, then we have:

$$q = \mu/Y^{\max} + m, \quad (17.18)$$

where q is specific rate of energy source consumption, $q = (1/x)(\delta S_E/\delta t)$.

It should be noticed that Y^{max} is a parameter, but not the yield of a real culture that always has some nonzero maintenance requirements. It is a very common mistake in the application of the maintenance concept to a particular organism: to take the real measured Y value and pick up from literature some average m coefficient. The correct way would be either to borrow concurrently two parameters Y^{max} and m or to treat actually observed Y as a variable that is altered along with specific growth rate μ according to Equation 17.17:

$$Y = \frac{\mu Y^{max}}{\mu + mY^{max}} \tag{17.19}$$

There is another way to formulate maintenance requirements by stating that the net growth of cells μ is the difference between true growth (μ_{true}) and endogenous decay of cellular components (specific rate, a):

$$\mu = \mu_{true} - a, \mu_{true} = \mu + a$$

Then, for the rate of energy source uptake, we have

$$\frac{\mu x}{Y} = \frac{\mu_{true} x}{Y^{max}} = \frac{(\mu + a)x}{Y^{max}} \quad \text{or} \quad \frac{1}{Y} = \frac{1}{Y^{max}} + \frac{a}{\mu Y^{max}} \tag{17.20}$$

Comparing Equations 17.17 and 17.20, we see that $a = mY^{max}$.

17.2.5 Experimental Determination of *m*

To practically determine the maintenance coefficient, the microorganisms are grown in chemostat culture limited by energy sources at several dilution rates D (numerically D is equal to specific growth μ if steady state is achieved). At each D, we have to measure steady-state biomass $\tilde{x}$ and residual energy source substrate, $\tilde{s}$ to calculate specific rate of substrate uptake $q_s = (s_0 - \tilde{s})D/\tilde{x}$; q_s measurement may be substituted by any appropriate integral characteristic of catabolic activity, for example, aerobic respiration (O_2 uptake, CO_2 production), anaerobic respiration (release of CH_4, NO_3^-, sulfides, ...), formation of fermentation products, and so on. These data are fitted to Equation 17.17 or 17.18, m and Y^{max} being found as nonlinear regression parameters. An example is presented in Fig. 17.1. Most available experimental data do obey this relationship. However, considerable deviation occurs for slowly growing cells in chemostat running at very low dilution rates or in dialysis culture and chemostat with biomass retention. The experimental Y values for slowly growing cells are higher than predicted by Equations 17.17 and 17.18 (see insets in Fig. 17.1). Thus, maintenance coefficient varies

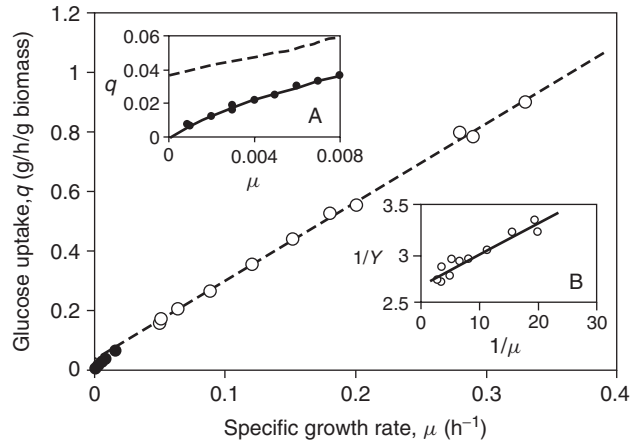

Figure 17.1. Experimental data used to determine maintenance coefficient in continuous culture of microorganisms. Main panel: variation of glucose uptake rate in regular chemostat (open circles) and culture with cell recycle (closed circles) as dependent on specific growth rate. Inset A: data for low growth rates under higher magnification. Inset B: double-reciprocal plot of $1/Y$ versus $1/\mu$ (Eq. 17.17) used for determination of m and Y^{max}. Solid curves were calculated from SCM (2), the dotted curve was calculated from Equation 17.18. Note that it fails at low growth rates (see inset A).

in response to nutritional status and could not be taken as an absolute constant; under substrate deficiency, the cells adjust their maintenance requirements to lower values by reducing turnover rate, osmotic work, and motility (2).

The described experimental technique is indirect because it is based on measurements of μ-dependent Y variation rather than m itself, and there are some assumptions needed to be confirmed (e.g. that m is constant and that maintenance requirements are the only reason of Y variation). However, some components of maintenance requirements are available for direct estimation. In particular, we can assess the total turnover rate of cellular material, a, which is one of the main components of maintenance requirements (Eq. 17.20). The principal cell constituents that are turned over are proteins, nucleic acids, and cell wall polymers. The turnover rate is very close to *endogenous respiration*, which is the oxidation of those compounds produced from the turnover (breakdown) of cellular macrocomponents. Accurate measurements of endogenous respiration need to be made under normal growing conditions. It is known that the simple removal of cells from nutrient broth by filtration with subsequent washing and incubation in buffer renders strong stress and may alter the normal turnover rate (7). To avoid artifacts, we can use a label substitution technique (Fig. 17.2). The chemostat culture is fed alternately from two bottles containing unlabeled and labeled $^{14}C(U)$ substrate respectively. The $^{14}CO_2$ evolution rate is recorded after switching to unlabeled substrate, when the main source of $^{14}CO_2$ are cell components. The calculated a value was

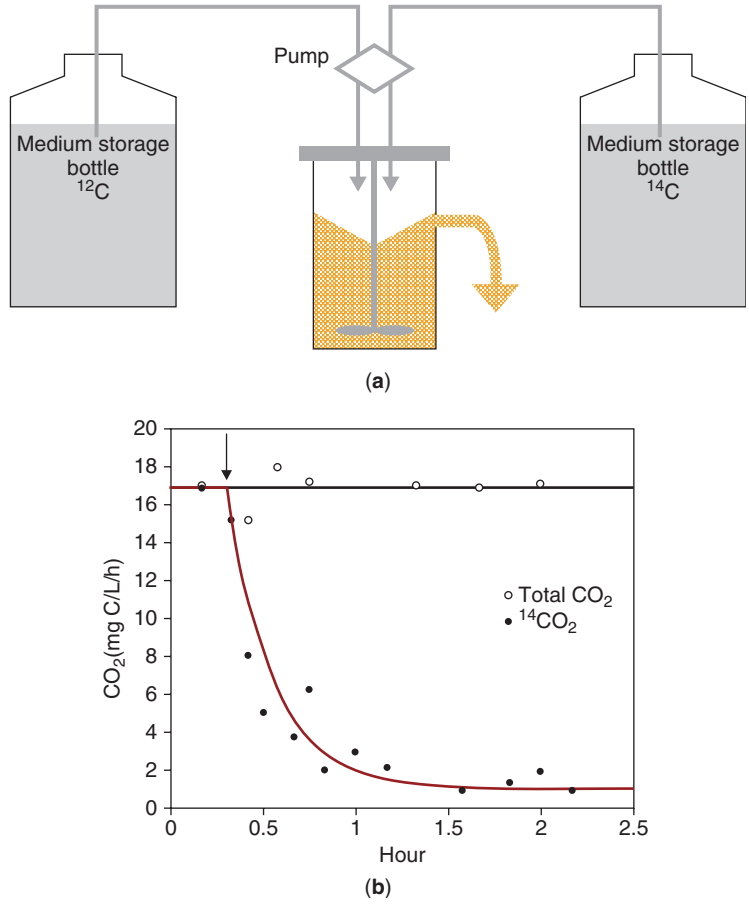

Figure 17.2. Label substitution technique for determination of turnover rate of cellular macromolecules. (a) experimental setup including two medium reservoirs containing ^{14}C- and ^{12}C-glucose pumped into cultivation vessel through two-way valve. (b) example of $^{14}CO_2$ evolution dynamics before and after (arrow) switching of medium feed. Glucose-limited culture of *Pseudomonas fluorescens* 1472, $D = 0.08\ h^{-1}$ (8).

found to be rather high, accounting for the major part of total maintenance determined by the indirect method (2). The endogenous respiration declined at the low growth rate, indicating that under starving conditions, self-adjustment of the maintenance requirement occurs mainly as a reduction in the turnover rate of macromolecules.

Finally, we would like to comment on another method to measure maintenance coefficient which was claimed to be simple and direct (9) but turned out to be too protracted. Principle of this technique agrees well with the formal concept of maintenance: chemostat culture limited by energy source is run with complete cell recycling (Fig. 17.3), growing cells are retained in the vessel and total biomass is expected to increase until a steady-state value, $\tilde{x}$, is reached when maintenance requirements are just met by the limiting substrate addition. Then the maintenance coefficient can be found as $m = D(s_0 - \tilde{s})/\tilde{x}$. However actual behavior of all tested microorganisms in the described recycling system was different (10): instead of approaching steady state, they continued to grow exceeding many times $\tilde{x}$-level, based on prior m-determination in conventional chemostat culture. The only reasonable explanation is that maintenance rate is not constant for particular organism. Chronic starvation triggers expression of stress-response genes, their products have essentially lower maintenance demand. These starvation-adaptive events sometimes are observed as stepwise raises in cell biomass during continuous cultivation reflecting synchronized abrupt decrease in m values from 12 to 5.3, 4.3 and then eventually to 2.5 mg glucose/h/(g biomass) (curve 2, Fig. 17.3). General conclusion is that under chronic starvation (supply of energy source below the maintenance limit) cells may follow one of three routs: (i) to die/lyse, (ii) to enter the state of dormancy, or (iii) to continue slow growth, by reducing maintenance requirements. The fourth route—the maintenance of viability of vegetative cells without their growth—is forbidden.

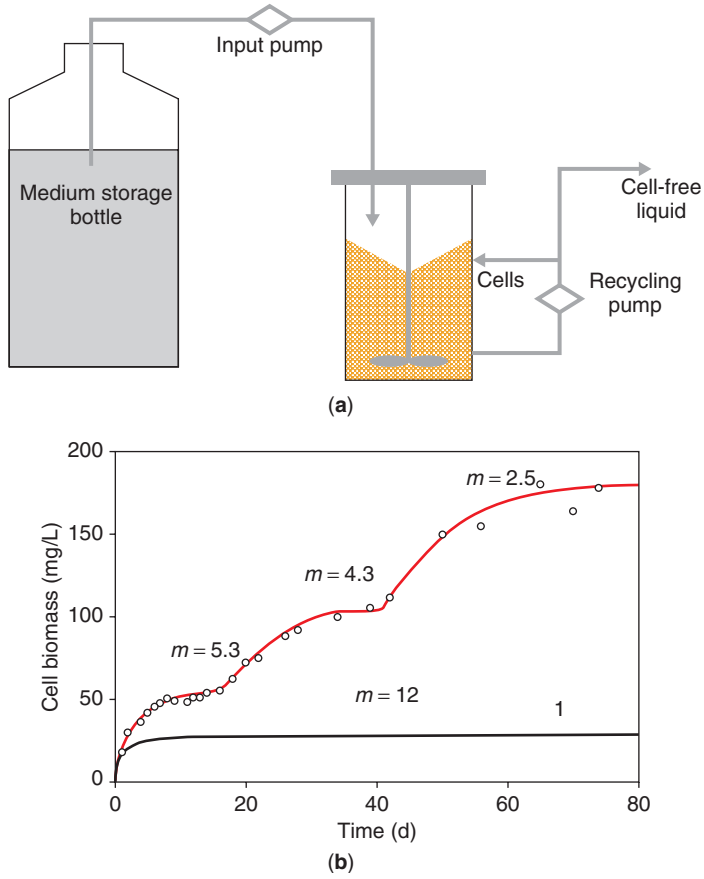

Figure 17.3. Growth dynamics of microorganisms in continuous culture with complete biomass recycling. (a) Experimental design (6,9). (b) The calculated biomass dynamics assuming maintenance requirement ($m = 0.012$ g/h/g DW) as found preliminary in regular chemostat (curve 1) and the actual biomass of yeasts *Debaryomyces vanrijiae* (curve 2) displaying spontaneous stepwise decrease in m from 5.3 to 2.5 mg/h/(g DW) (2).

17.2.6 Maintenance Requirements and Wasteful Catabolism

The described concept of maintenance requirements was the subject of intensive debates (11). One of the strongest arguments against it was an apparent increase in $Y^{\max}$ observed in chemostat cultures limited by P, N, and other conserved substrates under conditions of energy excess. To preserve the constancy of the "true" yield, Pirt (12) had to modify Equation 17.18 in the following way:

$$q = \frac{\mu}{Y^{\max}} + m + m'\left[1 - \frac{\mu}{\mu_m}\right] \qquad (17.21)$$

where $m'(1 - \mu/\mu_m)$ is the second μ-dependent component of maintenance energy that operates under excess of energy substrate.

However, it is better to differentiate maintenance requirements *sensu stricto* as a minor component of the cell energy budget that is observed under energy-limitation and wasteful use of catabolic substrate under energy excess. In physiological terms, these two groups of nonproductive catabolic reactions are completely different. The first reactions are mainly responsible for compensation of turned-over macromolecules and therefore belong to the category of regular primary catabolism. The catabolic reactions of the second group include excretion into environment of partly oxidized substances (*overflow metabolism*), uncoupling of respiration from ATP generation by metabolic inhibitors, functioning of futile cycles, or substrate oxidation through alternative oxidases without ATP generation. These and related phenomena take place in chemostat culture limited by conserved substrates (opposite to limitation by energy source) as well as during lag phase of batch culture started from starving inoculum. We will discuss the mathematical formulation of these phenomena in the section devoted to growth kinetics.

17.2.7 Variation in Biomass Yield from Conserved Substrates

Yield on conserved substrates varies mainly as a result of alterations in biomass chemical composition expressed by parameter σ_s, the intracellular content of deficient element or cell quota (Eq. 17.9). For most of known cases, the content σ_s increases parallel to growth acceleration (Fig. 17.4). As yield and cell quota are inversely related to each other (Eq. 17.9), then Y values decrease with growth rate. The physiological mechanisms of this variation are as follows. The intensive growth requires higher *internal concentration* of some conserved limiting substrates that preserve their chemical identity after uptake (K^+, Mg^{2+}, vitamins). Other conserved substrates (sources of P, N, S, etc.) are incorporated into macromolecular cell constituents (mainly nucleic acids and proteins) whose *intracellular content* also should be kept high at high growth rate. Both types of changes in cellular composition are manifested as σ increase, and both of them require additional maintenance energy (to maintain concentration gradient or compensate turnover of macromolecules). The observed μ-dependent variation in σ is therefore a compromise between biosynthetic requirements and energy conservation that is attained because of optimal metabolic control of cell performance. However, it would be erroneous to consider μ as truly independent variable setting up chemical composition of cells. In fact, both μ and σ are functions of one common independent variable, the limiting substrate concentration in the medium, s. For steady-state chemostat culture we have:

$$\mu = \frac{q}{\sigma} = \frac{1}{\sigma}\frac{Q\tilde{s}}{K_s + \tilde{s}}, \sigma = \sigma_0 + \frac{(\sigma_m - \sigma_0)\tilde{s}}{K_\sigma + \tilde{s}} \qquad (17.22)$$

where μ is specific growth rate and q is specific substrate uptake rates, σ_0 and σ_m are respectively lower and upper limits of σ variation, low limit $\sigma \to \sigma_0$ is attained when $\tilde{s} \to 0$ and upper limits $\sigma \to \sigma_m$ when $\tilde{s} \to \infty$. By excluding $\tilde{s}$ from both these equations, we arrive at following relationship between σ and μ:

$$\mu = \mu_m \frac{\sigma_m(\sigma - \sigma_0)}{\sigma[\lambda(\sigma_m - \sigma_0) + \sigma - \sigma_0]}, \quad \lambda = \frac{K_s}{K_\sigma} \qquad (17.23)$$

Under realistic assumption $\lambda \approx 1$ ($K_s \approx K_\sigma$) we have:

$$\sigma = \frac{\sigma_0}{1 - (1 - \sigma_0/\sigma_m)\mu/\mu_m}, \quad Y = Y_m - (Y_m - Y_0)\frac{\mu}{\mu_m}, \qquad (17.24)$$

where Y_m and Y_0 are respectively upper and lower limits of yield variation ($Y_m = 1/\sigma_0$, $Y_0 = 1/\sigma_m$). As we can see, the linear relationship between Y and μ is normally observed in chemostat culture (Fig. 17.4).

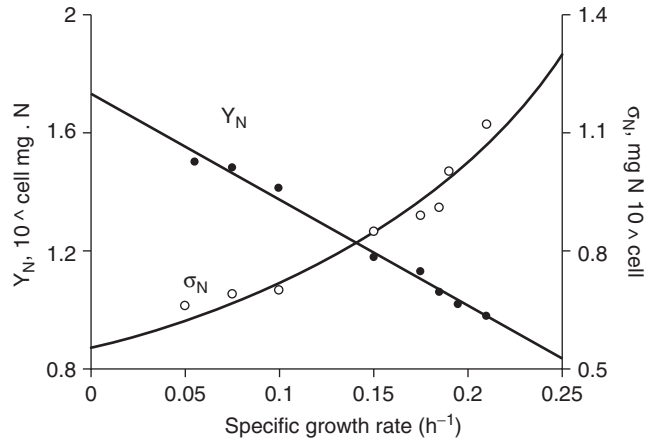

Figure 17.4. Relationship between stoichiometric parameters Y and σ and specific growth rates of *Chlorella vulgaris* grown in chemostat culture limited by nitrogen source. The curves are calculated using Equations 17.23 and 17.24 (13).

17.2.8 Microscopic Approach in Studies of Growth Stoichiometry

Equations 17.1–17.24 exemplify the *macroscopic approach* in studying of microbial growth stoichiometry. Its typical features are the use of gross formulas for biomass and metabolic products, evaluation of total mass balance for chemical elements (C, N, P), and formal description of microbial growth as a single-step conversion of substrate(s) into biomass. By contrast, the *microscopic approach* focuses on the much more complex real metabolic reactions and attempts to account for a limited but still quite large number of individual metabolic intermediates. The final aim of this approach is to organize the biochemical information into a consistent picture of microbial metabolism at the level of entire cell.

The microscopic approach has become possible by virtue of advancements in biochemistry, which has succeeded in establishing a sufficiently full picture of metabolic processes in certain microorganisms. The pioneering work, in this area, was done by Bauchop and Elsden (14), who were able to sum up the balance of ATP for fermenting microorganisms. As a result, a relation was established between the biomass yield (a macroscopic quantity) and the number of generated ATP moles (a stoichiometric characteristic of real catabolic reactions):

$$Y_{\mathrm{ATP}} = MY_{x/s}/n \qquad (17.25)$$

where n = moles of ATP made available to the organism by the metabolism of 1 mol of energy source; M = molecular weight (gram) of energy source. The following example illustrates the Y_{ATP} calculation: if biomass yield of some organisms aerobically grown on glucose is 0.52 g CDW/g, then $Y_{x/s}$ is 1.49 g CDW/g of oxidized

glucose (calculated from Eq. 17.6) or $Y_{x/s} = 1.49 \times 180 = 268$ g CDW/mol (180 is glucose molecular weight); assuming that P/O = 2 (i.e. 2 mol of ATP produced/atom oxygen taken up) and that two ATP moles are produced via glycolysis (substrate phosphorylation) we arrived at $n = 2 + 12 \times 2 = 26$ and $Y_{ATP} = 268/26 = 10.3$ g CDW/mol ATP. Careful determination of n and Y_{ATP} is possible only for anaerobic growth of fermenting microorganisms generating ATP via substrate phosphorylation. The mean value tends to be around 10.5 g CDW/mol ATP (Fig. 17.5). For aerobic growth, we need to make assumptions on the P/O ratio. As soon as the respiratory chain of bacteria differ widely for various organisms and growth conditions, this assumption can never be reliable. To avoid this obstacle, an interesting approach was proposed: microbial culture is grown in a chemostat limited by two carbon-containing energy sources, their ratio is varied while the total carbon feed rate is kept constant; yield measurements should allow one to determine both parameters (P/O and Y_{ATP}) by linear regression (1).

Today, microstoichiometry is quickly progressing as so-called metabolic balancing. Cell growth is viewed as a set of transport and intracellular metabolic reactions known for some particular organisms. As a rule, the produced metabolic networks are composed of a combination of true stoichiometric equations for individual metabolites and empirical gross equations (Table 17.2). The amount of such equations vary in different models from 20 to 30 to more than 100. For example, van Gulik and Heijnen (16) describe yeast growth by a set of more than 90 reactions including glycolysis and the citric acid cycle (14 reactions); phosphoenolpyruvate (PEP) phosphotransferase; pentose phosphate pathway (6 reactions); glyoxylate shunt (2 reactions); oxidative phosphorylation (4 reactions); CO_2 interaction with tetrahydrofolate (THF) (3 reactions); transport of inorganic P, NH_4^+, SO_4^{2-}, acetate, lactate, pyruvate, glucose, gluconate, succinate and citrate (totally 10 transport reactions); amino acid synthesis (15 reactions) and polymerization (2 reactions); nucleotide synthesis (9 reactions); RNA synthesis; ATP consumption for maintenance; fatty acids synthesis (2 reactions); formation of glycogen and polysaccharides; and finally, the biomass formation from proteins, polysaccharides, RNA, fatty acids, and glycerol.

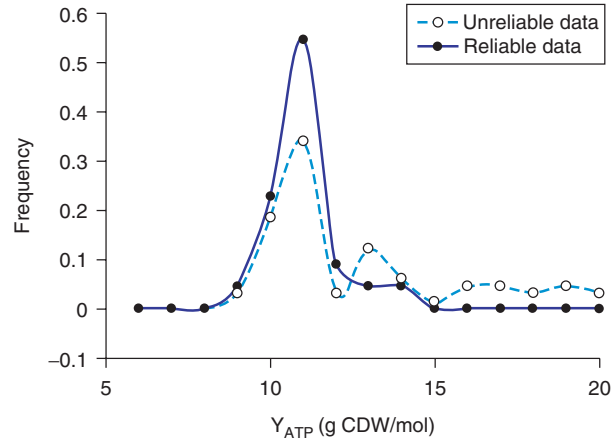

Figure 17.5. Frequency distribution of experimentally measured values of Y_{ATP} at different degree of creditability. The reliable data refer to studies of anaerobic growth with direct measurements of fermentation products (plotted from database in Ref. 15. Note that these data are normally distributed with mean value 10.55, whereas all data display considerable skewness.

For each compound, i, involved in a metabolic system, a mass balance can be defined:

$$\frac{dC_i}{dt} = r_{Ai} + \Phi_i \tag{17.26}$$

where C_i is concentration of ith compound, r_{Ai} and Φ_i denote the net rates of, respectively, i chemical conversion and transport over the boundaries of bioreactor (fluxes of CO_2, O_2, nutrients, cells and products). Most metabolic balancing equations are applied to steady-state growth (which means that no intracellular accumulation of metabolites occurs). In such cases, the differential equations like Equation 17.26 are reduced to linear algebraic ones. Besides, an extensive use of matrix calculus is customarily made to obtain a concise notation. The problem of experimental support of such model is especially important (16). The degree of freedom, df, of

TABLE 17.2. Examples of True Stoichiometric (1–4) and Empirical Gross Equations (17.5) to Represent Cellular Processes

Reaction	Equation	
Glycolysis reaction	Glucose + ATP → Glucose-6-P + ADP + H	(17.1)
	Glucose-6-P → Fructose-6-P	(17.2)
	0.5 Fructose-6-P + 0.5 ATP → Glyceraldehyde-3-P + 0.5 ADP + 0.5 H	(17.3)
Oxidative phosphorylation	NADH + 0.5 O_2 + d_1ADP + d_2Pi + $(1 + d_1)$H → $(1 + d_1)H_2O$ + NAD + d_1ATP	(17.4)
Biomass formation	a_1 Proteins + a_2 Polysaccharides + a_3 RNA + a_4 Lipids → Biomass	(17.5)

the resulting system of linear equations is equal to the total number of unknown rates (both intracellular and exchange reactions) minus the total number of linear equations. To resolve the system, df rates have to be measured, and then the system is fully *determined*. If the number of measured rates is greater than df, then the system is *overdetermined*, and the redundancy of the data can be used for statistical analysis and error minimization. However, it is much more typical to have an *underdetermined* system when the sum of measured rates is less than df. In this case, the number of possible solutions is infinite unless additional constraints are applied (e.g. maximization of biomass yield, minimization of energy expenditure) to find the one and only one solution by the linear optimization technique.

In most studies, flux estimates are obtained using measurements of substrate consumption and product formation. This approach has proved to be efficient in some particular biotechnological cases, such as when only specific pathways need to be considered (17) or if the contribution of flux for cellular growth is weak, as with mammalian or hybridoma cells (18). The more complex microbial systems are turned out to be seriously underdetermined. In such cases, the application of metabolic balancing requires the use of one or another maneuvers: (i) to lump together several sets of reactions (19); (ii) to utilize data from *in vitro* enzyme assays; (iii) to make assumptions on numeric values of some stoichiometric growth parameters, such as Y_{ATP}, P/O, and H^+/e ratios, which are the subject of controversial debates (16).

However, the best solution would be to get direct experimental data on *in vivo* flux and resolve the system. Isotopic tracers are one of the best candidates for such a purpose. We will illustrate this point by one of the early published work (20). *Corynebacterium glutamicum* was grown in chemostat culture continuously fed with [1 $-^{13}$C]-glucose; when steady state was established, the cells were harvested and hydrolyzed and the amino acids were separated by ion-exchange chromatography and analyzed by NMR spectroscopy. NMR provides data on ^{13}C enrichment at each specified carbon position of amino acid. Because metabolic pathways for amino acid synthesis are exactly defined, then the entire central metabolism can be assessed for *in vivo* fluxes, including determination of the forward and back rates of bidirectional reactions. In *C. glutamicum*, the flux through the pentose phosphate pathway turned out to be 66.4% (relative to glucose input flux 1.49 mmol g CDW h); the entry into tricarboxylic acid cycle, 62.2%, and the contribution of the succinylase pathway to lysine synthesis, 13.7%. The total net flux of the anaplerotic reactions (carboxylation of PEP/pyruvate into oxaloacetate/malate) was quantitated as 38%, the true forward flux of C3 $\rightarrow$ C4 being 68.6% (1.8 times of 38%) and a back flux of C4 $\rightarrow$ C3 being 30.6% (0.8 times of 38%).

The metabolic balancing proved to be very promising and useful to identify metabolic constraints for intensive synthesis (overproduction) of products such as amino acids. Last decade flux balancing was efficiently applied to development, testing and optimizing of recombinant strains (21–25). Majority of industrially significant microorganisms are fully sequenced; their gene expression patterns and proteomic data give valuable data on potential size of stoichiometric matrix describing intracellular metabolic reactions. The actual intracellular fluxes depend critically on intracellular concentrations of metabolic intermediates, primarily cofactors such as NAD/NADH (26,27). So far, this approach is restricted to steady-state analysis which is not sufficient to predict microbial performance under real-life transient conditions (28). However, progress in this research direction is amazingly fast and novel computational algorithms are able to deal with nonstationary metabolic fluxes (29).

17.3 KINETICS OF CHEMICAL AND ENZYME REACTIONS

We need to introduce some basic principles of kinetic analysis of chemical and enzymatic reactions. Quantitative description and understanding of microbial growth dynamics and kinetics are impossible without some elementary knowledge in underlying scientific disciplines. Enzymatic and chemical reactions play an essential role in biotechnology, which is one of the most important fields in industrial development.

17.3.1 Order and Molecularity of Chemical Reactions

The molecularity of any chemical reaction is defined by the number of molecules that are altered in the reaction (Table 17.3). The order is a description of the number of concentration terms multiplied together in the rate equation (Table 17.4). Hence, in a first-order reaction, the rate is proportional to one concentration of reactant; in a second-order reaction, it is proportional to two concentrations or to the square of one concentration. For a simple single-step reaction, the order is generally the same as the molecularity. For a complex reaction involving

TABLE 17.3. Molecularity of Chemical Reaction

Molecularity of reaction	Reactants		Product
Unimolecular or monomolecular	S	$\rightarrow$	P
Bimolecular	S + S	$\rightarrow$	P
Or	$S_1 + S_2$	$\rightarrow$	P
Trimolecular or termolecular	S + S + S	$\rightarrow$	P
Or	$S_1 + S_1 + S_2$	$\rightarrow$	P
Or	$S_1 + S_2 + S_3$	$\rightarrow$	P

TABLE 17.4. Kinetic Order of Chemical Reactions

Reaction Order	Differential Equation	Dimension of Rate Constant	Dynamics of Residual Reactant	Dynamics of Product Accumulation
Zero	$\frac{ds}{dt} = -k$	(concentration)(time)$^{-1}$	$s(t) = s_0 - kt$	$p(t) = p_0 + kt$
First	$\frac{ds}{dt} = -ks$	(time)$^{-1}$	$s(t) = s_0 \exp(-kt)$	$p(t) = s_0[1 - \exp(-kt)]$
Second	$\frac{ds}{dt} = -ks^2$	(concentration)$^{-1}$(time)$^{-1}$	$s(t) = \frac{s_0}{1 + ks_0t}$	$p(t) = \frac{s_0^2kt}{2(1 + s_0kt)}$
Second	$\frac{dp}{dt} = -ks_1s_2$	(concentration)$^{-1}$(time)$^{-1}$	$s_1(t) = s_{01} - p(t)\ s_2(t) = s_{02} - p(t)$	$p(t) = \frac{s_{01}s_{02}(1 - \exp[(s_{02} - s_{01})kt])}{s_{01} - s_{02}\exp[(s_{02} - s_{01})kt]}$
Pseudofirst $s_{01} \gg s_{02}$	$\frac{dp}{dt} = -ks_1s_2$	(concentration)$^{-1}$(time)$^{-1}$	$s_2(t) = s_{02}\exp(-ks_{01}t)\ s_1(t) \approx s_{01}$	$p = s_{02}[1 - \exp(-ks_{01}t)]$

[a] t, time; s, reactant concentration; p, product concentration; s_0, reactant concentration at $t = 0$.

a sequence of unimolecular and bimolecular steps, the molecularity is not the same as its order. Reactions of molecularity greater than 2 are common, but reactions of order greater than 2 are very rare. For instance, a trimolecular reaction, such as $A + B + C \rightarrow P$, as a rule proceeds through two elementary steps, $A + B \rightarrow X$ and $X + C \rightarrow P$, each of which are of the second or first order. Very often, bimolecular reactions between S_1 and S_2 occurs under the condition that their respective concentrations $s_2 \gg s_1$ (e.g. if the second reactant S_2 is solvent), then we have a *pseudo first-order* reaction. Some reactions are observed to be of the zero order, that is, the rate appears to be constant, independent of the concentration of reactant. This is a characteristic feature of catalyzed reactions and occurs if reactant is present in such large excess that the full potential of catalyst is realized.

17.3.2 Dimensions of Rate Constants

Knowledge of dimensions is very useful to check the correctness of derived kinetic equations: the left- and right-hand sides of equations must always have the same dimensions. This general rule is applicable to all mathematical models (not only in chemical kinetics). It is incorrect to add or subtract terms of different dimensions, although you may multiply or divide them. For example, if expression "$\ldots(1 + s)$" occurs in an equation, where s has dimension (concentration), then either it is incorrect, or the 1 is a concentration that happens to have a numerical value of 1 unit. The operation rising to power is allowed for only simple dimensionless numbers, for example, expression $e^{2.5t}$, where t is time, is correct only if 2.5 has dimension (time)$^{-1}$. The comparison of velocities of two reactions does make any sense only for kinetic terms of the same dimension. If the kinetic order of inspected reactions is different, then we have to equalize the respective rate of expressions; for example, the second-order rate constant k (time)$^{-1}$ (concentration)$^{-1}$ should be multiplied by instant concentration of reactant s to be compared with the first-order rate constant having dimension (time)$^{-1}$. The dimensions of the zero-, first-, and second-order rate constants are shown in Table 17.4.

17.3.3 Reaction Dynamics

If rate constant and so-called initial conditions [concentrations of reactants at zero-time $(s_{01}, s_{02}, \ldots)$], are known, then it is possible to calculate the time course of reactions either in terms of dynamics of residual reactant concentration, $s(t)$ or product accumulation, $p(t)$. For this purpose, we have to integrate a differential equation under specified initial conditions (see results of integration in Table 17.4). The dynamics of $s(t)$ is linear in the case of a zero-order reaction, exponential in the case of the first order and hyperbolic in the case of the second-order reaction. The difference between the last two dynamic curves can be made visible with a semilogarithmic plot of log (concentration) versus time; it should become linear for the first-order reaction and remain to be curvilinear for the reaction of higher order.

17.3.4 Reaction Half-Time

The reaction half-time ($\mathbf{t_{0.5}}$) is a very popular kinetic parameter. It is easily calculated from integral equations by putting $s = s_0/2$ when $t = t_{0.5}$. A unique feature of the first-order reaction is the constancy of $t_{0.5}$ independently of the initial reactant concentration s_0. However, the half-time of other reactions does depend on s_0; it increases for zero-order reactions and decreases for the second-order reactions with increase in s_0. Thus, it is not recommended to use half-time as a parameter or estimator for reactions other than first-order reactions.

17.3.5 Determination of the Order of Reaction and Numeric Values of Kinetic Constants

If the reaction has an order n and rate constant k, then the reaction rate v and reactant concentration s are related by the equation:

$$v = -\frac{ds}{dt} = \frac{dp}{dt} = ks^n \tag{17.27}$$

The simplest way to find both unknown values (n and k) would be to measure reaction rate v at several concentrations of reactant. Then a plot of log(rate) against log(concentration) gives a straight line with a slope equal to n and intercept equal to $\log(k)$: $\log v = \log k + n \log s$. If there are several reactants, then it is useful to know the order in respect to each one. For this purpose, you need to have several experiments with variation of each reactant concentration while keeping the other concentrations constant.

The most frequent goal is the determination of the first-order rate constants. There are some special methods to determine the values of the first-order rate constants from the experimental curves of product formation or substrate depletion dynamics. Some of them were designed to improve the accuracy of k determination if s_0 is unknown (methods of Guggenheim, Kezdy–Swinbourne, and other, see details in Ref. 30). Today these methods are replaced by computer-aided nonlinear regression (e.g. "Solver" in MS Excel). Apart from being more convenient than graphic methods, the nonlinear regression has higher precision and generates useful statistics (e.g. confidence limits for k and s_0 based on scatter degree of experimental data and selected P-level).

17.3.6 Derivation of Basic Kinetic Equations for Enzymatic Reactions

Contrary to simple chemical reactions, enzyme-catalyzed reactions proceed through *reversible* formation of the dynamic *enzyme-substrate complex* (ESC). The word *reversible* is essential because the ESC can be decomposed into free enzyme E and product P or dissociate back to E and substrate S. There are many ways to simulate mathematically the mechanism of the enzymatic reaction. We will consider here equilibrium, steady-state, and general non-steady-state approaches.

17.3.7 Equilibrium Approach

This approach was used by Michaelis and Menten (31) to describe the effect of sucrose concentration on invertase activity. They assumed that the first step of ESC formation is so rapid that could be represented by an *equilibrium constant* K_s:

$$\overset{e}{\mathrm{E}} + \overset{s}{\mathrm{S}} \overset{K_s}{\longleftrightarrow} \overset{x}{\mathrm{ES}} \overset{k_2}{\longrightarrow} \mathrm{E} + \overset{p}{\mathrm{P}}, \tag{17.28}$$

where e, s, x, and p denote the concentrations of free enzyme, substrate, ESC, and product, respectively. The equilibrium constant, K_s, is defined as $K_s = es/x$. The instantaneous concentrations s and e are not directly measurable, but they could be expressed in terms of the initial, measured concentrations e_0 and s_0, using mass–balance relationships:

$$e_0 = e + x \qquad s_0 = s + x, \qquad x \ll s,\ s \approx s_0 \tag{17.29}$$

The overall reaction rate, v is a simple first-order reaction with rate constant k_2:

$$v = dp/dt = -ds/dt = k_2 x \tag{17.30}$$

The x value can be found from expression for K_s and mass–balance conditions (Eq. 17.29): $x = e_0 s/(K_s + s)$. Substitution of this expression into Equation 17.30 finally produces

$$v = \frac{k_2 e_0 s}{K_s + s} \tag{17.31}$$

17.3.8 Steady-State Approximation

This approach was applied by Briggs and Haldane (32) for the following scheme of enzymatic reaction

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{ES} \xrightarrow{k_2} \mathrm{E} + \mathrm{P} \tag{17.32}$$

This scheme implies the reversibility of ESC formation instead of much more restrictive equilibrium postulate. However, still there was steady-state assumption in respect to ESC formation:

$$dx/dt = k_{+1}(e_0 - x)s - k_{-1}x - k_{+2}x \approx 0 \tag{17.33}$$

Therefore, $x = k_{+1}e_0 s/(k_{+1}s + k_{-1} + k_{+2})$, and substitution of this expression into Equation 17.30 gives:

$$v = -\frac{ds}{dt} = k_{+2}x = \frac{k_{+1}k_{+2}e_0 s}{k_{+1}s + k_{-1} + k_{+2}} = \frac{k_{+2}e_0 s}{\frac{k_{-1}+k_{+2}}{k_{+1}} + s} = \frac{V_s}{K_m + s} \tag{17.34}$$

Equation 17.34 is what usually called the *Michaelis–Menten equation*, the fundamental equation of enzymatic

kinetics. It contains two parameters, K_m, the *Michaelis constant*, and V, the *maximum velocity*. V is the rate of reaction that would occur under full substrate saturation of an enzyme's active sites ($s \gg K_m$). In reality, the V value can be never attained, because extremely high substrate concentrations inhibit enzymes (see later text). It is clear also that V is not a fundamental property of enzyme because it depends upon e_0, the enzyme concentration. More advantageous as a specific enzyme characteristic is the *catalytic constant* or *turnover number'* k_{cat} which is V/e_0. For reaction scheme 32, k_c is identical with k_{+2}, but in general the more noncommittal notation k_{cat} is preferable (e.g. k_{cat} may differ from k_{+2} if the product formation from ESC is a reversible reaction). Numerically, the Michaelis constant, K_m is the substrate concentration that provides half the maximal reaction rate. Contrary to this simple practical definition, the mechanistic interpretation of K_m is not so lucid. Sometimes, K_m is interpreted as a substrate binding constant, K_s, assuming that $k_{+2} \ll k_{-1}$. This is a very dubious assumption. There are very few enzymes for which the individual values of k_{+2} and k_{-1} are known. Ironically, the best-studied examples (e.g. horseradish peroxidase) present just opposite case: $k_{+2} \gg k_{-1}$. It is important that many specific mechanisms (not necessarily Eqs 17.28 and 17.32) generate the same steady-state rate Equation 17.32–17.33. However, the particular expression for K_m should be different for each individual case.

Although undefined in mechanistic terms, the parameters K_m and V are very useful at the first steps of kinetic studies:

1. The use of Equation 17.34 allows the expression of the complex effects with simpler terms.
2. K_m and V are helpful as predictive parameters to design a valid enzyme assay. One practical recommendation is to keep substrate concentration in incubation mixture at the level of 10 K_m or higher.
3. Equation 17.34 permits one to obtain at least rough estimate of *in vivo* enzyme activity provided the internal substrate concentrations are known.

17.3.9 General Non-Steady-State Approach

Reaction scheme 17.32 contains four variables (*s, p, e*, and x) constrained by two mass–balance equations ($e_0 = e + x$, and $s_0 = s + p + x$). Therefore it is enough to integrate just two differential equations (e.g. Eqs 17.33 and 17.34) to characterize the whole system. A typical example of a numeric solution is shown in Fig. 17.6. We can see that enzyme-catalyzed reaction proceeds through three definite phases well separated on the time scale. Each phase is now safe to analyze with simpler mathematical expressions because any assumptions could be tested against the full exact solution.

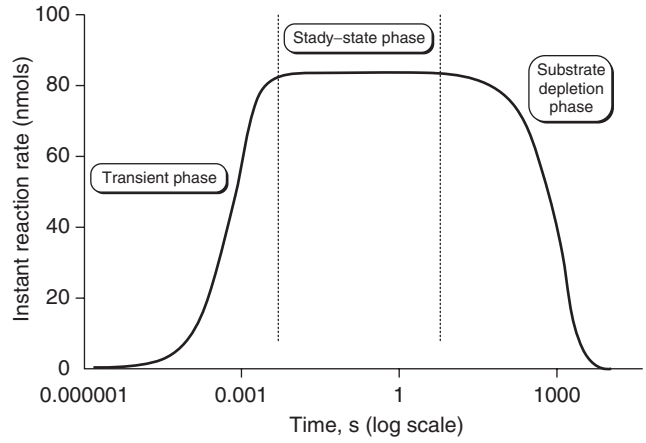

Figure 17.6. Time course of reaction proceeding by the Michaelis–Menten mechanism. Numeric integration of Equations 17.33–17.34: $s_0 = 10^{-4}$ M, $e_0 = 10^{-8}$ M, $k_{+1} = 10^6$ M/s, $k_{-1} = 10^3$ s^{-1}, $k_{+2} = 10^2$ s^{-1}.

1. The first *transient phase* occurs before the steady-state concentration of ESC is reached. It occupies less than 10^{-3} s for most of enzymes. During this phase, the substrate concentration remains fairly constant ($s \approx s_0$) allowing for the following analytical solution:

$$x(t) = \frac{k_{+1}e_0s_0}{A}[1 - e^{-At}],$$
$$v(t) = \frac{Vs}{K_m + s}[1 - e^{-At}],$$
$$A = k_{+1}s_0 + k_{-1} + k_{+2} \qquad (17.35)$$

   As compared with Equation 17.34 it contains a relaxation term $[1 - \exp(-At)]$ that is zero when t is small, but tends to 1 as t increases above $\tau = 1/A$. Accordingly, the rate of enzymatic reaction is initially zero but increases rapidly to the steady-state value as the exponential term decays. Because the relaxation term contains s_0, then the experimentally observed delay depends on substrate concentration. It allows for direct determination of individual rate constants k_{+1} and $(k_{-1} + k_{+2})$ by techniques such as in stopped-flow (33).
2. The second *steady-state phase* is characterized by the constancy of reaction rate due to the exact balance between the rates of ESC formation and breakdown ($dx/dt = 0$) while the substrate concentration remains close to the initial value s_0. This phase proceeds for at least several seconds. As a rule, it is enough to measure the *initial velocity* of enzymatic reactions unaffected by substrate depletion or product accumulation. Steady-state kinetics is the most popular research domain; it is the most accessible and developed and provides the

most kinetic data. However, it fails to determine individual rate constants as fully as the transient and relaxation approaches do. Steady-state equations were derived earlier (Eq. 17.34).

3. The third phase is characterized by considerable changes in the concentrations of substrate and product. Thus, we can no longer assume that $s = s_0$ and should integrate the complete set of Equations 17.32,17.33. However, very good precision provides the quasi–steady state approximation $ds/dt \gg dx/dt \approx 0$. Then we arrive at a relatively simple differential equation that is solved analytically:

$$\frac{ds}{dt} = -\frac{Vs(t)}{K_m + s(t)} \tag{17.36}$$

For initial conditions $s = s_0$, $p = 0$, $t = 0$, we have

$$K_m \ln \frac{s_0}{s} + s_0 - s = Vt \tag{17.37}$$

Equation 17.37 is called the *integrated Michaelis–Menten equation*. It remains to be valid not only for initial rate measurements but for any point within the reaction progress curve.

17.3.10 Experimental Determination of Kinetic Parameters of the Michaelis–Menten Equation

Until recently, most enzyme kinetic experiments have been analyzed by means of one of linear plots (Table 17.5). Linear plots are used to examine an agreement of experimental data with Equation 17.34 as well as to determine numeric values of parameters K_m and V from slopes and intercepts. Today, this graphic approach seems to be too cumbersome as compared with much more efficient computer routines. The main objection is also that any linear transformation introduces some statistical bias (ironically, the highest bias is attributed to the most popular double-reciprocal plot!). In addition, manual line drawing is very arbitrary, so obtained parameters could not be assessed statistically for confidence limits. However, plotting of original or linearized data is useful as an illustration and the first sketchy estimate of enzymatic parameters. For definitive work, it is advisable to avoid all plots and to use a nonlinear regression with following assessment of confidence limit for determined parameters (2).

17.3.11 Reversible Enzymatic Reactions

The majority of biochemical reactions are reversible. To account for this feature, the Michaelis–Menten mechanism

TABLE 17.5. Linear Plots (after Ref. 30)

$\frac{1}{v} = \frac{1}{V} + \frac{K_m}{V}\frac{1}{s}$	Lineweaver–Burk or double-reciprocal plot
$\frac{s}{v} = \frac{K_m}{V} + \frac{s}{V}$	Langmuir–Hanes plot
$v = V - K_m\frac{v}{s}$	Eadie–Hofstee plot
$V = v + \frac{v}{s}K_m$	Direct linear plot

can be modified as follows:

$$\underset{e_0-x-y}{E} + \underset{s}{S} \underset{k_{-1}}{\overset{k_{+1}}{\rightleftarrows}} \underset{x}{ES} \underset{k_{-2}}{\overset{k_{+2}}{\rightleftarrows}} \underset{y}{EP} \underset{k_{-3}}{\overset{k_{+3}}{\rightleftarrows}} \underset{e_0-x-y}{E} + \underset{p}{P} \tag{17.38}$$

Contrary to the basic scheme 17.32, there are two intermediates, one of which is the normal ESC and another is the *enzyme-product complex* (EP). The substrate, S and product, P can interconvert to each other. Application of the steady-state approach to this scheme results in the following equation:

$$\begin{aligned} v &= \frac{V^f s/K_m^s - V^r p/K_m^p}{1 + s/K_m^s + p/K_m^p} \\ V^f &= \frac{k_{+2}k_{+3}e_0}{k_{-2} + k_{+2} + k_{+3}}, \\ K_m^s &= \frac{k_{-1}k_{-2} + k_{-1}k_{+3} + k_{+2}k_{+3}}{k_{+1}(k_{-2} + k_{+2} + k_{+3})}, \\ V^r &= \frac{k_{-1}k_{-2}e_0}{k_{-1} + k_{-2} + k_{+2}}, \\ K_m^p &= \frac{k_{-1}k_{-2} + k_{-1}k_{+3} + k_{+2}k_{+3}}{k_{-3}(k_{-1} + k_{-2} + k_{+2})} \end{aligned} \tag{17.39}$$

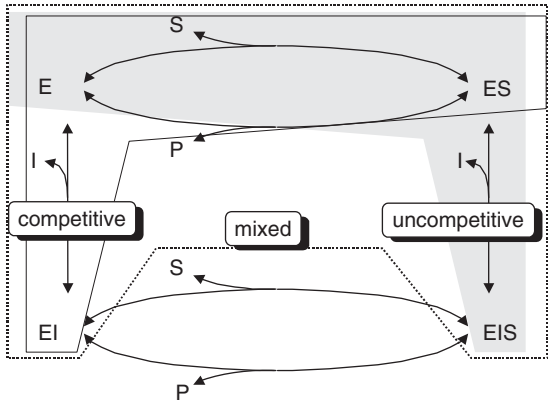
where superscripts f and s denotes parameters of forward reaction, while r and p are indicators of reverse reaction.

When a reaction is at equilibrium, the net velocity must be zero and, consequently, if s_∞ and p_∞ are the equilibrium values of s and p, it follows from Equation 17.39 that equilibrium constant K is expressed via kinetic parameters (the *Haldane relationship*):

$$K = p_\infty/s_\infty = V^f {K_m}^p / V^r {K_m}^s \tag{17.40}$$

Equation 17.39 implies that the rate must decrease as the product accumulates, even if the decrease in substrate concentration is negligible. Thus, reversibility is closely associated with and requires the *product inhibition*. In many essentially irreversible reactions (e.g. invertase-catalyzed hydrolysis of sucrose) product inhibition is also significant. It can be explained by scheme 17.38 with only the second step being irreversible. In such a case, the accumulation of product causes the enzyme to be sequestered because of the

EP complex and reaction rate are as follows (compare with Equation 17.39):



$$v = \frac{V^f s/K_m^s}{1 + s/K_m^s + pK_m^p} = \frac{V^f s}{K_m^s(1 + pK_m^p) + s} \qquad (17.41)$$

17.3.12 Inhibitors and Activators

Compounds that reduce the rate of enzyme-catalyzed reactions when they are added to the reaction mixture are called *inhibitors*. Just opposite effects (increase of reaction rate) are caused by *activators*. Both of them belong to the category of *modifiers*. We will concentrate here on inhibitors as having more practical application and even more specifically on *reversible* inhibitors, which form various dynamic complexes with enzymes. The *irreversible* inhibitors are known as *catalytic poisons* (many heavy metals, such as mercury); their binding to enzyme molecules reduces activity to zero, leaving no room for quantitative analysis.

The reversible inhibitors can form complexes with free enzymes or enzyme–substrate complexes as shown in the scheme of Botts and Morales (30)

There are three major simple (or linear) inhibition mechanisms, which can be generated from this scheme by omitting some of the six involved:

1. *Competitive* inhibition if *EIS* is missing (inhibitor binds to the same site on the enzyme as the substrate forming abortive nonproductive complex *EI*).
2. *Uncompetitive* if *EI* is missing and *EIS* occurs as a dead-end complex; it implies that the inhibitor-binding site becomes available only after the substrate has bound.
3. *Mixed* if *EI* and *EIS* both occur but are not interconvertible (the complex *EIS* does not break down to products; this situation frequently occurs when the inhibitor is reaction product). The particular case of mixed inhibition is *pure noncompetitive inhibition*, which takes place if two inhibitor dissociation constants (for *EI* and *EIS*) are exactly matched to each other.

For all types of inhibition, the Michaelis–Menten equation remains valid: under constant inhibitor concentration, i, the v–s relationship is of the same hyperbolic type as predicted by Equation 17.34, the only difference is that apparent values of K_m and V are now more or less simple functions of I (Table 17.6).

Some parameters (in boldface in Table 17.6) are not affected by inhibitors, whereas others are changed: competitive inhibitors increase K_m, pure noncompetitive inhibitors reduce V, uncompetitive inhibitors decrease at the same degree both V and K_m leaving first-order rate constant V/K_m to be unchanged. In mixed inhibition, there are no unchanged parameters.

One interesting case is so-called substrate inhibition. It occurs when two substrates are bound to the same active site on the enzyme, forming nonproductive triple complex ES_2

$$E + S \overset{K_s}{\longleftrightarrow} \begin{matrix} ES \\ {\scriptstyle K_{ss}\uparrow\downarrow} \\ ES_2 \end{matrix} \xrightarrow{k_2} E + P$$

then enzyme reaction rate is (34):

$$v = \frac{Vs}{K_s + s + s^2/K_{ss}} \qquad (17.42)$$

where K_{ss} is the dissociation constant for complex ES_2.

17.3.13 Cooperativity

Many enzymes respond to changes in metabolite concentrations (substrates, modifiers) with much higher sensitivity as compared with predictions from the classic hyperbolic

TABLE 17.6. Types of Inhibition

Type of Inhibition	V^{app}	$V^{app}/K_m{}^{app}$	$K_m{}^{app}$
Competitive	V	$(V/K_m)/(1 + i/K_i)^a$	$K_m(1 + i/K_i)$
Uncompetitive	$V/(1 + i/K'_i)$	V/K_m	$K_m/(1 + i/K'_i)$
Mixed	$V/(1 + i/K'_i)$	$(V/K_m)/(1 + i/K_i)$	$K_m(1 + i/K_i)/(1 + i/K'_i)$
Pure noncompetitive	$V/(1 + i/K_i)$	$(V/K_m)/(1 + i/K_i)$	K_m

[a] K_i = [I][E]/[EI]. K'_i = [I][ES]/[EIS].

Equations 17.34–17.42. This property is generally known as *cooperativity*, because it is thought to arise from cooperation between the active sites of the polymeric enzymes. As a rule, such enzymes consist of several *subunits* and display so-called sigmoid or S-shaped dependence of rate on substrate concentration. Many cooperative enzymes (but not all!) have *active sites* binding substrate and *allosteric sites* binding effectors. There are *homotropic* and *heterotrophic* cooperative effects caused by interactions between, respectively, identical and different ligands (e.g. substrate and an allosteric effector).

To explain the cooperativity and associated sigmoid kinetics, a number of models have been suggested. The earliest one is the Hill equation, which was originally designed to describe the S-shaped curve of oxygen binding to hemoglobin. It was assumed that each protein molecule E binds n molecules of ligands S in a single step, an amount of other possible forms ($ES_{n-1}, ES_{n-2}, \ldots ES$) being negligible:

$$E + nS \overset{K_h}{\longleftrightarrow} ES_n$$

where K_h is respective equilibrium constant. The fractional saturation of protein (enzyme or hemoglobin), Θ is given as

$$\Theta = \frac{\text{number of occupied binding sites}}{\text{total number of binding sites}} = \frac{[ES_n]}{[E] + [ES_n]} = \frac{[S]^n}{K_h + [S]^n} \tag{17.43}$$

Equation 17.43 can be rearranged into

$$\frac{\Theta}{1-\Theta} = \frac{[S]^n}{K_h}, \quad \log\left[\frac{\Theta}{1-\Theta}\right] = -\log K_h + n \log[S] \tag{17.44}$$

A plot of $\log \Theta/(1-\Theta)$ against log [S] known as *Hill plot*, should be a straight line of slope n (so). This equation is used to fit the experimental binding and kinetic data displaying sigmoid shape. When plotting kinetic measurements, it is assumed that $\Theta = v/V$, maximum velocity V should be known from independent measurements taken at saturation substrate concentration. However, the results of fitting should be interpreted with care. Firstly, Hill equation is empirical and generally provides good agreement only in the Θ range 0.1–0.9 (the discrepancy at extreme s is probably caused by neglecting other forms of ESC apart from ES_n). Secondly, parameter n (*Hill coefficient*) could not be interpreted as the number of subunits in the fully associated protein, rather it is an index of cooperativity.

Monod, Wyman and Changeux (35), proposed a general model explaining cooperativity and allosteric phenomena within a simple set of postulates:

1. Each subunit of enzyme can exist in two different conformations, designated R (relaxed) and T (tense).
2. All subunits of a molecule must occupy the same conformation at any time (e.g. for tetrameric enzyme only R_4 or T_4 are permitted, not R_3T or R_2T_2, etc.).
3. The two states are in equilibrium with constant $L = [R_4]/[T_4]$.
4. The affinity of ligand to subunit depends on conformation state: $K_R = [R][S]/[RS]$, $K_T = [T][S]/[TS]$, $c = K_R/K_T$.

The general equilibrium solution of this scheme is rather bulky, so we demonstrate one particular case of tetrameric protein, if $c = 0$ (i.e. $K_R \ll K_T$, S binds only to the R state), then we have

$$\Theta = \frac{(1 + s/K_R)^3 s/K_R}{L + (1 + s/K_R)^4} \tag{17.45}$$

At high s when $s/K_R \gg L$, we can neglect the term L in the denominator, and the entire expression is converted to no more than simple hyperbolic Langmuir isotherm. At low s, the contribution of L is considerable, so the saturation curve rises slowly from the origin displaying the S-shape.

There are other models describing the mechanisms of cooperativity and allosteric effects, for example, sequential model of Koshland, Nemethy and Filmer, the association–dissociation model Freiden and other (see details in Ref. 30).

17.3.14 Effects of pH

Every enzyme contains a large number of acidic and basic groups. Some of them are either fully deprotonated (aspartate, glutamate) or fully protonated (arginine, lysine). However, several groups with pK_a 5–9 (imidazole group of histidine, thiol sulphydryl group of cysteine) do change their ionization state when pH is varied. Assume as a first approximation that enzyme is represented as a dibasic acid H_2E and only singly ionized complex, HES^-, is able to react to give products:

$$\begin{array}{ccccc} H_2E & & H_2ES & & \\ \uparrow\downarrow K_1^E & & \uparrow\downarrow K_1^{ES} & & \\ S + HE^- & \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} & HES^- & \xrightarrow{k_{+2}} & HE^- + P \\ \uparrow\downarrow K_2^E & & \uparrow\downarrow K_2^{ES} & & \\ E^{2-} & & ES^{2-} & & \end{array}$$

Then the reaction rate is dependent on H^+ concentration, h, as follows (30):

$$v = \frac{Vs}{K_m + s}, \quad V = \frac{\widetilde{V}}{\left(\frac{h}{K_1^{ES}} + 1 + \frac{K_2^{ES}}{h}\right)}, \quad \frac{V}{K_m} = \frac{\widetilde{V}/\widetilde{K}_m}{\left(\frac{h}{K_1^{E}} + 1 + \frac{K_2^{E}}{h}\right)}, \quad (17.46)$$

where $\widetilde{V}$ and $\widetilde{K}_m$ are the pH-corrected constants. It is clear that pH-dependent variation of V reflects the ionization of ESC, while V/K_m reflects the ionization of the free enzyme. The pH-effects on K_m is more complicated being affected by both. Generally the dependence of enzyme activity on pH is described by Equation 17.46 as a bell-shaped curve with maximum at $\frac{1}{2}(pK_1 + pK_2)$.

17.3.15 Effects of Temperature

In chemical kinetics, the dependence of reaction rate on temperature is explained by *transition-state theory* developed by Eyring as early as in 1930–1935. It is based on the use of thermodynamics and principles of quantum mechanics. The reaction proceeds through a continuum of energy states and must surpass the state of maximum energy, when transient activated complex is formed. Then the dependence of reaction rate constant k on absolute temperature, T is expressed as follows:

$$\frac{d \ln k}{dT} = \frac{\Delta H^* + RT}{RT^2} \quad (17.47)$$

where R is the gas constant and ΔH^* is the enthalpy of activated complex formation. The classic *Arrhenius* equation may be obtained from Equation 17.47 under a simplified condition $\Delta H^* + RT \approx \Delta H = E_a$ (where E_a is *activation energy*). Most often Arrhenius equation is used in its integrated form

$$\ln k = \ln A - E_a/RT \text{ or } k = A \exp(-E_a/RT) \quad (17.48)$$

where A is the integration constant, interpreted as the frequency of collisions of reacting molecules. Apart from mechanistic derivations, there are a number of empirical expressions relating k and Celsius temperature T_c. The most popular is exponential formula:

$$\ln\ k = \ln\ A - \alpha T_c \text{ or } k = A \exp(\alpha T_c) \quad (17.49)$$

where α is empirical constant related to widely used temperature coefficient $Q_{10} = \exp(10 \times \alpha)$.

All presented mathematical expressions predict exponential or almost exponential increases of chemical reaction rates with temperature. However, enzymatic reactions deviate from this relationship at high temperature because of thermal denaturation of enzymes. Assume that denaturation is reversible with equilibrium constant $K_T = [E']/[E]$, where E is active enzyme molecules and E′ is inactive one. Then the combination of Equation 17.48 with the van't Hoff relationship for $K_T (-RT \ln K_T = \Delta G^\circ = \Delta H^\circ - T\Delta S^\circ)$ results in

$$v = \frac{A \exp(-E_a/RT)}{1 + \exp(\Delta S^\circ/R - \Delta H^\circ/RT)} \quad (17.50)$$

where ΔG°, ΔS°, and ΔH° are the standard Gibbs free energy, enthalpy, and entropy of denaturation reaction, respectively, and v is the observed rate of biological process. This equation produces a curve with single maximum and fits to the most of available experimental data on temperature dependent variation of enzymatic activity.

Sometimes denaturation is irreversible, and there are no possibilities for simple mathematical expressions, because temperature effects are time-dependent. However, still numeric solution of respective differential equations can be used.

17.4 SIMPLE MODELS OF MICROBIAL AND CELL GROWTH

This section deals with simple unstructured models. These models mainly ignore any changes in cell quality (biochemical composition, spectrum of enzymatic activity, etc.) induced by environmental factors.

17.4.1 Main State Variables and Growth Parameters

There are two types of growth models, *deterministic* and *stochastic*. The former describe clear determined and regular processes. The latter deal with random or stochastic processes. The main variables used in deterministic models are the same as in chemical kinetics, concentrations of biomass, substrates, and products, and stochastic models consider instead the probabilities, frequency distributions, variance, and so on. For example, a stochastic model can consider the probability of a single bacteria cell dividing under specified environmental conditions. Although any real-life biotechnological process has both deterministic and stochastic components, most useful growth models are strictly deterministic. In this section, we will concentrate on this type of model, and the stochastic counterparts will be considered only in section titled "Cell Cycle." The major state variables of deterministic models describing cell growth are described in Table 17.7. The concentration of biomass and

TABLE 17.7. Major State Variables of Deterministic Models

Variable	Notation	Dimension (Examples)
Concentration of cell biomass	x	g CDW/liter of cultural liquid
Cell number[a]	N	10^9 cell/mL of cultural liquid
Single-cell mass[a]	m_1	g CDW/cell
Mycelium length[b]	L	meter/liter of cultural liquid
Tips number[b]	n	10^6 tips/mL of cultural liquid
Concentration of limiting substrate	s	gram/liter of cultural liquid
Concentration of product	p	gram/liter of cultural liquid or gram/gram of CDW

[a]For unicellular organisms (bacteria, yeasts).
[b]For filamentous organisms (fungi, actinomycetes).

cell number are related to each other by simple formula:

$$x = m \cdot N \tag{17.51}$$

where conversion factor m is the average dry mass of a single cell. In some studies, it is safe to assume m to be a constant and use both variables x and N as equivalent measures of growth. However, the average size and mass of single cells vary depending on the nature of studied organisms and environmental conditions (see section titled "Cell Cycle"); therefore, it is advisable to make a selection. The biomass, x, has obvious advantage in studies aimed at understanding or control of mass flows, and cell number, N, is preferred in population studies when, for example, mutation or plasmid transfer is an essential factor controlling the efficiency of the biotechnological process.

The choice of method to determine biomass or cell number depends on many factors (6). Today, the preference should be given to those techniques that allow exact and automated measurements (Table 17.8). The most advanced analytical methodology is now available for automatic recording of gaseous or volatile substrates, intermediates, and end products, such as methane, CO_2, O_2, H_2, volatile fatty acids, alcohols, and other fermentation products (infrared and mass spectrometry, gas chromatography, NMR, etc.).

The *primary* state variables that are measured directly in cell culture are usually recalculated into the *secondary* growth characteristics: gross growth rate, $\mathrm{d}x/\mathrm{d}t$; specific growth rate, $\mu = (\mathrm{d}x/\mathrm{d}t)/x$; degree of multiplication, x/x_0; biomass doubling time, $t_\mathrm{d} = \ln 2/\mu$; growth yield, $Y = -\mathrm{d}x/\mathrm{d}s$; product yield, $Y_{p/s} = -\mathrm{d}p/\mathrm{d}s$, $Y_{\mathrm{p/x}} = \mathrm{d}p/\mathrm{d}x$; specific rate of substrate consumption, $q_\mathrm{s} = -(\mathrm{d}s/\mathrm{d}t)/x = \mu/Y$; specific rate of product formation $q_p = (\mathrm{d}p/\mathrm{d}t)/x = \mu Y_{p/x} = \mu(Y_{p/x}/Y)$. Most of the listed secondary growth characteristics are called *specific* rates expressed as a first-time derivatives of measured variable *per unit of cell mass*. The specific rates are not sensitive to variations in total cell biomass, so they can be considered as analogous to enzyme activity in most kinetic derivations. The specific growth rate, μ, may be viewed as the activity of an autocatalytic enzyme producing itself. The specific growth rate, μ, measured from biomass dynamic, x, can differ from that estimated from the increase in cell number, N (denoted as μ_N). It follows from Equation 17.51 that

$$\mu = \frac{1}{x}\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{1}{x}\frac{\mathrm{d}(N \cdot m)}{\mathrm{d}t} = \frac{1}{N \cdot m}\left[N\frac{\mathrm{d}m}{\mathrm{d}t} + m\frac{\mathrm{d}N}{\mathrm{d}t}\right]$$
$$= \frac{1}{m}\frac{\mathrm{d}m}{\mathrm{d}t} + \frac{1}{N}\frac{\mathrm{d}N}{\mathrm{d}t} = \mu_\mathrm{cell} + \mu_N \tag{17.52}$$

If mass of single cell m is constant, then $\mu_\mathrm{cell} = 0$ and $\mu = \mu_N$. Otherwise we have to take into account m-variation.

17.4.2 Validity of Exponential Growth Low

One of the earliest postulates in microbial kinetics is that under optimal nonrestrictive conditions (nutrient media containing all essential components at nonlimiting concentrations, absence of inhibitors, adequate physicochemical parameters, perfect mixing) the increase in biomass ($\mathrm{d}x$) during an infinitely small time interval ($\mathrm{d}t$) is proportional to this time interval and the instant biomass concentration (x), that is

$$\mathrm{d}x = \mu x \mathrm{d}t, \text{ or } \mathrm{d}x/\mathrm{d}t = \mu x \tag{17.53}$$

where μ is the proportionality coefficient. If μ is constant, integration of Equation 17.53 gives

$$\ln x = \ln x_0 + \mu t \Rightarrow x = x_0 \exp(\mu t) \tag{17.54}$$

where x_0 is biomass at zero-time or *inoculum size*.

According to early views, true exponential growth occurs only in the case of symmetrically dividing bacteria with equal probability of subsequent division for the mother and daughter cells. Organisms with asymmetrical multiplication (budding yeasts) were thought to obey the exponential low only approximately, whereas the growth of filamentous organisms (fungi, streptomycetes) was

TABLE 17.8. Methods Used for Determination of Microbial Biomass

Method	Measuring Principle	DL[a]	Advantage	Disadvantages
Dry mass	Mass of separated and dried solids	50	Provides direct unconditional estimate	Interference from dead cells and noncell solids
Wet mass	Mass of separated material	50	Simplicity, quickness	The variation of wet biomass bulk density
Wet biovolume	Linear dimension of pelleted cells or colony	100	Simplicity, quickness	The variation of wet biomass bulk density
Particulate organic carbon	CO_2 after cell separation and combustion	1.0	High precision and sensitivity, provides direct estimate of mass	Interference from dead cells and noncell solids
Biuret proteins	Colorimetric reaction of peptide bonds	1.0	High uniformity	Variation of protein-to-biomass ratio, possible extracellular accumulation
Folin–Ciocalteu protein	Colorimetric reaction of tyrosine and tryptophan	0.1	High sensitivity	Variation of protein-to-biomass ratio and amino acid composition of cell protein, possible extracellular accumulation
DNA	Colorimetric estimation of deoxyribose	1.0	High specificity, constancy of the DNA cellular content	Possible extracellular accumulation
ATP	Bioluminescence assay	10^{-5}	High sensitivity and specificity	Variation of the intracellular ATP pool
Fatty acids	Gas or liquid chromatography, colorimetric reaction	1.0	High specificity, allows identification of composition of mixed culture	Variation of the intracellular content, possible extracellular accumulation
Metabolic potential	Rate of added substrate uptake or product formation	10^{-3}–10	High specificity, quickness	Variation in conversion factor from measured rate to biomass
Opacity	Light scattering	0.1	Simplicity, quickness, automation	Interference from noncell solids, cell aggregation, wall growth
Electrical measurements	Conductivity, capacitance	1	Simplicity, quickness, automation	Variation of conversion factor, interference from electrolytes in the medium
Manual microscopy	Cell count, measuring of hypha length	10^{-5}	Low cost, sensitivity, allows visual assay of biomorphological structure	Time-consuming, low precision
Image analysis	Computer-aided count	10^{-5}	Combined benefit of manual and automated quantification, speed, generation of size distribution	High cost
Coulter counter	Automated count and sizing	10^{-5}	Quickness, automation, generation of size distribution	Interference from noncell solids
Plating	Growing of the colonies on Petri dish	10^{-5}	Low cost, high sensitivity	Time-consuming, low precision

[a]DL = detection limit, the minimum CDW required for an estimation with an error <2% (mg).

deviated considerably. However, direct measurements performed from 1930 to 1960 (see Ref. 6) revealed that exponential growth does occur in all prokaryotes and eukaryotes independent of their biomorphological features, including protozoa, fungi, and homogeneously cultivated plant and animal cells. The deviation is observed only as a result of growth-associated change in the environment. Wang and Koch (36) made very precise measurements of μ dynamics by growing *Escherichia coli* directly in an aerated cuvette of the computer-linked double-beam spectrophotometer. They found temporary slowdowns in the complex peptone plus beef-extract media attributed to diauxie phenomena (e.g. depletion of some preferred oligopeptides) and a gradual increase of the μ value during sequential subculture in succinate minimal medium. Long-term cultivation of microorganisms in continuous turbidostat or pH-auxostat culture (37) revealed that the increase in μ is mainly result of autoselection of mutants having higher maximum specific growth under specified cultivation conditions [see section titled "Population Dynamics (Mutations, Autoselection, Plasmid Transfer)"].

17.4.3 Early Views of Cell Growth

The derivation of the exponential growth equation was done for binary dividing bacteria, based on the geometric progression $2, 2^2, 2^3 \ldots$ (38):

$$N = N_0 2^n \tag{17.55}$$

where n is the number of divisions, $n = t/t_d$.

The growth dynamics were viewed as a succession of distinct phases approximated with empirical formulas (39)

$$N = N_0 \exp[\mu F(t) t] \tag{17.56}$$

where function $F(t)$ undergoes stepwise changes as shown in Table 17.9.

The alternative way to describe growth dynamics was to use *the logistic equation* borrowed from demographic studies (40):

$$\frac{\mathrm{d}N}{\mathrm{d}t} = rN\left(1 - \frac{N}{K}\right) \text{ or } \frac{\mathrm{d}x}{\mathrm{d}t} = rx\left(1 - \frac{x}{x_m}\right) \tag{17.57}$$

TABLE 17.9. Stepwise Changes of Function $F(t)$

Initial Stationary Phase	$F(t) = 0$
Lag phase, $1.56 \le n \le 2.7$	$F(t) = t^{n-1}$
Logarithmic growth phase	$F(t) = 1$
Negative growth acceleration phase	$F(t) = t^{-t-1}$
Maximum stationary phase	$F(t) = 0$
Accelerating death phase, $1.56 \le n \le 2.7$	$F(t) = t^{n-1}$
Logarithmic decrease phase	$F(t) = -1$

where r is the net growth rate (the difference between true growth and death rates) and K or x_m are the upper limits of respectively population density or biomass (K is used preferentially in ecological literature, being called the carrying capacity of the ecosystem). This equation simulates S-shaped growth dynamics frequently observed in natural ecosystems and cell cultures.

Similar (but not identical) equation of cell biomass dynamics would be produced if we assume that the limiting substrate is consumed according to first-order kinetics and is converted to biomass with a fixed yield factor

$$Y = (x - x_0)/(s_0 - s), \tag{17.58}$$

then:

$$\frac{\mathrm{d}s}{\mathrm{d}t} = -ks, \quad s = \frac{x_0 + Ys_0 - x}{Y} = \frac{x_m - x}{Y},$$
$$\Rightarrow \frac{\mathrm{d}x}{\mathrm{d}t} = -Y\frac{\mathrm{d}s}{\mathrm{d}t} = kx_m\left(1 - \frac{x}{x_m}\right) \tag{17.59}$$

17.4.4 Monod's Model

This model still is very popular because of its elegant simplicity. It played an important role in the history of microbial growth kinetics as a first encouraging example when the theoretical development based on mathematical formalisms came before novel experimental designs. As compared with simple exponential Equation 17.53 this model (41) takes into account the mass-conservation condition linking substrate uptake to biomass formation through constant yield factor, Y (Eq. 17.2) and the dependence of the specific growth rate on limiting substrate concentration:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \mu(s)x = \mu_m \frac{s}{K_s + s}x$$
$$\frac{\mathrm{d}s}{\mathrm{d}t} = -\frac{1}{Y}\frac{\mathrm{d}x}{\mathrm{d}t}. \tag{17.60}$$

By substitution of s by x through Y (Eq. 17.58) we can reduce equation set 60 to a single equation having the analytical solution:

$$\mu_m t = (1 + P)\ln(x/x_0) - P\ln(Q - x/x_0) + P\ln(Q - 1), \tag{17.61}$$

where $P = YK_s/x_m$, $Q = x_m/x_0$, $x_m = Ys_0 + x_0$, while s_0 and x_0 are respectively s and x at $t = 0$.

Equation 17.61 contains three parameters, Y, μ_m, and K_s, that can be thought of as passport data for a particular organism (e.g. for *E. coli* grown on glucose at 30°C $Y = 0.23$, $\mu_{\mathrm{m}} = 1.35\ \mathrm{h}^{-1}$, and $K_{\mathrm{s}} = 4\ \mathrm{mg\ l}^{-1}$) and describe the S-shaped growth dynamics of a batch culture. The initial conditions, s_0 and x_0 are set by the experimenter, who

selects the inoculation dose and medium composition. Thus, knowing the values of all these entities, the growth dynamics can be calculated *prior to the experiment*. Moreover, this model was used as a basis for development of the *chemostat theory* to understand and predict the behavior of microbial cultures in continuous-flow bioreactors before the respective hardware was constructed. For this purpose, original Equation 17.60 was modified as follows (42):

$$\frac{dx}{dt} = (\mu - D)x, \quad \mu = \mu_m \frac{s}{K_s + s} x$$
$$\frac{ds}{dt} = D(s_r - s) - \frac{1}{Y}\mu x, \quad D = \frac{F}{V}, \qquad (17.62)$$

where s_r is the concentration of limiting substrate in the fed fresh medium delivered with pump from reservoir, F is the pumping rate (cubic centimeter/hour), V is culture volume (cubic centimeter), and D is the dilution rate defined as the ratio $D = F/V$ (h^{-1}).

The mathematical analysis of Equation 17.62 allows us to make the following conclusions on the growth kinetics of continuous culture:

1. The described open system attains stable *steady state*, when $dx/dt = 0, ds/dt = 0$, and variables x and s are not changed with time (denoting steady-state concentrations $\tilde{x}$ and $\tilde{s}$ respectively). From the first equation it follows that $\mu = D$, that is, the specific rate of microbial growth is equal to the dilution rate, which is under the full control of the experimenter. From the second equation, we find

$$\tilde{x} = Y(s_r - \tilde{s}), \qquad (17.63)$$

   As compared with Y expression for batch culture (Eq. 17.58), this formula no longer contains the term, x_0, the inoculum size. Thus, a steady-state culture is not dependent on past history, and its properties are determined solely by current cultivation parameters.
2. The dilution rates permitting stable microbial growth (i.e. those D, at which $\tilde{x} > 0$), are confined between 0 and washout point or *critical dilution rate*, D_c

$$D_c = \mu_m s_r/(K_s + s_r) \qquad (17.64)$$

3. The specific growth rate μ does not depend on either s_r or x and is governed solely by the substrate concentration in the cultural liquid. On the other hand, the indirect effect of s_r on μ may be evaluated from the dependence of $\tilde{x}$ on D, as soon as $\tilde{x}$ and $\tilde{s}$ are linked by the conservation condition in Equation 17.63.

The most important biological implication of the chemostat theory was the discovery of the fact that microorganisms can grow endlessly with any rate between 0 and μ_m. Such substrate-limited growth is nevertheless exponential, because two subsequent acts of cell division will be separated by a constant time interval. Earlier, substrate limitation had been observed only transiently at the end of the exponential phase of batch growth. The most important biotechnological implication of the chemostat model was the concept of *controlled cell biosynthesis* which implies the purposeful manipulation of microbial culture to optimize the productivity by such tools as changing the flow rate and the composition of medium in continuous-flow bioreactors.

17.4.5 Derivation of the Monod Equation from Mechanistic Considerations

The equation relating μ and s is known as *Monod equation*:

$$\mu = \mu_m \frac{s}{K_s + s} \qquad (17.65)$$

It was introduced by the author as a purely empirical relationship resembling adsorption isotherm. However, many microbiologists did view the Monod equation as something having deep inherent meaning rather than as just an empirical formula. Below, we shall outline a number of attempts to deduce this equation logically from the conjectured growth mechanisms.

1. *The Bottleneck Concept.* There is an obvious similarity between the Monod and Michaelis–Menten equations. A theoretical "substantiation" for this similarity can be the bottleneck postulate originally put forward by Blackman (43). According to this postulate, the growth rate of a cell is on the whole determined by a single *enzymatic master reaction*. Microbial metabolism is symbolized as a unidirectional chain of reactions of substrate S conversion to cell biomass X′ via some hypothetical intermediates $P_1, P_2 \ldots P_n$:

$$S + X' \xrightarrow{k_1} P_1 \xrightarrow{k_2} P_2 \longrightarrow \ldots \xrightarrow{k_n} P_n \xrightarrow{k_{n+1}} 2X' \qquad (17.66)$$

   Assuming steady state in respect to intermediate concentration $p_i, dp_i/dt = 0$, we arrive at the Monod equation, composite parameters μ_m and K_s being expressed via elementary kinetic constants of individual enzymatic reactions:

$$\frac{dx}{dt} = \mu_m \frac{s}{K_s + s} x; \quad \mu_m = \frac{1}{\sum_{i=2}^{n+1} 1/K_i};$$
$$K_s = \frac{1}{k_1 \sum_{i=2}^{n+1} 1/K_i}, \qquad (17.67)$$

where $x = x' + p_1 + \ldots p_n$. The "bottleneck" idea can now be formulated as follows. If one of the constants $k_j \ll k_i, i = 2, \ldots, n+1, i \neq j$, then $\mu_m = k_j$ and $K_s = k_j/k_1$, and so the jth enzymatic reaction is the master reaction.

The obvious shortcomings of the reaction scheme 17.66 are the unjustified oversimplification of the cell metabolism (which is a network, rather than a simple unidirectional sequence of reactions) and the lack of a definite interpretation of variables x' and p in real biochemical terms. An evaluation of the characteristic times of major intracellular metabolic reactions showed that there could be two possible "bottlenecks": (i) uptake of limiting substrate (processes of active transport, transphosphorylation of sugars, etc.) (44) and (ii) the formation of intracellular protein-synthesizing structures such as rRNA and the ribosomal proteins (45).

2. *Stochastic Considerations.* Microbial populations were assumed to consist of active (which utilize the substrate) and inactive cells (46). The probability of a transition from the inactive state to the active one was supposed to be proportional to s, whereas the probability of the reverse transition was s independent. From these assumptions, a relationship between μ and s, can be inferred, similar to Equation 17.65.
3. *Derivations Based on Mechanistic Considerations of Protein Synthesis (47).* The rate of protein synthesis, dp/dt, is supposed to be determined by rRNA concentration R and by the size of the amino acids pool, A, $dp/dt = kxRA/(K_A + A)$, $k =$ constant. Other conditions are defined as: $R = R_0 + (R_m - R_0)\mu/\mu_m$, $A = bs$, and $P = p/x$, where R_m and R_0 are respectively, the upper and lower limits of R variation, and P and b are constants. For a steady-state chemostat culture, $dp/dt = 0$ and $dx/dt = (1/P)(dp/dt) = 0$, then

$$\mu = (k\ R_m/P)s/(R_m K_A/\beta R_0 + s) = \mu_m s/(K_s + s). \quad (17.68)$$

Here again, the Monod equation is derived through a consideration of underlying intracellular processes.

Needless to say, none of the cited derivations are free from criticism. The Monod equation remains empirical. Any attempts to provide the mechanistic interpretation of this equation inevitably lead to much more complicated mathematical expressions (see section titled "Structured Models").

17.4.6 Biological Meaning and Experimental Determination of Growth Parameters K_s and μ_m

The parameter μ_m, maximal specific growth rate, has very lucid biological meaning: it is the upper limit of μ variation on specified nutrient medium. It could not be attained in reality because of its asymptotic nature: $\mu \to \mu_m$ as $s \to \infty$. However, in practice μ_m is achieved if $s \gg K_s$. It should be remembered that μ_m is not absolute maximum of growth rate, as it depends on the nature of the limiting substrate. For example, *E. coli* has μ_m above 2.5 h^{-1} on complex beef-extract medium and below 1.0 h^{-1} on minimal medium with succinate. Saturation constant, K_s could be defined functionally as such concentration of limiting substrate which provides specific growth rate equal to 0.5 of μ_m. We can say also, that K_s is a measure of cell affinity to substrate: the lower is K_s the better the organism is adapted to consume substrate from diluted solution. Any other definitions are speculative, for example, K_s interpretation as the dissociation constant of ESC of the cellular enzyme involved in the first step of substrate conversion.

There are several ways to determine numeric values of K_s and μ_m:

1. *Batch Culture, Differential Form of Monod Equation.* The biomass dynamics, $x(t)$ are followed from the start of the exponential phase until the complete consumption of the limiting substrate and the attainment of the maximal cell density, x_m. The residual substrate concentration, s is calculated from mass–balance (Eq. 17.58). Yield is calculated as $(x_m - x_0)/s_0$ (the s_0 value should be known) and corresponding $\mu(t)$ values from the slopes $d(\ln x)/dt$. Finally, parameters K_s and μ_m are to be found graphically or from nonlinear regression as in the case of the Michaelis–Menten equation (see below).
2. *Batch Culture, Initial Growth Rates.* The inoculum size, x_0, and the duration of experiment are chosen to minimize the uptake of added substrate: $s \approx s_0$ (48). Typically, bacterial cell density should be of the order 10^{-5} or less, and is measured by such sensitive instruments as the Coulter Counter. The quasi–steady state growth rate is measured at several s_0 values and then fitted to Equation 17.65 as described before. In numerous determinations made at much high cell densities (when we can no longer neglect substrate consumption) it was anyway observed that dependence of μ on s_0 is formally described by Monod equation with s replaced by s_0 (see as example, Ref. 49). The explanation of these results could be made only by more complex structured models; however, the described procedure is not appropriate for K_s and μ_m determination.
3. *Batch Culture, Integral Form of Monod Equation.* The S-shaped curve of biomass dynamics is fitted directly to Equation 17.61 either through preliminary linearization or nonlinear regression (preferential). Sometimes (e.g. when cells are grown in opaque media) it is more convenient to follow the dynamics

of residual substrate, $s(t)$, product formation, $p(t)$, for example, CO_2 evolution, or even dynamics of O_2 uptake (respiration). In these cases, we can integrate the set of differential Equations 17.60 in terms of $s(t)$ or $p(t)$ dynamics taking into account mass–balance relationships (Eqs 17.7,17.8 and 17.58 and similar).

4. *Steady-State Chemostat Culture.* The chemostat provides the opportunity for estimations under steady-state condition which is commonly believed to be more reliable. By running an experiment at different dilution rates, D, the corresponding $\tilde{s}$ values may be measured, and, therefore, the dependence of $\mu = D$ on $\tilde{s}$ can be obtained, in principle, as accurately and carefully as desired. Such an approach, however, may and frequently does encounter serious technical problems because of high affinity to limiting substrate of some microorganisms. There is the need (i) to select highly sensitive analytical techniques to measure extremely low residual concentrations of particular substances, (ii) to develop instant sampling procedures to minimize substrate loss, and (iii) to eliminate apparatus-related artifacts such as nonperfect mixing, fluctuations in nutrient medium supply. This can always be accomplished by use of radio-labeled substrate, some other tips are covered in specific experimental works (50). However, the most essential objection to this method is that organisms at various steady-states do change their kinetic properties which are not accounted by Monod's model (see section titled "Structured Models").
5. *Non-Steady-State Chemostat Culture.* The measurements are made during short-term experiments started by addition of different amounts of limiting substrate to a steady-state chemostat culture. Then substrate uptake or respiration rates are recorded in perturbed culture until the new steady-state is established (2). The opportunity of continuous culture is that the physiological state of cells just before perturbation is well defined and reproducible. On the other hand, these experiments do provide data on affinity to substrate (K_s) and maximal rates of respiration, for example, Q_{CO2}, or uptake, Q_s, which are related but are not identical with μ_m:

$$\mu_m = Y_{p/x} Q_{CO2} = Y_{s/x} Q_s \tag{17.69}$$

where stoichiometric parameters $Y_{p/x}$ and $Y_{s/x}$ should be determined in independent experiments. Immediate assay of μ_m in such an experimental setup is possible as follows: the steady state is perturbed by setting the dilution rate by 20–100% higher than critical value D_c (Eq. 17.64). The washout dynamics is followed and μ_m is determined from approximate relationship (6): $x \approx x(0)\exp[(\mu_m - D)t]$, where $x(0)$ is biomass before perturbation. More rigorous estimate of μ_m could be provided if such washout experiments are made at several (at least two) input substrate concentrations s_0 to account for the fact that s_r is still not infinity.

17.4.7 Modification of the Monod Equation

It was found that not all experimental data could be reasonably well fitted by Equation 17.65. The best-fit hyperbola often passed above experimental points at small s and below them at large s. A better fit was claimed to be provided by using the following, entirely empirical equations (51–53):

$$\mu = \mu_m[1\text{-}\exp(-Ks)] \tag{17.70}$$

$$\mu = \mu_m s^n/(K_s + s^n) \tag{17.71}$$

$$\mu = \mu_m s/(K_s x + s) \tag{17.72}$$

The preference of the first expression, Equation 17.70 is questionable. An expansion of the Monod equation by addition of the third parameter, n in Equation 17.72, or introduction of the second variable, x in Equation 71, does improve the approximation capability of kinetic equations. We can even provide the mechanistic basis for this improvement. Thus, the Moser equation is similar to the Hill equation in enzymology (Eq. 17.43) indicating the cooperativity effects in performance of some "master" reaction of cellular metabolisms. The Contois equation could be interpreted in terms of growth autoinhibition by-products, because under the realistic assumptions [(i) $x \gg x_0$, (ii) $xY_{p/x}/K_p \gg 1$ and (iii) product, p, formation is coupled with growth], the apparent saturation constant K_s^{app} displays linear relationship with biomass x resembling the Contois expression:

$$\begin{aligned} K_s{}^{\text{app}} &= K_s(1 + p/K_p) \\ &= K_s[1 + Y_{p/x}(x - x_0)/K_p] \approx K_s x, \end{aligned} \tag{17.73}$$

An account of maintenance requirements. Powell (54) assumed that substrate uptake rate, q obeys the Michaelis–Menten kinetics, then from Equation 17.18 it follows that

$$q_s = Q_s/(K_s + s) = \mu/Y^{\text{m}} + m \tag{17.74}$$

If μ_m is defined as $\mu_m = Y Q_{\text{s}}$ (6), then

$$\mu = \frac{\mu_m s}{L_s + s} - mY^m = \mu_m \left(\frac{s}{K_s + s} - \frac{s^*}{K_s + s^*} \right),$$

$$s^* = \frac{mY^m}{\mu_m - mY^m} \tag{17.75}$$

If we define $\mu_m = Y^m(Q_s - m)$ (2), then

$$\mu = \mu_m \frac{(s - s^*)}{K_s + s}, \quad s^* = \frac{K_s m Y^m}{\mu_m} \tag{17.76}$$

Equations 17.75 and 17.76 both predict the occurrence of threshold substrate concentration s^*, below which growth is impossible. It yields a substantially better fit to experimental data. The difference is that according to Equation 17.75 the parameter μ_m is the specific growth rate under imaginary conditions of substrate excess and zero maintenance requirements, whereas Equation 17.76 implies the traditional definition of μ_m as the specific growth rate under substrate excess: $\mu \to \mu_{\mathrm{m}}$ when $s \to \infty$.

17.4.7.1 Account for Substrate Leakage. Mathematically identical to Equation 17.76 modification of the Monod equation was proposed for the case of conserved substrates. However, the biological meaning is entirely different: if the specific leakage rate is assumed to be constant, then a decrease in s down to some threshold value s^* will lead to the counterbalance of the two reverse processes (uptake and leakage), so that the net consumption of the limiting substrate will be zero.

17.4.7.2 Account of Inhibitory Effects. A few valuable refinements of the Monod equation were borrowed from enzymology, most often they were noncompetitive and substrate inhibition. The former inhibition mechanism is simulated by the so-called *Monod–Ierusalimsky* equation:

$$\mu = \mu_m \frac{s}{K_s + s} \times \frac{K_p}{K_p + p}, \tag{17.77}$$

The growth retardation with an excess of such substrates as phenol, methanol, and ethanol is described by an analogue of Haldane's equation (55):

$$\mu = \mu_m \frac{s}{K_s + s + s^2/K_{ss}} \tag{17.78}$$

Equation 17.78 simulates a single-peak curve, and so one and the same μ value may be obtained at two different s, one in the substrate-limiting range, $\mathrm{d}\mu/\mathrm{d}s > 0$ (stable), and the other in the substrate inhibition range, $\mathrm{d}\mu/\mathrm{d}s < 0$ (unstable). A sustainable maintenance of a population under conditions of substrate inhibition is possible either in the second stage of a two-stage chemostat or in the case of plentiful wall growth in a conventional chemostat (56).

17.4.7.3 Account of Diffusion Effects. We will present one example of such models (54). The basic assumption is that substrate is taken up by an enzyme that obeys Michaelis kinetics and is localized on the inner side of cell membrane. The actual substrate concentration around the enzyme active centers is smaller than in the solution, because of a limited diffusion rate. By applying a simplified Laplace equation, it was found eventually that

$$\mu = \frac{\mu_m(K_s + L + s)}{2L}\left(1 - \sqrt{1 - \frac{4Ls}{(K_s + L + s)^2}}\right) \approx \mu_m \frac{s}{K_s + L + s}, \tag{17.79}$$

where L is a factor determined by membrane permeability and by the maximum rate of the enzymatic reaction.

17.5 STRUCTURED MODELS

The unstructured models (such as Monod's model or its modifications) are able to predict and describe only simplest manifestation of growth phenomena. Sometimes it is declared that Monod-type models are able to describe only *balanced* and *steady-state* growth. The analysis of more complicated unbalanced and non-steady-state growth requires formulation of structured models.

17.5.1 Definitions

Balanced growth was defined by Campbell (57) as a proportional increase in the amounts of all cell components, in other words, balanced growth produces cells of the same quality without any variation of composition. The terms *steady state* and *non–steady state* stem from chemical and enzyme kinetics. The first one refers to such a regime when the reaction rate remains constant, because of exact balance between formation and breakdown of intermediary products such as the ESC. In microbial culture, the growth is called *steady state* if *specific* rather than *total rates* remain constant. In an open system such as a chemostat, both total ($\mathrm{d}x/\mathrm{d}t$, $\mathrm{d}s/\mathrm{d}t$) and specific rates $\mu = (1/x)\mathrm{d}x/\mathrm{d}t$, $q_s = (1/x)\mathrm{d}s/\mathrm{d}t$ tend to have constant steady-state values. A closed system such as a batch culture should be considered under steady state only during the exponential phase when μ and q_s are constant. The linear growth with a constant total rate ($\mathrm{d}x/\mathrm{d}t = \mu x = \text{const.}$) is characterized by monotonously declining μ, and is not steady-state growth. However, under some conditions (such as in dialysis culture) it may attain *quasi–steady state*, when $\mathrm{d}s/\mathrm{d}t \approx 0$.

The non-steady-state kinetic regimes take place before establishment of steady state or after its perturbation. In enzyme kinetics, non-steady-state measurements are taken

in the millisecond range of time scale. In microbial cultures, similar non-steady-state transient and perturbation processes advance much more slowly, typically during several hours and days. An example is transient process in the chemostat induced by changes in D or s_r (fed substrate concentration). In such growth, μ, q_s, q_p and other metabolic rates exhibit continuous variation in time. The attractiveness of non-steady-state studies for microbiology and biotechnology is obvious:

- They allow a wider range of hypotheses to be tested and yield much more data on the studied objects;
- They have higher practical value in biotechnology, steady-state operation is the exception rather than the common routine because of unavoidable disturbances in cultivation conditions;
- They provide additional tools for optimal regulation of cell performance in the bioreactor, because purposeful non-steady-state growth may display greater efficiency and higher productivity (58).

By *structured*, we mean mathematical models describing growth-associated changes in microbial cell composition. It includes mass balance equations for all assigned intracellular components. Their concentrations can be expressed either per unit volume of fermentor vessel, $(c_1, c_2, .., c_n)$, or per unit cell mass, $(C_1, C_2, .., C_n)$, and, hence, $C_i = c_i/x$. The mass balance equations can be written as follows,

$$\sum_{i=1}^{n} c_i = x, \quad \sum_{i=1}^{n} C_i = 1. \tag{17.80}$$

For each variable C_i a differential equation is written that takes into account all sources, r_+, and sinks, r_-, as well as its dilution from cell mass expansion (growth),

$$\frac{dC_i}{dt} = r_+(s, C_1, \ldots, C_n) - r_-(s, C_1, \ldots, C_n) - \mu C_i \tag{17.81}$$

The simplest structured models with n no more than 2 or 3, are called two or three-compartment models. For example, a model (59) incorporated two compartments, (i) nucleic acids and (ii) proteins combined with other active cell components. The model variables also included concentrations of the limiting substrate and the inhibitor. Compared to Monod's model, the proposed set of four equations was able to account for a much wider range of dynamic patterns. Specifically, it simulated D-dependent changes in the cell composition (chemostat) and all known growth phases of batch culture from the lag to decline. However, the choice of variables in this model was more or less arbitrary, and so it should be regarded more as an interesting illustration rather than a research tool.

During the last two decades, much more realistic structured models based on biochemical data have been developed. The simulation model of *E. coli* growth (60) contains the following dynamic variables: glucose and NH_4^+, as exosubstrates, CO_2 and acetate, as products excreted into the medium, amino acids, ribonucleotides, deoxyribonucleotides, monomeric precursors of cell wall components, rRNA and tRNA, nonprotein polymeric components, glycogen, guanosinetetraphosphate, enzymes transforming ribonucleotides into deoxyribonucleotides, ATP, NAD(H), and protons. Altogether, the dynamic model amounts to a system of 21 differential and 14 algebraic equations. An even more complicated model simulating growth of *Bacillus subtilis* (61) is the set of 39 nonlinear and coupled differential equations containing nearly 200 parameters! These models are able to simulate particular growth features such as changes in cell sizes, shape and composition, as well as the D-dependent variations in replication time brought about by the shifts in glucose concentration. However, the predictive capability of such an intricate dynamic model should be still estimated as modest as compared with invested modeling efforts: they are still a "caricature parody" of real cell but already too complex to be studied by conventional mathematical tools (stability analysis, parameters identification, etc.) or to be used in biotechnological applications. The "best choice" of a mathematical model lies, apparently, midway between unstructured and highly structured models outlined here. One of the known compromises has been found through attempts to express quantitatively the *cell physiological state*.

17.5.2 Physiological State of Chemostat Culture

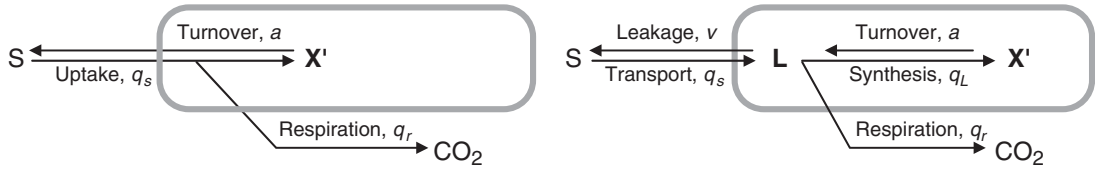
The term was coined by Malek (62) without giving a clear definition. The impetus for the development of the concept of a physiological state was the evidence on changes in the chemical composition of microorganisms as dependent on dilution rate, D and medium composition in chemostat culture (63). It has been found that some of the studied parameters remained constant (e.g. DNA and total carbon), while others exhibited regular D-dependent variations, either an increase (RNA content, cell sizes) or a decrease (the content of reserved polysaccharides). Those properties, that were D-dependent, were recognized as components of the *vector of the physiological state*.

Powell (54) combined and put on a quantitative mathematical footing three notions, which were beforehand separated and cloudy: (i) physiological state, (ii) past history and (iii) non-steady-state growth kinetics of microbial culture. The specific rate of substrate uptake, q_s, was presented as a product

$$q_s(s) = q'_a(s)S(s) \tag{17.82}$$

where $S(s)$ is a simple saturation function, for example, a Michaelis hyperbola, $S(s) = s/(K_s + s)$, and $q'_a(s)$ is a function associated with the microbial physiological state. The instant value of $q'_a(s)$ is determined by way in which s varies until the given moment (τ h ago), effects of later events contributing more than earlier ones. Transient processes are influenced by the past history of the culture in the following manner. Suppose that a steady-state growth of a chemostat culture is upset and the residual substrate concentration jumps from $s(0)$ to $s(1)$. Immediately, q_s will increase from $Q(0)S[s(0)]$ to $Q(0)S[s(1)]$. If no further changes in $s(1)$ occur, then Q will also eventually attain a new steady-state value equal to $q'_a[s(1)]$. In essence, Q is the potential metabolic activity, that is, the specific rate of a key metabolic process measured just at the moment of relief from substrate limitation. The transient Q dynamics are described as

$$\text{net change} = \text{production} - \text{dilution caused by cell growth}$$



$$\frac{dQ}{dt} = r(Q, s) \qquad - \mu(Q, s)Q \tag{17.83}$$

"Substance Q" may, in reality, be represented by a single enzyme or multienzymatic complexes, as well as by ribosomes or other cell components occupying the bottleneck position. Monod's model, supplemented by Equation 17.83, made possible at least a qualitative understanding of chemostat transient processes triggered by a D switch (64).

17.5.3 Synthetic Chemostat Model (SCM)

The SCM (2) combines Powell's ideas with new molecular data on microbial growth. The basic SCM interprets microbial growth as a conversion of exosubstrate S into cell macromolecules $\mathbf{X}'$ either directly (left) or via a pool of intermediates $\mathbf{L}$ (right).

Macromolecular cell components are susceptible to degradation (turnover), and monomeric metabolites can escape into environment because of leakage. Contrary to simple growth models, the composition of cells is allowed to vary (therefore, X' and $\mathbf{L}$ are vectors) in response to a changing environment because of the adaptive nature of microbial metabolism. At the heart of the SCM are the solution of the problem, how to cope with these variations, and how to describe adaptive changes in cell composition by relative simple models.

All macromolecular cell constituents are divided into two groups: primary cell constituents necessary for intensive growth (P-components), and components needed for cell survival under any kinds of growth restriction (U-components). The characteristic examples of P-components are ribosomes (rRNA and ribosomal proteins) and enzymes of the primary metabolic pathways. Their intracellular content increases parallel to an increase in μ. The contribution of U-components to cell biomass decreases with growth acceleration. Examples are enzymes of the secondary metabolism, protective pigments, reserved substances, and transport systems of high affinity.

The analysis of available data as well as mass-conservation conditions allowed the formulation of several rules of variation of cell components taking place because of optimal control of cell biosynthesis:

1. Amounts of P- and U-components expressed as a fraction of total cell mass (P and U, gram/gram of biomass respectively) vary within the upper ($P^{\max}$, $U^{\max}$) and low ($P^{\min}$, $U^{\min}$) limits, the latter being the constitutive part.
2. An increase of one individual P-component is accompanied by increase of other P-components.
3. The total enlargement of P-sum is accompanied by corresponding decrease of U-sum and *vise versa*.
4. The P/U-ratio is controlled by limiting substrate concentration in environment.

These rules are translated into mathematical terms as follows:

$$\frac{P_1 - P_1^{\min}}{P_1^{\max} - P_1^{\min}} \approx \ldots \approx \frac{P_n - P_n^{\min}}{P_n^{\max} - P_n^{\min}} = r;$$

$$\frac{U_1 - U_1^{\min}}{U_1^{\max} - U_1^{\min}} \approx \ldots \approx \frac{U_m - U_m^{\min}}{U_m^{\max} - U_m^{\min}} = 1 - r;$$

$$\overline{r} = \frac{\overline{s}}{K_r + \overline{s}} \tag{17.84}$$

where variable r (*index of physiological state*) is already scalar (not vector!) function controlled by environmental factors, for example, concentration of the limiting substrate; symbols $\overline{r}$and $\overline{s}$ stand for steady-state concentrations of r

and s respectively. The r values in steady-state chemostat culture change from zero (in culture at almost zero growth rate, when $\overline{s} \to 0$ and all P-components come down to low limits) to 1.0 (in unlimited culture, when $\overline{s} \gg K_s$ and P-components attain maximum). During transients caused by sudden s changes, an instant r value goes toward new steady state (compare with Eq. 17.82):

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \mu \times \left(\frac{s}{K_r + s} - r \right) \tag{17.85}$$

The introduction of the r-variable greatly simplifies the use of structured models, because the adaptive variation of cell composition (and metabolic activity which is determined by the intracellular content of particular enzymes) now could be expressed via one single "master" variable r. For example, the specific rate of substrate uptake q_s is defined as:

$$q_s = r\frac{Qs}{K_s + s} + (1 - r)\frac{Q's}{K'_s + s} \tag{17.85a}$$

where the first and the second terms on the right side stand respectively for low (P-component) and high (U-component) affinity of transport system. Similar r-dependent expressions are derived for other reactions (q_L, ν, a) and stoichiometric parameters. The full set of basic SCM for chemostat culture is given as follows:

$$\begin{aligned}
&\frac{\mathrm{d}s}{\mathrm{d}t} = D(s_r - s) - q_s x, \\
&\qquad q_s = rQ\frac{s}{K_s + s}, \quad \text{or} \quad \text{equation 17.85a} \\
&\frac{\mathrm{d}x}{\mathrm{d}t} = \mu x - Dx, \quad \mu = Y(q_s - m) - a, \\
&\qquad m = m_0 r, \quad a = a_0 r \\
&\frac{\mathrm{d}r}{\mathrm{d}t} = \mu \times \left(\frac{s}{K_r + s} - r \right)
\end{aligned} \tag{17.86}$$

As compared with the Monod model (Eq. 17.62), the SCM contains one additional differential equation for variable r, index of physiological state. This variable reflects the changes of all cellular P-components, but it can be viewed specifically as a total cellular RNA content, easily measurable variable. The saturation constant K_r shows how fast the content of P-components approaches maximum with raising the limiting substrate concentration in chemostat. Other growth parameters remain similar to their equivalents in the Monod model. The only difference is that parameters assumed to be constant in the Monod model (maintenance coefficient, turnover rate, substrate maximal uptake rate and saturation constant) are treated by SCM as functions of slow variable r. The instant maximal substrate uptake rate is given as product rQ, where Q is a true maximal rate measured in a fully established substrate-sufficient continuous culture. The maintenance requirements are given as product $m = m_0 r$, where m_0 is the upper limit of the m-variation. The turnover rate a is introduced as $a = a_0 r$, where a_0 is the upper limit of turnover rate variation.

Originally Equation 17.84 was introduced as a convenient semiempirical relationship satisfying most experimental observations. Its validation recently came from molecular-genetic studies. Several genes and their products were found to play the role of master regulator and metabolic coordinator as dependent on the state of environment. All bacteria have functionally similar but chemically diverse master regulators. In *E. coli* and other γ-proteobacteria, there are two forms of a sigma subunit of RNA polymerase: σ^{S} (*rpoS*) and σ^{70} (*rpoD*) which are expressed under stress and normal growth conditions respectively. While rapidly growing cells contain very little σ^{S}, exposure to many different stresses results in rapid and strong σ^{S} induction which is then followed by transcription of numerous σ^{S}-dependent genes (more than 70) responsible for stress-protective functions. Substrate limitation results in increased *rpoS* transcription, whereas high osmolarity, low temperature, acidic pH, and some late-log-phase signals stimulate the translation of *rpoS* mRNA. In addition, carbon starvation, high osmolarity, acidic pH, and high temperature stabilize σ^{S}, which, under nonstress conditions, is degraded with a half-life of one to several minutes (65–68).

This finding explains the presence of two groups of cellular macromolecules, **P** and **U** (they are eventually products of two cascades initiate respectively by σ^{70} and σ^{S}). Linear approximation of vectors **P** and **U** through scalar r is firmly supported by the fact that sigma factors turn on/off simultaneously the entire group of genes (at least 70 under stress and probably higher number of genes under normal growth conditions). Finally the coupling between starvation and other forms of stress justifies our selection for formulae $r(\overline{s})$ as a main link between the state of environment and cell composition. This fact also explains old observations that any stress-resistance is expressed in a higher degree in starving cells as compared with cells actively growing in a rich nutrient media.

Contrary to all known chemostat models, SCM provides adequate simulation of D-dependent variation of microbial physiological state. Under energy- and C-limited growth, it was expressed as an increase of apparent K_{s}, potential uptake and respiration rates, maintenance ratio, and turnover parallel to increase of D. Under N limitation, a similar trend was complemented by considerable decrease of Y_{N} due to alteration of cell composition in favor of N-rich P-components (Fig. 17.7). SCM adequately describes the transient growth caused by shift-up in chemostat culture. The phenomena of overshoot in substrate concentration and undershoot in biomass during

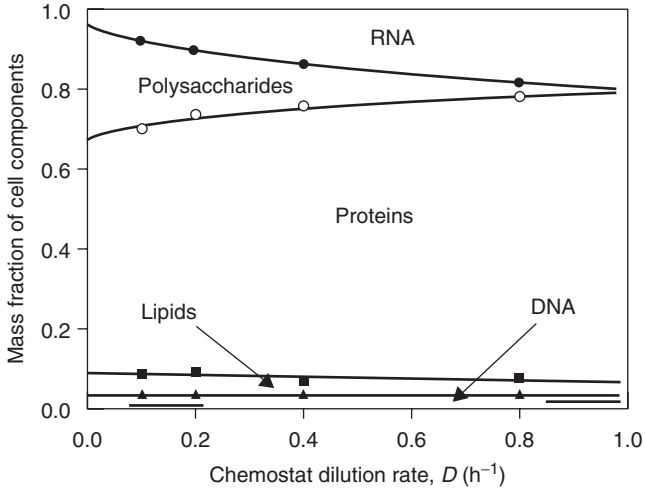


Figure 17.7. Simulation of D-dependent changes in cell composition of *Aerobacter aerogenes* grown in NH_4^+-limited chemostat culture. The curves are calculated from SCM (2), the original experimental data are from Ref. 69.

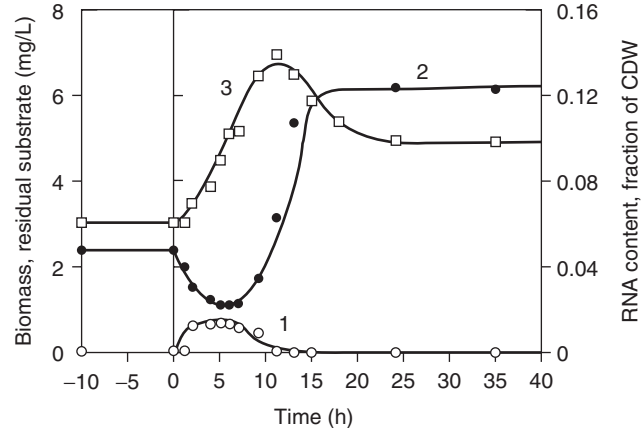

Figure 17.8. SCM simulation of transient growth induced by change of chemostat dilution rate. Residual glycerol concentration (1), biomass (2) and cell RNA content (3). At $t = 0$ dilution rate was shifted from 0.004 to 0.24 h^{-1}. Redrawn from Ref. 2, the original data (69) are for chemostat culture of *A. aerogenes* limited by glycerol.

transient growth are explained by slow adjustment of cell composition (RNA content, respiratory activity) to new growth conditions (Fig. 17.8). Batch culture limited by carbon and energy source was simulated by SCM on the whole from inoculation to death stage; conventional growth phases (lag, exponential, deceleration, stationary, decline) were generated automatically without setting any specific conditions (Fig. 17.9). It is important that SCM realistically describes and predicts not only net growth but also the survival dynamics of starving cells after substrate depletion. During this phase, surviving bacteria sustain very slow cryptic growth at the expense of cell turnover and metabolites leakage. The rate of decline in biomass gradually decreases as the result of buildup of some U-components (parallel to the decrease of such P-components as ribosomes and CN-sensitive respiration enzymes). Batch culture limited by conserved substrate (the source of N, P, Mg, Fe, or other) has an interesting feature: the growth is not stopped after substrate depletion but proceeds at an even higher rate. SCM explains this phenomenon by the partitioning of deficient elements between mother and daughter cells.

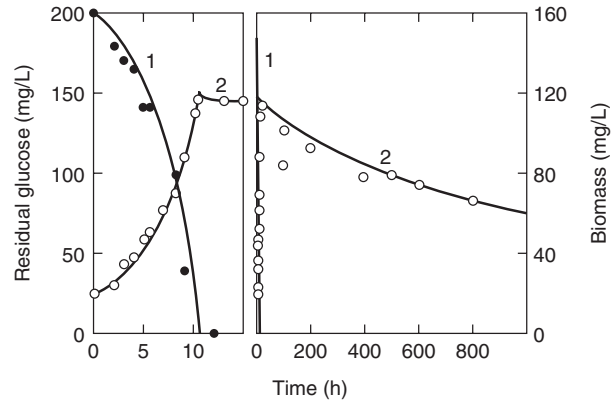

Figure 17.9. SCM simulation of complete dynamic curve of batch culture: residual glucose (1) and biomass (2) of yeasts *D. vanrijiae* (old name *D. formicarius*) grown on glucose-mineral medium (2). Note that contrary to old empirical models (Eq., 17.56, Table 17.9), all growth phases are reproduced automatically without specifying preset time ranges.

17.5.4 Cell Cycle

The term *cell cycle* is used to designate the regularly repeated sequence of events that occur between consecutive *cell divisions*, for example, the formation of two identical daughter cells from one cell, which takes place in most known bacteria. Equivalent cell cycle events include *budding* (most yeasts and budding bacteria), *branching of hypha* (filamentous organisms), *fragmentation* (actinobacteria). The majority of available data have been obtained for rod-shaped bacteria (*E. coli, Salmonella typhimurium, Bacillus cereus*) under steady-state growth conditions when the cell cycle consists of three distinct phases:

1. The growth of the newborn cell without chromosome replication from the initial mass m_0 until some critical initiation mass m^*
2. DNA replication (C period)
3. Separation of daughter cells (D period).

17.5.4.1 Relationship between Cell Size and Specific Growth Rate. The periods C and D are constant and occupy in the case of *E. coli* about 40 and 20 min

respectively independently of environmental conditions. However, the duration of the first phase does depend on cultivation conditions: the time of the single-cell mass increase from m_0 to m^*, is inversely related to the specific growth rate, μ. It is this difference that yields μ-dependent variations of cell sizes, because faster-growing cells produce for the same $\tau = C + D$ time bigger cell mass than do slower growing cells. It became clear from the following simple algebra:

The steady-state growth of an individual cell proceeds exponentially throughout the entire cell cycle [$m = m_0 \cdot \exp(\mu t)$]. At the time of the second part of the cycle it takes exactly τ min for the cell to enlarge from critical mass m^* to $2m_0$: Hence

$$2m_0 = m^* \cdot \exp(\mu\tau) \Rightarrow m_0 = 0.5m^* \cdot \exp(\mu\tau) \quad (17.87)$$

Equation 17.87 remains to be valid for steady-state culture at any μ which can be varied from 0 to μ_m. Assuming that cell critical mass m^* is constant and does not depend on growth rate, we see that Equation 17.87 predicts μ-dependent variation mass of newborn cells m_0 and hence the average mass and size of the bacterial population. This finding is supported by numerous experimental studies from the beginning of this century (70) that displayed the positive correlation between cell size and growth rate. Because the term $\mu\tau$ is rather small ($\mu\tau \leq \mu t_d = \ln 2$), it is difficult to notice the exponential curvature of the experimental curve. Thus, a linear approximation is frequently used to relate the average cell size $\overline{m}$ ($\overline{m} \approx m_0 \cdot 2 \cdot \ln 2$ for rod-shaped bacteria, see derivation below) and μ:

$$\overline{m} = \overline{m}(0) + k\mu \quad (17.88)$$

The regression parameters $\overline{m}(0)$ and k have meaningful biological interpretation: y-intercept, $\overline{m}(0) \approx (\ln 2)m^*$ is equal to approximately 69% of the cell critical mass m^* initiating chromosome replication, and slope $k = [\exp(\mu_m\tau) - 1]/\mu_m \approx \tau$, is close to the duration of C + D periods.

The postulate on the constancy of the critical mass, m^* was derived from the observation that the cell has accurate control over its size-at-division and poorer control over its age-at-division (71). Recently, accurate measurements with flow cytometry (72) revealed that m^* is inversely related to the specific growth rate; slowly growing cells tend to initiate DNA replication at a slightly higher critical mass as compared with intensively growing cells. However, we may safely assume that m^* variation is much smaller than the variation of cell mass during the cell cycle: $dm^*/dt \ll dm/dt$.

17.5.4.2 Simulation of Cell Cycle by Simple Deterministic Structured Model. In biochemical terms, it is difficult to envisage how cell mass *per se* could determine when to initiate replication. A more likely candidate is some mass-related parameter, such as intracellular concentration of some signal metabolite like *initiator protein*, according to the popular model proposed by Helmstetter and Cooper (15,73). It was postulated that the initiation of DNA replication is triggered by a threshold intracellular concentration of protein V^*, this protein is synthesized at a rate proportional to the total growth rate and requires exactly one mass doubling time to reach its threshold concentration again. This mechanism is translated into mathematical form of structured model such as SCM as follows (2):

$$\frac{dV}{dt} = \Theta(\mu + a) - \mu V$$

$$\frac{d\lambda}{dt} = \zeta \begin{cases} \text{if } V \geq V^* \text{ then } \zeta = \zeta_1 > 0 \text{ else } \zeta = 0 \\ \qquad\qquad \text{(initiation)} \\ \text{if } \lambda \geq \lambda^* \quad \text{then} \quad \lambda = \lambda/2, \quad V = 0, \quad m = m/2 \\ \qquad\qquad \text{(division)} \end{cases} \quad (17.89)$$

where Θ is the fractional contribution of protein V to total cell synthesis. The V content is an intrinsically transient entity: even during steady-state growth, it continuously changes between zero (Helmstetter and Cooper postulated the annihilation of the initiator protein after every replication cycle) to an upper threshold value, V^* which is less than the potential steady-state level, $\Theta(\mu + a)/\mu$. The second variable, λ imitates the replicating chromosome: it sets up the discontinuity associated with cell division.

Analysis of coupled equation set 89 reveals that this model is stable toward perturbations. Suppose that by chance, the content of initiator protein has risen to some abnormally high level. The immediate result would be several more frequent cell divisions with smooth reversal to normal multiplication pace. Similar events take place under the opposite situation of V deficiency: several divisions are delayed resulting in production of abnormally long cells, but then steady state is restored. The negative feedback mechanism that brings things back into line is based on the dynamic nature of variable V: it is characterized by unique stable steady state that is approached from different initial conditions.

It may be easily shown that the described model adequately simulates various morphological effects exhibited during non-steady-state growth (Table 17.10).

17.5.5 Statistical Analysis of the Population Distributions

Equations 17.87–17.89 were derived by using deterministic approach, which assumes that all cells in the microbial population are exact copies of each other and their division is

TABLE 17.10. Morphological Effects during Non-Steady-State Growth

Effects	Explanation
The longer lag phase in batch culture when growth is surveyed by cell count rather than biomass measurements	The partial synchronization of cell division is delayed as compared with mass growth until attainment of the value $2m$
The accumulation of enlarged cells during transition from lag to exponential growth phase	The $\mu-m$ relationship (Eq. 17.87) combined with the transient misbalance in V synthesis (Eq. 17.89)
The formation of dwarf cells in starving population	The small cells are produced during very slow cryptic growth of surviving organisms
The accumulation of division potential if division is blocked by inhibitor, then after block release all missing division takes place in quick sequence	This phenomenon is simulated by Equation 89 and explained by overproduction of initiator protein in the presence of inhibitor

completely asynchronous. However, real culture is always heterogeneous, individual cells differ in size, age, metabolic activity and cellular composition. Experimental assessment of heterogeneity became possible due to rapid advance of analytical tools such as computer-aided microscopy, flow cytometry, electronic count and sizing of cells with Coulter counter.

There are two possible approaches to the mathematical description of age heterogeneity: the discrete approach, where several age groups of cells are introduced, and the continuous approach, which utilizes the *distribution function* of cells by age (74). The first approach is usually applied to multicellular organisms (plants and animals) whose individual age can be instantly determined; it is often based on use of matrix notation, for example, Leslie matrices (75,76). For bacteria, direct estimation of individual cell age (i.e. how many minutes ago given cell was born by a binary division) is practically insolvable task. Newborn cells are generally smaller than mature cells just before their division but the cellular sizes depend not only on age but also on the quality of nutrient medium and other factors. Therefore, the most fruitful approach in microbial kinetics is to deal with mathematically derived continuous *age distribution functions* of cells and then relate them to experimentally measured size distribution function based on various hypotheses on cellular division.

McKendrick (77) and later von Foerster (78) introduced the *age density function* $n(t, \tau)$ of bacterial cells as follows: consider population containing $N(t)$ cells. Select all those cells which, at time t, have ages between τ and $\tau + \Delta\tau$. Let their number be $\Delta N_\tau(t)$. Then the age density function is defined as the limit:

$$\lim_{\Delta\tau\to 0} \Delta N_\tau(t)/\Delta\tau = n(t, \tau)$$

It has the property that

$$N(t) = \int_0^\infty n(t, \tau)\, \mathrm{d}\tau$$

The von Foerster equation (78,79) states that

$$\frac{\partial n(t, \tau)}{\partial t} + \frac{\partial n(t, \tau)}{\partial \tau} = -\lambda \cdot n(t, \tau) \tag{17.90}$$

where λ is cell loss function, the initial age distribution $\beta(\tau) \equiv n(0, \tau)$ and cell birth rate $\alpha(t) \equiv n(t, 0)$

von Foerster equation remains too abstract, as it does not show explicitly the effect of environmental conditions, such as limiting substrate concentration. This gap has been filled in by introducing the age distribution function into chemostat model (74):

Modified Von Foerster equation

$$\frac{\partial n}{\partial t} + \frac{\partial n}{\partial \tau} = -(w + D)n(t, \tau) \tag{17.91}$$

Cell proliferation

$$n(t, 0) = 2\int_0^\infty wn(t, \tau)\, \mathrm{d}\tau \tag{17.92}$$

Initial age distribution

$$n(0, \tau) = \Gamma(\tau) \tag{17.93}$$

Total cell concentration

$$\frac{\mathrm{d}N}{\mathrm{d}t} = \int_0^\infty wn(t, \tau)\, \mathrm{d}\tau - DN \tag{17.94}$$

Limiting substrate concentration

$$\frac{\mathrm{d}s}{\mathrm{d}t} = -\int_0^\infty \rho n(t, \tau)\, \mathrm{d}\tau + D(s_r - s) \tag{17.95}$$

where w and ρ are specific rates of cell division and substrate consumption, D is dilution rate and s_r is substrate concentration in the medium feed.

Numeric solution of the normalized set of Equations 17.91–17.95 displays a number of new counterintuitive properties observed in some chemostat experiments but not reproduced by a nonstructured and nondistributed chemostat model (Eq. 17.62 above), such as spontaneous synchronization of cellular divisions and oscillations in residual limiting substrate and cell density after abrupt changes in D.

Equations 17.90–17.95 deal with age distribution of microbial (mostly rod-shaped bacteria) cells. Now we will look to relationship between cellular age and size. If certain conditions are met, the culture is fully desynchronized, cells grow according to some deterministic low, all divide into two and only two identical daughter cells, and there are no cell elimination, then age distribution is given by (71)

$$\phi(\tau)\mathrm{d}\tau = 2\mu e^{-\mu\tau}\mathrm{d}\tau : 0 \le \tau \le \ln 2/\mu = t_d, \qquad (17.96)$$

where μ is specific growth rate, t_d is mean doubling time, τ is the age since birth, and $\phi(\tau)\mathrm{d}\tau$ is the frequency of cells whose ages are between τ and $\tau + \mathrm{d}\tau$.

Assuming that cells grow exponentially between divisions, then the frequency of mass distribution is

$$\phi(m)\mathrm{d}m = 2m_0/m^2\mathrm{d}m : m_0 \le m \le 2m_0, \qquad (17.97)$$

where m_0 is the mass of newborn cell and $\phi(m)\ m + \mathrm{d}m$ is the frequency of cells whose masses are between m and $m + \mathrm{d}m$. The mean cell size is $2m_0 \cdot \ln 2$ (calculated as an integral of $m \cdot \phi(m)\mathrm{d}m$).

If cell growth between two consecutive divisions is linear, then (80):

$$\phi(m)\mathrm{d}m = 4 \cdot \ln 2/m_0 \exp(-m \cdot \ln 2/m_0)\mathrm{d}m : m_0 \le m \le 2m_0, \qquad (17.98)$$

Equations 17.96 and 17.97 are called *canonical* age or mass distributions to emphasize that they are an idealized form applicable when cell division takes place at a precise size. Assuming that momentary distribution of size-at-division of individual cells is *normal* and *random* (not correlated with other cell cycle events), we can obtain computer-simulated curves for any fixed level of noise expressed as the coefficient of variation (CV). As shown in Fig. 17.10, random variations of size-at-division tend to round the corners of the canonical distribution.

Another source of cell size variation can be nonequal separation of mother cells into two daughter cells. It is characterized by the K-distribution which is the distribution of the ratio of daughter cell length to mother cell length. The average values absolutely necessarily equals 0.5, but CV is at best about 4% (e.g. for well-behaved *E. coli* strains) and can attain rather high values for other organisms. The deviation of observed versus predicted size distribution may be caused also by cell death and different kinds of cell pathology (abnormally long or dwarf cells).

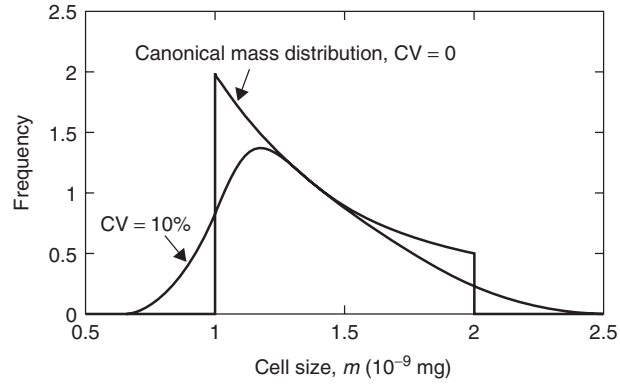

Figure 17.10. Distribution of cell sizes (as single-cell mass) for canonical case where there is no variation in the size-at-division and for the case of normal distribution of size-at-division with CV = 10% (see details in Ref. 71).

Collins and Richmond (81) introduced an entirely different approach based on the use of three distributions:

$$v_m = \mu\left\{2\int_0^m \Psi\mathrm{d}m - \int_0^m \phi(m)\ \mathrm{d}m - \int_0^m \lambda(m)\ \mathrm{d}m\right\}/\lambda(m) \qquad (17.99)$$

where V_m is growth rate of cells of size m, $\lambda(m)$ is the extent population distribution, Ψ is the momentary distribution of dividing cells, and $\phi(m)$ is the momentary distribution of newborn cells. This equation allows the calculation of the mean growth rate of cells of particular size class. Instead of this analytical method, Koch in his work with Shaechter (71) proposed the synthetic approach. Starting from the set of specific postulates of the cell multiplication mechanism (linear or exponential growth of cell mass between divisions, kind of control, the evenness of the division) they derived the size or age distribution which then was compared with the observations.

17.5.6 The Growth Law

Some believe that there should be a general law of cell growth that can be discovered by sensitive methods of analysis. The rate of biomass growth throughout the cell cycle was hypothesized to be linear, bilinear, exponential, double-exponential, and so on. Two limiting cases have generally been considered: the exponential and linear growth models proposed respectively by Cooper and Kubitschek (71). To differentiate between these two mechanisms three classes of experiments have been used:

1. Size measurements of individual cells growing in the microculture by use of phase contrast microscopy

or recently developed confocal scanning light microscopy combined with image analysis.

2. Pulse-chase labeling of cells with their subsequent separation into different phases of the cell cycle. Most frequently, labeled uracil and leucine are used as precursors of RNA and protein synthesis respectively. There are two major sources of errors in this approach: poor resolving power of separation methods and artifacts associated with effects of exogenous compounds on intracellular fluxes (feedback inhibition, pool expansion, label dilution, etc.). One of the best options for separation is probably the "baby machine" based on membrane elution principle (73). To minimize the second source of error, the mutants blocked in the synthesis of the probe compound can be used.
3. Analysis of the frequency distributions of steady-state populations (Eqs 17.91 and 17.92). However, the resolving power of this approach is rather low because linear and exponential models produce similar patterns.

Most of the obtained results are in better agreement with the exponential growth model rather than with the linear model. However there are some serious doubts about whether there is a unique simple mathematical growth law describing bacterial growth during the division cycle. Cooper (73) proposed distinguishing three categories of cell components that are synthesized with a unique pattern:

1. Cytoplasm (proteins, RNA and ribosomes, small molecules) that are accumulated exponentially
2. Cell DNA that is replicated in a linear fashion as a sequence of constant and zero rates
3. Cell surface composed of peptiodoglycan and membranes that are synthesized exponentially during most parts of the cell cycle but immediately before cell division the synthesis accelerates to accomplish new pole formation.

Thus, the growth pattern of the whole cell is the sum of these three patterns. Because the cytoplasm is the major constituent (up to 80% of CDW), the growth of the cell should be approximately exponential.

17.6 POPULATION DYNAMICS (MUTATIONS, AUTOSELECTION, PLASMID TRANSFER)

17.6.1 Description of Mutation and Autoselection

The continuous culture turned out to be very efficient tool to study mutation and autoselection (82). Let N be the total cell concentration, M the concentration of mutants, μ the specific growth rate of the main nonmutated part of the cell population and η the specific growth rate of neutral mutants, then

$$\frac{dM}{dt} = \lambda\mu N + \eta M - DM,$$
$$\frac{dN}{dt} = \mu N - \lambda\mu N - DN \qquad (17.100)$$

where λ is the mutation rate expressed as the ratio of the numbers of mutants to total number of cells formed. If $\lambda \ll 1$ and $\mu = \eta$, in the steady state, we obtain, $\mu = \eta = D$, and

$$\frac{dM}{dt} = \lambda N D \quad \text{or} \quad M = M_0 + \lambda D N t. \qquad (17.101)$$

If $\eta > \mu$, then the original strain will be displaced by the mutant, otherwise, if $\eta < \mu$, M will tend to a lower limit $M^* = \lambda N/(1 - \eta/D)$.

Experimental studies of phage resistant mutants in a tryptophan-limited chemostat culture of *E. coli* showed that the period of linear M increase in accordance with Equation 17.95 was fairly short. Every 20–100 generations there was an abrupt fall in the number of mutants, after which the linear growth resumed at the same rate (82). The observed "sawtooth" dynamics in M were explained by Moser (52) as a combined effect of mutation and selection. The original wild clone gives not a single but a whole array of mutations with subsequent reversions. Let us denote the total cell population in a chemostat culture as N, which is the sum of all subpopulations including original and emerging variants, $N = \sum N_i$. All possible transitions between variants are given by the matrix, $\lambda_{i\to j} (j = 1, \ldots, n; i = 1, \ldots, n; j \neq 1)$. Then the chemostat model takes the following form

$$\frac{dN}{dt} = \sum_{j=1}^{n} \frac{dN_j}{dt} = \overline{\mu}(s)N - DN, \quad \overline{\mu} = \frac{1}{N}\sum_{j=1}^{n} \mu_j N_j,$$
$$\frac{dN_j}{dt} = \mu_j(s)N_j - DN_j - \sum_{i\neq j}^{n} \lambda_{j\to i} N_j + \sum_{j\neq i}^{n} \lambda_{i\to j} N_i, \qquad (17.102)$$
$$\frac{ds}{dt} = D(s_0 - s) - \sum_{j=1}^{n} \mu_j(s) N_j / Y_j,$$
$$\mu_j(s) = \mu_m \frac{s}{K_{sj} + s}$$

Every drop in the "sawtooth" dynamics of neutral mutants detected by their phage-resistance can be interpreted as the appearance of other types of spontaneous mutant with higher growth capabilities. In a chemostat culture, such mutants overcompete and displace all other cells by virtue of their higher affinity to limiting substrate (a decreased K_s value). Let such a mutant be denoted by

the subscript k and $\overline{\mu}(s)$ be the average growth rate of all other subpopulations. The selection pressure for this mutant, σ, is given by

$$\frac{\mathrm{d}(M_k/N)}{\mathrm{d}t} = \sigma\frac{M_k}{N} = [\mu_k(s) - \overline{\mu}(s)]\frac{M_k}{N}. \qquad (17.103)$$

If $K_{sk} < K_{sj} (j \neq k)$, then $\sigma > 0$ until a new equilibrium is established. In this process, the original cells will be displaced by the mutants, and the growth-limiting substrate concentration will decrease from $\overline{s}_1 = DK_{sj}/(\mu_m - D)$ to $\overline{s}_2 = DK_{sk}/(\mu_m - D)$, and the culture density will rise by $Y(\overline{s}_1 - \overline{s}_2)$.

17.6.2 Autoselection in Turbidostat and pH-Auxostat

The affinity to substrate was not always the only driving force of selection outcome. A number of instructive examples were reviewed by Pechurkin (37)

1. In turbidostat and pH-auxostat, autoselection is in favor of mutants with higher maximum specific growth rates, $\sigma = \mu_{mk} - \mu_{mj} > 0$. Because the population density is kept constant instrumentally and the dilution rate is allowed to vary, then autoselection results in the increase in D from μ_{mj} to μ_{mk}.
2. Mutation toward a higher growth efficiency, $Y_k > Y_j$, will lead to the same result as an increase in μ_m : $\sigma = \mu_k - \mu_j = (\mu_{mk} - \mu_{mj})s/(K_{sj} + s)$, as soon as $\mu_k = q_s Y_k$ and $\mu_j = q_s Y_j$.
3. Growth of a mutant with a higher resistance to inhibitory metabolic products can be described by Equation 17.77 with $K_{pk} > K_p$. Under selection pressure $\sigma = \mu_k - \mu = \mu_m \frac{s}{K_s+s}\left(\frac{K_{pk}}{K_{pk}+p} - \frac{K_p}{K_p+p}\right)$ the original population will be completely displaced, and the product concentration will reach a higher steady-state level, $\overline{p} = \mu_m K_{pk}\overline{s}/(K_s + s)D - K_{pk}$.
4. A mutation resulting in enhanced adhesion to fermentor walls will lead to accumulation of slow-growing cells (as the adhesion prevents washout), eventually we have $\sigma = \mu_k + D - \mu_j$.

17.6.3 Extrachromosomal Cell Elements (ECE)

The present-day "hot spot" in microbial population genetics is the study of such ECE as plasmids, phages, transposons, and insertion elements. Normally ECEs do not carry genes, absolutely essential for growth, but they improve stress-resistance of host cells, thus according to SCM (see section titled "Structured models"), ECEs should be identified as U-components. Indeed, experimental data and mathematical simulation of plasmid replication in *E. coli* including turnover of plasmids, transcription and translation activities of the host cell (83) confirmed decrease of plasmid number with growth rate.

The best-studied R-plasmids are responsible for bacterial growth in the presence of antibiotics, but under normal conditions (with no antibiotics present) their synthesis becomes too heavy a burden for the host cell, which is manifested in a decreased growth rate (84). Among more than 100 R-factors studied, about a quarter were found to increase the bacterial generation time by 15% (85). For this reason, plasmid-bearing strains are unable to compete with plasmid-free populations, although there are a few exceptions. Thus, colicin-positive cells carrying respective plasmids are able to withstand the competition with faster-growing plasmid-free strains by virtue of antagonistic inhibition. In recent years, various dynamic models of autoselection have been proposed that take into account the ECE-related effects, including the transfer of ECEs within the population, their segregation loss, changes in μ arising from the ECEs carriage, and so on. Some of these models have interesting biotechnological and medical applications (86).

17.7 MICROBIAL GROWTH IN VARIOUS CULTIVATION SYSTEMS

The array of laboratory cultivation systems that define the dynamic patterns of microbial growth is summarized in Table 17.11. Microbial growth patterns are distinguished by three features:

- Regime of substrate supply (1, continuous supply; and 2, single-term addition)
- Elimination of growing microorganisms (α, yes; β, no)
- Magnitude of spatial gradients (a, homogeneous systems; b, heterogeneous systems).

Each specific cultivation procedure can be represented by a point inside a cube with the axes 1 to 2, α to β, and a to b. The 2b combination is logically forbidden because, any spatial segregation results in protracted substrate utilization and so transforms a batch process into a continuous one. The dynamics of microbial growth in any type of cultivation system can be described by the following mass–balance equations:

$$\begin{aligned} \frac{\mathrm{d}s}{\mathrm{d}t} &= F - G(s) - \mu(s)x/Y - mx, \\ \frac{\mathrm{d}x}{\mathrm{d}t} &= V - H(x)x + \mu(s)x, \end{aligned} \qquad (17.104)$$

where F is the substrate input rate; $G(s)$ is the rate of unused substrate removal from cultivation vessel (washout, leaching, evaporation, etc.); V is the rate of microbial

TABLE 17.11. Matrix of Cultivation Techniques

	Substrate Input			
	Continuous (1)		Single-term (2)	
Spatial Organization	Cell Eliminated (α)	No Elimination (β)	Cell Eliminated (a)	No Elimination (b)
Homogeneous (a)	$1a\alpha$ Chemostat Turbidostat pH-auxostat abd bistat	$1a\beta$ Chemostat with recycle Fed-batch Dialysis culture	$2a\alpha$ Phased culture	$2a\beta$ Simple batch
Heterogeneous (b)	$1b\alpha$ Plug-flow (tubular culture) Colonies	$1b\beta$ Column packed with microbe attached	Forbidden combination	

biomass input, which may be a single-term inoculation or continuous delivery of cells to the fermentor (specially designed or unintentional, e.g. contamination); and $H(x)$ is the rate of microbial elimination, such as washout, death, grazing, or lysis. The rest of the notation is conventional. To simulate microbial growth dynamics in a particular homogeneous system, one has to make the following selection: $F(t) = 0, s_0 > 0$ for a category 2 (batch culture), $F(t) > 0$ for category 1 (continuous cultivations); $H(t) = 0$ for systems retaining cell biomass (dialysis, fed-batch, simple batch, column with immobilized cells), and $H(t) > 0$ when cell elimination occurs (chemostat, turbidostat, phased culture, etc.)

Spatially heterogeneous systems can be simulated either by partial derivatives or compartmental models (e.g. the total biomass x of a microbial colony may be represented as a sum of the peripheral and central components).

17.7.1 $1a\alpha$—Homogeneous Continuous Culture (Continuous-Flow Fermentors with Complete Mixing)

There are two subgroups within this type of cultivation technique. In the first one, steady-state growth is maintained naturally by the microbial culture itself. Self-regulation is performed through negative feedback that originates from the dependence of the growth rate on substrate concentration (chemostat) or on temperature (caloristat). In the second group, electronic devices are used for the automatic adjustment of dilution rate to the instantaneous growth rate of the microbial culture. Electronic control is based on the sensing of cell density or growth-linked products, that is, optical density in turbidostat (87), culture liquid viscosity in viscostat (88), CO_2 concentration in output air in CO_2-auxostat (89), dissolved oxygen tension in pO_2-auxostat (90), culture pH in pH-auxostat (91), and so on.

In theory, the steady-state growth may be established in chemostat between 0 and μ_m, but in practical terms neither very low nor very high values are attainable because of the long time needed to reach the steady state in the first case and the risk of culture washout in the second. The second group of continuous techniques (turbidostat, pH-auxostat, viscostat, etc.) are capable of maintaining steady growth at high s when either $\mu \to \mu_m$ or under substrate inhibition, when $d\mu/ds < 0$. The most popular device among them is definitely pH-auxostat; its advantage is based on the following beneficial features: (i) low cost and availability of pH control, (ii) short response time, (iii) no interference from wall growth (as in turbidostat), (iv) possibility to use clear and opaque media. There is also a potpourri mixed technique known as the *bistat* (92), which combines a chemostat and a pH-auxostat. Bistat provides widest range of cultivation conditions from a limited ($0.05\mu_m < \mu < \mu_m$) to unlimited growth ($\mu \sim \mu_m$) as well as growth under substrate or product inhibition.

The mass–balance equations for the chemostat and its modifications have already been given (Eqs 17.62–17.64). In a simple, complete mixing cultivator, all cells have an equal probability of being washed out, hence $\mu = D$. If there is substantial wall growth, biomass retention, or feedback, then $\mu < D$; this difference increases with the extent of biomass retention in the fermentation vessel. In terms of our scheme, such cultivation systems correspond to points on the edge $1a\alpha$ to $1a\beta$.

In recent years, chemostat has been used under deliberately nonstationary conditions. For example, A-stat (acceleration-stat) was proposed which provides linear increase in dilution rates from minimal values to D_{crit} (93–95). If D-acceleration rate is low enough (from 0.02 to 0.001 h^{-2}), then the entire transition dynamics of continuously growing microorganisms remains smooth which greatly accelerates the full-range screening of studied strains in continuous culture. Moreover, the response of culture to D-changes provides valuable additional information relevant to real-life of biotechnological applications which are seldom maintained under perfectly stationary conditions. Another non-steady-state version of chemists was called D-stat because dilution rate is maintained constant while one of other environmental parameters (temperature, pH, pO_2, concentration of inhibitors, and so on) is varied in linear or nonlinear

fashion (93). Such technique may be useful in modern biotechnological studies aimed at selection of bioagents under extreme conditions.

17.7.2 1$a\beta$—Continuous Cultivation without Cell Washout

This group embraces cultures with batch or continuous dialysis, fed-batch culture (FBC), and batch culture with a supply of limiting substrate via the gas phase (gases and volatile compounds). It also includes the chemostat with complete biomass feedback by means of filtration (9). The limiting substrate is supplied into the dialysis culture through a semipermeable membrane and, in the case of a gaseous nutrient, through the gas–liquid interface. In both cases, mass transfer is reasonably well described by Fick's law. Substrate delivery via dialysis membrane is cheaper but slower than filtration, filters (even with tangential flow) tend to be easily plugged with cells than dialysis membrane—these factors should be considered before a final choice of the cell retention method. The culture volume remains fixed in all systems, with the exception of a FBC. In a FBC, a constant nutrient feed F provides a linear increase of culture volume V during the cultivation span; the dilution rate $D = F/V$ is decreased hyperbolically. The great advantage of these cultivation techniques for biotechnology is that they provide the possibility of realizing very slow continuous growth accompanied with derepression of synthesis of many secondary metabolites. With a constant limiting substrate flux, Fs_r, the absence of cell washout means that at each subsequent moment an equal ration is shared by an increasing microbial biomass, and, as a result, μ eventually falls down to negligible values or even to zero (the maintenance state). Unlike the chemostat, no true steady state is established in this case, but when the substrate is virtually depleted, we have $ds/dt \sim 0$ and the system reaches a quasi–steady state (6). If a quasi–steady state approximation is found to be sufficient, then extremely slow continuous growth can be obtained after a reasonable period of time, perhaps a few weeks, as compared to the several months needed in a chemostat.

17.7.3 2$a\alpha$—Continuous Cultivation with a Discontinuous Supply of Limiting Substrate

Suppose we have a simple chemostat culture fed by nutrient medium lacking just one essential component. This component is added as a small volume of concentrated solution at regular and sufficiently large time intervals, Δt. Then

$$\frac{ds}{dt} = D[s_r(t) - s] - q(s)x, \quad \frac{dx}{dt} = \mu(s)x - Dx, \tag{17.105}$$

$$s_r(t) = \begin{cases} A > 0, & \text{when } t = i\Delta t,\ i = 0, 1, \ldots, n \\ 0, & \text{otherwise} \end{cases}$$

This cultivation method was originally used to obtain synchronized cell division (96). A continuous phased culture (97) is a repeated simple batch culture, that is, at regular intervals, Δt, half of the culture volume is withdrawn and the fermentor is refilled with an equal volume of fresh medium. Under such conditions, repeated batchwise growth proceeds with biomass increasing cyclically from x_0 to $2x_0$. Obviously, the growth dynamics are governed by the time interval between consecutive substrate additions Δt. If $\Delta t < \ln 2/\mu_m$, a sawtooth nonlimited growth takes place as in a turbidostat. With $\Delta t < \ln 2/\mu_m$ the culture should be washed out and, when $\Delta t > \ln 2/\mu_m$, the maximal attainable biomass decreases with increasing Δt because of endogenous biomass decomposition and waste respiration during the lag phase.

17.7.4 2$a\beta$—Simple Batch Culture

Cultivation begins at the initial limiting substrate concentration, s_0, and inoculum size, x_0. The biomass reaches its maximum, x_m, when the limiting substrate is depleted, $s = 0$, and then declines even in the absence of exogenous elimination, so that $x \to 0$ as $t \to \infty$ Description of batch dynamics has been given earlier: specified growth phases are described by simple nonstructured models (Eq 17.56), while entire dynamics—by SCM and other structured models (Eqs 17.84–17.86, Fig. 17.9).

17.7.5 1$b\alpha$—Plug-Flow (Tubular) Culture

The inoculum and the medium are mixed on entry into a long reactor tube and the culture flows in the tube at a constant velocity without mixing. In each small element of culture liquid, moving along the spatial coordinate z at a linear velocity $f = F/A$ (where F is flow rate, cubic centimeter/hour, and A is the cross-section area, cubic centimeter), growth of biomass proceeds as in a simple batch culture. To account for the culture movement *per se*, we have to pass from ordinary to partial derivatives and replace dx/dt by $\partial x/\partial t + f\partial x/\partial z$ ("along-the flow-growth rate"). Allowing in addition for some dispersion of the moving front by diffusion, we can write (98)

$$\frac{\partial s}{\partial t} + f\frac{\partial s}{\partial z} = D_s\frac{\partial^2 s}{\partial z^2} - q(s)x$$
$$\frac{\partial x}{\partial t} + f\frac{\partial x}{\partial z} = D_x\frac{\partial^2 x}{\partial z^2} + \mu(s)x \tag{17.106}$$

where D_s and D_x are the diffusion coefficients of the substrate and microbial cells, respectively.

17.7.6 1$b\beta$—Continuous-Flow Reactors with Microbes Attached

The nutrient solution is pumped through column filled with adsorbent material and is utilized as it moves by growing

immobilized cells. The mass balance equations for a packed column are obtained from Equation 17.106 by simplifying the equation for x,

$$\frac{\partial s}{\partial t} + f\frac{\partial s}{\partial z} = D_s\frac{\partial^2 s}{\partial z^2} - q(s)x(z)$$
$$\frac{\partial x}{\partial t} = \mu(s)x = Y[q(s) - m]x \qquad (17.107)$$

Bacterial cells accumulate faster on the top of the column because of larger $q(s)$ values and as a result, a distinctive spatial biomass distribution develops in the form of an hyperbolic decrease of x with column depth. Growth does not reach steady state with respect to x until cell elimination becomes well expressed (the effects of inhibitory products, endogenous cells decomposition, and leaching).

17.7.7 1*bα*—Colonies

Besides continuous-flow columns, other heterogeneous systems are widely used. Especially popular is plating on solid media made from natural or synthetic gels (agar, PAAG, silica gel, synthetic alumosilicates, etc.) as well as on some porous materials (sand, glass beads, glass fiber). Impregnated with nutrient solution, such materials are used to grow microorganisms in the form of colonies or lawns.

At first glance, it is tempting to consider these techniques as analogies of a simple batch culture with single-term substrate input (type 2*bβ* in Table 17.11). However, a closer look at the mechanism of colony growth reveals a greater resemblance to chemostat culture. Here we will outline our considerations.

The spread of a colony over a solid substrate, for example, a layer of agar, proceeds by the growth of only a peripheral zone with biomass, x_p (Fig. 17.11). Then

$$\frac{ds}{dt} = -q(s)x, \quad \frac{dx}{dt} = \mu_w x_p - ax, \qquad (17.108)$$

where a is the specific decay rate of cellular components. Straightforward geometrical analysis shows that the linear spread rate for a regularly shaped colony (a cylinder, a sphere, or a strip) of size R is given by the following relation (2,6):

$$\frac{dR}{dt} = \mu_w w = K_r, \quad \text{or} \quad R = R_0 + K_R t, \qquad (17.109)$$

where K_r is the colony linear expansion rate, millimeter/hour; μ_w is the microbial specific growth rate within the peripheral zone; and w is the zone width.

In the case of unicellular organisms (e.g. bacteria, yeasts) which are incapable of penetrating into the gel's matrix, the substrate is available through passive diffusion to the peripheral zone from the underlying gel layer. As the colony grows this flux diminishes, K_r decreases, and eventually the growth stops altogether. The filamentous organisms (fungi and actinomycetes) are able to propagate both on the surface

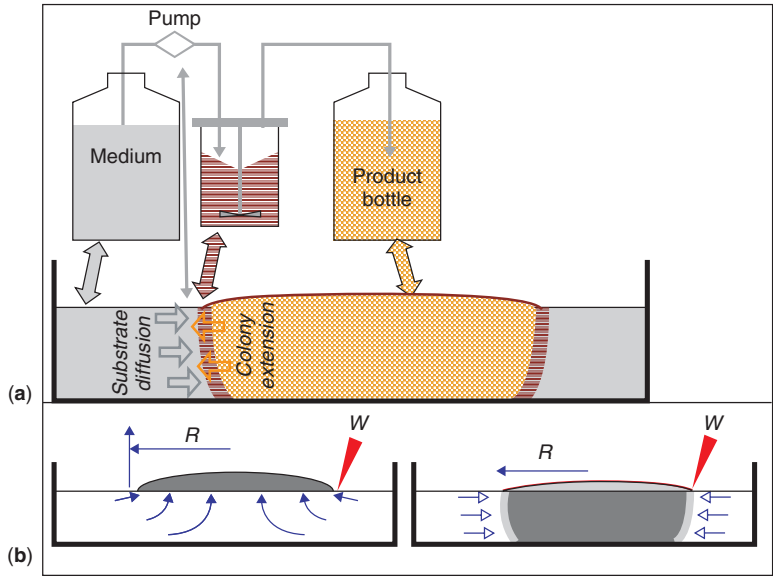

Figure 17.11. Kinetic mechanisms of colony growth (a) Illustration of the similarity between growing colony and chemostat culture (see text for explanation). (b) Schematic illustration of the difference between the growth modes of bacterial (*right*) and fungi (*left*) colonies. Note that unicellular organisms (*bacteria*) do not penetrate into the agar layer as opposed to filamentous fungi. *Arrows* indicate directions of substrate diffusion across concentration gradients. R and w are, respectively, radius and width of the peripheral zone of the colony.

and in the depth of gel. As a result, their growth is not completely dominated by diffusion effects and the colony front advances at a faster rate than substrate is depleted at the boundary zone. The colony spreads at a constant radial rate, K_r, until the Petri dish is filled or the agar deteriorates from dryness. (In the case of rich nutrient media, there are also effects of self-inhibition by metabolic products approximated by Eqs 17.76 and 17.77.)

Thus, the colony growth is (i) continuous, (ii) substrate-limited, (iii) directed, and (iv) spatially ordered. Properties (i) and (ii) suggest a strong similarity between growth of a colony (especially a fungal one) and that of a chemostat culture. If so, a colony's peripheral zone is analogous to the cell culture in the fermentor, and its central part is comparable with the waste cell suspension that is discharged into the product bottle. A steady running of a pump, delivering medium at a rate, F (cubic centimeter/hour), corresponds to the active and uniform substrate utilization by the growing mycelium at a rate $K_r A$ (cubic centimeter/hour, A is the area of colony–medium interface). Finally, both cultivation systems are characterized by the elimination of propagating biomass, that is, by the expulsion of grown cells (mycelium) from further active growth (either by washing out or by the motion of the colony front). In both cases, the elimination rate is equal to biomass growth in the active compartment. The essential deviation from the chemostat lies in properties (iii) and (iv). Spatial differentiation of hypha and the direction of colony expansion are governed by spatial gradients of limiting substrate and, possibly, some metabolic products. Steepness of gradients is partly diminished by the effects of metabolic translocation along hypha over distances of the order of w.

It can be concluded from the previous discussion that colony growth belongs to class $1b\alpha$, and not to $2b\beta$. In general, it is very likely that the $2b$ combination is an empty, logically forbidden combination, because a single-term momentary input of substrate may only be realized in a homogeneous system. Any spatial segregation whatever will actually prolong the consumption of substrate and, therefore, transform a batch process into a continuous one. For this reason, growth on any insoluble substrate (lignocellulose and other plant polymers, oil droplets, grains of sulfur, etc.) should always be treated as a continuous process. The solid-phase fermentation can also not be anything but continuous, whether new portions of substrate are added to the reactor or not (Obviously, this applies to the growth mechanism itself and not to the engineering operation.).

17.7.8 Biofilms

Microbial biofilms represent particular case of colonial growth ($1b\alpha$) on the surface of any solid material. Biofilms grow on nearly every surface that is in contact with water and humid air, even at extremely low nutrient concentrations. Their presence includes negative effects, such as biofouling and biocorrosion, but also positive effects if used in biofilm reactors for the degradation or production of chemical substances (99–101). Most often biofilms as object of biotechnological studies are formed by natural multispecies community, but recently there were reported numerous studies on laboratory biofilms prepared from pure cultures (102).

Biofilms are composed of bacterial cells embedded in extracellular polysaccharide matrix (e.g. linear polymer of *N*-acetyl-D-glucosamine residues in *E. coli*) that mediates intercellular adhesion and attachment to abiotic surfaces. Attachment and detachment of cells in biofilms is also controlled by extracellular signal molecules (quorum-sensing). Young biofilms is presented by the monolayer of cells, further growth leads to a buildup of the multilayered spatially differentiated biofilm: the peripheral surface zone facing incoming nutrients, oxygen and other essential growth factors contain the metabolically active cells, whereas the deeper submerged parts are occupied by dormant and starving and possibly intoxicated cells. The architecture of the mature biofilms can vary from flat, homogeneous biofilms, to highly structured biofilms, characterized by void spaces and towers of cells encased in an extracellular matrix (Fig. 17.12).

Generally growth rate of cells within biofilms is much lower as compared with planktonic form or agitated culture, therefore it is not surprising that gene expression profile of cells from biofilms is close to one found in planktonic cells at stationary phase (103). Many physiological features of bacteria from biofilms resemble ones in stationary phase: decreased cell size, low RNA content, resistance to antibiotics, synthesis of protective extracellular polymers and pigments. To simulate the described physiological state of cells in the biofilm, one should use structured models, for example, SCM and take into account the spatial differentiation, at least into peripheral and deep parts of biofilm.

Until now, the major focus in quantitative/mathematical description of biofilms were mass transfer through water-biofilm boundary, particularly diffusion of O_2 and antibiotics (6,104). Another focus is the modeling of physical factors responsible for observed architecture of mature biofilms. Two major modeling approaches are used: cellular automata (CA) that performs discretization of cell mass along a grid, and individual-based modeling (IbM) that represents cell aggregates as spherical particles which can absorb nutrients, grow and move in response to sheer forcing and other mechanical effects. Hermanowicz (105) used stochastic CA model; detachment of cells at the biofilm/liquid interface occurred with a given probability, defined as function of an overall shear stress and parameter quantifying biofilm strength. The deterministic description

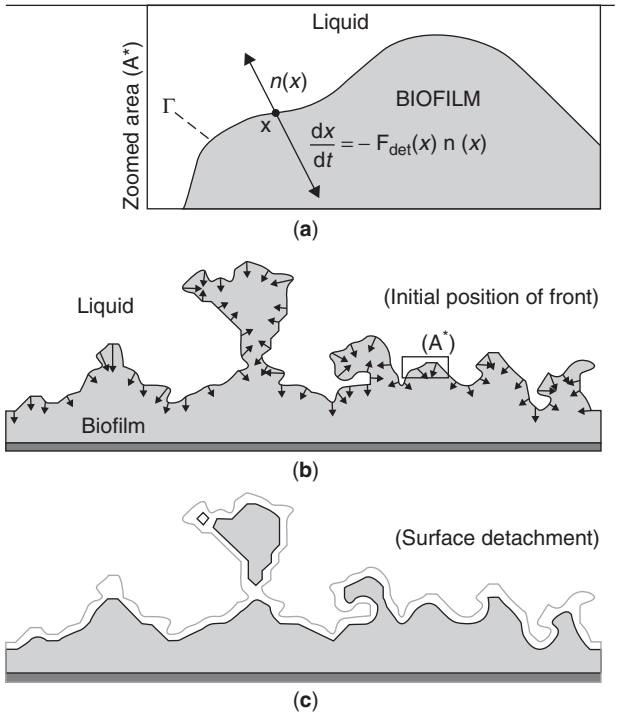

Figure 17.12. Computer simulation of biofilms (100). (a) The zoomed in fragment of biofilms, x is spatial coordinate, F_{det}, is detachment speed function, and $n(x)$ is the vector normal to the surface. (b) Position of the biofilm front before detachment is applied, arrows indicate the detachment speed vectors. (c) The biofilms after application of the surface detachment, loss of biomass clusters by sloughing.

of biomass detachment is based on use of computational fluid dynamics (CFD) (106,107) which generates velocity profiles of the moving liquid and then calculates the propagation of stresses along the elastic biofilm. Detachment occurs when stresses exceeded the local strength of the biofilm. The application of this method allowed the generation of realistic biofilm formation patterns correlated with the flow regime and the substrate load (Fig. 17.12).

MICROALGAE, MASS CULTURE METHODS

Emílio Molina Grima, Jose María Fernández Sevilla, and Francisco Gabriel Acién Fernández

Department of Chemical Engineering, University of Almería, Almería, Spain

18.1 INTRODUCTION

Microalgae have been cultured commercially for about 50 years for applications in secondary wastewater treatment (1) and use as animal feeds (2,3) and fertilizers (4), in production of chemicals (5,6), and in secondary metabolites with pharmaceutical potential (7), as well as other purposes. Microalgae can also provide several different types of renewable biofuels. These include methane produced by anaerobic digestion of the algal biomass (8), biodiesel derived from microalgal oil (9), and photobiologically produced biohydrogen (10). The idea of using microalgae as a source of fuel is now being taken seriously because of the escalating price of petroleum and, more significantly, the emerging concern about global warming that is associated with burning fossil fuels (11). However, the major focus of algal mass cultures is on relatively specialized niche applications; nevertheless, progress remains slow relative to biotechnological use of bacteria, yeasts, and animal cells. A cost-effective culture of microalgae requires substantially improved biomass productivity, better utilization of the available light, and more efficient use of carbon dioxide, which is the principal carbon source.

In the past few decades, most of the research in this field has been aimed toward the development of open outdoor mass cultures, resulting in large-scale production facilities currently in operation throughout the world (12). Open outdoor mass culture systems, such as ponds and raceways, typically operate at low cell densities (0.01%–0.06% w/v); consequently, harvesting is expensive and economic returns are low. In addition, species control is difficult in open systems, and much of the incident radiation is wasted. The low productivity of open systems has prompted the development of enclosed photobioreactors(PBRs) (i.e. transparent tubes or containers in which the culture may be circulated by various devices). Enclosed PBRs allow a more controlled culture environment, including improved temperature control. The fact is that most microalgal strains can only be cultured under controlled conditions and protected from the environment. This is only possible with fully closed PBRs (13). The design of closed PBRs must be carefully optimized for each individual algal species, according to its unique physiological and growth characteristics (14). Successful designing of PBRs relies on attaining a proper balance of engineering and biological factors that are interdependent and also depends on the species being cultured. Of course, from a commercial perspective, reliability and the costs of construction and operation are also important. The physical rate processes of concern are the light delivery, the gas–liquid mass transfer, temperature control, fluid dynamics, and mixing. The biological rate processes of concern are photosynthesis, growth, and production of metabolites.

This chapter details the major types of bioreactors used in mass culture of microalgae. The basic requirements for successful outdoor culture are noted, and the physics and biology of mass cultivation are discussed.

18.2 BIOREACTORS FOR MICROALGAE MASS CULTURES

Three microalgae—*Chlorella*, *Dunaliella*, and *Spirulina*—are currently produced commercially on a relatively large scale (approximately 1000 tons each per annum). The current commercial production systems for these species are mostly open raceway ponds. Many commercially useful algae are difficult to cultivate in open systems because they require a mild culture environment that is highly susceptible to contamination by other algae, bacteria, protozoa, and fungi. The inability to cultivate desirable algal species that contain valuable products (e.g. astaxanthin, aquaculture feeds, polysaccharides, and polyunsaturated fatty acids) in open ponds has increased interest in closed systems. Closed PBRs are suitable for the production of strains rich in high value products, and also allow taking advantage of the metabolic flexibility of microalgae: the generation rate of the desired product can be enhanced by setting proper culture conditions. Thus, for the successful production of microalgae on an industrial scale, it is necessary to design and use PBRs and production systems that accomplish the requirements of the individual microalgae cells. Two dominant environmental factors require substantial attention: sunlight and temperature (15,16). Also, other design parameters such as light regime, mixing, and heat and mass transfer must be fine tuned for proper operation (17,18).

A variety of closed PBRs has been proposed to suit the particular characteristics of different microalgal strains. Closed systems that have been and are being studied include the following: (i) bags culture, which are widely used for culture of algae for aquaculture (2,19); (ii) alveolar panels and other flat plate reactors of various designs (20–22); (iii) stirred tank reactors with internal illumination (23,24); (iv) bubble-column and airlift reactors (25,26); and (v) tubular reactors (27–29). The most scalable designs correspond to horizontal or helical tubular systems, as well as combinations of vertical flat panels and bubble columns, and therefore these types of PBRs have attracted most interest. Some of the major types of PBRs are discussed in the following text.

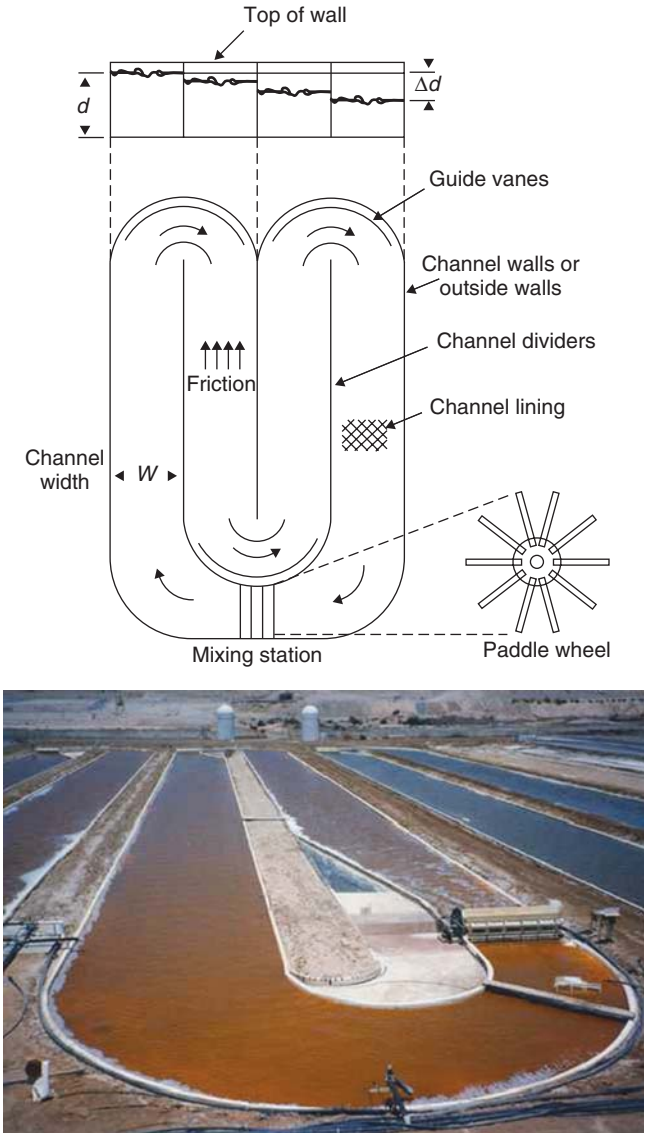

Figure 18.1. Diagram and photograph of an open raceway showing in detail a paddle wheel used for mixing. The channel length is the distance traveled by the culture from the discharge side of the paddle wheel to the entering side. [From Ref. (1). With permission.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

18.2.1 Open Raceways

Open raceways, or shallow mixed ponds for microalgal production, were introduced in the 1950s and early 1960s by Oswald *et al*. (30). The principles for design and construction of shallow paddle stirred raceways for large microalgal production were reviewed by Doodd (31) as well as Oswald (32). The pond is set in a meandering configuration with channels utilizing various designs of paddle wheel mixers that promote low shear environment. The simplified diagram of an open raceway, showing the nomenclature of the major parts, is depicted in Fig. 18.1.

The selection of a suitable bottom lining and wall construction is important to the success of the open pond. The lining may be made of concrete or sheets of plastic and rubber material. The size of commercial ponds varies from 1000 to 5000 m^2 and stirring is accomplished with one or two paddle wheels per pond. A wheel of large diameter (ca. 2 m) revolving slowly (e.g. 10 rpm) is preferable to smaller diameter wheels that rotate faster and produce excessive shear damage and foam. Under these conditions,

biomass concentrations of up to 1.0 g/L and productivities of 0.1 g/L/day are possible, although only species such as *Dunaliella*, *Spirulina*, or *Chlorella* are suitable for production in these systems (33).

18.2.1.1 Technical Issues

18.2.1.1.1 Supply of Carbon Dioxide. Techniques for the supply of CO_2 represent an important element in the raceway, particularly for species grown near neutral pH. Several systems have been developed, aimed at supplying CO_2 efficiently to shallow suspensions. In most cases, the gas is supplied in the form of fine bubbles. Owing to the shallowness of the suspension, the residence time of the bubbles is not sufficient to allow all the CO_2 to be dissolved; therefore, losses to the atmosphere are difficult to control. The most effective method currently available for transferring CO_2 to algal cultures is counter-current carbonation (32) in which the gas is injected as minute bubbles into a column of culture. The culture velocity is adjusted so that small bubbles of CO_2 rise against the current. Using this technique, Laws *et al*. (34) have reported a 70% efficiency in CO_2 transfer compared to 13%–20% if it is supplied in bubble form (35).

18.2.1.1.2 Mixing. The evolution of the open culture technology is the reflection of the mixing systems that have been developed in parallel with them. Mixing is necessary in order to avoid cells settling and sticking to the bottom and to avoid thermal stratification of the culture. Properly designed paddle wheels are by far the most efficient and durable pond mixers. They discharge all of the culture entering them and are thus highly efficient. The engineering design of a raceway equipped with paddle wheels has been comprehensively described by Oswald (32). With reference to Fig. 18.1, consider culture flowing at depth d in a channel with finite width, w, and unspecified length, L. The channel length, L, which corresponds to the assumed change in depth for a given friction factor and a culture velocity (v) is given (32):

$$L = \frac{\Delta d(dw/(w+2d))^{4/3}}{v^2 \cdot n^2} \tag{18.1}$$

where n is the Manning friction factor (s/m$^{1/3}$), L is the channel length that corresponds to the assumed change in depth (Δd), and w is the channel width. The value of n varies according to the relative roughness of the channel. Experimentally determined n values in algae growth channels vary from 0.008 to 0.030 (32); the former being for smooth plastic-lined channels and the latter for relatively rough earth. The channel velocity, v, effect on the paddle wheel's power requirements, is calculated as:

$$P = \frac{Q \cdot \rho \cdot \Delta d}{\eta} \tag{18.2}$$

where P is the power (kW), Q the culture flow rate in motion (m^3), ρ is the specific weight of culture (kg/m^3), Δd is the change in depth (m), and η is the efficiency of the paddle wheel. Because $\Delta d = s \cdot L$ and taking into account that s, the rate of loss of energy in the channel per unit length, is a function of v^2, the power consumption, P, increases as the cube of velocity. It is therefore worthwhile to minimize velocity whenever energy is a major cost factor. Typical values of flow rates range between 15 and 30 cm/s, whereas the power supply is around 1 W/m^3. Velocities greater than 30 cm/s result in large values of Δd in long channels and may require high channel walls and higher divider walls. Note that, for a finite value of the channel width, w, the permissible mixing channel length, L, and thus the mixable area, $a = L \cdot w$, is a function strongly dependent on depth, d.

The control of contaminants in open pond systems is the most important problem raised by this technology. Additionally, they have many other drawbacks related to temperature control and culture depth. The culture depth cannot be reduced below 12–15 cm; otherwise, a severe reduction of flow and turbulence would occur. This obliges to work with a large areal volume of 120–150 L/m^2 (16), requiring maintenance of rather low cell concentration (around 500 mg/L). A low cell concentration in turn increases the cost of harvesting and of pond maintenance and greatly increases the extent of contamination by foreign species. These problems could, at least in principle, be minimized by PBRs designs that allow shallower cultures, maximize cell densities, allow better process control, and minimize contamination. These objectives can be met with closed PBRs that are described in the next section.

18.2.2 Enclosed Photobioreactors

PBRs can be defined as algal culture systems that do not allow direct exchange of gases (e.g. CO_2, O_2, H_2O) and gross contaminants between the culture and the atmosphere. PBRs generally may be grouped into two classes: tubular and flat plate. These groups can be further classified into several categories: (i) vertical tubular bubble PBR, which are rigid and are placed vertically up to some practical height of few meters; (ii) tube reactors placed horizontally, inclined, in fence-type configuration, or in spiral manners; and (iii) flat plate and alveolar PBRs, which are made of multiple interconnected channels (their cross-sectional area may be rectangular, square, or circular) that constitute flat reactors. Only flat panel and tubular PBRs have been built to sizes exceeding 1000 L (36–38), whereas for column systems a maximum of 125 L has been proposed as optimum (26,39). Summary of the state of the art in close PBRs has been provided (40,41), some of which are in commercial operation. A brief description follows.

18.2.2.1 Bubble Columns. In vertical column reactors, bubble columns or airlift, aeration, and agitation are provided by injection of CO_2-enriched air through an inlet tube at the bottom of the column. Practically speaking, the vertical column can be extended only to a few meters high; otherwise, a prohibitively expensive structure would be needed for support. James and Al-Khars (25) studied the growth and the productivity of *Chlorella* and *Nannochloropsis* in a vertical airlift PBR. Contreras Gómez (42), showed that the average annual volumetric productivity of a draught tube airlift (0.1 m in diameter) was about 1.0 g/L/day in culture of *Phaeodactylum tricornutum*. Sánchez Mirón *et al*. (26) reported an average annual productivity for the same microalgae using a 0.2 m in diameter and 2.1 m tall bubble column (Fig. 18.2) of 0.49 g/L/day.

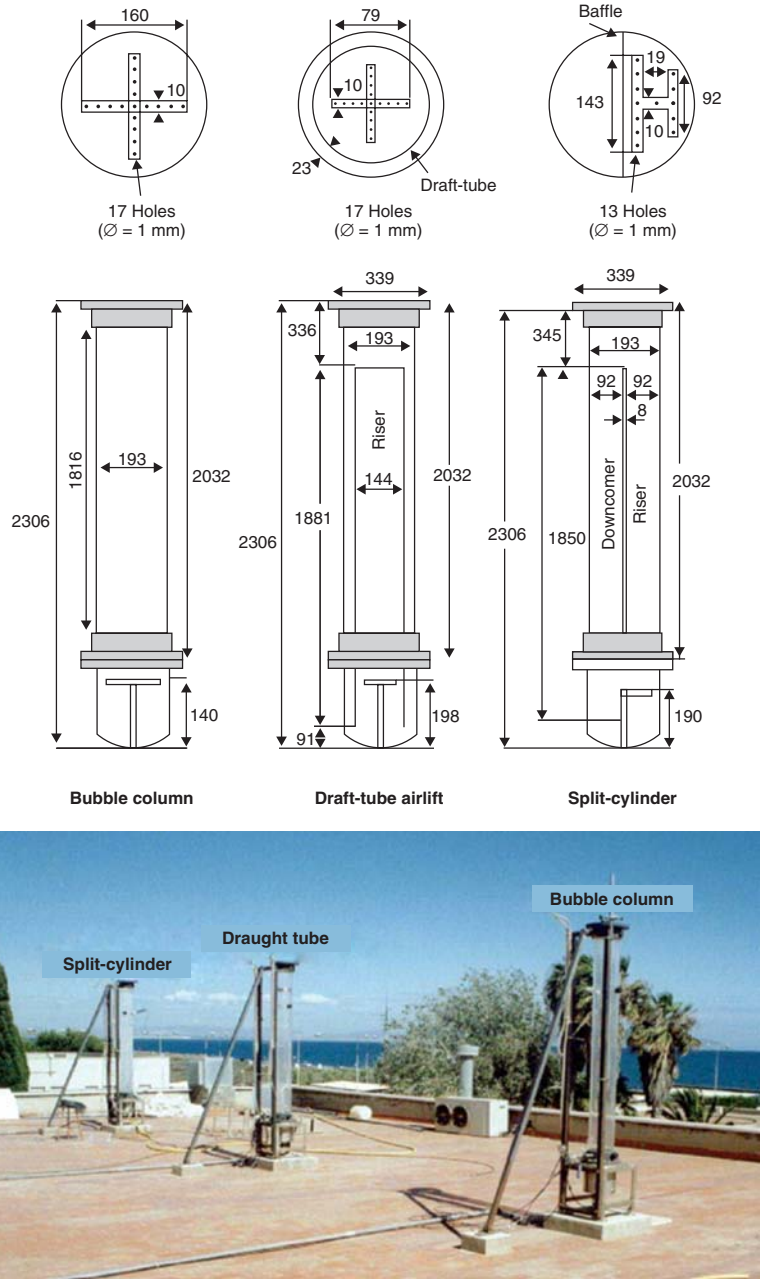

Figure 18.2. Diagram and photograph of several vertical tubular photobioreactors. Different configurations are obtained according to the position of internal walls. Dimensions in mm. [From Ref. 26. With permission.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

A major advantage of tower reactors is that oxygen does not accumulate in the growth medium because it reaches an outlet after a short path, equivalent to the vertical axis of the reactor, and the sterility to the level demanded in pharmaceutical industry is potentially higher than in other tubular systems. For the usual gas flow rate employed (corresponding to superficial gas velocity of less than 0.05 m/s), the average volumetric mass transfer is about fourfold the estimated value for a horizontal tube with a reported 3% maximum gas holdup (26). In view of this result, vertical tubular PBRs such as bubble columns should easily maintain a dissolved oxygen (DO) level only a little higher than the air saturation value. Consequently, the vertical reactors experience little oxygen inhibition. Because of a reduced level of DO, the photooxidation-associated loss of biomass and product metabolite is lower in bubble-column reactors. Photooxidation occurs especially when high levels of DO combine with an intensely irradiated environment. Also, tower bioreactors are potentially easier to keep sterile compared to other tubular systems. The major drawback with respect to the tubular system, positioned either horizontally or inclined, is that the reactor is always at a large angle to the sun's rays and substantial amount of solar energy is thus reflected at the central hours of the day. Under identical conditions, the volumetric biomass productivity in a bubble column is roughly 60% of that in a horizontally placed serpentine PBR (26,39).

The hydrodynamics of the flow in bubble columns and tubular reactors are generally quite different. The necessarily gas sparged bubble-column and airlift reactors tend to have substantially greater gas holdup than horizontal tubular reactors. The latter are virtually free of gas, and any bubbles present are localized to a narrow zone along the upper portion of the tubes; moreover, the bubbles are relatively small. In contrast, there are many more and larger bubbles in vertical PBRs and the gas–liquid flow is much more chaotic than the highly directional flow in a small diameter horizontal tubular reactor. Differences in gas holdup and the bubble size affect light penetration, gas-liquid mass transfer, mixing, and shear stress level. For best performance, bubble columns need to be operated at the highest feasible aeration rates consistent with the shear tolerance of the microalgae; however, the aeration must not be so high as to produce a gas holdup level that prevents light transmission through the column. Ideally, the culture environment in the column should be manipulated to promote formation of relatively large bubbles ($d_b > 0.006$ m) that rise rapidly. This also contributes to the enhancement of the radial flow into and out of the central dark core and, consequently, the productivity.

18.2.2.2 Tubular Photobioreactors. The first described outdoor tubular reactor was made of a serpentine immersed in a water bath, using a 3-cm-diameter glass tubes, with the total length of illuminated tubes being 33.3 m (i.e. 1 m^2, with the connections consisting of opaque rubber tubing) (43). The culture was recirculated in the system by a motor-driven pump at 15–30 cm/s, and the gas exchange system was a bubble column which injected 5% CO_2 at a rate of 1–1.5 mL/min. The total culture volume was 40 L. This system is essentially identical to other newer systems, particularly those developed by Gudin in France (44)—with tubes placed horizontally on the floor—and Pirt in England (45)—with the tube placed vertically on the floor. In the last two systems, the culture was recirculated, as in the Tamiya concept, by means of pumps. However, they commented on the problems of such pumps when dealing with fragile, shear sensitive cells, and recommended the use of airlifts, for both culture recirculation and CO_2 supply (and O_2 degassing).

Although with a few modifications, the designs of other tubular reactors that have been proposed, namely the two plane tubular reactors (18,46), the near-horizontal tubular reactor (47), the helical bubble reactor (48,49), the α-tubular reactor (50), and the parallel flow tubular PBR (51), are essentially of the same nature as those used in Pirt or Gudin (44,45). Figure 18.3 depicts a scheme of a fully instrumented tubular PBR like that proposed by Gudin *et al*. setup in the authors' laboratory. The PBR consists of a vertical external-loop airlift pump that drives the culture fluid through the horizontal tubular solar receiver. The airlift section (riser, downcomer, and degasser) has a height of 3.5 m. The gas-injected riser and the downcomer sections are extensions of the solar receiver tube. The solar receiver is made of transparent Plexiglas tubes (0.05 m internal diameter, 0.005 m wall thickness) joined into a loop configuration by Plexiglas joints to obtain a total horizontal length of 98.8 m. The solar receiver is submerged (~0.05 m) in a shallow pool of water that is maintained at 21 ± 2°C by cooling with a heat pump when needed. The bottom and the inside walls of the pool are painted white to improve reflectance. The surface area of the pool is 21.4 m^2. The total culture volume of the bioreactor is 0.22 m^3.

For the efficient and reliable large-scale culture of microalgae in PBRs, several operational, environmental, and design variables need to be assessed. The most important design criteria are, likely, the efficiency of light utilization (which, in turn, is related with the productivity of the system), a homogeneous turbulence regime, and the capability of the system to match the conditions required by the particular microalgae through time and in all the reactor volume. From the commercial point of view, the capital cost of construction and operation (directly related to the CO_2 consumption efficiency) are, of course, also critical (51). The on-line data acquisition of DO, pH, and temperature inside the culture allows for

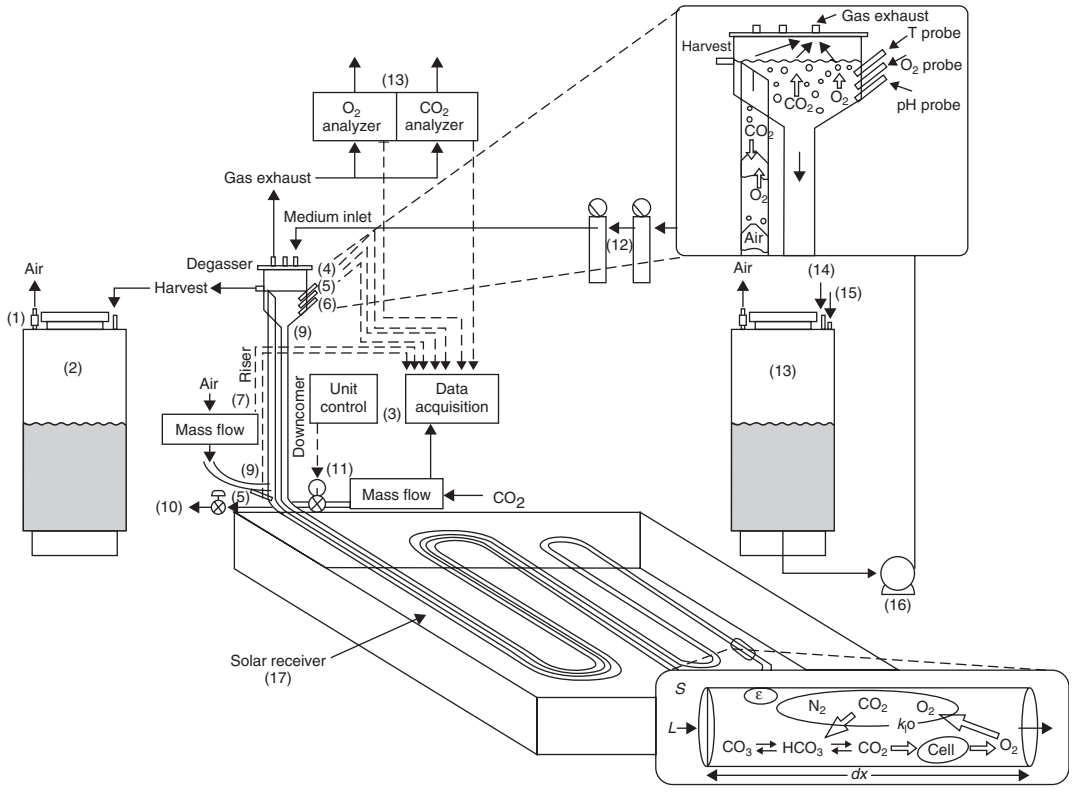

Figure 18.3. Scheme and image of tubular photobioreactor and additional equipment (1 air filter, 2 harvest tanks, 3 control units, 4 temperature sensors, 5 dissolved O2 probes, 6 pH probes, 7 risers, 8 downcomers, 9 air injections, 10 samplers, 11 CO_2, 12 medium sterile filters, 13 fresh mediums, 14 nutrient inlets, 15 sea water inlets, 16 pumps, 17 thermostatic water pools). [From Ref. 52 With permission.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

rapid characterization of the physiological state of the cells. The measurement of CO_2 and O_2 molar flow at the gas inlet and outlet enables the estimation of the mass transfer capability of the system and the efficiency of CO_2 utilization. The measurement of the biomass concentration and product/s content/s allows the estimation of the biomass and product productivities.

This type of PBR has been extensively used on a pilot scale, biomass productivities of 2.76 g/L/day with *P. tricornutum* (52), of 1.76 g/L/day with *Porphyridium cruentum* (53), and of 0.55 g/L/day with *Haematococcus pluvialis* (54) being reported. This PBR is now applied on an industrial scale. Thus, after an upscaling period of nearly 3 years, an industrial tubular system was established near Wolfsburg, Germany (Fig. 18.4). This closed system is apparently the largest PBR to have gone into successful production. It consists of compact and vertically arranged horizontal running glass tubes of a total length of 500,000 m and a total PBR volume of 700 m^3. In a glasshouse requiring an area of only 10,000 m^2 an annual production of 130–150 tonnes of dry biomass was demonstrated to be economically feasible under Central European conditions (13). Other industrial plants based on tubular PBRs have been also set up in Germany and Spain. In Spain, the Fundación CAJAMAR built a 30-m^3 plant for the production of a proprietary strain (*S. almeriensis*) on a commercial scale, according to good manufacture practices for the food industry (Fig. 18.4). The plant is based on 10 individual tubular-type PBRs (tubes arranged horizontally in a fence configuration), 3 m^3 working volume each, installed in a greenhouse. The production capacity of the plant is 7–10 tonnes of dry biomass per year.

Photographs of two industrial-sized tubular photobioreactors. *Top*: 700 m^3 glass tube PBR producing *Chlorella* biomass in Germany. *Bottom*: A 30-m^3 plant for the production of *Scenedesmus almeriensis* in Spain, property of Fundación CAJAMAR. [From Ref. 13. With permission.] [With permission from Ref. 38.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

18.2.2.3 Flat Panels. Flat-panel PBRs have important advantages for mass production of photoautotrophic microorganisms and may become a standard reactor type for the mass production of several algal species. The construction of flat-plate reactors dates back to the early 1950s (55). Samon and Leduy (20) used vertically translucent flat plates, illuminated on both sides and stirred by aeration. Tredici and Materassi developed this idea (21,56) proposing a rigid alveolar panel. Pulz *et al*. (57) used flat panels with inner walls arranged to promote an ordered horizontal culture flow that was forced by a mechanical pump. The most innovative aspect of the Pulz reactor was that parallel plates were packed together; close enough to attain 6 m^3 of culture volume on 100 m^2 of ground area, with a total illuminated culture surface of ca. 500 m^2. The research of Hu and Richmond (58,59) resulted in a type of flat-plate reactor made of glass sheets, glued together with silicon rubber to make flat vessels. This simple methodology for the construction of glass reactors provided the opportunity to easily build reactors with any desired light path. Zhang *et al*. (60) reported a biomass productivity of 1.0 g/L/day, with *Synechocystis aquatilis* in outdoor flat panels, at aeration rates of 0.05 v/v/min. Tredici *et al*., (21) used a vertical alveolar panel (1.2 cm wide, tilt 25 degrees, south faced, 2.2 m^2) for the production of *Anabaena azollae* and *Spirulina platensis*, attaining biomass productivities of 15 g/m^2/day at air flow rates of 1.0 v/v/min, the maximum biomass productivity obtained being 24 g/m^2/day. Cheng-Wu *et al*., (36) operated a 500-L flat plate reactor, 10-cm light path, using *Nannochloropsis* sp., an annual average productivity of 24 g/m^2/day being reported. Zou and Richmond (61) noted that the optimal light patch for *Nannochloropsis* sp cultures was 10 cm, yielding biomass productivities of 0.5 g/L/day and 50 g/m^2/day in summer, using a flat-panel PBR. Recently a new design of a vertical flat-panel PBR consisting of a plastic bag located between two iron frames

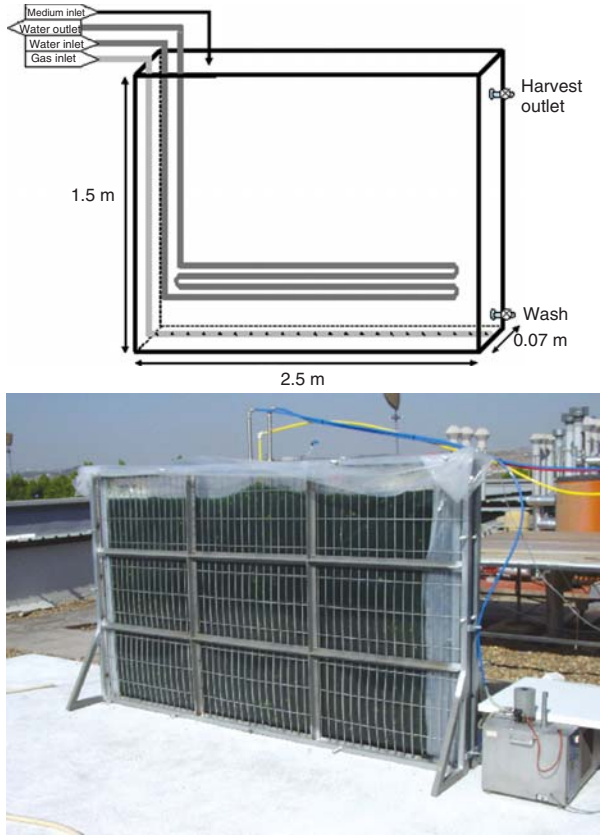

Figure 18.5. Diagram and photograph of a flat-panel photobioreactor. The reactor is equipped with an aeration system, heat exchanger, medium inlet, and harvesting valve for the continuous operation of the photobioreactor. [With permission from Ref. 38.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

was proposed (62); this brings a substantial cost reduction to this type of reactors (Fig. 18.5). Mass transfer, mixing, and heat transport in flat panel reactors have also been recently studied (63). This last reference demonstrates that the east/west orientation is the most favorable because the total solar radiation intercepted increased by 5%, with regard to horizontal placement, and homogenized the radiation intercepted over the year. The main advantages of this reactor are the low power consumption (53 W/m^3) and the high mass transfer capacity (0.007/s).

18.2.3 Comparison

For the mass cultures of microalgae, open pond systems have mainly been the dominating systems up until now. However, closed systems of light-distributing tube or plate design, known as *photobioreactors*, are now increasingly finding new applications both for high value products in pharmacy and cosmetics as well as for aqua and agricultural uses. Table 18.1 summarizes the advantages and disadvantages of both types of culture systems.

TABLE 18.1. Advantages and Disadvantages of Open and Closed Algal Cultivation Plants

Parameter	Open Ponds	Closed Systems (PBR Systems)
Contamination risk	Extremely high	Low
Space required	High	Low
Water losses	Extremely high	Almost none
CO_2losses	High	Almost none
Biomass quality	Not susceptible	Susceptible
Variability as to cultivable species	Not given, cultivation possibilities are restricted to a few algal varieties	High, nearly all microbial varieties may be cultivated
Flexibility of production	Change of production between the possible varieties nearly impossible	Change of production without any problems
Reproducibility of production parameters	Not given, dependent on exterior conditions	Possible within certain tolerances
Process control	Not given	Given
Standardization	Not possible	Possible
Weather dependence	Absolute, production impossible during rain	Insignificant, because closed configurations allow production also during bad weather
Period until net production is reached after start or interruptions	Long, approximately 6–8 wk	Relatively short, approximately 2–4 wk
Biomass concentration during production	Low, approximately 0.1–0.2 g/L	High, approximately 2–8 g/L
Efficiency of treatment process	Low, time-consuming, large volume flows due to low concentrations	High, short-time, relatively small volume flows

[From Ref. 12. With permission.]

18.3 MAJOR FACTORS GOVERNING THE PRODUCTION OF MICROALGAE

The biomass productivity in any culture system depends on how closely the culture conditions match the requirements of the selected strain. Because mineral nutrient limitation is easily avoided in a microalgal mass culture, light availability inside the PBR and temperature are found to be

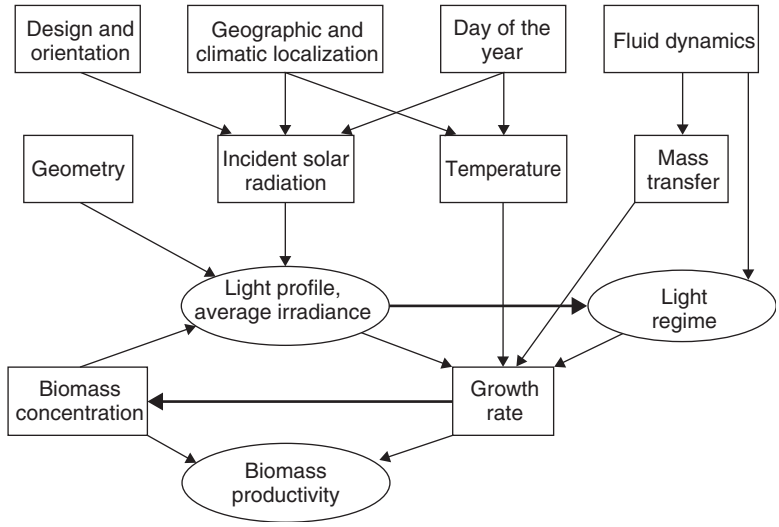

Figure 18.6. Relationship between major factors influencing the biomass productivity of microalgal mass cultures. [From Ref. 70. With permission.]

the main management factors in obtaining optimum system profitability. Thus, when temperature culture is kept within an appropriate interval, light availability is the only factor determining growth. Figure 18.6 shows the relationship between the different factors governing biomass productivity under outdoor conditions. The key factor is the growth rate, which is a function of the light profile within the reactor and the light regime at which the cells are subjected. Once this function is known, it becomes possible to obtain a correlation between biomass productivity and the average irradiance within the reactor, I_{av}. On the other hand, I_{av} is a function of the irradiance impinging on the reactor surface, I_0, which is, at the same time, dependent on geographic and environmental factors. The geographic location and day of the year determine the solar incident radiation and therefore the temperature in the culture. While temperature can be kept within a narrow interval by using suitable thermostatic systems, solar radiation cannot be controlled.

The incident solar radiation, which is a function of climatic and geographic parameters of the facility location (64), as well as the design and orientation of the PBR (50,58,63), determines the maximum energy available for growth. The incident solar radiation, along with the PBR geometry and the biomass concentration, determines a heterogeneous light profile due to cell mutual shading inside the culture (65,66). The light availability or average irradiance inside the culture can be calculated by a volumetric integration of the irradiance profile. The cell metabolism adapts to this light availability and so does the biochemical composition and growth rate (52). However, the PBR fluid-dynamics also determine the mass transfer and the light regime of the cells. The latter is affected by the time the cells spend in zones with a different irradiance level and the frequency of movement into and out of these zones (67–69). This light regime affects the behavior of the cells, determining the extent at which the cells are exposed to the photic and the dark zones of the PBR, and thereby the efficiency of using solar radiation by the cultures. The biomass concentration is in itself influenced by the growth rate, which is a function of the average irradiance, temperature, mass transfer, and light regime. Both, the growth rate and the biomass concentration, determine the final biomass productivity of the system (Fig. 18.6). Thus, in an optimum system where there are no limitations other than light, a direct interrelationship among light availability, rate of photosynthesis, and productivity may be expected. In fact, it seems that other limitations do not only limit growth through their direct effect but also impose a limitation on the ability to utilize the absorbed solar energy. This may result in a photoinhibitory response further limiting the ability of the photosynthetic apparatus to operate at its maximal efficiency (71). The present section considers the above-noted issues that influence biomass productivity in outdoor conditions.

18.3.1 Light Distribution and Average Solar Irradiance Inside Photobioreactors

When considering commercial-scale microalgal culture, the source of light is usually sunlight as artificial light is too expensive for most products. The effects of outdoors illumination in microalgae cultures are not completely clear. This is because just about all the studies concerning the characterization of the photosynthetic response to light (72–75) have been conducted under carefully controlled

laboratory conditions, in which temperature and irradiance were constant and the irradiance used was significantly lower than that of peak solar irradiance prevailing outdoors. Outdoor conditions are very difficult to simulate in laboratory; the impinging irradiance on cultures grown outdoors changes within a few hours from zero at dawn to over 2000 $\mu E/m^2/s$ at noon (i.e. a rate several times above saturation), and within a few additional hours thereafter, declines to zero again as evening sets in. This large and fast change in irradiance during the day may shift the culture from being light limited in the morning to being light inhibited at noon and thereafter light limited once again as light intensity diminishes further in the afternoon and evening.

Information concerning light distribution in microalgal mass culture systems is scant. Existing methods of estimating average illumination employ an approach consisting of the following: (i) estimation of the total photosynthetically active incident radiation at the surface of the PBR, (ii) use of Beer–Lambert's law to determine the radiation level at any depth inside the culture as a function of the concentration of the cells and the light absorption characteristics of the cellular pigments, and (iii) the integration of the local values over the total volume of the culture. Rigorous solutions for different geometries and PBRs have been developed. Thus, Acien Fernández *et al*, (67) developed a comprehensive model for light distribution and average solar irradiance inside a horizontally placed tubular outdoor PBRs. That model has been further generalized for use with bubble-column-type reactors (39). The mathematical model determines the distance traveled by an incident ray of light to any point inside the culture and estimates the local irradiance by taking into account the light attenuation due to biomass. The incident total radiation is divided into direct and disperse radiation.

The model is mathematically complex. For example, the angle of incidence of direct radiation on the PBR surface is a function of five variables: day of the year, solar hour, geographic latitude, surface slope, and surface azimuth angle (i.e. the deviation of the projection on a horizontal plane of the normal to the surface from the local meridian, with zero due south, east negative, and west positive) (76,77). Figure 18.7 shows the local irradiance profiles either in a horizontal or vertical arrangement at 8 and 12 solar hours. As expected, as the solar hour changes, curves of local irradiance at the same internal ratio adjust to the sun's position in both arrangements. In the morning, the vertical reactor facing the sun has much higher direct irradiance values than the opposite side; this difference being lower in the horizontal reactor. However, at noon, the irradiance distribution in the vertical, unlike the horizontal, is practically homogeneous. This profile is because, during midday, the contribution of disperse irradiance to total irradiance in relation to the direct irradiance is very important in the vertical arrangement. Therefore, the level of irradiance for each internal radius and for any hour of the day is higher in the horizontal reactor tube than in the vertical. The irradiance distribution inside the culture and the patterns of cell movement inside the PBRs are also different.

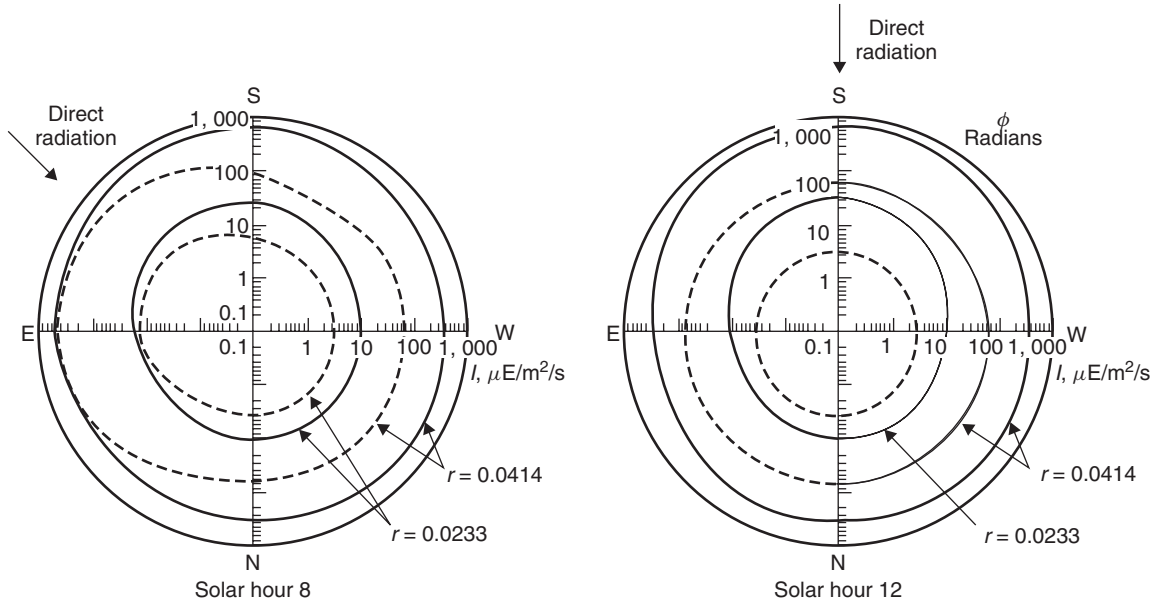

Figure 18.7. Polar plot of irradiance profiles in the cross-section of a bubble-column-type photobioreactor (PBR) (dashed lines) and horizontal loop tubular PBR (solid lines) for the 0.041 m and 0.023 m internal radii at the 8 and 12 solar hours.

Another simplified model to calculate I_{av} (Eq. 18.3) has been also proposed (78). This model is suitable for any combination of disperse and direct light as long as it is impinging uniformly on the reactor surface. According to this model, the average irradiance, I_{av}, is a function of irradiance measured in the center of an empty reactor, I_o, the extinction coefficient of the biomass, K_a, the optical light path, p, and the biomass concentration in the culture, C_b.

$$I_{av} = \frac{Io}{K_a \cdot p \cdot C_b}(1 - \exp(-K_a \bullet p \bullet C_b)) \qquad (18.3)$$

This model has been successfully used to analyze the influence of light on the behavior of indoor and outdoor cultures for different microalgae (52,53).

18.3.2 Light Saturation Constant and the Photoinhibition Phenomenon

Algal growth is related to light intensity. According to Goldman (13), the generalized curve relating algal growth to light intensity has the shape shown in Fig. 18.8. The curve has four main features: (i) at some low growth rate, the growth is balanced by decay, and the net growth rate is zero; (ii) the initial slope of the curve represents the maximum efficiency of growth in response to light; (iii) there is a saturating light intensity at I_s for which $\mu = \mu_{max}$; (iv) at some light intensity $I_p > I_s$, the growth is inhibited and $\mu < \mu_{max}$. Because most algal species become light saturated at a fraction of peak solar-light intensity, much potentially useful solar energy is essentially wasted for photosynthesis. The light saturation constant depicts the intrinsic capacity of cells to utilize light energy, and thus it should be given special attention in mass cultures of photoautotrophs. The selection of algal strains having a high

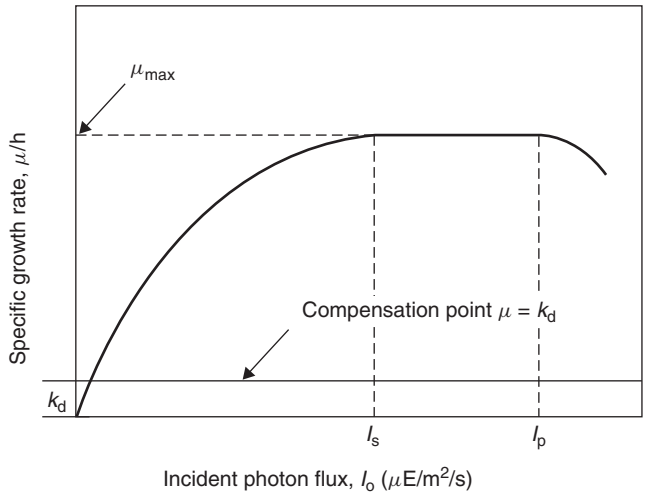

Figure 18.8. Dependence of the growth rate (μ) on the incident photon flux (I_o). [From Ref. 15. With permission.]

I_s value is desirable to avoid the saturation effect. A high saturation constant gives rise to a double advantage on photoautotrophs exposed to high photon flux densities (PFD). It increases the efficiency by which high PFD may be utilized and concomitantly diminishes the occurrence and magnitude of photoinhibition, which would substantially reduce the output rate of sensitive strains in outdoor cultures.

Photoinhibition, which may be defined as depression of the photosynthetic capacity due to supraoptimal light intensities in great excess of that required to saturate photosynthesis (16), has been much studied in algae. Shading the culture by shad nets is a normal practice that provides protection from the light inhibitory effect. The kinetic of photoinhibition and its recovery in *Porphyridium cruentum* was previously studied (79). A linear relationship was found between the specific rate of photoinhibition and the specific light absorption rate. Temperature was found to have a most pronounced modifying effect on photoinhibition. At 15°C, no damage could be detected at 2300 μE/m^2/s, even after 45 min of illumination. In contrast, at 35°C, 84% inhibition of photosynthetic activity was observed within 10 min of exposure to irradiance. *P. cruentum* cells recovered readily when transferred to low light (90 μE/m^2/s) and darkness, the specific rate of recovery was independent of the light intensity to which the cells were exposed during the inhibitory treatment. Photoinhibition in outdoor mass cultures can be detected with high sensitivity from changes in variable chlorophyll fluorescence (80). The Fv/Fm ratio (variable to maximum fluorescence yield) is a convenient measure of the potential maximum quantum yield of PSII, and it has been assumed as a measure of photoinhibition (81).

The existence of photoinhibition in continuous outdoor cultures of *P. tricornutum* has been evidenced (52). Figure 18.9 shows how I_{av} varies with the dilution rate regardless of the tube diameter, hence indicating that the cultures adapt mainly to average irradiance. At D= 0.025/h, I_{av} increased only slightly with increasing I_{wm} (slope = 0.014 ± 0.004); the mean value of I_{av} for the whole range was 84 ± 9 μE/m^2/s. With smaller tube diameter and/or higher external irradiance, I_{wm}, the biomass concentration increased as expected for self-shaded light-limited growth. However, the slight increase in I_{av} with I_{wm} points to some photoinhibition by external irradiance, although this is not very extensive due to the high biomass concentrations. At D = 0.040/h, I_{av} values are higher (163 ± 20 μE/m^2/s) than at D = 0.025/h because of the lower steady-state biomass concentrations. The greater light availability gives rise to a higher specific growth rate as well as photoinhibition, because of the greater increase in I_{av} with I_{wm} (slope = 0.032 ± 0.004). At 0.050/h dilution rate, the exponential increase in I_{av} with I_{wm} caused by the low steady-state biomass concentration, underlines the existence of photoinhibition,

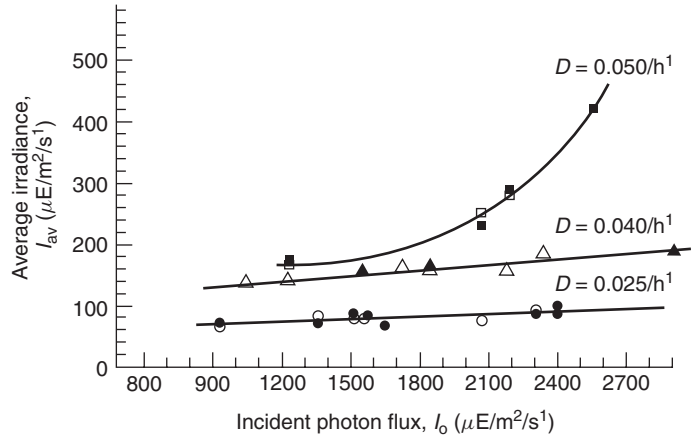

Figure 18.9. Variation in average irradiance I_{av} inside the culture with daily mean photosynthetic irradiance inside the pond I_{wm} for the various dilution rates and the photobioreactors used. [From Ref. 52 With permission.]

and thus the one-to-one relationship between μ and I_{av} no longer applies.

Photoinhibition is caused by oversaturation of photosystem II, which damages the D1 protein that carries the binding site of the electron carrier (82,83). This photoinhibition effect is quite distinct from that of temperature rise that occurs in uncontrolled systems as a function of the PFD. At low light intensities, the few damaged D1 protein molecules are replaced rapidly and the net damage to the photosynthetic apparatus is negligible. Under this situation, a dark period reduces growth rate (photosynthesis) because fewer photons are captured but no gain is obtained from the dark time. In contrast, under conditions of intense illumination, part of the light energy impairs the photosynthetic apparatus. Repair and damage proceed simultaneously and the observed growth is the sum of the two processes. If a dark period is introduced under this situation, the duration of the photosynthetic period declines, but the damaging period is also reduced, while the photon trap repair continues during the dark time. Consequently, during the next light period, a substantially rejuvenated photon trap compensates for the loss in photosynthetic time. Under these circumstances, alternating light/dark periods do not reduce growth, which may in fact be slightly enhanced. Nevertheless, the length of the dark period is important: lengthening the light period beyond an optimal value produces loss of growth. The optimal or critical dark period is not a fixed quantity; instead it depends on the PFD of the previous light period and the fluid residence time in zones of different irradiance.

To explain the influence of light regime in the behavior of microalgal cultures, a mechanistic model of photosynthesis has been recently published (84). The model considers that photosynthesis in microalgal cell occurs only in the photosynthetic unit (PSU), a portion of the thylakoidal membrane that brings together photon receptors, electron carriers, and the enzymes necessary for regenerating NADPH and adenosine triphosphate (ATP). During photosynthesis, a resting-state PSU^o is rapidly activated by absorption of photon, giving activated PSU*, which is deactivated slowly in enzyme-mediated reactions to regenerate PSU^o. However, excess of photons convert functional PSU_f into nonfunctional PSU_{nf}. The kinetics of processes involved in these transitions are modeled and the characteristic parameters determined. Figure 18.10 summarizes the scheme of the mechanism proposed. The proposed model can take into account the influence of the light regime characterized as a frequency, ν, of change from light to dark zones and a so-called "duty cycle," ϕ, that represents the predominance of light or dark zones. The simulated effect of the frequency of changes from light to dark in the photosynthesis efficiency is shown in Fig. 18.11 (expressed in relative terms as ν/β, the ratio of frequency to β, and the microalgae sensitivity to the frequency of changing light; (see Ref. 84 for further detail). Figure 18.11 shows how important it is to have an adequate frequency of renovation from light to dark zones for an efficient use of light and that no matter how high the light availability is (represented on the x-axis as $\phi \cdot I/\alpha$, see reference for details), the photosynthetic response is poor if ν is small compared to β (see line $\nu/\beta = 0.1$ in Fig. 18.11). This dynamic mechanistic model of photosynthesis also accounts for photoadaptation as described by Marra (85) and photoinhibition. The well-known "flashing light effect" is also evident in Fig. 18.11 because, at a fixed light intensity, the photosynthetic response greatly increases with frequency especially for $\phi \cdot I/\alpha$ above 1.0 (which means the microalgae are close to light saturation).

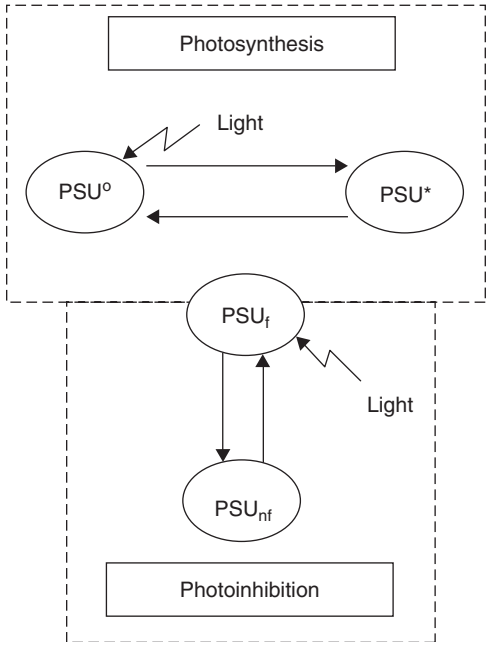

Figure 18.10. Schematic representation of photosynthesis and photoinhibition. A resting PSU° is activated to PSU* by absorption o flight. Excess photons reversibly convert functional PSU_f to nonfunctional PSU_{nf}. [From Ref. 84. With permission.]

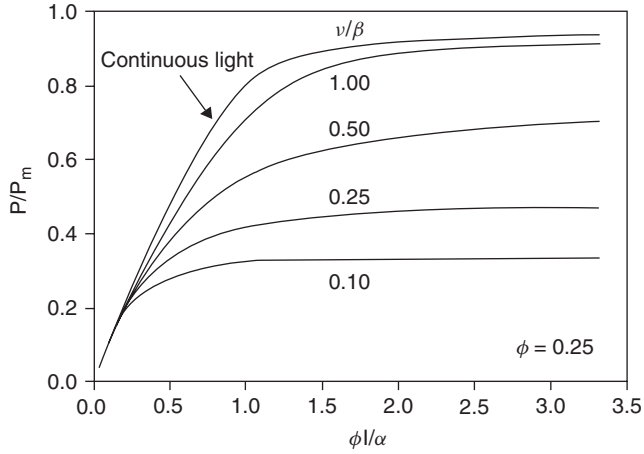

Figure 18.11. Variation in the relative photosynthetic response (P/P_m) with a dimensional light intensity (ϕ/α) at different light regimes of increasing frequency (n). A full photosynthetic response ($P/P_m \approx 1$) is possible only for light regimes with a flashing frequency close to the microalgae characteristic frequency, $\beta(\nu/\beta \approx 1)$. [From Ref. 84. With permission.]

Clearly, therefore, the principal problem of designing or choosing a PBR is assuring, for any species with defined photosynthetic characteristics, that the largest possible fraction of cells experiences optimal exposure to light in the largest possible reactor volume.

18.3.3 Biomass Productivity

Many studies on the influence of environmental variables on biomass productivity have been carried out in the laboratory, but very few have been performed under outdoor conditions. Some models have been proposed specifically for outdoor alga ponds (65,86–88). Incropera and Thomas (64) present a model for determining the mean irradiance in an open pond as a function of climate and geographic location parameters. Starting from estimated irradiance values, a six-parameter growth model, four of which are obtained experimentally, and which does not consider photoinhibition, is proposed. This model, which predicts maximum productivities of about 34 g/m^2/day in June, was not experimentally verified. On the other hand, Sukenik *et al*., (86,87) proposed a five-parameter mathematical model to estimate the biomass productivity in outdoor systems, which considers that the cells adapt to mean irradiance inside the culture. However, they do not take into account the existence of photoinhibition, and their results are not valid at low biomass concentration. In spite of this, the model estimates productivities from 10.2 to 27.2 g/m^2/day, although this has also not been experimentally verified. By using mean temperature and irradiance data, Gutterman *et al*., (88) proposed a growth model for open systems. The model estimates the variation of culture parameters such as DO, temperature, pH, and biomass concentration, by considering empirical linear relationship, and does not consider photoinhibition either. The estimated maximum productivity was 38 g/m^2/day at irradiances of 2500 μE/m^2/s. In all these cases, under no photoinhibition conditions, a one-to-one relationship between the growth rate and the average irradiance is considered. One of the most used equations to relate these variables is the one proposed by Molina Grima *et al*., (65). Studies suggest that growth models that express μ in terms of the average irradiance raised to some power greater than unity better fit experimental observations (78,79).

$$\mu = \frac{\mu_{\max} I_{\mathrm{av}}^{\mathrm{n}}}{I_{\mathrm{k}}^{\mathrm{n}} + I_{\mathrm{av}}^{\mathrm{n}}} \tag{18.4}$$

None of these models consider the effect of photoinhibition, because they estimate that maximum productivities are reached at very low biomass concentration, when the mutual-shading effects are negligible and the culture may be considered light saturated. However, these cultures could not have been carried out, as photoinhibition in the middle of the day decreases growth rate, even leading to culture washout.

To consider the photoinhibition phenomenon, modification of Equation 18.4 has been proposed (Eq. 18.5) (52), where a, b, and c are empirical parameters, whereas I_{k} and I_{i} are the irradiance constant and irradiance of photoinhibition respectively. This equation accounts for photoinhibition and the fact that the dependence of μ on the

average irradiance varies with the incident irradiance level, I_o. This equation was established from outdoor cultures of *P. tricornutum* UTEX 640, carried out during 3 years in two different tube diameters of tubular PBRs (52).

$$\mu = \frac{\mu_{\max} I_{\text{av}}^{\left(b+\frac{c}{I_0}\right)}}{I_k\left(1+\left(\frac{I_0}{I_i}\right)^a\right)^{\left(b+\frac{c}{I_0}\right)} + I_{\text{av}}^{\left(b+\frac{c}{I_0}\right)}} \qquad (18.5)$$

On the basis of this equation, a macromodel has been proposed to estimate the year-long biomass productivity of microalgal cultures, which is useful for outdoor tubular PBRs (52). In this model, the solar irradiance impinging on the reactor surface is determined as a function of the day of the year and location. By taking into account the geometry of the system, the average irradiance to which the cells are exposed inside the culture, I_{av}, is determined. Finally, in order to correlate the growth rate, μ, with I_{av}, the influence of solar irradiance (an environmental variable), tube diameter (a design variable), and dilution rate (an operational variable) on continuous cultures were analyzed in two different tubular PBRs. Thus, the relation between μ, the impinging irradiance on the reactor surface, I_o, and I_{av} has been described for light-limited growth, which at the same time is partially photoinhibited (Eq. 18.5), the characteristic parameter values that reproduced the experimental results being obtained ($\mu_{\max} = 0.063/\text{h}$, $I'_k = 94.3$ $\mu\text{E/m}^2\text{/s}$, $K_I = 768.4$ $\mu\text{E/m}^2\text{/s}$, $n_1 = 3.04$, $n_2 = 1.209$, and $n_3 = 514.6$, $r^2 = 0.9945$). In this form, by the conjunction of the solar irradiance estimation, the estimation of the average irradiance inside the culture, the kinetic model, and the biomass productivity along the year can be estimated (52). The estimated values reproduced the experimental productivities with less than 20% error. Therefore, the biomass productivity over the annual cycle as a function of geographic location and reactor geometry was obtained (Fig. 18.12). This methodology could be extended to other strains. If photoinhibition would not have been considered, as in previous models (65,86–88), the experimental results could be adjusted to the hyperbolic model that only considers photolimitation (Eq. 18.4) (90). The estimated values, in this case, had an error of over 20%, some of them over 45%.

From the previous analysis, several conclusions already emerge and can be used to optimize biomass production in microalgae mass cultures: (i) the optimum dilution

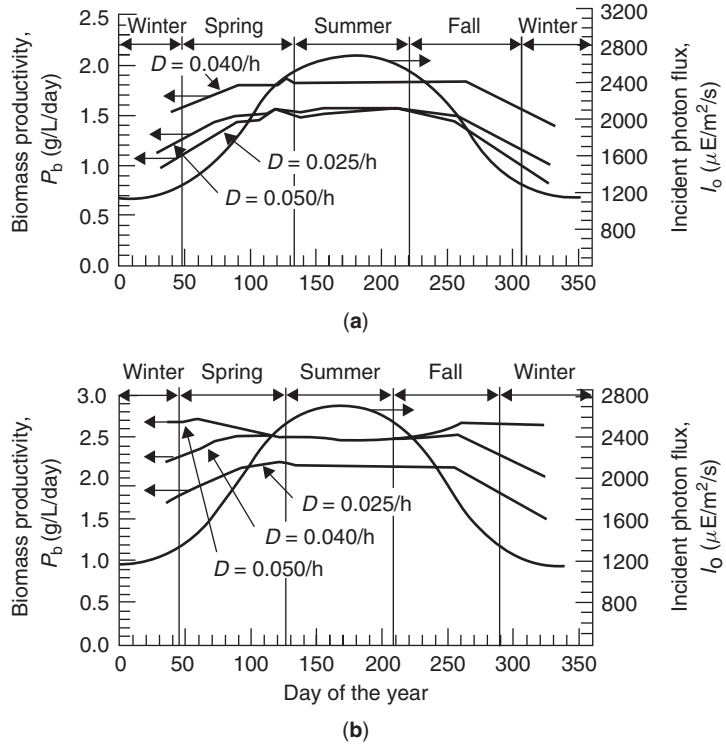

Figure 18.12. Comparison of estimated productivities during the year, with only photolimitation, and with photolimitation plus photoinhibition. (a) Tubular photobioreactor (PBR) 0.06 m tube diameter; (b) tubular PBR tube diameter 0.03 m. [From Ref. 52. With permission.]

rate is not a constant value, but varies over the year as a function of incident radiation and tube diameter, and therefore of average irradiance; (ii) the larger the tube diameter, the more extensive the photoinhibition effect, although the simultaneous existence of photolimitation and photoinhibition permeate the growth to be maintained and thus reaches quasi-steady states; and, (iii) ultimately, the microalgal growth is determined by the photolimitation–photoinhibition regimes in dense cultures.

18.3.4 Temperature

Many studies in both open ponds and closed reactors have shown that temperature is an important factor affecting productivity. The highest biomass growth rate can be obtained only at the optimal temperature for growth. Although there are microalgal strains adapted to extreme temperature conditions, low or high, most microalgae grow optimally at 15–30°C. Below this value, the growth is depressed by the reduction of metabolic kinetics, whereas above this value temperature and oxidative stress appear and the yield of the cultures greatly decreases. Some other strains tolerate higher temperatures, up to 45°C, being adequate for outdoor culture due to lower refrigeration requirements.

Although this effect is obvious and well documented under laboratory conditions, the magnitude of the effect on the annual production of biomass outdoors does not seem to be sufficiently documented. The diurnal variation in temperature that affects cultures in open raceways results in temperature-limited growth during a significant fraction of the day. Lee *et al*., (75) showed that the light yield (g biomass/kJ) increased some three- to fivefold with increasing temperature in cultures of *Chlorella*, an effect that may be easily observed with other microalgae. The response of microalgae to temperature shows a typical behavior of other microorganisms as bacteria, yeast, or fungi, an Arrhenius's type equation being usually used to model this behavior.

$$\mu_{\max} = \mathrm{A} \exp\left(\frac{-\mathrm{B}}{T}\right) \tag{18.6}$$

where A and B are empirically determined constants for a range of temperatures, T. However, in outdoor cultures, the temperature is not constant and varies simultaneously with the solar cycle and the cells adapt to this variation in a process similar to the adaptation phenomena related to the light variation. The temperature of the culture at night is yet another important factor that affects the net output rate of biomass. The effect of temperature on dark respiration is, of course, very well documented (28,46,52).

To maximize the yield of outdoor microalgal cultures, it has been proposed to maintain the cultures cold during the night and to heat them to the temperature of operation just before sunrise, then cool them during the hours of maximum irradiance by water spraying systems to avoid overheating of the cultures (91,92). However, the capacity of these systems is limited and their application is only possible under certain environmental conditions (temperature, humidity, etc.). The other strategy considers the use of heat reservoirs to recirculate cool water trough a heat exchanger inside the PBR, thus homogenizing the temperature of the cultures over the solar cycle and reducing the power consumption.

18.3.5 Fluid Dynamics and Mixing

In order to achieve high productivity, microalgal cultures have to be mixed. The method of providing adequate mixing (turbulence) is, however, critical because many algae are quite sensitive to shear stress (27,93). It has been proposed that, when light is the limiting factor for growth, stirring represents the most practical way to attempt to distribute solar energy evenly to all cells in the culture. Stirring affects the flashing light effect by changing the duration that the cells are exposed in the photic zone and the time they remain in the dark zones inside the reactor (this concept is often referred to as *light regime*, introduced by Richmond, (16)). This field has been intensively investigated by Laws *et al*. (94), who introduced a simple technique for utilizing the flashing light effect in shallow but optically dense outdoor algal cultures by inserting an array of small foil segments across the width of a continuous flume at intervals of 1.2 m along the length of the flume. The wing-shaped foils create a vortex circulation that produces an ordered pattern of vertical stirring. By using these foils, Laws *et al*. (94) obtained averaged photosynthetic efficiencies (based on the photosynthetic active radiation [PAR]) of 9.6 and 7.5, respectively, with and without the foil in place.

In tubular PBRs and ponds, higher flow rates generally enhance productivity. Typical values of flow rates range between 20 and 30 cm/s. This flow can be achieved by using the paddle wheel devices in open reactors, or peristaltic, diaphragm, centrifugal pumps, or airlift devices in closed systems. However, the use of these equipments introduces shear forces in the culture. Airlift systems are generally less damaging to the cells and are most effective. In tubular reactors, the airlift system is the usual method for maintaining a degree of turbulence in the mass culture. The higher velocity in the tube controls the turbulence and shear effects, determines the mixing behavior and the mass transfer capacity, and it greatly influences the axial oxygen concentration profiles in the tube. The liquid velocity, U_{L}, may be estimated by an extension of the well known and widely tested model developed by Chisti (95).

$$U_{\mathrm{L}} = \left[\frac{g h_{\mathrm{d}} \varepsilon_{\mathrm{r}}}{2 C_{\mathrm{f}} \frac{L_{\mathrm{eq}}}{D}} \frac{A_{\mathrm{r}}}{A_{\mathrm{d}}}\right]^{0.5} \tag{18.7}$$

where f is the Fanning friction factor that can be calculated using the Blasius equation.

$$C_f = 0.0791\,\mathrm{R_e}^{-0.25} \tag{18.8}$$

where Re is the Reynolds number, or $(\rho_L U_L \mathrm{D})/\mu$. Here D is the tube diameter, and ρ_L and μ are the density and the viscosity of the liquid respectively. As shown in Equation 18.7, the superficial liquid velocity in the tubular PBR is a function of gas holdup in the riser, ε_r, the height of the dispersion, h_D, and the ratio between the cross-sectional area of both the riser and the downcomer. The gas holdup follows a potential relationship with the power supply (Eq. 18.9) (95), the power supply due to aeration being a function of the density of the liquid, ρ_L, the gravitational acceleration, g, and the superficial gas velocity in the aerated zone, U_G (Eq. 18.10).

$$\varepsilon = 3.32 \cdot 10^{-4} \left(\frac{P_\mathrm{G}}{V_\mathrm{L}}\right)^{0.97} \tag{18.9}$$

$$\frac{P_\mathrm{G}}{V_\mathrm{L}} = \rho_\mathrm{L} g U_\mathrm{G} \tag{18.10}$$

18.3.6 Mass Transfer, Oxygen Accumulation, and Carbon Uptake

Microalgae perform photosynthesis, then oxygen is produced and carbon dioxide is taken up from the environment. If oxygen is not removed from the culture medium, it accumulates. Similarly, carbon dioxide must be provided such that availability of carbon does not become a limiting factor. Removing oxygen and supplying carbon dioxide are problems of gas–liquid mass transfer. Therefore, modeling of an algal reactor must consider gas–liquid mass transfer and how it is affected by hydrodynamics.

Oxygen concentrations above air saturation generally inhibit photosynthesis in microalgae (96). In cultures of *A. azollae* performed in vertical alveolar panels, the yield of the cultures decreases when the DO accumulates up to 400% with respect to saturation with air (21). In *P. tricornutum*, the photosynthetic activity not only decreases at DO concentrations exceeding 100% saturation (i.e. 100% with respect to saturation with air) but also below this value. A maximum photosynthesis rate of 0.0036 $\mathrm{molO_2/m^3/s}$ was measured at 100% saturation, reducing by 15% at DO concentrations of 0% and 300% saturation. At DO concentrations of 475% saturation, the photosynthesis rate declined sharply to 0.0016 $\mathrm{molO_2/m^3/s}$ (55% reduction) (18). Regarding CO_2, Weissman *et al*. (97) reported that CO_2 concentration in bulk liquid of at least 65 mM and pH 8.5 were required for optimal productivity of some marine- and saline-water diatoms. Similarly, Markl and Mather (98) observed a low critical CO_2 for *Chlorella vulgaris*: Concentrations as low as 60 mM enabled unlimited photosynthesis. In principle, CO_2 limitation can be easily avoided by supplying it in excess, but use of carbon dioxide represents a major operational expense of microalgal culture; hence, loss of residual CO_2 in the exhaust gas needs to be minimized.

Whatever the PBR design considered, it is possible to ensure a sufficient mass transfer capacity so that photosynthetically generated oxygen does not accumulate at excessively high concentrations. Thus, considering a maximum biomass productivity of 2.0 g/L/day with 50% carbon content in the biomass and a photosynthesis ratio of 1 $\mathrm{molO_2/molCO_2}$, a mass transfer coefficient of 0.006/s would be needed to prevent DO levels exceeding 300% saturation. To achieve this mass transfer capacity in flat-panel PBRs, the power supply must be 53 $\mathrm{W/m^3}$, as compared to 40 $\mathrm{W/m^3}$ in bubble columns (26,99), and 2400–3200 $\mathrm{W/m^3}$ in tubular PBRs (49,100,101). This shows that oxygen removal into the exhaust gas phase is substantially easier in flat-panel and bubble-column reactors than in tubular ones, although in the latter it was also enough to avoid excessive oxygen accumulation.

To adequately supply CO_2 from a gas phase to the culture, it is necessary to take into account that the dissolved carbon dioxide is in equilibrium with carbonate and bicarbonate species. These equilibria are pH dependent. Loss of dissolved carbon dioxide due to uptake into algal cells is partly compensated by regeneration from carbonates and bicarbonates. Consequently, carbon dioxide uptake is accompanied by changes in pH. The relevant equilibrium and the corresponding equilibrium constants that need to be considered are (100):

$$\mathrm{H_2O} \leftrightarrow \mathrm{H^+ + OH^-}\quad \mathrm{K_w} = [\mathrm{OH^-}] \cdot [\mathrm{H^+}] = 10^{-14} \tag{18.11}$$

$$\mathrm{CO_2 + H_2O} \leftrightarrow \mathrm{H_2CO_3} \leftrightarrow \mathrm{HCO_3^- + H^+}\quad \mathrm{K_1} = [\mathrm{HCO_3^-}] \cdot [\mathrm{H^+}]/[\mathrm{CO_2}] = 10^{-6.381} \tag{18.12}$$

$$\mathrm{HCO_3^-} \leftrightarrow \mathrm{CO_3^{2-} + H^+}\quad \mathrm{K_2} = [\mathrm{CO_3^{2-}}] \cdot [\mathrm{H^+}]/[\mathrm{HCO_3^-}] = 10^{-10.377} \tag{18.13}$$

To ensure a sufficient supply of CO_2, different strategies have been proposed. Lee and Hing (103) have suggested supplying carbon dioxide by diffusion through silicone tubes containing the pure gas. Camacho Rubio *et al*., (100) proposed the use of short-time injections of pure CO_2, whereas Mazzuca *et al*., (104) proposed the injection of CO_2–air mixtures. Although all these strategies reduce the carbon losses with regard to on–off injection, the most advantageous system is the use of model predictive control to adequately inject pure CO_2 into the reactor (105,106). In this way, carbon losses lower than 5% were achieved.

The adequate design and operation of PBRs require both the removal of oxygen and the supply of CO_2. In both cases, the major variable determining it is the mass transfer coefficient. The mass transfer from the gas phase to the culture suspension in open ponds has been extensively studied (98,107).In aerated systems, the volumetric gas–liquid mass transfer coefficient has been referenced to increase potentially with the power supply (Eq. 18.30) (95).

$$K_L a_L = 2.39 \cdot 10^{-4} \left(\frac{P_G}{V_L} \right)^{0.86} \tag{18.14}$$

18.3.7 Power Supply and Stress Damage

Power is supplied to microalgae cultures to increase the mass transfer and avoid toxic levels of DO, to reduce the nutrients gradient in the culture broth, to avoid cell sedimentation in the reactor, and to force the cells to move from dark to light zones, enhancing the photosynthesis. However, excessive aeration and/or agitation by pneumatics and mechanical devices may produce cell damage if the microalgae are susceptible to hydrodynamic and mechanical shear forces, affecting the culture performance. Power supply promotes mass transfer in both directions: CO_2 from the gas phase to the bulk liquid and DO from the bulk liquid to air bubbles. To avoid excessive oxygen levels, the mass transfer capacity of the system must be enough to remove the oxygen generated by photosynthesis (18,101). Power supply also promotes an adequate light–dark cycle regime. In both cases, there is an optimum value of power supply that ensures enough mass transfer to prevent excessive oxygen accumulation and adequate light regimes. However, the optimum could differ for both variables.

All the power supplied to the culture is dissipated, excessive power supply damaging the cells. Factors determining the shear sensitivity are the type of microalgae, the composition, and thickness of the wall cell, when present, the size and morphology of cells—the presence of flagella is a very important factor the intensity and nature of the shear stress (laminar/turbulent regime, presence of pumps, etc.), and finally the growth environment to which the cells are exposed (pH, temperature, irradiance, etc.) (27,108). The energy dissipation rates in the fluid are linked to shear stress, shear rates, the microeddy length scale, and other characteristics of flow (108,110).

In aerated systems, the power supplied may damage cells when the bubbles detach at the sparger, during the eventual breakup or coalescence of the bubbles within the bulk liquid and, above all, when bubbles burst at the culture surface. Bubble bursting has been recognized as the main factor that harms cells in aerated cultures. The mechanism of the bubble rupture and cell damage has been extensively studied. It is well established that small bubbles are more damaging than larger ones and that the higher the aspect ratio of the reactor (height/diameter ratio), the lower is the bubble-associated damage.

On the other hand, either in aerated or in nonaerated systems, the power supply may also damage the cells because of interactions between the wall of the PBR and the cells. The wall shear stress is a function of the liquid velocity and the friction coefficient, which, at the same time, is a function of the Reynolds number. One additional cause of damage when the culture is subjected to mechanical forces, as those produced by stirrers, paddle wheels, or pumps, is the interaction between the cells and the stirrer, or the damage caused by the passing of the cells through the pump cavity (27). In open systems, implemented by paddle wheels, the shear rate is a function of the number of revolutions per second and the diameter of the impeller. When pumps are used for liquid impulsion, the shear rate is a function of the Reynolds number within the pump cavity.

Finally, power supply gives rise to a certain level of turbulence within the bulk liquid, which determines the length of the small microeddies through which the supplied power is dissipated. Cell damage has been reported when the turbulence is so intense that the fluid microeddy size approaches cellular dimensions (length scale of microeddies < size of the cells) (110). In contrast, if the length scale of the microeddies is greater than the cells, the cells are dragged by the eddies and this turbulence in the bulk liquid does not cause any damage. The energy dissipated per unit mass determines the length scale of the microeddies and the shear rate at which the cells are subjected (99).

The power supply required for flat-panel PBRs is extremely low, with a maximum of 53 W/m^3, and high power input is not suitable for microalgal cultures because of the likelihood of cell damage due to intense turbulence (93,110,111). In bubble columns, the maximum power supply that does not damage the growth of *Dunaliella tertiolecta* is 98 W/m^3 (108), whereas the maximum power supply tolerable for *P. tricornutum* ranges from 230 (99) to 270 W/m^3 (42). The highest power supply in aerated systems ranges from 280 W/m^3 in flat-plate PBRs (57) to 200 W/m^3 in bubble column or internal airlift systems employing split cylinders and draught tube sparger PBRs (26). However, the power supply in tubular PBRs is usually much higher. Thus, in helical PBRs, the power supply ranges from 800 to 3400 W/m^3 (29,49), similar to 2500 W/m^3 in horizontal tubular PBRs (100). In spite of the higher power supply in tubular PBRs, damage to algal cells has never been documented in these types of PBRs (26). This is because the culture velocity in tubular loops usually does not exceed 0.5 m/s, which is less than half the threshold damage value of 1.14 m/s (101). These data point out the different nature of stress in bubble-column flat-plate PBRs and tubular PBRs.

It has been demonstrated that shear rate is the main variable determining the fluid-dynamic stress damage, the value

of shear rate that determines the existence of stress damage varying as a function of strain and culture conditions (99). The shear rate in bubbled cultures, by aeration, is a function of the bubble rise velocity, U_B, and the mean bubble diameter, d_B. The bubble rise velocity can be estimated as 0.24 m/s, while the bubble diameter is a function of fluid properties and fluid-dynamic conditions with the equation proposed by Calderbank (112). These equations are as follows:

$$\gamma_{\text{aeration}} = \frac{2U_B}{d_B} \tag{18.15}$$

$$d_B = 4.15\left(\frac{\sigma^{0.6}}{(\text{Pe/V})^{0.4}\rho_L^{0.2}}\right)\varepsilon^{0.5} + 0.0009 \tag{18.16}$$

The shear rate in peristaltic and diaphragm pumps can be calculated as the shear rate in the cavity pump. Thus, it is a function of the properties of the fluid, the liquid velocity in the cavity pump, and the friction coefficient, C_f. The liquid velocity in the cavity pump is calculated taking into account the acceleration factor and the diameter of the cavity pump. These same terms can be used to calculate the Reynolds number inside these pumps. The equations relating these variables are as follows:

$$\gamma_{\text{pump}} = \frac{1}{2\ \mu_L} C_f \rho_L U_L^2 \tag{18.17}$$

$$C_f = 0.072\left(\frac{\rho_L U_L d}{\mu_L}\right)^{-0.25} \tag{18.18}$$

For the centrifugal pump, the shear rate can be calculated as a function of the impeller velocity and the Reynolds number inside the impeller. The equations relating these variables are (110):

$$\gamma_{\text{pump}} = 6.3N\ Re^{0.5} \tag{18.19}$$

$$\text{Re} = \frac{N\rho_L d^{0.5}}{\mu_L} \tag{18.20}$$

18.4 TUBULAR PHOTOBIOREACTORS DESIGN

Tubular PBRs are the most widely used closed systems for the culture of microalgae. This section proposes a design strategy for them.

18.4.1 Biomass Productivity and Solar Radiation

Biomass productivity is the variable that needs to be optimized in designing a PBR for mass culture of microalgae. As commented in the previous section, production of biomass is governed mainly by the availability of light. This is evaluated using the well-known principles of astronomy (to establish the position of the sun relative to the PBR), solar power engineering (to determine the intensity of the incident radiation), and the Beer–Lambert relationship, as summarized elsewhere (19). For otherwise fixed conditions, the geometric arrangement of the solar collector tubes also determines the irradiance on the surface of the tubes because the mutual shading by tubes is influenced by how they are arranged over a given surface area. From these principles, the average irradiance inside the tube, I_{av}, can be calculated as a function of tube diameter and arrangement of the tubes.

On the other hand, the growth rate, μ, is a function of average irradiance. Various relationships have been developed for this dependence (Eqs 18.4, 18.5). Thus, from the knowledge of the characteristics parameters of the algal strain (i.e. μ_{max}, K_a, I_k, and n), the growth rate may be determined for any combination of external irradiance and the diameter of solar collector tubes. Once the specific growth rate is known, the volumetric productivity of continuous cultures is calculated:

$$P_{bv} = \mu C_b \tag{18.21}$$

where P_{bv} is the volumetric productivity and C_b is the concentration of the biomass in the harvest stream of the continuous flow bioreactor. The areal productivity P_{ba} is related to the volumetric productivity, P_{bv} as follows:

$$P_{ba} = P_{bv}\frac{V}{S} \tag{18.22}$$

where V is the volume of the culture and S is the surface occupied by the reactor.

18.4.2 Power Supply and Liquid Velocity

The design of a tubular PBR must guarantee that the flow in the solar tube is turbulent (i.e. the minimum Reynolds number should exceed 3000) so that the cells do not stagnate in the dark interior of the tube. At the same time, the dimensions of the fluid microeddies should always exceed those of the algal cells so that turbulence-associated damage is prevented. The need to control eddy size places an upper limit on the flow rate through the solar tubing. The length scale of the microeddies may be estimated by applying Kolmogorof's theory of local isotropic turbulence (109).

$$\lambda = \left(\frac{\mu_L}{\rho}\right)^{3/4}\xi^{-1/4} \tag{18.23}$$

where λ is the microeddy length, ξ is the energy dissipation per unit mass, μ_L is the viscosity of the fluid, and ρ is the

fluid density. The specific energy dissipation rate within the tube depends on the pressure drop

$$\xi = \frac{2C_f U_L^3}{d_t} \tag{18.24}$$

where C_f is the Fanning friction factor, which may be estimated using the Blausius equation (Eq. 18.8). Thus, for any selected strain, the cell size is known. Using this value as microeddies length, the maximum energy dissipation rate per unit mass is calculated (Eq. 18.23), and from this the maximum liquid velocity that approaches microeddies length to cell size (Eq. 18.24).

Another restriction on the design of the solar collector is imposed by the acceptable upper limit on the concentration of DO. Thus, the length of the solar collector must be shorter than necessary to achieve an oxygen concentration in the culture that inhibits the photosynthesis. This maximum length, L, is calculated as a function of the liquid velocity, DO concentration, and photosynthesis rate as follows (100):

$$L = \frac{U_L([O_2]_{out} - [O_2]_{in})}{R_{O2}} \tag{18.25}$$

where U_L is the liquid velocity (lower than the maximum velocity imposed by microeddies length), $[O_2]_{in}$ is the oxygen concentration at the entrance of the solar collector (i.e. the saturation value when the fluid is in equilibrium with the atmosphere), $[O_2]_{out}$, is the oxygen concentration at the outlet of the solar collector (i.e. maximum acceptable value that does not inhibit photosynthesis), and R_{O2} is the volumetric rate of oxygen generation by photosynthesis (function of biomass productivity designed). If circulation of the culture is performed by pumps, the type and power of the used pump determines the liquid velocity, whereas if airlift systems are used the liquid velocity is a function of height and aeration rate on it (Eq. 18.7).

18.4.3 Combining Flow and Gas–Liquid Mass Transfer

Design of tubular PBRs must consider gas–liquid mass transfer and hydrodynamics. The carbon dioxide gas injected is transported from the gas phase to the aqueous medium to provide the inorganic carbon and control the pH of the culture. For otherwise fixed conditions, the inorganic carbon supplied is incorporated into cells at a specific rate determined by the rate of photosynthesis. Similarly, the oxygen is produced at a specific rate and transferred from the culture to the gas phase. All these aspects have been treated in a tubular reactor equipped with an airlift system (100). By applying mass balances to the different zones of the reactor for which the fluid-dynamic conditions remained constant, the carbon dioxide and oxygen transfer between the liquid and gas phase was modeled. For the liquid phase, the changes in concentrations of DO and dissolved inorganic carbon along the loop can be related to the gas–liquid mass transfer rates and the generation/consumption rates by mass balances as follows:

$$Q_L d[O_2] = K_l a_{llO_2}([O_2]^* - [O_2])S\mathrm{d}x + R_{O_2}(1 - \varepsilon_l)S\mathrm{d}x \tag{18.26}$$

$$Q_L d[C_T] = K_l a_{llCO_2}([CO_2]^* - [CO_2])S\mathrm{d}x + R_{CO_2}(1 - \varepsilon_l)S\mathrm{d}x \tag{18.27}$$

In these equations, $K_l a_{llO2}$ and $K_l a_{llCO2}$ are the volumetric gas–liquid mass transfer coefficients for oxygen and carbon dioxide respectively; dx is the differential distance along the direction of flow in the solar tube; $[O_2]$, $[C_T]$ and $[CO_2]$ are the liquid phase concentrations of oxygen, inorganic carbon, and carbon dioxide respectively; ε_l is the gas holdup; S is the cross-sectional area of the tube; R_{O_2} and R_{CO_2} are the volumetric generation and consumption rate of oxygen and carbon dioxide respectively; and Q_L is the volumetric flow rate of the liquid. Note that the concentration values marked with asterisks are equilibrium concentrations, i.e., the maximum possible liquid phase concentration of the component in contact with the gas phase of a given composition. The mass balance considers the total inorganic carbon concentration $[C_T]$ and not just that of carbon dioxide. This is because C_T takes into account the dissolved carbon dioxide and the carbonate, CO_3^{2-}, and bicarbonate, HCO_3^-, species generated by it.

As for the liquid phase, a component mass balance can also be established for the gas; hence:

$$\mathrm{d}F_{O_2} = -K_l a_{llO_2}([O_2]^* - [O_2])S\mathrm{d}x \tag{18.28}$$

$$dF_{CO_2} = -K_l a_{llCO_2}([CO_2]^* - [CO_2])S\mathrm{d}x \tag{18.29}$$

Here F_{O_2} and F_{CO_2} are the molar flow rates of the two components in the gas phase. Note that, because of the changes in molar flow rates, the volumetric flow rate of the gas phase may change along the tube. The equilibrium concentrations of the two gases in the liquid can be calculated using Henry's law relationships:

$$[O_2]^* = H_{O_2} P_{O_2} = H_{O_2}(P_T - P_v)\frac{F_{O_2}}{F_{O_2} + F_{CO_2}} \tag{18.30}$$

$$[CO_2]^* = H_{CO_2} P_{CO_2} = H_{CO_2}(P_T - P_v)\frac{F_{CO_2}}{F_{O_2} + F_{CO_2}} \tag{18.31}$$

where H_{O_2} and H_{CO_2} are the Henry's constants for oxygen and carbon dioxide, P_{O_2} and P_{CO_2} are the partial pressures

(or mole fractions) of the components in the gas phase; the partial pressures can be calculated knowing the total pressure (P_T), the vapor pressure (P_v), and the molar flow rates F_{O_2} and F_{CO_2} at any location in the system.

Equations 18.26–18.29 along with the Equations 18.30 and 18.31 for equilibrium concentrations, and the initial conditions, allow numerical integration and, hence, the determination of the CO_2 and O_2 axial profiles in the liquid phase and the molar flow rates of the two components in the gas phase. The accuracy of the proposed equations was verified by Camacho Rubio *et al*., (100) who used these equations for estimating the behavior of a tubular PBR along the day. As shown in Fig. 18.13, through any 24-h period, the simulated data—pH, carbon dioxide losses, and the amount of carbon dioxide injected—closely agreed with the measurements. Although, the degree of correlation differs for different variables, the mean of errors for the entire set of variables is lower than 15%. The predictive capabilities of proposed equations demonstrate its potential as a scale-up tool. The model is simple and can be adapted to any PBR and photoautotrophic strains. Moreover, because the model simulates the system behavior as a function of the tube length and operational variables (superficial gas velocity in the riser, composition of the carbon dioxide injected in the solar receiver, and its injected rate), it allows the rational design and scale-up of PBRs.

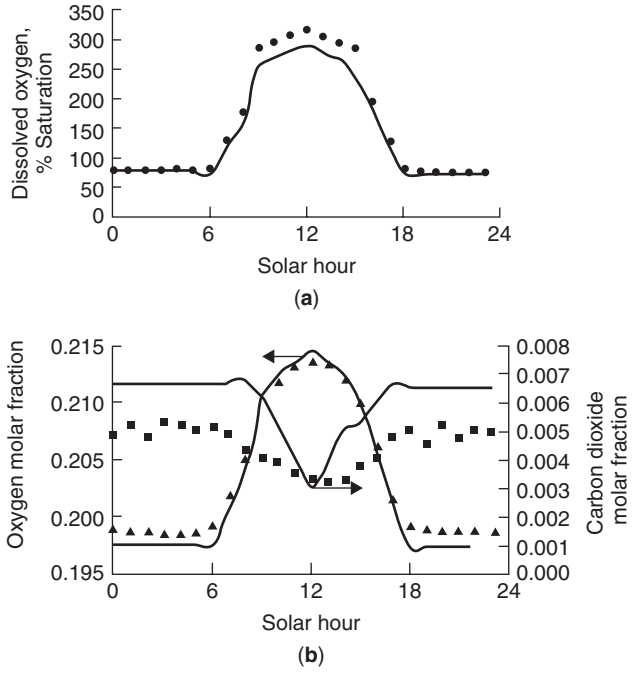

Figure 18.13. Comparison between experimental (symbols) and simulated (lines) data of pH, total inorganic carbon, oxygen, and carbon dioxide in the liquid and gas phase, on an outdoor tubular photobioreactor 0.22 m. [From Ref. 100. With permission.]

18.4.4 Oxygen Removal and Temperature Control

Once the solar collector is designed, it is necessary to design the unit for removal of oxygen and temperature control. This is performed in bubble columns or airlift devices. The use of bubble columns is favorable because these systems are widely used at the industrial scale. The mass transfer coefficient can be calculated as a function of the aeration rate (Eqs 18.10,18.14), then the volume of the bubble column necessary to remove oxygen can be calculated as:

$$V = \frac{Q_L([O_2]_{in} - [O_2]_{out})}{K_L a_L([O_2^*] - [O_2])_{lm}(1 - \varepsilon)} \tag{18.32}$$

where Q_L is the liquid flow rate entering the bubble column, $[O_2]_{in}$ is the oxygen concentration at the inlet of the bubble column, $[O_2]_{out}$ is the oxygen concentration at the outlet of the bubble column, $K_L a_L$ is the volumetric mass transfer coefficient, and ($[O_2^*]$–$[O_2]$) is the driving force for the transport of oxygen from the liquid to the gas phase, calculated as mean logarithmic value from the entrance to the outlet. To avoid recirculation of bubbles from the bubble column to the solar collector, the superficial liquid velocity down must be lower than the bubble rise velocity, U_b. Thus, the minimum diameter of bubble column, d_c, is calculated (Eq. 18.33), along with the minimum height of the column necessary, h_c, (Eq. 18.34).

$$d_c = \sqrt{\frac{4Q_L}{\pi U_b}} \tag{18.33}$$

$$h_c = \frac{4V}{\pi d_c^2} \tag{18.34}$$

Analogous to mass transfer, the heat transfer equipment must be designed. The equipment must be designed to remove the heat absorbed by radiation. This is a function of solar radiation collected by the solar collector, Q_{rad}, and the thermal absorptivity of the culture, a_{rad}. Finally, the area of heat exchanger necessary, $A_{exchanger}$ is calculated as a function of the overall heat transfer coefficient, $U_{exchanger}$, and temperature of cooling water as:

$$A_{exchanger} = \frac{Q_{rad} a_{rad}}{U_{exchanger}(T_{culture} - T_{water})} \tag{18.35}$$

18.4.5 Case Study

Equations 18.21–18.35 were used to design an industrial size PBR operated in a greenhouse in Almería, Spain. First, the light availability inside the greenhouse was calculated according to the solar radiation knowledge, although measurements were performed to validate it. Then, simulations were performed to determine the optimal tube diameter.

Selection was performed on the basis of the microalgae to be produced, *S. almeriensis*, and its characteristic parameters (μ_{max}, I_k, n), the objective being to maximize the size of the reactor that would allow a year-long biomass productivity of roughly 1.0 g/L/day. From this analysis a maximum tube diameter of 0.10 m was selected. According to the target biomass productivity, the photosynthesis rate was calculated, and the maximum length of the solar collector was established accordingly to 400 m. Finally, a bubble column was designed to connect it to the solar collector to remove oxygen generated by photosynthesis as well as to control the temperature of the culture (113). The designed tubular PBR was built (Fig. 18.14) and operated for more than 1 year. Figure 18.15 shows the biomass productivity values measured during the operation of the PBR in an annual cycle. It is observed as the performance of the industrial unit is quite similar to the predicted productivities using the model, Equations 18.21–18.34, with biomass productivities through the year higher and lower than the 1.0 g/L/day average. Now, this design strategy has been applied to build a pilot plant size facility (30 m^3) for the production of the same strain (see Fig. 18.4, bottom).

18.5 PHOTOSYNTHETIC EFFICIENCY IN MICROALGAL MASS CULTURES

As stated earlier, production of microalgae biomass in PBRs face the challenge of improving the efficient use of the enormous high PFDs impinging on the earth's surface. The photosynthetic efficiency (Ψ) of biomass growth is defined as the energy stored in biomass per unit of light energy absorbed (91). This parameter is of fundamental importance in biomass production because the biotechnology for algae production should naturally aim to achieve the maximum attainable photosynthetic efficiency so as to produce the most biomass possible per unit land area (open ponds) or volume (enclosed systems). The explanation accepted for calculating Ψ is as follows (91): Microalgae, as green plants, use only the PAR, which constitutes about 43% of the total solar radiation at the earth's surface and has an energy input equivalent to that of monochromatic light at 575 nm. One Einstein of 575 nm light contains 49.74 kcal of energy, and assuming that free energy stored in photosynthesis is 114 kcal/mol of reduced CO_2, the theoretical maximum energy efficiency for the photosynthetic reduction of CO_2 to glucose with white light is $114/(8 \times 49.74) = 0.286$, or approximately 29% (91). In the previous calculations, it was accepted that the Z-scheme of photosynthesis and thus the light requirement for the transfer of four electrons are eight photons. It should be stressed that, under field conditions, much lower photosynthetic efficiencies have been obtained. The maximum practical photosynthetic efficiency is still a problem to be resolved (114). However, a theoretical photosynthetic yield of 6% to 7% of total solar energy seems possible (115); this represents, depending on the geographic location, a biomass productivity of 35–70 g/m^2/day. A photosynthetic efficiency of 10% during a period of 122 days has been reported (114). These experimental results are in agreement with Richmond (91). Therefore, it is obvious that the challenge to the algal industry may be defined as producing biomass on a large scale under outdoor conditions with efficiency similar to that obtained under controlled laboratory conditions.

Figure 18.14. Photograph of an industrial-size tubular photobioreactor built according to design equations proposed (Eqs 18.21–18.35). [With permission from Ref. 38.] (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

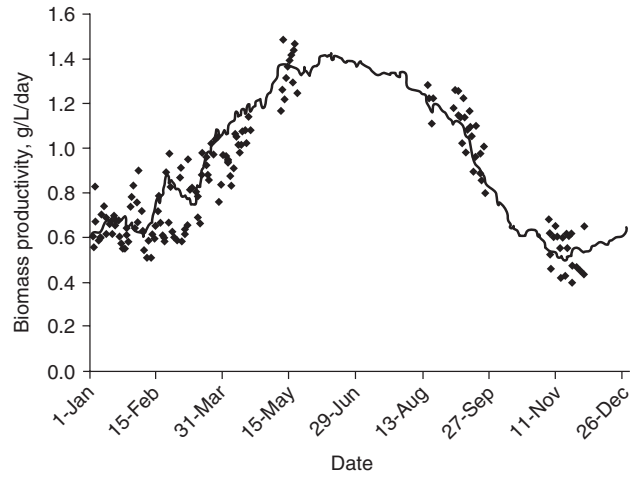

Figure 18.15. Variation in biomass productivity during an annual cycle in the industrial-size tubular PBR built according to proposed strategy design (Eqs 21–35). Data correspond to experimental values, whereas line corresponds to data predicted by the model used in the design.

Goldman (15) summarized the information on algal yields reported for over 30 years. Although the early effort in mass algal culturing resulted in yields no better than 10–15 g dry weight/m^2/day for short periods; currently, it is not uncommon for sustained yields to reach 20–25 g/m^2/day. The maximum growth yields of algae may be represented by models that integrate the factor, limiting production. Goldman presented a thorough study of maximum yield potential of algae based on the thesis that algal production under proper conditions is limited only by light (91). The equation derived was as follows:

$$P_b = 0.28 \cdot I_s \left(\ln \frac{0.45 \cdot I_0}{I_s} + 1 \right) \tag{18.36}$$

in which P_b is the productivity of the system (g/m/^{2}/day), I_0 is the total irradiance at the culture surface, I_s is the saturating light intensity for which the growth rate is the maximum (i.e. at which $\mu = \mu m$). Because the maximum available intensity of sunlight striking the earth's surface is lower than 800 cal/cm^2/min, Equation 18.36 predicts that, for a range of I_s values between 0.02 and 0.06 cal/cm^2/min as is typical for microalgae culture, the upper limit for algal yield is 30–60 g dry weight./m^2/day. According to this model, the factor that most strongly influences algal yield is I_s. These figures, again, are far from those predicted in the carefully conducted indoor cultures work. Why is there a large discrepancy between the outdoor production and those obtained from most laboratory work?

The laboratory work reported above was carried out under conditions of low intensities, at or below saturation for photosynthesis. In practice, when dealing with sunlight, the major problem is not the maximal quantum efficiency but the fraction of absorbed photons that can be actually be used in photosynthesis (97). The problem is that, if algal photosynthesis saturates at low light intensities, but algal cells have a high extinction coefficient (high pigment content), then more light is absorbed than can be used in photosynthesis. Depending on the actual saturation and incident light intensities, the extinction coefficient, K_a, and the biomass concentration, the maximum efficiency (regardless of the minimum quantum requirement) is reduced by a factor of about two- to fivefold from that possible at low light levels.

A new procedure for calculating yields in microalgal mass cultures, at high incident irradiances, was proposed by Molina Grima *et al*. (78). The new approach is based on the averaged irradiance for the assessment of the photon flux absorbed by the biomass. The starting point of Molina Grima and coworker's procedure is the definition of the quantum yield, Ψ_E, in a microalgal culture systems. The quantum yield, Ψ_E, is defined as the amount of biomass generated by the unit of radiation (usually photons or Einstein) absorbed by the culture. Because it represents the ratio of biomass generation to absorbed photon flux, it can be calculated by the expression:

$$\Psi_E = \frac{P_b}{F_{vol}} \tag{18.37}$$

where P_b stands for the volumetric biomass productivity and F_{vol} for the photon flux absorbed in the volume unit. This coefficient can be converted to energy units, commonly noted Ψ_{kJ}, by taking into account the average range of the light used (kJ/E). The photosynthetic efficiency (i.e. the bioenergetic yield), Ψ, quantifies the percent of light energy that is converted to chemical energy and can be calculated as the product of Ψ_{kJ} by the biomass combustion heat, Q_b.

$$\Psi = \Psi_{kJ} \cdot Q_b \tag{18.38}$$

18.5.1 Absorbed Photon Flux

This is a complicated question, especially when it must be evaluated in geometries other than flat reactors. Many factors such as light-scattering effects may lead to a misevaluation of the absorbed flux and, in every case, they need to be evaluated by direct measurement of the light leaving the PBR (96). In this sense, it must be noted that the light absorbed can be evaluated by integrating the local volumetric rate of energy absorption (117) into the total reactor volume. This integral can be readily obtained from the extinction coefficient of biomass, K_a, and the average irradiance I_{av}.

$$F_{vol} = I_{av}\ K_a\ C_b \tag{18.39}$$

The calculation of the photon flux absorbed by the procedure has several advantages. It is independent of the system geometry once I_{av} is known, and can thus be used in any type of PBR as long as I_{av} can be determined by any means. Photon flux losses due to reflection of light off the reactor walls that cannot be neglected (96) are easily obviated by measuring the irradiance inside the culture. Therefore, the irradiance impinging on the reactor surface is taken into account for the determination of I_{av}. The validity of equation 18.39 for assessing the absorbed photon flux has been checked experimentally in a culture of *Isochrysis galbana* (78) and by using data published by Lee and Erickson (118) in a quite different culture of *Chlorella* in a paralellepipedical flat PBR. *I. galbana* showed a maximum efficiency of conversion light into biomass, $\Psi_{E\,max}$ of 0.6 g/E was obtained at $I_0 = 820\ \mu E/m^2/s$ and $D = 0.030/h$; and the maximum capacity of the biomass to metabolize light was found to be 13.1 μE/g/s (78). Above this value, a significant drop

in system efficiency was observed. Moreover, the biomass productivity to be expected in an outdoor tubular PBR growing *I. galbana* was predicted to be in agreement with the actual value (28).

18.6 OPERATIONAL CONSIDERATIONS

For successful maintenance of a microalgal culture facility, the performance of the culture should be continuously assessed in order to prevent the development of conditions that, in turn, could give rise to significant losses. In this sense, the on-line information on DO, temperature, pH as well as the daily microscopic observation make up an excellent source of information for characterizing the physiological state of the culture. Measurement of growth should be accompanied as a rule by detailed microscopic evaluation. Any buildup in the number of other organisms in the culture should be regarded as a warning signal. It might be that the temperature may have deviated too much from the optimal; or it might be a signal that the concentration of a particular nutrient had declined below the optimal. On the other hand, careful monitoring of the nitrogen concentration gives information about the possible depletion in mineral nutrients in the continuous cultures. This information can be used as a guideline for adding, in equivalent amounts, the entire formula of the elements making up the growth medium. Besides, the concentration of DO is a reliable and sensitive indicator of conditions that relate to growth and productivity. There are many indications that early detection of an unexplainable decrease in DO concentration or a decline in the normal rate of the daily increase in DO in outdoor mass culture serve as a reliable warning signal that the culture is stressed and may quickly deteriorate (91).

Cleaning and reliability of the microalgal mass culture are two other important operational considerations from a commercial point of view. Algal cultures grown in closed reactors may have a problem with fouling of the walls of the reactors by the algae. Chamont *et al*. (119) have patented a system using recycling balls for continuous cleaning of the walls of a tubular PBR. Other systems based on small particles that move with the culture have been also developed, although they have not been patented and remain as know-how of the companies. Using such a system, fouling has not been a major problem in the operation of these reactors. Reliability is also an important aspect. Algal cultures grown in tubular PBRs are reasonably stable and several species have been cultured including the marine algae, *P. tricornutum*, *Tetraselmis chuii*, and *Isochrysis* sp. for periods in excess of 3 months (28,120) and *S. almeriensis* for more than 8 months. These systems are particularly suited for continuous or semicontinuous culture, and this permits much better control over the culture conditions and provides a consistent product quality, something that is very difficult to achieve in open systems.

An additional operational advantage of most closed systems is that the cell concentrations reached are much greater than those achieved in open system, thus reducing the harvesting cost. As can be seen in Fig. 18.16, the actual cell density, however, has to be managed carefully in order to maximize productivity. At low cell densities, especially in outdoor systems, the algae may be severely photoinhibited, whereas at very high cell densities self-shading can reduce productivity as individuals algal cells do not receive the optimum level of light.

In short, the aim of management is to achieve and sustain the optimal state of the culture. For maximum biomass productivity, solar irradiance should be the sole limitation.

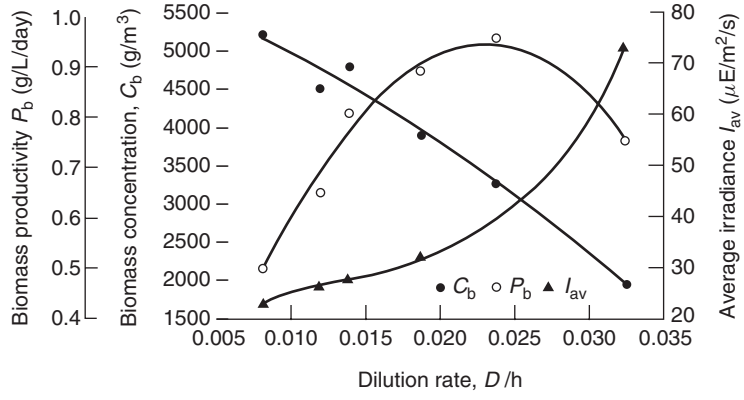

Figure 18.16. Effect of dilution rate, D, on the steady-state biomass concentration, C_b, the biomass productivity, P_b, and the average irradiance inside a PBR, I_{av}. Data were obtained in an outdoor continuous culture of *P. tricornutum*, in a concentric tube airlift bioreactor. [From Ref. 39. With permission.]

TABLE 18.2. Comparison of Properties of Different Large-Scale Algal Cultures Systems

Reactor Type	Mixing	Light Utilization Efficiency	Temperature Control	Gas Transfer	Hydrodynamic Stress	Species Control	Sterility
Unstirred ponds	Very poor	Poor	None	Poor	Very low	Difficult	None
Open raceway	Fair–good	Fair–good	None	Poor	Low	Difficult	None
Airlift	Uniform	Good	Excellent	High	Low	Easy	Easily achievable
Bubble column	Fair	Fair	Excellent	Fair	Low	Easy	Easily achievable
Tubular	Almost uniform	Good	Excellent	High	Low–high	Easy	Achievable
Biocoil	Uniform	Excellent	Excellent	Low–high	Low–high	Easy	Achievable

[From Ref. 41. With permission.]

However, when a metabolite is the desired product, the operational conditions promoting maximal biomass productivities could be different than those for maximizing the productivity of the product.

18.7 CONCLUDING REMARKS

Microalgae represent a large and unknown resource with the genetic potential to produce valuable compounds. The development of algal biotechnology depends, in particular, on the identification of more high value products in algae. However, microalgal biotechnology at present is a limited and small component of the overall field of biotechnology, where advances in industrial fermentation, therapeutic proteins, genetically engineered plants and animals, and diagnostics have attracted major commercial interest and are resulting in many novel products. Currently, there is great interest in the production of biofuels from microalgae. Although the production of microalgal biodiesel is technically feasible, the economy of producing it needs to improve substantially to make it competitive with petrodiesel, but the level of improvement necessary appears to be attainable.

Table 18.2 compares the main algal culture system described in this chapter along with their properties. From this Table, it is clear that open systems are deficient in several aspects. Despite this, open raceway systems are being used on a commercial scale for culturing a few species, and especially for waste treatment applications. The two principal advantages of open culture systems are a small capital investment for production of the biomass and the use of a free source of energy. They are the simplest methods but the productivity obtained is far from the theoretical maximum. Much improvement in photosynthetic activity could be obtained through an increase in the ability of photosynthetic complex to utilize more light before becoming saturated. The goal must be to improve the photosynthetic machinery so that light saturation will take place at a higher light intensity, accompanied by resistance to photoinhibition.

Enclosed PBRs that allow better control of operational conditions may be more suited for reaching this goal. PBRs also have an important role to play in increasing the diversity of algae species for culturing the sensitive and highly valuable strains used in the production of fine chemicals. Enclosed outdoor tubular PBRs have demonstrated the potential of this technology with high biomass productivity of microalgal species such as *Porphyridium*, *Isochrysis*, and *Phaeodactylum*, which, due to the better control of the culture parameters, allow the biochemical composition to be modified by changing the system operating variables and are specially useful for valuable products such as polyunsaturated fatty acids, polysaccharides, antioxidant, and so on. This technology is more capital intensive than the open pond technology but this additional cost can be justified. Temperature and fouling are major problems in such systems. Nonetheless, it should be noted that it is not possible to say that one culture system is better than another. The commercial target, geographic location, and metabolite to be produced determines the choice: axenic or nonaxenic, continuous or batch culture, intensive or extensive culture, opens pond or closed PBRs.

Acknowledgments

The authors wish to acknowledge the contribution of all the colleagues of the Marine Biotechnology Group of the University of Almería that have worked with us on this subject. Special acknowledgement to the financial support of the Plan Andaluz de Investigación (Junta de Andalucía), Dirección General de Investigación (MEC), and European Union for some of the work reported in this manuscript.

NOMENCLATURE

A_d	Cross-sectional area of the downcomer (m^2)
A_r	Cross-sectional area of the riser (m^2)
C_b	Biomass concentration (g/L or g/m^3)
D	Depth channel (m)
f	Fanning friction factor

F_{vol}	Photon flux absorbed in unit volume ($\mu E/m^3/s$)
h_D	Height at which the degasser is situated (m)
I	Hourly incident photosynthetic radiation ($\mu E/m^2/s$)
I_{av}	Photosynthetically active hourly average irradiance inside culture ($\mu E/m^2/s$)
I_0	Solar irradiance impinging on the reactor surface ($\mu E/m^2/s$)
I_s	Saturating light intensity for which the growth rate is maximum ($\mu E/m^2/s$)
K_a	Absorption coefficient (m^2/g)
K_1	First equilibrium constant for bicarbonates buffer (mol/m^3)
K_2	Second equilibrium constant for bicarbonates buffer (mol/m^3)
K_W	Dissociation constant of water
L	Channel length (m)
L_{eq}	Equivalent length of the solar receiver (m)
N	Manning friction factor (s m_1/3), or characteristic parameter of the hyperbolic growth model
n_1	Characteristic parameter of the photolimitation–photoinhibition model
n_2	Characteristic parameter of the photolimitation–photoinhibition model
n_3	Characteristic parameter of the photolimitation–photoinhibition model
P	Power consumption for the culture flow in the channel (kW)
P_b	Biomass productivity ($g/m^3/h$)
Q_b	Heat of combustion of biomass ($\mu E/g$)
S	Cross-section of the tube (m^2) or surface occupied by the photobioreactor
S	Rate of loss of energy in the channel, (dimensionless)
U_L	Superficial liquid velocity in the tube (m/s)
v	Mean culture flow velocity channel (m/s)
w	Width channel (m)
ψ	Bioenergetic yield coefficient (%)
ψ_E	Quantum yield (g/E)
ψ_{kJ}	Energetic yield (g/kJ)
η	Efficiency of the paddle wheel (-)

MICROBIAL GROWTH MEASUREMENT

ARTHUR L. KOCH
Indiana University, Bloomington, Indiana

19.1 INTRODUCTION

In biotechnology, the denominator is biomass; for example, yield is the desired product per unit of biomass. Biomass concentration is one of the major determinants to identify the stage of the culture cycle. It is necessary to understand the controlling points in the physiology of the bacterial growth. Biotechnologists have extensively talked about growth phase and idiophase as the key measures of fermentation technology. There are a number of approaches for biomass measurement, but they are not very good and have significant limitations. The reader should supplement the treatment presented here with a previous chapter (1) and its revisions, which details a number of procedures and leads back to the earlier literature. Another useful overview is provided by Sonnleitner *et al*. (2). The former paper comes from the approach of a physiologist, and the latter is from the point of view of biotechnologists. For historical interest, the collected source is by Dawson (3).

19.1.1 Principles

Principles of bacterial growth are discussed in microbial physiology texts. I would particularly recommend that by White (4). Although there are many books on bioprocessing, most do little to discuss biomass measurements. The book by Pirt in 1975 (5) was a milestone in the field of microbe growth for product formation; newer publications are now available (6,7), but they do little for the estimation of biomass.

19.1.2 Definitions of Growth

To measure biomass and bacterial growth rate, precise definitions are needed. Although biomass is fundamental to carrying out technology, we have to first consider the growth process that makes the biomass and examine its several definitions. The most basic definition of growth is based on the ability of individual cells to multiply, that is, to repetitively initiate and complete cell and organismal division. This definition implies monitoring the increase in total number of discrete bacterial particles. There are three basic ways to do this: by microscopic enumeration of the particles, by electronic enumeration of the particles passing through an orifice (Coulter counter), and by modern flow cytometry. Assessment of particle number would falsely include dead cells and detritus, which would tend to lower estimations of growth rate. The rate would be artificially raised by the progressive dissolution of aggregates of bacteria and the fragmentation of nongrowing filamentous organisms. An increase in cell number is not exactly correlated with an increase in biomass or useful product. Commonly, at the end of an exponential growth phase, cell division overshoots biomass production and the cells become smaller.

A second definition of growth involves determining the increase in colony-forming units (CFU). Because some cells may be dead or dying, this definition of growth may be different from the one based on the detection of discrete particles as a function of time. Although in the long run, the increase in the number of organisms capable of indefinite growth is the only important consideration for the

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

physiologist, this is not so for the biotechnologist, for several reasons. First, for strain purity, each new production run starts afresh from starter cultures; these cultures would have been specially treated much differently than the cells in the actual production run. This care is to avoid contamination and the buildup of unwanted mutants. Second, dead, dying cells and stationary cells may be the productive members of the culture in terms of product formation. This second definition is the reason that colony counting and most probable number (MPN) methods of measurement are so important. It must be noted that viable counting methods, which seem so natural to a bacteriologist, are really quite special in that cultures are diluted so highly that individual organisms cannot interact. For example, these methods cannot, in principle, be applied to obligate sexually reproducing organisms requiring male–female interaction or to colonial organisms such as myxobacteria that in certain conditions need to be part of a large mass of organisms that produces sufficient exoenzymes to grow. Even when applied to the prokaryote, there are special restrictions and limitations; for example, CO_2 must be available in sufficient concentration, although this need not be supplied if many organisms are present generating CO_2. This and possible detoxification of the medium can lead to a lower count than would have occurred in the more concentrated actual culture. To illustrate, consider a single bacterium and an isolated mammal, both introduced into an environment without any individuals of their own kind. The former would produce a colony, whereas the latter could only produce a viable colony if the founding individual was a pregnant female.

A third definition of growth (and the practical one) is based on an increase in biomass. Macromolecular synthesis and increased capability for the synthesis of cell components are the obvious basis for the measurement of growth by everyone interested in microbes and what they can do. From our point of view, the whole process of chromosome replication and cell division is an essential but minor process that seldom limits growth; what usually limits growth is the ability of enzymatic systems to use available resources to form biomass. Moreover, the restriction of growth of the culture is usually the result of the depletion of resources or degradation of the local environment.

A fourth definition of growth is based on the organisms' action in chemically changing their environments. This category can be simply considered as a different consequence of the increase in biomass. However, it allows the rate of the growth process and the biomass production to be estimated in indirect ways. Most important in industry, the gases coming from the fermentation are analyzed, and the consumption of oxygen and production of carbon dioxide are used as effective and efficient means to follow growth. Especially important is the use of mass spectrometer methods, because of their precision and the ability to automate measurements, and growth of cultures can be followed usefully and effectively.

Biomass is the result of growth; it has various different definitions according to purpose. In most biotechnology, biomass is organic material that is cheap and can be converted into fuel, or heat, or structural materials. It is necessary that such sources be self-generating, cheap, and available. Whether biomass is alive or dead is less relevant; the assumption is that it was, or at least once was, alive. If one has a mixture of coal and fresh plant material, the term biomass is fully ambiguous. For product formation, there is less ambiguity; microbial biomass requires the expenditure of resources, and useful products may be produced by the organisms that may be living or dead according to which of the definitions of growth is used.

19.1.3 Balanced Growth

These four definitions of growth become equivalent under a single circumstance: the state of balanced growth (8). This is certainly an academic concept, but its practicality is clear. An asynchronous culture can be said to be in balanced growth when all intensive properties are constant in time. An intensive property is one that does not matter how big the system is. An extensive property is another term from physical chemistry and refers to those properties of the system that are proportional to the amounts of substances of various kinds in the system. Thus, biomass and cell number are extensive properties of a culture and proportional to the volume of culture considered. These properties increase regularly and exponentially with time during balanced growth. However, temperature or ratios (such as DNA, RNA, or product per cell) are intensive properties that do not change during balanced growth. The application of this physical–chemical principle to bacteriology lies in the assumption that if a culture is grown for a long-enough duration (usually with many subcultures) so that the biomass is sparse enough not to alter the environment significantly, sooner or later the organisms will come to achieve the same growth state for any particular constant environment, no matter what the cell's condition was initially—be it log, lag, or the stationary state. Once this balanced growth state has been achieved, if the conditions remain the same, the culture will remain in balanced growth indefinitely. This would be true of a culture that had grown in a continuous culture or one that was diluted manually at periodical intervals, avoiding entry into either lag or the stationary state. However, if a nutrient is exhausted, or if the culture is altered by mutation and selection, or if the physical nature of the environment is changed, then balanced growth would cease and the culture would be in some nonbalanced state of growth.

The criteria given above are too stringent to be fully met with any practicality, but it is readily possible to study

cultures that are substantially in balanced growth by growing the cultures that are maintained at low density by dilution and using arbitrarily any one measure to follow growth, for example, biomass assayed turbidimetrically. If the doubling time remains constant over an extended period of time, then it is a good assumption that growth is balanced. Studies of these cultures can lead to an understanding of the properties of individual cells in the idealized state of balanced growth. However, they would not bear on the properties of aggregates or clumps of cells or of cells reacting to some calamity or catastrophe in their environment.

Although we may consider any extensive property of a culture in balanced growth, let us first focus on biomass and call it as X for tradition's sake. The rate of formation of biomass will be proportional to the amount of biomass. Call the proportionality constant, μ, then:

$$dX/dt = \mu X$$

Using the laws of calculus, this equation can be integrated and a boundary condition ($X = X_0$ when $t = 0$) is imposed, yielding the well-known equation for exponential growth:

$$X = X_0 e^{\mu t}$$

However, every cellular substance, or even an extracellular product of the cells, could be substituted for our X. Thus, after growth becomes balanced, the increase of any component or group of components will be exponential in time. If the ratio of one substance to every other is to remain constant, the same proportionality constant must apply for every component. This common value of μ is called the *specific growth rate* or *growth rate constant*. Not only any substance but also any combination of substances or the rate of change of any substance will increase exponentially with this same specific growth rate, μ. Practically, this allows the rate of oxygen uptake, heat production, or production of an internal or external metabolite to be used as an index of growth. It will also allow growth to be monitored by the depletion of some medium component or the change in conductivity of the medium.

Intensive properties, such as μ and the ratio of the concentrations of different cell substances, must necessarily remain constant under conditions of balanced growth. In addition, the distribution of cell sizes and the average number of chromosomes will stay constant. An average cell will have a time-independent constant rate of carrying out every cellular process, and newly arisen daughter cells will have a constant probability of being able to form a colony (i.e. the percentage of nonviable cells will remain constant). Therefore, under these special conditions, no matter what measure of growth is used (whether it is particle counting, colony formation, chemical determination of a cell substance, or consumption or excretion of a substance), the same specific growth rate will be obtained and that rate will be constant through time.

19.1.4 Changes in Cell Composition at Different Growth Rates of Balanced Growth

Organisms respond to environmental conditions, both physical and chemical, by altering their own composition. These changes have been well documented for certain enteric bacteria but may occur with all prokaryotes (9). In general, favorable growth conditions mean faster growth, which requires a higher concentration of ribosomes and associated proteins. In terms of gross composition, the most obvious difference in the comparison of a faster culture with a slower culture is the greater RNA content in the former (10). Also, under favorable growth conditions, the cells can lay down reserve materials such as glycogen and poly-β-hydroxybutyric acid. These changes in composition lead to the possible pitfall of the bacteriologist falsely relating one measure of growth to others when comparing growth in different environments.

19.1.5 Unbalanced Growth

Although balanced growth conditions lead to reproducible cultures, much of physiology deals with the responses of organisms to changes in their environment that lead to progressive changes in the organism (i.e. to the study of unbalanced growth). When a stationary culture is inoculated into fresh medium, the properties of organisms drastically change through the course of the batch culture cycle. Though only very well documented for certain enteric bacteria, similar changes probably apply with other prokaryotes. The exact course of changes in composition and morphology depends on the medium and on the age and condition of the inoculum. Culture cycle phenomena have relevance to growth measurements. These phenomena are particularly important in ecological studies, where the conditions under which the organisms grow are critical and, to a large degree, uncontrollable. The changes in characteristics are also involved in response to the fluctuations under natural conditions (11,12). For biotechnology purposes, it is the progression of changes in the so-called idiophase of growth that are paramount.

Noting that a "typical bacterial culture" generally means one of *Escherichia coli* (13), a typical bacterial culture cycle progresses as follows. When a stationary culture is diluted into rich medium, macromolecular synthesis accelerates. The components of the protein-synthesizing system (i.e. ribosomal proteins and ribosomal RNA) are made first. Only after considerable macromolecular growth has ensued, cell division does take place. During this lag phase, the average size of cells significantly increases. When the capacity of the medium to support rapid balanced

exponential growth is exceeded, metabolic processes (both intermediate metabolism and macromolecular synthesis) are slowed down. Different processes slow differentially in a way to make small, RNA-deficient cells. Finally, the cells die and may eventually lyse.

19.1.6 Pitfalls in Measuring Growth

Errors in measuring bacterial growth fall into four classes. The first major pitfall is the general tendency of most organisms toward clumping or a filamentous habit of growth. This can occur even under mildly toxic conditions with bacteria that ordinarily divide regularly. The second pitfall is the differential viability of injured bacteria under different culture conditions. Repair processes may permit the recovery of viable cells under some, but not other, conditions. A third major pitfall is the possible development of resistant stages. Bacteria known to form resistant stages, such as spores, pose no problem because the controls and measurements to correct for such differentiated forms are well known; but when resistant stages are not suspected, error can arise. The fourth pitfall pertains to the way in which the inoculum is exposed to the new environment. Different results may be obtained if the concentration of an agent is raised gradually, if it is raised discontinuously, or if a high concentration is temporarily presented and then removed or lowered, such as when a concentrated solution of a nutrient is added and the mixing is not rapid. The cell concentration at the time of challenge can be critical. Bacteria may have special ways, sometimes inducible mechanisms or sometimes unknown ones, to protect themselves against toxic agents. Finally, the protection may be dependent on the number of organisms cooperating in detoxification.

19.1.7 Mycelial Habit of Growth

The evaluation of mycelial growth (the first pitfall) is both easier and much more difficult than that of well-behaved organisms that engage in binary fission and then promptly separate. The problems and methods for colonial growth have been discussed by Calam (14) and will be briefly dealt with here. Filtering filamentous cells, with or without drying, is easier than with smaller nonfilamentous cells.

The rate of increase in size of the colony in one, two, or three dimensions depends on the rate of elongation of those terminal hyphae that happen to be growing perpendicular to the surface of the colony, but the mobilization of resources into the mycelial mass depends on the surface area of the colony (15,16). Therefore, particularly with shake cultures, the results depend on the nature and size of inoculated fragments; with large fragments, growth becomes limited at an earlier stage by the diffusion of nutrients into the mycelial mass. Thus, the major pitfall with the mycelial habit of growth is that the growth quickly deviates from exponential growth and depends on the geometry of growth and the nature of the inoculum. In shake cultures, the apparent growth may depend on the shape of the vessel and on the shaking speed, its character (circular or reciprocal), and the distance moved, because all of the above can affect the tendency of the mycelia to break into smaller pieces. An important aspect of biotechnology is controlling the filamentous versus pellet conformations.

19.1.8 Cell Differentiation

The change of enteric bacteria from large, RNA-rich forms in the exponential phase to small, RNA-poor forms in the stationary phase has many of the aspects of differentiation. However, bacteriology has much clearer examples of cell differentiation in the cases of transition of rod to coccus, vegetative bacillus to endospore, and in the formation of exospores, cysts, and buds. The tendency to form filaments in certain circumstances can also be considered as a differentiation. These changes and their reversal pose potential pitfalls for all approaches to growth measurement.

19.1.9 Adsorption of Cells to Surfaces

Many bacteria naturally adhere to certain surfaces or can adapt and mutate to achieve a high avidity for solid surfaces, including glass. Many experiments with chemostat culture have failed to achieve their primary goal because the organisms are adhered to the vessel walls. Therefore, plastic or Teflon should be used whenever there is long-term contact of the organism with a culture vessel (16). Other approaches to minimizing the effects of growth on vessel walls include the use of large culture volumes in large containers, the use of violent agitation, and the frequent subculture of the bacteria into fresh glassware. These are the conditions in large biofermenters, but not during the production of the starter cultures. In addition, the use of detergents, vegetable oils, silicone coatings, and a high-ionic-strength medium may, to some degree, alleviate this problem.

This problem is particularly pertinent during dilution of the culture for measurement by highly sensitive means, such as microscopic and plate counts. It is, therefore, given consideration in the discussion of those methods (1,17,18).

19.2 DIRECT PARTICLE COUNTS

For many biotechnology purposes, the counting methods that can be used are limited because the growth medium generally contains particulate matter. This does not preclude their use in the development of strains and other phases of biotechnology.

19.2.1 Microscopic Enumeration

Microscopic enumeration is a commonly used technique that is quick and cheap and uses equipment that is readily available in the bacteriological laboratory. However, the technique is subject to gross errors. These can be overcome to a large degree using improvements suggested by the work of Norris and Powell (19). Precise details are given in my earlier review of this subject that is a further modification of this method (1), and some versatile techniques that have some of the characteristics of viable counts or metabolic measurements are given in the work by Murray *et al*. (20).

Methods and equipment, some linked to computer programs, are now available to record, scan, and view a microscope field. Software and hardware are available that enable a sample to be placed in a counting chamber viewed by a microscope, and then an electronic count can be made from the image. The computer can distinguish between cells adhering side by side and between a long cell and a pair of sister cells that have completed division but have not separated. The capability exists to measure the biomass from the density of the pixels because the phase contrast (see later text) is a measure of the biomass. For filamentous organisms, the computer could output the total length of hyphae and convert that into biomass (21,22). Direct enumeration from charge-coupled device (CCD) images with highly intelligent computer filtering will allow distinguishing the bacteria or fungi from the particulate matter in the brew in many cases.

19.2.2 Electronic Enumeration

The Coulter Counter (Coulter Electronics, Hialeah, Fla.), its commercial competitors, and particularly the laboratory-built versions have been important in the development of bacterial physiology for the past 70 years. Such instruments are used routinely in clinical hematology. They are also very useful in the enumeration of nonfilamentous yeasts and protozoa, but not of mycelial or filamentous organisms.

The principle of electronic enumeration is as follows. A fixed volume of diluted cell suspension is forced to flow through a very small orifice connecting two fluid compartments. Electrodes in each compartment are used to measure the electrical resistance of the system. Even though the medium readily conducts electricity, the orifice is so small that its electrical resistance is very high. Consequently, the electrical resistance of the rest of the electrical path is negligible by comparison. When a cell is carried through the orifice, the resistance further increases because the conductivity of the cell is less than that of the medium. This change in resistance is sensed by a measuring circuit and converted into a voltage or current pulse. The counting rates can be very high, but beware of coincidence errors. The pulses are counted by an electronic circuit similar to that used in counting radioactivity. Very small pulses are eliminated by a discriminator circuit. Very high pulses, which might result from dirt or other irrelevant particles, are eliminated by an upper discriminator. In advanced models, the pulses may be analyzed by size and stored in a multichannel analyzer; later, the data can be recovered and plotted in a histogram, and the numbers, mean size, and standard deviation can be calculated. All the data may be collected, and the discrimination against pulses that are very high or very low can be carried out as the data are analyzed. The instruments have some method of forcing an accurately known volume through the orifice during the counting period. This is usually done by displacing the fluid in contact with a mercury column past triggering electrodes that conduct effectively through the mercury, but not through the diluent medium.

There are three major problem areas in electronic enumeration. The first problem concerns the size and shape of the cells. Some bacterial cells are very small (less than 0.4 μm^3), and the resistance pulses produced as they pass through the orifice are comparable to the noise generated by the turbulence that develops in the fluid flowing through the orifice. One can set the discriminator dial on the instrument to reject the turbulence noise, but one loses sample information, particularly about newly divided cells. One can run blanks and subtract the blank values, but blanks are particularly variable for small cell sizes. In addition, a pattern of turbulence can become established, remain for a while, and then be replaced with another pattern. This can cause major interference. Determining the size of cells has many difficulties, including the effect of the path that the particle takes through the orifice and the resistance of the various layers and compartment of the cell. Therefore, this potential use of the instrument is not discussed in this chapter. Finally, the overall error increases when the blank has large statistical variation. This is not a major problem for biotechnology because currently used microbes are relatively large.

The second major problem for physiological studies in electronic counting results from the failure of cells to separate promptly from each other after cell division. This, and the tendency to form filaments and aggregates, can be minimized by the careful choices of the organism and the conditions. Possibly, it can be reduced by vortexing or sonicating the sample. It was fortuitous for the advancement of microbial physiology that *E. coli* was chosen for physiological and genetic studies in the 1940s and 1950s because only a relatively small number persists in pairs or chains or in the form of aggregates. There is the related problem of coincidence, which is the passage of more than one cell through the orifice in a short enough time so that a single larger cell is registered by the electronic equipment. This problem can be dealt with by increasing the dilution so that the probability of coincidence is reduced.

The third major problem is technical: the clogging of the orifice in electronic counting. The resistance change

is a smaller proportion of the total electrical resistance of the orifice when the orifice diameter is larger. Consequently, for small rod-shaped bacteria such as *E. coli*, orifices with diameters in the range of 12–30 μm must be used. The exact choice is a trade-off between the increased signal strength of small apertures and the increased noise and probability of becoming clogged. Clogging is best prevented by ultrafiltration of all reagents. Alternatively, the diluent can be prepared and allowed to settle for a long time (months) in a siphon bottle so that the particulate-free solution can be withdrawn from above. Additional information about this technique can be found in the works by Drake and Tsuchiya (23) and Kubitschek (24).

19.2.3 Flow Cytometry Technique

Flow cytometry became an extremely powerful method for the study of many aspects of the biology of eukaryotes two decades ago. The instruments are now common in hospitals and in clinical research laboratories. Because prokaryotes are smaller, it is only more recently that the instrumentation and methods have been refined and are coming into their own in the study of bacteria. The instruments operate by forming a small-diameter stream of the sample suspension. This is encased in a stream of particulate-free fluid. The tube through which they flow constrict in such a way that the stream of the sample is made still narrower in diameter. This process is called *hydrodynamic focusing*. The flowing stream is examined with laser light with various frequencies and angles, and the output of the detection circuits is used to detect when a particle passes through and determine its characteristics. The design permits the analysis of biomass by light-scattering methods and by fluorescent staining of chemical components such as DNA. This is discussed in the section Flow Cytometry Methods. The electronic circuits allow cells to be counted very rapidly. Growth can be followed by the increase in counts in samples examined at intervals. The problems for the application to prokaryotes is in sensitivity and background noise.

The original designs were made for the study of problems in immunology. Applications, including microbiology, have been previously described (25–27).

Another quite different instrumental design was developed in Norway (28,29). It depends on flow directly onto a microscope slide on an inverted microscope. This instrument uses an inverted microscope essentially operated in the dark-field mode. It uses a high-intensity mercury arc. Now, with commercially available equipment, it has been utilized to study a variety of problems. Clever applications have been described (30,31).

The instrument of the first type uses a well-collimated laser source and fiberoptics. Great care is needed to maintain the instrument and its calibration. Routinely, polystyrene beads are mixed with the biological sample in a fixed amount. They have a uniform size and serve to quality control the electronics. By relating the biological count to the bead count, the concentration of biological particles can be determined. These kinds of controls can be used with the second type of instrument, which is cheaper and is now in use in many laboratories for many microbiological purposes. It is also capable of counting at very fast rates.

19.3 COLONY COUNTS EQUAL VIABLE COUNTS

Bacteriology really became an experimental science when Herr Dr Robert Koch listened to Frau Fannie Hesse and developed the agar plate. This allowed not only the cloning of pure strains but also the enumeration of colonies arising from individual viable cells. Many variations have been developed and used in the ensuing century: (i) spread plates, (ii) pour plates, (iii) thin-layer plates, (iv) layered plates, and (v) membrane filter methods. Although these techniques are very useful in the development of industrial strains, they consume too much time and cannot be used on-line.

These techniques are described in many places (1). The pour-plate methods have variations in which the cells are grown in roller tubes or microtubes (32) and are examined with low power microscopes when the colonies are small (33). There are many individual variations of techniques, sometimes resulting from historical accidents and sometimes resulting from special bacteriological circumstances. Automation of colony counting has put additional special restrictions on techniques, but allows colonies on the Petri dishes to be counted rapidly without operator error.

It must be further emphasized that mycelial organisms pose special problems. To some degree, they can be overcome by sonication or shearing. A practical approach is to conduct a pilot study to find the amount of ultrasound that produces the maximal count that optimizes the separation of propagules from each other and minimizes their destruction by the physical treatment.

In the future, the development of growth media that is perfectly clear and can be solidified in uniform layers on a new generation of microscope slides will permit the analysis by telometering and computer analysis only after a few hours of incubation. In some cases, observation will be repeated and the difference in the images is used to compute the growth rate as well as the initial CFU and viable biomass. Selectivity and identification of special properties with dyes and chemical reactions could be used as well. Again, particulate matter can be a problem, but less severe as the microcolonies grow to be larger than the detritus in the medium.

19.3.1 Spread Plates

The sample is pipetted onto the surface of solidified agar medium in a Petri dish, and then the cells are distributed with a wire, glass, or Teflon spreader. In the spread-plate technique, the growth forms surface colonies. It is reliable when methods to transfer all of a defined volume of cell suspension to the surface of the agar are used. The method is additionally useful because surface colonies are required to produce the proper color responses with many indicator agars that depend on the redox state of the colonies. In many cases, different colors are given from subsurface colonies because the oxygenation is different, and, therefore, the acid production and reducing potential are different than on the surface, and the selectivity is usually much less. (See Murray *et al*. (20) for recent improvements in technique.)

19.3.2 Pour Plates

An aliquot sample of diluted cells is pipetted into an empty sterile Petri dish; molten, but cool (45°C), agar medium is poured onto the sample; and the contents are mixed by swirling and then allowed to harden. The pour-plate technique is a standard technique. Its main advantage is that most colonies are subsurface. Therefore, they are small, making it possible for a plate to have many colonies and still be countable. This method has a large dynamic range, and automation can be very useful.

19.3.3 Thin-Layer Plates

The use of thin-layer plates came out of virology. The sample is pipetted into a tube containing a small volume (2.5–3.5 mL) of molten but cool (45°C) soft agar (0.6–0.75%) medium. This is then poured onto previously poured and hardened (1.5–2% agar) medium in a Petri dish, and the overlay is allowed to harden. This was the technique developed to measure virus plaques in the 1940s.

19.3.4 Layered Plates

Layered plates are like thin-layer plates except that an additional layer of agar medium is poured onto the newly congealed soft agar medium containing the cells so that all colonies are subsurface, but in the same plane. It is very useful because all colonies are subsurface and, therefore, much smaller and compact. Under the right conditions, they can be intensely colored because they are highly anaerobic. Many more colonies may be present, and yet the coincidence by fusion of colonies is small; this means that several thousand colonies per plate can be used to give meaningful results. This approach is especially recommended because the main difficulty with usual surface colony counting method is its lack of dynamic range. Rules have been issued that between 30 and 300 colonies are required for spread plates. The lower limit is set by statistical accuracy, and the upper limit is set by coincidence limitations. This 10-fold range is inconvenient for many purposes, because in many cases, one cannot predict the number within a factor of 10 when choosing the dilution factor. The extra care needed to prepare the overlay plates is justified because it allows the counting in a larger range of 30–2000 colonies. A second major advantage is flexibility for nutrient supplementation. Minimal agar can be used to pour the basal layer in a large number of Petri plates for indefinite storage. Stock supplies of the minimal soft agar can also be kept on hand. Then, 10- to 50-fold excesses of needed special nutrients can be added to the aliquots that are used for the molten top agar. In some cases, dyes and chromogenic substrates can be added as needed to the soft agar to allow screening of the colonies. Toxic substances can be incorporated to measure frequencies of resistant mutants.

19.3.5 Membrane Filter Methods

The diluted cells are filtered onto an appropriate membrane filter, which is then placed on an agar medium plate or onto blotter pads containing liquid medium. Sometimes, it is necessary to carefully prewash the membranes and the pads with water or medium and then sterilize them. It is also necessary to supply nutrients at a higher level because they must be diffused to where the cells are located.

19.3.6 Automation

Several chapters and books have been devoted to attempts to speed and automate growth measurement (34,35).

19.3.7 Special Situations

Certain organisms are very sensitive to substances present in agar. Meynell and Meynell (36) presented an excellent discussion of these problems. Injured organisms may have additional special requirements, and the entire 26th symposium of the Society for General Microbiology (37) was devoted to these problems. Genetically defective organisms pose individual problems that can be research problems on their own, such as the ability of various repair mutants to form countable colonies (38).

The problem of quantitating the number of organisms in cultures of strict anaerobes is discussed by Holdeman *et al*. (39) and Hungate (40).

19.3.8 Most Probable Number Method

The MPN method consists of making a number of replicate dilutions in a growth medium and recording the fraction

of tubes showing bacterial growth. The tubes exhibiting no growth presumably failed to receive even a single cell that was capable of growth. Because the distribution of such cells must follow a Poisson distribution, the mean number plated at this dilution can be calculated from the formula $P_0 = e{-}m$, where m is the mean number and P_0 is the ratio of the number of tubes with no growth to the total number of tubes. The mean number, estimated by $-\ln P_0$, is then simply multiplied by the dilution factor and by the volume inoculated into the growth tube to yield the viable count of the original sample. The MPN method is a very inefficient method from the point of view of statistics, because each tube corresponds to a small fraction of the surface of a Petri dish in a plate count. Consequently, many tubes or wells in a titer plate must be used, or the worker must be prepared to settle for a very approximate answer.

It is important to understand when the MPN method is of advantage. It can be used if there is no way to culture the bacterium on solidified medium, and it is preferred for mixed cultures if the kinetics of growth of the individual types are markedly different. Suppose some cells grow immediately and rapidly and end up making a large colony on solid agar that spreads over and obscures colonies of the organism of interest that form later. The small colony formers may be numerous but unmeasurable on plates because of the fewer but highly motile or rapidly growing bacteria. Another use of the method is when other organisms that are not of interest are present in the sample, and no selective method is available to prevent their growth. Thus, the method has utility when the bacterium of interest produces some detectable product (e.g. a colored material, specific virus, or antibiotic). Then, even though contaminating organisms may overgrow the culture, the numbers of the bacterium in question can be estimated by the fraction of the tubes that fail to produce the characteristic product. Finally, if agar and other solidifying materials have some factors (such as heavy metals) that may alter the reliability of the count or interfere with the object of the experimental plan, then the MPN method can be used to avoid these difficulties.

Modern developments in currently available laboratory techniques can be used to speed the execution of the MPN method and make it more efficient. Machines are available to fill the wells of plastic trays that have as many as 144 depressions. However, it may be better to use 96-well trays because most apparatus, such as hand-held pipets, currently use them. Scanning devices designed for other purposes can be used to aid in counting the number of wells with no growth. Similarly, automatic and semiautomatic pipets can be used to fill small test tubes. Because these procedures make it possible to examine many more cultures, the classical tables of fixed numbers of tubes and fixed dilution series are obsolete and should be abandoned. A different and more flexible approach and method of calculation has been provided (1). It may easily be optimized for the purpose at hand.

19.4 DIRECT BIOMASS MEASUREMENTS

Some measure of the bacterial cell mass or numbers of a culture is almost always used as the reference basis for the measurements of cellular metabolic activities, the types of morphological characters, or the amount of a chemical constituent; biomass and cell numbers are the two basic independent parameters of bacterial growth. The methods for measuring biomass seem obvious and straightforward, but in fact they are complicated if accuracy if sought. Furthermore, the results may be expressed in different ways and, in some of these ways, the values may be more relative than absolute.

19.4.1 Wet Weight

A nominal wet weight of bacterial cells originally in liquid suspension is obtained by weighing a sample in a tared pan after separation and washing the cells by filtration or centrifugation. However, in either case, diluent is trapped in the interstitial (intercellular) space and contributes to the total weight of the mass. The amount of interstitial diluent may be substantial. A mass of closepacked, rigid spheres contains in its interstices 27% of space. This is independent of sphere size. A mixture of sizes packs more densely, and close-packed bacterial cells may contain an interstitial volume of 5–30%, depending on their shape and amount of deformation. This is a problem that is readily solved if the washing step can be carried out with pure water.

Simple weighing or just measuring the packed volume of cells can be an excellent and rapid method with filamentous organisms or those that grow as pellets. Then filter, wash, and weigh (or centrifuge, and measure the height of the pellet). Both can be very rapid, and the procedures can be calibrated to correct for the exogenous water or shapes of centrifuge tubes. Because the particulate matter in the medium has different physical properties, it can be possible to separate the cells from the particulates and estimate the cell volume directly. This correction could be established with radioactive or fluorescent dextrans or other molecules that are too big to enter the cells.

19.4.2 Dry Weight

A nominal dry weight (solids content) of bacterial cells originally in a liquid suspension is obtained by drying a measured wet weight or volume in an oven at 105°C to constant weight. The cells could be washed with water (possibly extracting cell components), or (better) a correction

could be made for medium or diluent constituents that are dried along with the cells. Separating the cells by filtration poses particular problems. More problems arise if volatile components of the cells can be lost by oven drying, or if some degradation and volatilization occurs, evidenced by discoloration (particularly if a higher temperature is used). Some regain of moisture occurs during the transferring and weighing process in room atmosphere, so this should be done quickly within a fixed time for all replicate samples, especially if the relative humidity is high. It is best, of course, to use tared weighing vessels that can be sealed after drying.

It is possible that more accurate determination can be made by drying the sample to constant weight in a desiccator vessel with P_2O_5 and under oil-pump vacuum at 80°C or by lyophilization. Results with the three methods are indistinguishable within 1% for certain cases (41). An excellent discussion of dry weight procedures and errors is given by Mallette (42).

The dry weight of cells may be reexpressed on a wet weight basis (grams of solids per gram of wet cells) or on a wet volume basis (grams of solids per cubic centimeter of wet cells or per cubic centimeter of cell suspension).

Because the drying can be a time-consuming process, and adequate knowledge about the possibility of volatilization of some cell components is not known, in the future, adequate drying quickly at lower temperature could be done in specially designed vacuum ovens. Such procedures could also be calibrated for the residual water content. Often, a practical method is to dry the cells in a microwave oven.

19.5 BIOMASS BY LIGHT SCATTERING

Light-scattering methods are the techniques most generally used to follow the growth of pure cultures. The major advantages are that they can be performed quickly and nondestructively. However, they may give information about a quantity not of primary interest to the investigator. Although they can be powerful and useful, they can lead to erroneous results. Under a range of conditions, they give information about macromolecular content (dry weight) and not about the number of cells or the state of hydration.

To understand their use in biomass determination, only the basic principle of Huygens is needed. Electromagnetic radiation interacts with the electronic charges in all matter. When the light energy cannot be absorbed (colorless materials), a light quantum of the same energy must be reirradiated. This light photon may emerge in any direction. This means that all atoms in a physical body serve as secondary sources of light. The photons that propagate in the direction of the original wave will stay in phase with the wave arriving directly from the light source, but light reirradiated from different points in the body that propagate in other directions will differ in phase at an observation point. The phase will differ depending on the distance that the photon must travel throughout the object because light going through matter is slowed. (The degree of slowing is measured by the index of refraction.)

It is refraction that controls how light is bent and focused in large bodies such as prisms, lenses, raindrops, or a pane of glass. In the last case, all the light that is scattered in any direction except straight ahead cancels, leaving only a beam of light going in the original direction. However, it is slightly retarded relative to a light ray not going through the pane; this is the basis causing the index of refraction of substances to be greater than 1. For the present purposes, the deflection of the light into different directions is the basis for the three types of useful techniques that are outlined next.

19.5.1 Theoretical Aspects

When the particles are very small, the light scattered is given by the Rayleigh equation:

$$I = \frac{8\pi^4 r^6 \eta_0^4 \left[(\eta/\eta_0)^2 - 1\right]^2}{R^2 \lambda \left[(\eta/\eta_0)^2 + 2\right]^2} v I_0 v \left[1 + \cos^2(\theta)\right] \quad (19.1)$$

In this equation, I is the intensity of the scattered light at a given direction and distance; r is the radius of the spherical equivalent of the actual particle; η_0 is the index of refraction of the suspending medium; η is the index of refraction of the particle; v is the volume illuminated; I_0 is the intensity of the incident light; ν is the concentration of particles; θ is the angle of observation; R is the distance of the observer from the sample; and λ is the wavelength of light in vacuo. The factor depends on the angle of observation, θ, relative to the forward direction of the illuminating beam. The $[1 + \cos^2(\theta)]$ factor takes into account the two mutually perpendicular beams of plane-polarized light that comprise unpolarized light. For a given physical setup, most of these factors can be combined into an empirical constant.

In studies of bacteria, the biomass is commonly measured by turbidity. Turbidity is the amount of light scattered away from the forward direction and is thus a measure of the integral of all the scattered light. Similarly, for the flow cytometer applications, I must be integrated over the directions that are collected by the instrument's optics. This integral will be designated by F. In nephelometry, only light scattered at 90° to the primary beam is recorded. This measure is actually a mixture involving on one hand the size shape and orientation of the particles and on the other the inhomogeneities inside the chapter.

The range of very small particles where Equation 19.1 holds is called the *Rayleigh domain*. For this domain, the actual volume, index of refraction, shape, and orientation

of the particles are irrelevant to the total light scatter. Most viruses are sufficiently small for their total scattered light to belong to this domain. For such small particles, the total light scatter integrated over all angles is proportional to the square of the volume, V^2. This results because the Rayleigh equation contains the radius, r, raised to the sixth power, which is equivalent to the volume squared. From the relative index of refraction, $m = \eta/\eta_0$ of the cells and the refractive index increment, the particle dry mass, q, and the wet weight can be calculated as discussed next, but only if all the parameters in Equation 19.1 are known.

For somewhat larger particles with low index of refraction, such as most bacteria, which typically range from 0.3 to 3 μm in linear measure, light scattered from different parts of the particle can interfere both destructively and constructively as a result of phase differences. This defines the Rayleigh–Gans domain and is the relevant case for most microbes. The shape and orientation of the particles become important for this domain, where the particle's radius is comparable to λ', the wavelength of light in the suspending medium which is equal to $\lambda/\eta o$. For particles in this domain, it is sufficient to take only the constructive and destructive interference into account, whereas phase shifts as the light traverses the particle can be neglected. The light scattering in this domain can be treated relatively simply, and for calculation, Equation 19.1 need only be amended by multiplication with quantities called *P functions*. These functions are specific for shape, size, and orientation. Thus

$$I_{RG} = I(P(\theta)) \tag{19.2}$$

where I_{RG} is the light scattered as corrected by the Rayleigh–Gans method. The P functions are given and discussed in a variety of sources (see Ref. 1).

The mathematics of the third, the Mie, domain applies to particles of any size and index of refraction and are computer intensive. The computations can be carried out much more easily if the particles are spherical. For pigment-bearing cells, such as green and blue-green algae, the computations are very elaborate.

Although the Rayleigh–Gans or Mie mathematics apply as well to the simpler cases, we have defined the Rayleigh–Gans domain as the region in which interference, but not phase, must be taken into account, and the Mie domain is where both interference and phase shifts must be taken into account for accuracy. The choice of the appropriate mathematics depends on both the size and the index of refraction of the particle relative to the medium above that of the medium (i.e. on $\eta/\eta_0 - 1$).

Bacteria (e.g. *E coli* growing in minimal medium) belong to the Rayleigh–Gans domain and not the Rayleigh domain because they are large enough to require correction for interference; however, they do not belong to the Mie domain because they have only a small dry mass, being mostly, water, and have an index of refraction only slightly larger than the aqueous growth medium and thus do not elicit phase shifts. Typically, the index of refraction relative to the growth medium of many bacteria is 1.04. In any case, a relative index of refraction between 1.00 and 1.05 ensures that most bacteria suspended in their growth medium will fall in the Rayleigh–Gans domain (43–46).

Studies (43) show that dilute suspensions of most bacteria, independently of cell size, have nearly the same apparent absorbance per unit of the dry weight concentrations. Measurements at various angles (47) show that light is mainly collimated in the first few degree from the primary beam and at high angles almost purely measures the inhomogeneity within the bacterial cells.

Very different absorbancies (turbidities) are found per particle or per colony-forming unit with different sizes of bacterial cells. An approximate rule commonly assumed is that the dry weight concentration is directly proportional to the absorbance. This rule applies roughly to both cocci and rods and is a first approximation to a more precise rule, that is, the light scattered out of the primary beam is proportional to the four-thirds power of the average volume of cells in the culture. Objects smaller than bacteria, such as suspensions of viruses, will not obey these rules. The rules also fail to apply when the suspensions of very small bacteria have a bluish cast. Larger objects (yeasts and filaments and aggregates of bacteria) may still appear cloudy and not necessarily colored, but may not obey the rule. Where the rule applies, the proportionality constant relating the absorbency measurement to the dry weight concentration is the same for any good, well-collimated photometer.

19.5.2 Turbidimetry

Bacterial suspensions are in between the size limits of atoms and objects such as window panes. Consequently, most of the scattered light is deviated only slightly; it is directed almost but not quite in the same direction as was the incident beam. The light scattered from an atom or a very small particle inversely depends on the fourth power of the wavelength of light. For a pane of glass, there is no light left uncancelled in any but the original direction, so the light retains its original hue and the pane appears transparent. If the glass was powdered to the size of bacteria, a suspension of powdered glass or bacteria (like a cloud) would appear white but not transparent nor colored. Because bacterial suspensions appear cloudy or turbid, instruments to measure the phenomenon are called *turbidimeters* (*turbidus* = confused or disturbed).

The common practice in bacteriology is to use any available colorimeter or spectrophotometer to measure turbidity. Ideally, such instruments measure only the primary beam of light that passes without deviation through the sample and reaches the photocell. Usually, the measurement is made

of the light intensity relative to that which reaches the photocell when a sample of the suspending medium has replaced the cell suspension. From what has been said, an ideal photometer must be designed with a narrow beam and a small detector so that only the light scattered in the forward direction reaches the photocell. That is, the instrument must have well-collimated optics. Such an ideal instrument gives larger apparent absorbance values than simple instruments with poorly collimated optics, because in the latter a large percentage of the light scattered by the suspension is still intercepted by the phototube. Therefore, the measuring system responds as if there were less light scattered than is actually deviated from the forward direction.

If the instrument or the size of organism does not meet these criteria, valid measurements in many cases can be made by establishing a standard curve on either a relative or an absolute basis. Difficulty arises only as physical or biological conditions vary with the samples to be compared, because then the experimenter cannot be sure that the same standard curve applies.

These considerations apply only to dilute suspensions. Deviation from Beer's law must be applied after the absorbance exceeds about 0.3 when light of 500 nm or shorter is used. A good discussion of this question is given by Kavenagh (48). Failure to take this deviation into consideration is the most common difficulty encountered in the microbiological literature that involves turbidimetry. One way to avoid this problem is to restrict culture densities and use only dilute cultures for measurement (i.e. keep the absorbance below 0.3). It is usually better to make measurements at higher densities and correct for deviations from Beer's law. The longer the wavelength of light used, the less important the need for the Beer's law correction.

19.5.3 Nephelometry

Although most of the light scattered by bacteria is nearly in the forward direction, instruments that measure the light scattered at 90° from the primary beam have been used to measure bacterial concentrations. Instruments designed to make right-angle measurements of light scattering are called *nephelometer* (*nephelos* = cloud). Bacterial concentration may be measured with this nephelometric principle in a spectrofluorometer when the dials are set so that the excitation monochromator and the emission monochromator are at the same wavelength.

Nephelometric measurements can be ultrasensitive, so that very small concentrations of bacterial cells can be measured. If it is known which factors are important and whether elongated particles are oriented or randomly distributed in space, then light-scattering measurement over a range of angles can give information about several aspects: the state of aggregation of the protoplasm, such as whether the ribosomes are in polysomes or as monosomes within the living cell; the thickness of the cell envelope (46,47,49,50); and the distribution of cell mass from the center of the cell.

Wyatt (50) (see Wyatt Technology) has developed an apparatus to measure the angular dependency of the light-scattering signal from 30° to 150°. In this range, different organisms, different treatments of a culture, and cultures in different phases of growth give characteristic patterns. These may be of some use as a fingerprint technique for the diagnosis and study of drug action. For the reasons stated above, the light-scattering signals in the high angle range cannot be used reliably for growth measurement because they are sensitive to the details of subcellular structure.

Light-scattering measurements made over a range of angles from 0° to 20° are relatively independent of these three factors, but are more critically dependent on overall size. Measurement in this range could nondestructively yield the biomass concentration, the number concentration, the average axial ratio, and a measure of average biomass distribution around the center of the cells for bacteria in balanced growth.

It may be easily possible to build a device in which an inexpensive neon laser illuminates a flow through a cuvette or a series of cuvettes of different path lengths. It would be so constructed that little stray light from the laser arrives at the detectors. One detector monitors the input beam, and a second detector monitors the light scattered a few degrees from the direction of the primary beam, say at 4°. A third detector measures the light scattered at right angles, and software outputs the dry weight biomass and intracellular heterogeneity that is a measure of the physiological state of the cells. It would avoid problems of the failure of Lambert's law by having multiple path lengths and would usually neglect the signals from the path length cuvettes in which deviations from the Beer–Lambert law were important. A variation would have several laser beams. The appropriate choice would depend on the color of the surrounding medium and the size of the microbes. The farther into the infrared that can be used, the less the Beer's law correction is needed, but there may be more interference from medium constituents.

It is possible to put probes into the fermentation apparatus for light scattering, turbidity, and nephelometry that have light sources and light detectors. These methods usually fail because the organisms grow on the optical surfaces. It is possible to remove, sterilize, and reinsert the probes, but this could lead to contamination. There are some ways around the surface-growth problem that may be effectively implemented in the future to essentially by cleaning the optical surfaces *in situ*.

19.5.4 Flow Cytometry Methods

For the conversion of forward scatter measurements in flow cytometry, the intensity of light pulse from a passing particle must be converted to volume or wet biomass or dry biomass. Our analysis (51) showed that in the Rayleigh region, the biomass is related to the intensity raised to the 0.5 power, and in the Rayleigh–Gans region, the power is approximately 0.75 for the usual bacteria and is somewhere in between for the very small bacteria that we are studying. Rules have been developed to establish the exact power. The results are applicable to bacteria and very small bacteria ($0.02–0.6\ \mu m^3$) that are not usually spherical. The physical limitations and the mathematical basis of the calculations have been justified for the application of the proposed formula for practical use in microbial ecology and physiology of extremely small aquatic bacteria as well as the more well-studied forms. Although the method was developed for the small bacteria present in natural populations that are difficult to size by alternative methods, it will also be useful for industrial cultures of bacteria.

The major problem with both types of instruments discussed earlier is to convert the forward scattered light into a value proportional to the biomass of the particle. Although complicated, this problem has been solved for the first type of instrument (51). Consequently, the number of the channel of the multichannel analyzer can be related to biomass through a power law function. As of yet, a reliable way to do the same for the second class of instrument that uses an inverted microscope is not available. This does not prevent the instrument from being a very valuable instrument, but it will be more valuable when accurate sizes can be developed.

It may not be possible to theoretically analyze the light-scattering pulses from the second type of instrument and to convert them into dry weight biomass, but it is not impossible to imagine that something akin to the polystyrene latex beads that have become so useful in medical technology will be developed that have precisely defined size and an index of refraction in the range that includes most bacteria. Then, the second type of instrument will become useful for biomass determinations. As with light-scattering measurements, aggregation, clumping, and failure of cells to separate will remain problems to be coped with.

19.6 SAMPLING

Attention must be paid to analyzing an appropriate sample. Although this just takes attention to detail, it is so important that it should be emphasized again and again. During bioprocess technology, it is important to sample from a number of parts of the system. Pooling and mixing and then analyzing are appropriate, but in many cases, analysis of each part individually and the body of data analyzed statistically are efficient and useful.

Acknowledgment

I would like to thank George Hegeman and Matt Hilton for help in preparing this chapter.

MICROBIAL MEDIA COMPOSITION

ROSALIE J. COTE
Becton Dickinson Microbiology Systems, Sparks, Maryland

20.1 INTRODUCTION

The increased understanding of microbial biochemistry in recent decades, along with major advances in genetic and molecular techniques, has resulted in an expanding diversity of microorganisms entering the biotechnology arena. Be it novel uses for well-studied organisms, such as the commercial production of restriction endonucleases from many common bacteria and yeasts, or the potential for development of new applications from new species such as the unidentified hydrogen-producing bacterium FOX-1 (1), microorganisms, themselves, are integral components in the overall aspects of biotechnology from discovery, through research and development, to production.

For those biotechnologists not formally trained in classical microbial physiology, the too-prevalent assumption is that microorganisms function similarly to the purified reagents used in a well-documented chemical reaction. In reality, microorganisms (even authenticated and characterized strains) are heterogeneous conglomerations of multiple biochemical pathways with the potential for working antagonistically or synergistically, depending upon the environment in which the microorganism resides. For those strains under study in the laboratory or being potentially harnessed for bioprocess use, the microbial environment is the culture medium.

This chapter surveys elements of microbial media and other considerations of microbial nutrition that impact upon the general growth and metabolic activity of microorganisms. Although specific references are given for many useful compendia of microbial media formulations (2–7), the purpose here is not to further cite well-documented media and buffer formulations. The intent of this chapter and its specific examples is to illustrate general principles of controlled media design, formulation, and preparation for the cultivation of microorganisms.

20.2 ESSENTIAL NUTRITIONAL REQUIREMENTS

20.2.1 Water

Depending upon the physiological state of the organism, the chemical composition of bacteria is 70–90% water. As a polar solvent, water dissolves other compounds of similar chemical nature, which also happen to be the biologically important molecules such as amino acids, carbohydrates, and nucleic acids. The polarity of water helps to permit the hydrogen bonding necessary in the formation of the final working configuration of a cell's large macromolecules. As a polar solvent, water chemically forces nonpolar molecules such as lipids into hydrophobic aggregates that are integral in the formation cell membranes. The presence of water is critical to the existence of microorganisms. Under laboratory conditions, microorganisms are cultivated with liquid and solid media. In both situations, the adequacy and purity of water used in media preparation can drastically effect the performance and/or sustained viability of an organism.

Because the availability of high-quality, purified water has become increasingly affordable for even small laboratories, the use of tap water or marginally distilled

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

water for the preparation of media and reagents is not a recommended option. For most municipalities, tap water is seasonably variable with respect to its chemical and microbial content. Hard water ladened with calcium and magnesium will precipitate many media formulations, with deleterious results. The terms *deionized* or *distilled* water with respect to water purity are merely euphemistic unless actual determinations of residual ion and organic levels are known. Water passed through spent deionization beds or boiled and condensed through a scale-clogged distillation system is hardly purified. At minimum, water used in the preparation of microbial media and reagents for general laboratory purposes should meet U.S.P. specifications for purified water; other organizations such as the American Society for Testing and Materials (ASTM) and the National Committee for Clinical Laboratory Standards (NCCLS) have similar criteria with respect to the conductivity, resistivity, and total organic content for Type II water (8). Point of use deionization systems available from many manufacturers (e.g., Barnstead/Thermolyne Corporation, Dubuque, Ia. and Millipore Corporation, Bedford, Mass.) easily produce Type I, 18 MΩ water. Some systems include ultrafiltration to reduce pyrogen levels. Purified water for highly regulated applications and processes (e.g., biopharmaceuticals) must meet U.S.P. specifications for water for injection (9). Water, unless sterilized, should not be held for any length of time in storage containers such as bottles or carboys or allowed to stand in uncirculated piping systems (e.g., dead-legs) because there is a good probability that the water will become populated with bacterial biofilms that grow on container and piping walls. Bacterial contamination will organically pollute water purity in addition to increasing endotoxin and pyrogens to unacceptable levels for certain procedures including product purifications or animal injections. Note that pyrogens are lipopolysaccharides from bacterial membranes. With respect to purified water, they indicate bacterial contamination. Their presence, of course, in bacterial cultures is a mute point. Use of plastics for water storage containers may be a consideration because plasticizer leaching can cause inhibition of sensitive organisms.

20.2.2 Energy

All microorganisms require an exogenous source of energy. The biochemical mechanisms involved with this aspect of metabolism are diverse. *Lithotrophic* organisms obtain energy from inorganic sources. Lithotrophs fall into two metabolic categories with respect to energy procurement. *Photolithotrophic bacteria* and *cyanobacteria* obtain energy from light in conjunction with, respectively, reduced sulfur (e.g., hydrogen sulfide) or water, to release energy for biosynthetic functions. Variations in microbial chlorophyll molecules create adsorption spectra that, in nature, limit a given species to a particular photic zone. Under laboratory conditions, the light requirements necessary for cultivation reflect this consideration. For example, the green and purple sulfur bacteria, such as *Chlorobium* and *Chromatium*, with adsorption peaks above 750 nm, are cultivated under the red wavelengths of tungsten light. Cultures, however, should not be placed too close to an incandescent light source because the heat emitted from the bulbs can quickly raise the temperature of the culture vessel beyond the upper growth limits for an organism. Cyanobacteria (e.g., *Anabaena*) adsorb blue wavelengths of light below 700 nm. This requirement can be satisfied by cultivating the bacteria under fluorescent tubes that emit light at this range of the visible spectrum. *Chemolithotrophic* organisms utilize inorganic compounds for energy. Examples within this second form of energy procurement are *Sulfolobus* spp., which oxidize elemental sulfur to sulfuric acid, and *Nitrobacter* spp., which biochemically exploit the oxidation of nitrites to nitrates. Numerous new genera and species of prokaryotic chemolithotrophs that obtain energy from various inorganic electron donors have been isolated in recent years, including *Archaeoglobus* spp., *Methanococcus* spp., and *Pyrodictium* spp. (10). Many obligate lithotrophs are inhibited by organically rich environments and are best cultivated under chemically defined media conditions.

Organotrophic organisms obtain energy more conventionally from organic compounds. As with the lithotrophs, organotrophs many be either phototrophic or chemotrophic. *Photoorganotrophs* are represented in nature by the anaerobically cultivated purple nonsulfur bacteria (e.g., *Rhodospirillum*), which utilize light in conjunction with organic compounds such as malate, pyruvate, or yeast extract, rather than O_2, as electron acceptors to release energy for growth and nutrition. *Chemoorganotrophs* encompass a vast number of organisms from all the microbial groups including archaea and bacteria, fungi, protozoans, and nonphotosynthesizing eukaryotic cells that obtain energy from the oxidation or other dissimilation of organic compounds.

20.2.3 Major Chemical Elements (C, H, N, O)

Unlike energy-procuring mechanisms, which vary widely between microbial genera and species, the anabolic or biosynthetic requirements of eukaryotic and prokaryotic cells are remarkably similar. Molecular mechanisms for intracellular communication and structural components share much chemistry whether they are bacterial *E. coli* cells or fungal *Aspergillus nidulans* cells. Whereas individual strains may vary in their ability to manufacture basic cell components and metabolites due to specific

mutations at points within biochemical pathways, all known organisms share the same basic cellular needs for carbohydrates, lipids, proteins, and molecular combinations thereof. The elements carbon, hydrogen, nitrogen, and oxygen can be regarded as major essential elements of nutrition because they contribute in significant percentages to the biomass of cells. These major elements may be required in the gaseous form, as organically fixed compounds, or both. Iron, magnesium, phosphorous, potassium, sulfur, and other elements, although critically important to sustained growth and metabolic activity, are often termed minor or trace elements in that they collectively represent less than 2% of cellular dry weight.

20.2.3.1 Carbon. Nutritionally, carbon appears in cellular metabolism in two forms: carbon dioxide gas (CO_2) and organic molecules. CO_2 is required by all organisms for a number of biochemical functions including tricarboxylic acid (TCA) cycling and de novo fatty acid synthesis from acetyl-CoA. Although much of the carbon dioxide is metabolically recycled throughout the cell's biochemical pathways, an initial exogenous source of carbon dioxide is mandatory. Autotrophic organisms readily assimilate atmospheric carbon dioxide; yet, also, all heterotrophic organisms have some ability to fix this compound, although at a much-reduced capacity. Microbial cultures will sometimes experience long lag periods when subcultured at low-volume inoculum into fresh media. This phenomenon is often attributable to suboptimal CO_2 tension, which the culture slowly corrects with cellular respiration before any significant increase in biomass can occur. The term *CO_2 sparking* refers to the sudden increase in bacterial growth observed when a freshly inoculated culture is briefly sparged with the gas. An enriched atmosphere of 5% CO_2 is used for the cultivation of clinical (particularly for fresh isolates) bacterial strains. CO_2 incubators are most efficient for multipurpose cultivations, but the anaerobic gas-pack CO_2-generating systems offered by BBL (Becton Dickinson Microbiology Systems, Cockeysville, Md.) or Difco (Difco Laboratories, Detroit, Mich.) are recommended for small volume or infrequent use. Depending upon the absolute requirement, capnophilic (CO_2-requiring) bacteria can also be cultivated in jars in which inoculated test tubes or agar plates are placed along with a burning candle. The candle jar is then tightly sealed while the candle continues to burn until free oxygen in the jar is consumed. The resulting atmosphere achieves approximately 2% CO_2. Both the anaerobic gas-pack systems and candle jars have draw backs with respect to increased risk of culture contamination. Respiring cultures give off significant amounts of water, which raises the humidity within the sealed jars. As the jars themselves are normally not sterile at time of culture incubation, any environmental bacterial or fungal contaminant within the jar will proliferate in the additional moisture. Capillary action of excess water at the culture vessel openings (particularly petri dishes) can draw contaminating organisms or their spores into the culture vessel.

Autotrophs can use carbon dioxide gas as a sole source of carbon for biosynthesis. Although autotrophy is often regarded by nonbacteriologists as synonymous with photosynthesis, autotrophy and phototrophy are quite independent metabolic functions. For example, methanogenic archaea (e.g., *Methanobacterium* sp.), while nonphotosynthetic, are capable of utilizing carbon dioxide and hydrogen as sole sources of carbon and energy. Yet, as noted elsewhere, purple nonsulfur bacteria are photosynthetic but rely upon organic acids for metabolic reducing power and, ultimately, as the carbon source for biosynthetic functions. Whereas autotrophy is widely represented among prokaryotes, the ability to utilize CO_2 as a sole carbon source is not a general characteristic of fungi. Among filamentous fungi, *Cephalosporium* spp. and *Fusarium* spp. have been documented to be able to do so under long-term cultivation (11).

Heterotrophs obtain carbon principally from organic molecules such as carbohydrates, amino acids, or lipids. For heterotrophs, a compound utilizable for its carbon often also functions as an energy source. Although glucose is widely assimilated by many heterotrophic microorganisms, it is not necessarily the universal carbon source for culture medium supplementation. Many bacteria, whether their characteristics are genuswide or species-specific, show little or no stimulation by glucose and preferentially utilize amino or other organic acids. The marine genus *Oceanospirillum* falls into this category as do many individual species within the diverse genus *Clostridium*. In an extreme example, *C. aminovalericum* (ATCC 13725) appears to be limited to δ-aminovaleric acid as its singular assimilable source of both carbon and energy.

Some organisms can alternate between autotrophy and heterotrophy, depending upon environmental and nutritional conditions. For these cultures, biomass vigor and yield are most often greater with heterotrophic rather than autotrophic conditions; however, secondary metabolites produced can vary considerably between the two conditions.

20.2.3.2 Hydrogen. Certain archaea and bacteria can grow by utilizing atmospheric hydrogen (H_2) as an electron donor and, depending upon the organism, assorted compounds including carbon dioxide, oxygen, nitrate, or sulfate as terminal electron acceptors (10). The hydrogen-oxidizing genus *Hydrogenophaga* (12) is facultative with respect to energy metabolism in that it functions chemoorganotrophically in a nutritionally heterotrophic aerobic environment by metabolizing various amino acids

or sugars for sources of carbon and energy. However, in an atmosphere containing 60% H_2, 10% CO_2, 25% N_2, and 5% O_2, the organisms switch to chemolithoautotrophic pathways. *Methanobacterium thermoautotrophicum*, a strictly anaerobic archeaebacteria, metabolizes hydrogen and carbon dioxide as sole energy and carbon sources to yield methane and water (methanogenesis). For the anaerobic methanogens as well as the aerobic hydrogen bacteria, conditions favoring autotrophy require a high (60–80%) concentration of hydrogen for cultivation. Under all conditions, work with compressed hydrogen gas should be conducted with adherence to pertinent laboratory safety practices. Lower concentrations of H_2 (3–10%) are frequently included in gas mixtures for the cultivation of anaerobic bacteria in gas-generating systems and glove boxes where, in the presence of a palladium catalyst, trace amounts of inhibitory molecular oxygen are chemically reduced to water. The final form of hydrogen required for nutritional purposes is the molecularly combined element required by all organotrophic cells. Combined hydrogen originates from the catabolic metabolism of organic compounds assimilated by a cell as carbon and energy sources.

20.2.3.3 Oxygen. As already noted for combined hydrogen, the bulk of combined oxygen within cells originates from the complex nutritional compounds, including water, assimilated by the cell. If a medium provides enough matter to satisfy the carbon and energy requirements of a culture, then the combined oxygen requirements will also be met. However, molecular oxygen (O_2) is an important, often growth-limiting, variable in microbial nutrition. O_2 is the primary terminal electron acceptor for many aerobic and facultatively anaerobic organisms. In oxygen-depleted or diminished environments, cells with no other biochemical mechanisms for exploiting alternative electron acceptors stop metabolizing and cease multiplying. Facultative organisms switch to fermentative pathways. In either situation, the biochemical activity of the cells, as well as the secondary metabolites produced, is significantly altered by oxygen starvation. Be it large-volume fermentors or small-volume chemostats or Fernbach flasks, the need for O_2 sparging in bulk cultivation vessels is regarded as a basic cultivation requirement for aerobic organisms (13). Be that as it may, one should also be aware that significant O_2 gradients quickly form in liquid test tube cultures, particularly for those cultures that form surface mats or pellicles of growth. Various micrometabolies can occur within the cell population in a standing culture along the O_2 gradients from surface to bottom of the test tube that might, if unrecognized, cause undue problems in scale-up development. Cultures with strong O_2-requirements (even for those that do not form pellicles) may not grow to very high density in a test tube because of the limited liquid–air interface. Better liquid growth of these test tube cultures is effected by incubating the tube at a slant to increase the surface area of the culture, or by shaking.

20.2.3.4 Nitrogen. Cells can assimilate nitrogen by two methods. Nitrogen fixation is the ability to acquire elemental nitrogen from the air and to molecularly combine the element into chemical forms utilizable for biosynthetic processes. The bacterial genera *Azotobacter, Bradyrhizobium*, and *Rhizobium* are most recognized for this characteristic, although some facultative anaerobes as well as anaerobic bacterial species also have the capacity. Fungi are not recognized as competent nitrogen fixers. Nitrogenase activity is induced with cultivation on nitrogen-free media. Growth on chemically defined "nitrogen-free" media might presumptively select for potential nitrogen fixers; however, trace amounts of nitrogen from agars, chemicals, and glassware are present in sufficient concentration to permit effective scavenging and growth (albeit, less than optimal) by many non-nitrogen-fixing organisms. Conclusive nitrogen fixation is best determined by the acetylene reduction assay (14).

The second, and most widely utilized, microbial mechanism for nitrogen procurement is via combined nitrogen assimilation from inorganic or organic molecules. Media formulations satisfy combined nitrogen requirements either with inorganic salts [e.g., NH_4Cl; NH_4NO_3 or KNO_3; $(NH_4)_2SO_4$] or from organic compounds (e.g., amino acids). The ability to utilize inorganic salts as a nitrogen source varies widely even within species. The chemolithotrophs as a group effectively utilize inorganic ammonium or nitrate salts as sole sources for nitrogen. For other organisms, the inability to grow under chemically defined medium conditions with ammonium or nitrate salts as a sole nitrogen source is due not so much to the inability to assimilate the ion directly from the medium or to incorporate it as the glutamine precursor to all subsequent biosynthetic nitrogenous pathways, but to the specific need for additional nitrogenous growth factors such as purines, pyrimidines, amino acids, or small peptides. These kinds of nitrogenous nutritional requirements are discussed in greater detail in the section "Growth Factors".

Nitrate is not a preferentially assimilated or utilized source of nutritional nitrogen for many bacteria or fungi; concentrations as low as 0.2% are inhibitory to the growth of some bacteria. However, the use of nitrate in energy metabolism as a terminal electron acceptor is a widely used mechanism among bacteria and is termed dissimilatory nitrate reduction or denitrification. The biochemical pathways involved with nitrate assimilation for cellular syntheses and for dissimilatory nitrate reduction are different. Nitrate reduction occurs with either aerobic or anaerobic bacteria. Strains of *Clostridium perfringens*, for example, utilize nitrate as an electron sink, which

causes a shift from butyrate to acetate fermentation and an increase in growth yield (15). All recognized species in the extremely halophilic genus *Haloarcula* are capable of using nitrate as a sole nitrogen source and, in addition, are strong denitrifiers with the ability to readily tolerate and reduce 3 M concentrations of KNO_3 under either complex or chemically defined media conditions; aerobic growth of haloarculas with liquid media lacking nitrate supplementation is markedly limited compared to aerobic growth in media supplemented with 0.2% KNO_3 (R. J. Cote, unpublished data, 1995).

20.2.4 Minor and Microelements (Fe, Mg, K, P, S, and Others)

Trace metal function and speciation have been extensively studied in bacteria and fungi (16,17). Nutritionally essential metal ions function metabolically as enzyme cofactors in membrane transport and in structural components. Microbial response to trace metals is detectable at extremely low concentrations (i.e., microgram or nanogram quantities, depending upon the metal). However, the bioavailability of a particular metal is markedly dependent upon proper speciation of the ion as it occurs in the culture medium (18). Depending on interaction with other medium components or methods of sterilization, metal valences can change to nonusable forms, or the ions can irreversibly bind as insoluble precipitates. Although problems with metal-binding phenomena are often directed toward the nutritionally essential metals, the potential for significant and irreversible binding of ions to media components must also be taken into consideration in studies of bacterial resistance to heavy metals. Reports of bacterial resistance to silver and selenium (19,20) could not be verified when the metals were added to culture media in a manner that eliminated their binding to peptones (R. J. Cote and R. L. Gherna, unpublished data, 1994). Similar observations made regarding media influence and metal sensitization of *Enterobacter cloacae* to silver sulfadiazine (AgSu) (21) are explained by heavy-metal binding under complex media conditions. Tilton and Rosenberg (22) discuss the issue of heavy-metal sequestration in a study of the effects of agar on silver inhibition.

Microelement supplementation is not normally required in media formulated with chemically complex components such as yeast extract or protein hydrolysate because the essential metals are naturally present in these materials in sufficient concentration to provide optimum culture growth and performance. Well-designed, chemically defined formulations include calcium, iron, magnesium, manganese, phosphorous (as phosphate), potassium, sodium, and sulfur (as sulfate) in the form of inorganic salts. Other micronutrients may be required in the medium, depending upon the nature of the metal function under study or, in the case of general culture propagation, the purity of the water and cleanliness of the glassware used to prepare the medium. Understanding of cell physiology, as well as any physical interactions within the culture system, is a basic requirement when working with nutritional trace metals. For example, although boric acid is often included in trace metal mixes, a boron deficiency is practically noninducible for cultures grown in borosilicate glass vessels because enough of the element leaches from the glass to satisfy nutritional needs. Table 20.1 lists metal mix formulations that are useful for chemically defined cultivation of numerous microorganisms. As noted elsewhere in this chapter, the use of tap water to satisfy trace element requirements is not recommended because regional and seasonal variability in water purity can introduce considerable ionic variation in a medium, with frequently deleterious results.

The whitish haze or precipitate that develops in some media upon standing or after autoclaving is frequently caused by imbalanced metal compositions. Divalent and trivalent cations (i.e., Ca^{2+}, Fe^{2+}, Fe^{3+}, and Mg^{2+}) will spontaneously bind with OH^- and PO_4^{2-} groups in the medium to form insoluble hydroxides and phosphate complexes. The condition is most evident at neutral to alkaline pH values and is intensified by heat, either boiling or autoclaving. Similarly, precipitation caused by metal binding to proteinaceous material in the medium

TABLE 20.1. Trace Metal Mixes for Bacteriological Media

Metal mix A: Balch's trace element solution

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3.0 g
$MnSO_4 \cdot H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoCl_2 \cdot 6H_2O$	0.1 g
$CaCl_2$	0.1 g
$ZnSO_4 \cdot 7H_2O$	0.1 g
$CuSO_4 \cdot 5H_2O$	10.0 mg
$AlK(SO_4)_2 \cdot 12H_2O$	10.0 mg
H_3BO_3	10.0 mg
$Na_2MoO_4 \cdot 2H_2O$	10.0 mg
Distilled water	to 1.0 L

Suspend nitrilotriacetic acid in about 500 mL water and adjust to pH 6.5 with KOH pellets to dissolve. Add remaining salts one at a time. Bring final volume to 1.0 L with distilled water. Use 10.0 ml trace element solution per 1 L medium.

Metal mix B: modified Balch's trace element solution

To 1.0 L metal mix A add	
$NiSO_4 \cdot 6H_2O$	30.0 mg
Na_2SeO_3	20.0 mg
$Na_2WO_4 \cdot 2H_2O$	20.0 mg

These metals are included for the cultivation of methanogenic bacteria under chemically defined conditions.

Source: From Ref. 23, p. 158.

and darkening of chemically defined agar media are also frequently encountered in poorly designed or manipulated formulations. All of these adverse metal interactions are generally regarded as deleterious and growth limiting. Depending upon the composition of the medium, these kinds of chemical interactions can be eliminated by sterile filtration or separate autoclaving of inorganic salts and any phosphate buffers, and separate autoclaving of agar.

The use of chelating agents can also help to selectively maintain the solubility of polyvalent cations. Care must be taken when using powerful chelators such as ethylenediaminetetraacetic acid (EDTA) or nitrilotriacetic acid (NTA) because overchelation also depletes bioavailability of the metals. For microbial media, 0.5–2.0 mg/L EDTA or 15–150 mg/L NTA are reasonable concentrations. Mild chelation can be achieved with the use of specific amino acids (e.g., glycine, histidine) or carboxylic acids (acetate, citrate, succinate, tartrate). However, their use and concentration must be evaluated with respect to the function of the medium and the physiology of the microbial culture. For example, carboxylic acids are readily utilized carbon and energy sources for many microorganisms, and glycine is inhibitory at 1% concentration to many bacteria.

Under iron-deficient growth conditions, some bacteria produce and secrete chelators called siderophores to improve transport of ionic iron into the cell (24,25). Siderophores have been found in a number of diverse genera including *Aureobacterium (Arthrobacter) flavescens* (26), *E. coli, Klebsiella* (27), *Pseudomonas*, and *Mycobacterium avium* subsp. paratuberculosis (28). Other organisms rely upon the hemin molecule in blood as an easily assimilable iron chelate. A growth factor requirement for hemin is common among medically important bacteria. Hemin requirement (the X-factor) is diagnostic in the identification of *Haemophilus influenzae. Porphyromonas gingivalis* (29) and *Vibrio vulnificus* biotypes 1 and 2 require iron in the form hemin for growth and virulence (29,30). Whereas a number of classical media formulations (e.g., GC Agar) include crude hemoglobin as the source of the iron porphyrin molecule, use of hemin, instead, will produce a medium free of the heavy debris associated with hemoglobin. Hemin is used at a concentration of 0.5 mg/L medium. To improve solubility, initially suspend the compound in 1–2 mL 1 N NaOH, then add the hemin-NaOH solution to the bulk of the medium.

Many of the metals listed here that have been historically categorized as needed by microorganisms only in trace amounts have, in recent years, come to be evaluated on a different metabolic scale. Sulfur serves as an energy source for numerous species of bacteria, and thiosulfate seems to be utilized for energy by some fungi. While the role of sulfate as the terminal metabolic electron acceptor for the many anaerobic sulfate-reducing bacteria has been long recognized, new genera are currently being isolated that possess the ability to utilize one or more biologically important metals [(Fe (III), Mn (IV)], U (VI), and others] as terminal electron acceptors in biochemical dissimilatory metal reduction pathways (31). Because the function of terminal electron acceptor is not recyclable within the cell and bears a heavy metabolic load, the amounts of metal ion needed per liter for efficient energy transfer are orders of magnitude greater than those needed to satisfy trace element nutrition. One to four grams per liter is a guideline, depending upon the specific metabolism of the organism as well as the molecular weight and form of the metal salt selected for use.

20.2.5 Growth Factors

Given less than a dozen essential chemical building blocks and a source of metabolic energy to power the cellular machinery, some organisms, such as the wild-type *E. coli*, can synthesize every molecule needed for cell maintenance, growth, and reproduction. Many other microorganisms (even strains within the same species) are auxotrophic in that they have lost the ability to synthesize one or more key organic compounds essential to their physiology. These missing compounds are called growth factors and must be present in the culture medium if cell growth is to be vigorous, metabolically productive, and sustainable.

20.2.5.1 **L-*Amino Acids.*** L-Amino acids are common growth factor requirements for prokaryotes and eukaryotes. Many bacterial genera (e.g., *Lactobacillus* spp.) have multiple amino acid requirements. The requirement may be absolute or conditional and influenced by the presence and concentration of other amino acids (32–34). Similarly, a phenotypic amino acid requirement may disappear with the addition of an appropriate synthetic pathway intermediate. For example, a tryptophan "requirement" may actually be caused by a metabolic block earlier in the tryptophan pathway and might be satisfied by one of the earlier pathway intermediates (i.e., aspartic acid or indole). Because amino acids may share a common transport system, an excess of one amino acid can result in an increased need for a competing amino acid. Amino acid supplementation is not required in complex media containing peptones or other protein hydrolysates. In chemically defined media, the addition of 20–50 mg/L amino acid stimulates prokaryotic growth (100–200 mg/L for yeast), although adjustment of the concentrations is necessary for media optimization with multiple amino acid-requiring strains to chemically balance the formulation. The most notable exception is the requirement for glutamic acid, which, as precursor to all other amino acid biosyntheses, must be added at 200–500 mg/L to achieve

optimal growth of a bacterial culture. Amino acids, except glutamine, are stable with autoclave sterilization at the working concentrations used in media. Glutamine in aqueous solution will spontaneously break down with time to ammonium and pyrrolidone carboxylic acid residues. This reaction occurs more rapidly at elevated temperatures (37°C and above). The use of glutamine peptides in a medium can eliminate this problem, however, they are expensive for large-scale use. Concentrated stock solutions of amino acids may not be soluble, but neutralization of the stock solution with NaOH or KOH will increase solubility with the formation of amino acid salts for many of these compounds. Stock solutions of cysteine will autooxidize to cystine unless stored anaerobically (e.g., under N_2).

For many years, the perceived need by bacteria for combined amino acids (peptides or proteins) was satisfied by the argument that peptide transport utilized different systems than did amino acids; thus, the need for a specific peptide was actually an alternative cellular method for obtaining a specific amino acid contained within that peptide via a biochemically noncompetitive mechanism. However, increased knowledge of the role of peptides in protein trafficking suggests that peptide auxotrophies can affect cellular physiology and communication (35). Successful laboratory cultivation of *Thermoplasma acidophilum*, having no other known growth factor requirements, is dependent upon specific lots of powdered yeast extract containing a methanol-soluble growth factor, which purification revealed to be a small 1,000-MW peptide (36). Similarly, recent laboratory cultivation of *Treponema maltophilum* also included the requirement for a methanol-soluble growth factor from yeast extract (37). The treponeme requirement has not been further purified. Finally, successful cultivation of the protozoan *Entamoeba histolytica* in complex media enriched with peptone, vitamins, and serum is nevertheless dependent upon an unknown growth factor found only in certain lots of powdered yeast extract (38). Whether the elusive yeast extract growth factor is the same for all these metabolically dissimilar organisms or whether the relatively gentle methods used in the manufacture of yeast extract simply yield a large pool of assorted intact peptides possibly required by some microorganisms poses an interesting question.

20.2.5.2 Whole Proteins. Whole proteins (e.g., albumin, blood, egg, meat, serum) are not known to be essential requirements for microbial growth, although they are an integral medium component for many nutritionally fastidious microorganisms. Clinical isolates of mycobacteria have been historically cultivated with Lowenstein–Jensen medium, containing whole egg and inspissated (coagulated by heating at 80–85°C for 45 min) to form a solid matrix (39). Most mycobacteria, however, can be effectively cultured with Dubos medium or Middlebrook 7H9/or 7H10 media, in which the egg protein is replaced by the more defined components bovine serum albumin, catalase, dextrose, and oleic acid (40). Variations of chopped meat media (2) were for many years the recommended formulations for cultivation of pathogenic clostridia and similar bacteria, yet many of these strains give equal cell yield with the more defined, and more easily prepared, Reinforced Clostridial medium (40), although this basal medium frequently requires the addition of hemin and/or vitamin K_1 to satisfy the growth factor requirements of some strains; additionally, 0.5% cellobiose added to reinforced clostridial medium will enhance the growth of cellulolytic clostridia.

Defibrinated rabbit or sheep blood (5–10% v/v) is a common addition to media used for the cultivation of microorganisms pathogenic to animals. Human blood is not recommended for use for microbial culture work for health safety reasons and also because outdated blood obtained from banks is normally citrated. Citrated blood of any type should not be used in culture media because the anticoagulant may have negative effects on culture growth or hemolytic reactions. Although diagnostic hemolytic reactions differ between rabbit and sheep bloods, the ability to support microbial growth is generally the same. Human or sheep bloods, unless chocolated, are not used for the cultivation of *Haemophilus* spp. or other organisms requiring NAD because these fluids contain enzymes that inactivate the growth factor. Chocolate blood agar is prepared by heating the medium containing blood to 70–80°C for 15 min. Purchase of whole animal blood should be from a reputable supplier and pooled from animals on an antibiotic-free diet. Well-collected and processed defibrinated blood is free from clots and cell lysis. Although commercial blood suppliers carefully collect their products, each lot of blood should be checked for sterility prior to use. Not all types of bacterial contaminants found in blood will grow well in either of the U.S.P.-recommended sterility test media (i.e., Fluid Thioglycollate and Soybean–Casein Digest). To broaden the screening procedure, the battery of media should be enlarged to include Brain Heart Infusion (BBL 11059 or Difco 0037) to enhance the recovery of somewhat fastidious contaminants, as well as HTYE (Trypticase peptone (BBL), 0.5%; yeast extract 0.2%; HEPES, acid, 0.4%; adjust to pH 7.2 ± 0.1 prior to sterilization at 121°C for 15 min), which has wide versatility in the ability to cultivate diverse environmental heterotrophic organisms that do not grow well with conventional, general bacterial growth media. Whole blood should be stored under refrigeration (not frozen) and should be incorporated into media as soon as possible to help stabilize the fluid. Whole blood can not be stored longer than 2–3 weeks without significant deterioration. However, when stored at 4–8°C,

media containing blood can, for most media purposes, have a 4-month shelf life.

Serum (5–10% v/v) is an alternative to blood for the cultivation of pathogens. Horse, fetal, or newborn bovine sera are most frequently used for the cultivation of bacteria, whereas adult bovine serum is specified for the cultivation of many pathogenic protozoans. Sera vary in their intrinsic enzyme activity. For example, horse serum degrades glutamine, a necessary component in many animal cell line media formulations, and as already noted for chocolatizing whole blood, sheep and human blood can inactivate NAD. Preparation instructions for many media formulations call for serum heat inactivation (incubation of the serum at 56°C for 30 min) to inactivate the protein complement. This temperature may not be high enough to eliminate adverse serum enzyme activity. Conversely, heat inactivation may not be a universally advantageous specification for all microbial growth and performance. A researcher should investigate types of sera as well as the effects of heat inactivation upon the performance of a microbial culture.

Whole proteins and their hydrolysates supply an eclectic and undefined mix of nutrients, detoxifiers, and other molecules that slowly release or absorb metabolites that may be required for cell nutrition in small amounts but quickly become toxic at elevated levels (e.g., fatty acids). Proteins hydrolysates supply a myriad of nutritional growth factors and help control physical parameters such as pH and osmolarity.

Be that as it may, the use of proteins and their derivatives in media formulations is becoming problematical with respect to biotechnology for two reasons: (*1*) Because many of the products of interest produced by microorganisms are proteins or substances with chemical affinity to proteins, presence of a complex proteinaceous medium component can significantly complicate a product purification process. (*2*) Biotechnology applications under regulatory compliance are facing increasing scrutiny about the potential presence of unidentified adventitious agents in media components. The international concern with bovine spongiform encephalopathy (BSE) is real and pervasive throughout the field of biotechnology, ranging from final product, to the type and source of medium components used in the preparation of a frozen or lyophilized master cell bank used in the manufacture of a product.

The European Commission decision 97/534/EC bans the importation of specified risk materials (SRM) into the European Union member countries (including Australia, Canada, and New Zealand). U.S. biotechnology companies wishing to deal with the European market must be able to provide a declaration to customs agents that assures their product does not contain, nor is derived from, the specified SRM as defined in 97/534/EC. The specified risk material, in this instance, is defined as "the skull, including the brain and eyes, tonsils and spinal cord of bovine animals over 12 months, ovine and caprine animals which are over 12 months or have a permanent incisor tooth erupted through the gum, and the spleen of ovine and caprine animals" (41).

Many of the peptone hydrolysates used in biotechnology are of animal (bovine) origin and are manufactured from "leftovers" of the slaughterhouse trade. As large-scale animal processing is not a clean operation, SRM contamination of raw material used in the manufacture of peptones is probable, particularly where source material is not directly traceable to government-regulated, clean herds.

The degree of concern with animal peptones with respect to 97/534/EC varies with industry and product. For example, from a regulatory perspective, the manufacture of biopharmaceuticals, especially direct injectables, demands high scrutiny for presence and elimination of any SRM. But the use of an animal peptone in a medium used solely for clinical diagnostic purposes (e.g., a peptone used clinically in MacConkey agar to differentiate *E. coli* from other normal intestinal flora), might be of lesser concern because the peptone never comes in direct contact with animals or humans at risk to BSE or similar prion agents. Acid-hydrolyzed animal peptones are generally of lower risk than enzymatic hydrolysates because the acid and heat associated with acid hydrolysis inactivates viral agents. Ultrafiltration of peptone solutions and sera has been proposed as a mechanism for eliminating possible BSE contaminants as well as reducing endotoxin levels. In any event, the concern with BSE and related animal/human pathogenic agents has caused an escalation of documentation requirements for the tracking of animal-derived media components. Certificates of origin for sera, meat, and milk peptones can, and should, be obtained from reputable vendors of these materials. Although certificates of analysis are now routinely supplied by raw material vendors to the biotechnology industry, certificates of origin are currently customer driven and are generally supplied only as requested.

BSE has fostered much current interest in the development of nonanimal peptones. With yeast, soy, or wheat as the source protein, some of these "veggie peptones" have interesting nutritional attributes but, nevertheless, still suffer the drawback of elevated intrinsic carbohydrate levels characteristic of plant peptones.

Difficulties in medium optimization and performance currently preclude wide use of serum-free or SRM-free media with animal cell lines. However, design of SRM-free media for most bacteria and yeast are feasible and cost-effective.

20.2.5.3 Vitamins. Vitamins are biochemical catalysts and appear in cellular metabolism as coenzymes or as the prosthetic group of enzymes. Vitamins elicit microbial growth response at very low levels, at nanogram concentrations for vitamins such as biotin and cyanocobalamin

(vitamin B_{12}). Although many microorganisms are capable of synthesizing all of the required vitamins, many others are auxotrophic for one or more of these growth factors. The genus *Lactobacillus* characteristically has multiple vitamin requirements, and several strains within the group were widely used for many years in protocols for vitamin assays until replaced by instrumentation-based methodologies. The U.S.P. 23 still retains *Lactobacillus delbrueckii* subsp lactis (*L. leichmannii*) (ATCC 7830) as the assay organism for vitamin B_{12}. Marine bacteria frequently require B_{12}, whereas thiamine and biotin are necessary for the growth of many mycelial fungi. Menadione or its more active form, vitamin K_1, is a supplement for the cultivation of some clinical anaerobic bacteria. As noted with amino acids, a shift in medium composition can spare the need for a specific vitamin. *E. coli* (ATCC 10799; NCIB 8134) requires vitamin B_{12} when cultivated with a chemically defined minimal medium; when grown in the presence of 20 μg/mL methionine, the vitamin requirement is eliminated (42). Vitamin auxotrophies can appear as a need for the vitamin precursor, the intact vitamin, or as conjugates in coenzyme form. Koser noted, many years ago, that vitamin and amino acid auxotrophies in thermophilic bacilli are temperature variable (43). NAD and cocarboxylase (thiamine pyrophosphate) are coenzymes required by many pathogenic bacteria.

All of the vitamins are water soluble and heat stable at working concentrations used in media; coenzymes should be filter sterilized, as should concentrated vitamin stock solutions. Most vitamin stock solutions remain water soluble in significant concentrations, although biotin, folic acid, nicotinic acid, and riboflavin require neutralization with NaOH to retain solubility of the concentrate. Vitamin K and thioctic acid stock solutions are ethanol soluble. Ascorbic acid, used in microbial cultivation as an antioxidant, has a short life (about 3 weeks) in media; use of ascorbate salts rather than the free acid will improve stability. Table 20.2 lists a complete vitamin mix for the cultivation of bacteria and fungi. Yeast extract at a concentration of 0.1–0.5% is used as an undefined vitamin supplement for microbial growth in complex media; however, concentrations of yeast extract as low as 0.05% can elicit growth stimulation by organic growth factors, which may or may not be vitamins.

20.2.5.4 Nucleic Acid Precursors. Nucleic acid precursors are often required by nutritionally fastidious organisms when cultivated in defined or semidefined media. In some instances, the purine or pyrimidine will satisfy the requirement; more commonly, an organism needs preformed nucleosides or nucleotides. Organisms with these types of synthetic deficiencies will show a growth response to 5–50 μg/mL filter-sterilized additive.

20.2.5.5 Lipids. Lipids or their precursors are required by diverse organisms. Some pneumococci have a unique requirement for choline as a lipid precursor. *i*-Inositol is a structural component of some phospholipids. Inositol-deficient strains of *Neurospora crassa* and *Saccharomyces cerevisiae* have been used in studies of phospholipids and cell membrane structure. Fatty acids stimulate the growth of some fungi; certain mutants of *N. crassa* are auxotrophic for fatty acid synthesis (45). Rumen bacteria require short-chain fatty acids for growth. Many mycobacteria have a generalized requirement for exogenously supplied lipid. Various media formulations for nonglycerophobic mycobacteria include 2.0 mL/L glycerol, 0.05 g/L oleic acid, or 0.5 g/L Tween 80 to satisfy this requirement. Most of the bacterial mollicutes (anaeroplasmas, mycoplasmas, and spiroplasmas) require sterols. Cholesterol is a prevalent component in semidefined media formulations for these organisms, whereas fetal calf or horse serum supplies the growth factor in general-use complex mycoplasma media. *Eubacterium coprostanoligenes* (ATCC 51222) and *Eubacterium* sp. (ATCC 21408) represent a novel group of bacteria that use cholesterol and similar sterols as terminal electron acceptors (46,47). The former organism does not require cholesterol but metabolizes and requires phosphatidylcholine for growth, whereas the latter requires cholesterol as well as an alkenyl ether lipid for growth. These bacteria have been used in probiotic studies on decreasing the level of cholesterol in the digestive tract. All the lipids just mentioned are stable to autoclave temperatures. Short-chain fatty acids are water soluble; higher molecular weight lipids are soluble in less polar solvents such as ethanol or chloroform. In the presence of other media components at alkaline pH, some high-weight lipids can form growth-limiting soapy complexes. Separate sterilization of the fatty compounds helps to alleviate the problem.

20.2.5.6 Polyamines. Polyamines (e.g., putrescine, spermidine, spermine) are formed via the arginine pathway

TABLE 20.2. Balch's Vitamin Solution

p-Aminobenzoic acid	5.0 mg
Folic acid	2.0 mg
Biotin	2.0 mg
Nicotinic acid	5.0 mg
Calcium panothenate	5.0 mg
Riboflavin	5.0 mg
Thiamine HCl	5.0 mg
Pyridoxine HCl	10.0 mg
Cyanocobalamin	100.0 mg
Thioctic acid	5.0 mg
Distilled water	1.0 L

Mix all vitamins in distilled water. Adjust to pH 7.0, if necessary, to dissolve. Filter sterilize and store in brown bottle with refrigeration.

Source: From Ref. 44, p. 160.

and have undefined functions in the cell. Research on polyamines has been done principally in vitro where the compounds bind to and neutralize charges on DNA and RNA. Although high concentrations of Mg^{2+} exert the same general ionic neutralization effect, only polyamines have the ability to influence correct tRNA conformation. Much of the cellular polyamine appears bound to ribosomes. In *E. coli*, putrescine and spermidine account for half the total product of the arginine pathway (48). Polyamine supplements as growth stimulants appear in media for the cultivation of *Ureaplasma urealyticum* (2 p. 530), *Haemophtlus parainfluenzae* (49), *Veillonella atypica* (50), and other bacteria. Where complex media are used, there is generally a sufficient polyamine content in yeast extract to satisfy the requirements of deficient strains.

20.2.5.7 Unique Growth Factors. Any organism has the possibility to, either spontaneously or through human intervention, develop mutations in biosynthetic pathways. Thus, unusual or strain-specific growth factors are always a consideration in the development of media for "unculturable" organisms. Deliberate mutation for the inability to synthesize the cell wall component diaminopimelic acid was engineered into early recombinant host strains of *E. coli* as an attenuation factor to reduce the possibility of survival outside of laboratory cultivation. Until recently, *Bacteroides forsythus* had only been culturable in cocultivation with other oral anaerobic bacteria, until its requirement for *N*-acetylmuramic acid was recognized (51). As noted earlier for the L-amino acids, the inability to synthesize functional signal and transport peptides may be limiting factors in the protein chemistry of some organisms.

20.3 PHYSICAL PARAMETERS

20.3.1 pH

pH is a strong selection factor for microorganisms. Although most bacteria have a wide pH range (±3.0 pH units) at which measurable growth occurs, optimum growth is limited to a narrow range. Minimum and maximum pH values can often be distinct and sharply defined. Members of the genus *Bacillus* will grow at pH 6.8 but not at pH 6.5. Extreme halophiles with a biomass yield optimum at pH 7.4 continue to grow slowly at pH 7.0 and exhibit little or no growth below pH 6.7. Eukaryotic and prokaryotic organisms shift their biochemistry according to the pH of their environment and thus change cellular characteristics as well as metabolic by-products. Such changes in cultivation parameters can be consciously directed toward a particular application such as secondary metabolite production. Unfortunately, the effects of pH shifts are too often not critically examined, particularly at the small-scale cultivation stage. For example, in an unbuffered test tube culture of anaerobic carbohydrate-fermenting clostridia, acid production can quickly drop the medium to below pH 4.0, well outside the pH minimum of 6.5 necessary for significant growth. Either the culture will sporulate (if medium conditions are conducive to the process) or viability quickly diminishes as acid concentration increases. Effective media design must be constructed around the pH at which the medium is developed and will be used. Radical adjustment to media naturally posed at a particular pH too often leads to precipitation of components or other problems with performance. Inclusion of buffers, as well as the types of buffers used, are important considerations in media design.

20.3.2 Incubation Temperature

Incubation temperature influences microbial metabolism both with respect to the rates at which cellular processes run and the rates at which nutrients are assimilated. Strains of *Serratia marcesans* produce pink-pigmented colonies at 26°C but are colorless or slow to produce pigment at 37°C. Temperature effects may sometimes be subtle. Bacteria alter the fatty acid compositions of their phospholipids according to temperature. The proportion of low-melting-point fatty acids increases as growth temperature decreases (52,53). Organisms may display fairly broad temperature tolerances within a range, but as with pH, optimum growth range is fairly narrow. Psychrophiles characteristically exhibit efficient metabolic rates at temperatures below 15°C; the obligate psychrophilic bacterial species *Colwellia psychroerythrus* has a temperature optimum around 10°C and lyses above 20°C (54). Mesophiles are active between 20°C and 40°C. Free-living environmental strains are more tolerant of wider temperature ranges than are pathogenic strains that effectively function within only a few degrees of the body temperature of their hosts. Thermophilic microorganisms exist at temperatures above 40°C. Although some fungi (e.g., *Mucor miehet* and *Sporotrichum thermophile*) can grow at temperatures as high as 50°C, extreme thermophily, characterized by the ability to metabolize at temperatures above 70°C, is restricted to members of the archaea and, to a lesser extent, the bacteria.

20.3.3 Oxidation–Reduction Potential

Oxidation–reduction (redox) potential of the culture environment determines the ability of a microorganism to initiate growth. Redox values of media and respiring cultures are measured with a pH meter set to the millivolt (mV) mode and a platinum electrode. Aerobic organisms require positive millivolt conditions. Obligate microaerophiles require 0 to −100 mV; clinical anaerobes

less than −100 mV; obligate and extreme anaerobes less −200 mV. Actively metabolizing anaerobic cultures can drop redox levels below −300 mV. Media for obligate microaerophiles and anaerobes include reducing agents to lower the redox potential to a range optimal for a culture inoculum to be able to initiate metabolic activity. Subsequent cellular growth will maintain an overall redox condition reflecting the varying metabolic activities of the culture. Organic matter such as meat particles, yeast extract, and reducing sugars exert reducing effects in a medium. Filling a culture vessel almost to capacity with medium or adding 0.2% agar to the medium to retard diffusion of O_2 will be adequate to culture less fastidious microaerophiles. Anaerobic organisms with more stringent redox requirements need one or more chemical reducing agents included in the growth medium. Frequently used reducing agents, listed in terms of approximate redox potential in millivolts, include sodium thioglycollate (−100 mV), cysteine hydrochloride (−210 mV), titanium (III) citrate (−480 mV), sodium sulfide (−571 mV), and sodium dithionite (−600 mV). The overall redox level of a medium containing any of these reducing agents will, of course, be dependent upon the chemical interactions of all media components as well as the reducing agent. Media chemically reduced with any of these compounds should not be allowed to reoxidize, because the chemical structure of the reducing agents can be irreversibly altered by oxidation and lose effectiveness; in some instances, the oxidized forms of reducing agents can be toxic to cells (55). For some strict anaerobes cultivated under chemically defined conditions, it is best to add the reducing agent just prior to inoculation because reduced conditions are difficult to maintain under prolonged media storage. Ljungdahl and Wiegel (56), Breznak and Costilow (57), and Balch *et al*. (58) provide excellent detailed instructions for the cultivation of strict anaerobes.

20.3.4 Detoxifiers

Detoxifiers are required for the cultivation of some fastidious microorganisms. In the natural environment, metabolic by-products released by some organisms are enzymatically neutralized or utilized by other organisms for nutritional or other biochemical needs before the compounds accumulate to toxic levels. In vitro, for a pure culture lacking the appropriate enzymatic mechanisms to neutralize its own metabolic wastes, these metabolites can build to inhibitory concentrations before significant culture growth has occurred. The inability to break down hydrogen peroxide by organisms lacking catalase, and strain sensitivity to fatty acid accumulation are two common problems associated with metabolite accumulation in closed culture conditions. To cultivate these types of microorganisms, some media require the addition of detoxifiers, of which most are absorbents. Frequently utilized detoxifiers include blood/serum, bovine serum albumin (BSA, fraction V), catalase, and charcoal. More recently, liposomes have been utilized to slowly release lipid growth factors to deficient organisms, thus eliminating the toxic effects that a full "dose" of a medium lipid supplement would have for these organisms (59). Similarly, cylodextrins have been shown to effectively chelate and then slowly release potentially toxic, yet essential, nutrients for some clinical bacteria under semidefined growth conditions (60,61).

20.4 MEDIA DESIGN AND COMPOSITION

Optimal growth and performance of a microbial culture is most influenced by the design and composition of its growth medium. There is no one "best" medium for a particular application; however, there exist many examples of poorly designed and/or poorly manipulated media, or well-designed media being used for an inappropriate purpose, in which a microorganism manages to survive in spite of the medium and not because of it. Effective media design comes from an understanding of an organism's biochemistry and physiology, as well as the nutritional ecology of the environment from which the organism was isolated. Although isolation media are selective and frequently nutritionally suboptimal to limit the growth of unwanted organisms, general growth or maintenance media should provide conditions to sustain a culture at optimal morphology and physiology through repeated subcultures. Under microscopic examination, bacteria grown under favorable conditions do not have a misshapen or shriveled appearance; cell inclusions are generally minimal or absent; and cell lysis and/or spheroplast development is minimal or absent. At logarithmic phase of growth, motility is detectable for motile strains. Depending upon its application, a medium may be further defined in terms of chemical composition or optimized to increase biomass or cell product yield. An organism exhibiting optimal growth in a nutritionally balanced maintenance medium may not give high yields of a much-wanted metabolic by-product. Thus, medium optimization is a process directed toward a specific application. With so many nutritional and physical variables impacting upon microbial physiology, attempts at media optimization can become unnecessarily expensive, time-consuming, and largely unproductive when blindly tackled one variable at a time. Statistical methods using modified factorial approaches have been developed to aid in systematic media optimization for large-scale development (62), but for general laboratory purposes, knowledge and understanding of an organism's metabolic pathways and physical growth parameters can indicate specific areas in which quick design improvements to an existing formulation can effect significant results.

Media formulations may be chemically defined, in which discrete compound identity and concentration of all components are known, or chemically undefined, in which ingredients include one or more chemically complex substances such as protein hydrolysates and extracts. The choice of defined or undefined medium is dependent upon its application. Chemically defined media are useful in biochemical or metabolic studies of organisms. These types of formulations are also sometimes used in large-scale bacterial or yeast fermentations to produce products which further require stringent purifications such as those from recombinant DNA technology. General laboratory growth media for heterotrophic microorganisms as well as industrial media for large-scale production of metabolites (e.g., antibiotics, alcohols and other solvents) are often chemically complex. Scale-up of any medium formulation must include considerations of availability, cost, performance and lot-to-lot reproducibility of components as balanced against the value of the product. Chemically defined media can be expensive, particularly if the ingredients include a lengthy list of growth factors.

Microorganisms can transport only small molecules across their membranes. Large molecules (e.g., DNA, starch, proteins) can be nutritionally utilized by a microorganism only if it can synthesize and secrete the appropriate extracellular enzymes to digest large molecules into subunits small enough for assimilation into the cell. Because this type of enzymatic activity is absent from many organisms, in vitro microbial cultivation relies upon predigested macromolecules in the form of hydrolysates, peptones, and extracts and simple carbon compounds as nutritional substrates.

20.4.1 Protein Hydrolysates (Peptones)

Protein hydrolysates supply a mixed source of nitrogen and growth factors in the form of amino acids, nucleic acid fractions, peptides, and salts to a complex growth medium. For organisms possessing the metabolic capacity, protein hydrolysates can also serve as complex carbon and energy sources. Industrial large-scale fermentations using bacteria and fungi effectively use by-products from other industrial processes as proteinaceous material for media, including cottonseed, yeast, and soy. Although these substrates are chemically undefined, published analyses of their nutritional content greatly help in determining the appropriateness of a product for inclusion in a medium (63). Manufacturers of refined media and media components offer water-soluble products with more controlled nutritional composition. Table 20.3 lists and briefly describes the extracts and hydrolysates frequently encountered in microbiological laboratory media. Meat, milk, and soy commonly serve as starting material for the manufacture of hydrolysates. Digestion of these proteins can be by acid, alkali, or enzymatic hydrolysis. The source protein and method and degree of hydrolysis determine the nutritional characteristics of a hydrolysate. Prolonged hydrolysis releases free amino acids; more gentle hydrolytic processes yield mixtures of amino acids and peptides. The strong conditions of acid or alkali hydrolysis destroy much intrinsic

TABLE 20.3. Hydrolysates and Extracts

Hydrolysis method	Source	Product/manufacturer[a]	Characteristics
Acid	Casein	Acidicase (BBL) Casamino acids (Difco) Hy-Case (Sheffield)	Free amino acids; deficient in tryptophan and cystine; high intrinsic salt concentration unless designated salt-free
Enzymatic	Casein	Casitone (Difco) NZ-Amine (Sheffield) Trypticase (BBL)	Free amino acids and small peptides; high levels of tryptophan; low in carbohydrates
Enzymatic	Meat	Myosate (BBL) Thiotone (BBL) Primatone (Sheffield) Peptone (Difco) Proteose peptone (Difco)	Mixtures of amino acids and peptides; those designated proteose are hydrolyzed for a high peptide content; Thiotone high in sulfur
Enzymatic	Plant	Phytone (BBL) Soytone (Difco) Hy-Soy (Sheffield)	High in carbohydrates and vitamins
Mixed	Yeast/casein	Biosate (BBL)	Combines amino acids as well as vitamins lost during protein hydrolysis of peptones
	Casein/meat	Polypeptone (BBL)	
Autolysis	Yeast	Yeast extract (BBL; Difco; Sheffield)	High in amino acids, peptides, water-soluble vitamins, and carbohydrates

[a]Items listed are representative of a manufacturer's product line. Consult manufacturers' technical manuals for more information, Refs 39, 40, and 64.

vitamin content of a raw protein, as well as some amino acids such as tryptophan, and reduce the levels of serine and threonine. Acid-hydrolyzed protein hydrolysates are high in salt content formed during the neutralization step; however, some manufacturers feature acid-hydrolyzed peptones with additional processing to reduce the amount of salt [e.g., Casamino Acids (Difco 0230)]. Enzymatic digests contain free amino acids as well as small peptides while maintaining the vitamin content of the original source material. Enzymatic casein digests, reflecting the amino acid composition of the starting material, are high in tryptophan and low in cystine. Peptones from plant proteins [i.e., Soytone (Difco); Phytone (BBL)] contain intrinsic carbohydrate and, while conducive to rapid heterotrophic growth, can cause quick culture decline due to substantial metabolic acid production. Because of the carbohydrate level, plant peptones are also unsuitable in basal media for fermentation or sole carbon source utilization studies. For routine growth, peptones are normally added to media at concentrations of 0.5–1.0%. Growth of microorganisms with diverse and multiple nitrogenous auxotrophies (e.g., the lactobacilli) is enhanced by elevated peptone concentrations as well as nutritional supplementation with peptones of mixed sources and degrees of hydrolysis.

20.4.2 Carbon and Energy Sources

Microorganisms other than autotrophs require organic compounds as a source of carbon and energy. These can include simple sugars, complex carbohydrates, alcohols, amino and other organic acids, and short-chain lipids. Some organisms (e.g., *Aspergillus, Pseudomonas*) possess the complex metabolic machinery that permits numerous classes of organic compounds for carbon/energy substrates. Other taxa exploit specific classes of molecules metabolically ignored by or toxic to general heterotrophs. Methylotrophs (*Methylobacterium* spp., *Methylomonas* spp., *Methylophaga* spp., and others) can extract energy from C_1 compounds such as methanol and formaldehyde, whereas the metabolic diversity of the bacterial genus *Pseudomonas* has allowed selection of strains that can utilize the long-chained hydrocarbons in crude oil or attack the degradation-resistant chemical rings of cresols and phenols as sole carbon/energy sources. Assorted fungal genera (*Cladosporium, Candida*, and others) have been found as actively growing contaminants in aircraft and diesel fuels (65). The type and concentration of a carbon substrate present in a medium will affect overall growth rates, morphology, and metabolites of a culture. Sole carbon utilization profiles are used in identification matrices for prokaryotes and yeasts.

Carbohydrates and related compounds are preferential carbon sources for many genera of microbes. Hexoses are most diversely utilized, followed by the disaccharides, trisaccharides, smaller polysaccharides (starch and glycogen), and pentoses. Glycerol, mannitol, and sorbitol are commonly utilized alcohols. Under laboratory conditions with defined media and mixed sugars at normal substrate levels (e.g., 2–10 g/L), microorganisms often exhibit diauxic growth, in which a culture first utilizes the carbon compound that supports the greatest rate of growth, with concurrent catabolic repression of other substrates (66–68). Enzyme systems then shift accordingly as the organism switches to and consumes each less-preferential carbon compound. This results in a biphasic growth curve. However, under carbon-limited (e.g., microgram to milligram per liter concentrations) chemostat conditions that mimic the low-nutrient conditions of the natural environment, a number of organisms use the components of carbon mixtures simultaneously (69).

Proteolytic organisms have the capacity to utilize L-amino acids and related compounds as sole carbon/energy sources. This metabolic characteristic is more common among bacteria than fungi and varies widely between species; identification keys for the genus *Clostridium* use saccharolytic versus proteolytic metabolisms for species differentiation. As a group, the helical/vibroid Gram-negative bacteria (e.g., *Aquaspirillum, Azospirillum, Camplylobacter, Oceanospirillum*) do not ferment or oxidize carbohydrates but satisfy carbon/energy requirements with amino acid catabolism. *Legionella* spp. also use amino acids as carbon/energy sources. Filamentous fungi vary in their ability to utilize amino acids as effective carbon sources; none, however are limited to nitrogenous sources of carbon. Glutamic acid, alanine, arginine, and proline are frequently utilized by many prokaryotes and yeasts. The aromatic rings of the amino acids tryptophan, phenylalanine, and tyrosine, as well as the purine and pyrimidine rings of the nitrogenous bases, are not readily attacked by many organisms. The ability to do so is used for taxonomic speciation. Degradation of any of these ring compounds, however, is not presumptive of an organism's ability to further use the breakdown products as a sole source of carbon/ energy; in many cases, the compound is not so metabolized. Organisms that catabolize amino acids frequently utilize organic acids in the same fashion (e.g., *Oceanospirillum*). In addition, many carbohydrate-utilizing organisms are also capable of utilizing organic acids. For example, citrate and propionate utilizations are classical tests in the identification of the carbohydrate-metabolizing genus *Bacillus*. When used as sole carbon and energy sources, amino and organic acids may not be soluble at required substrate levels (2–5 g/L); however, neutralization with KOH or NaOH will form soluble salts of these compounds.

Some organisms have the capacity to utilize fatty acids and other nonpolar molecules as carbon and energy sources. In some instances, the requirement is absolute.

The bacterial genus *Leptospira* requires long-chain fatty acids (70), which are supplied in complex growth media by rabbit serum. The anaerobic sulfate-reducing *Desulfovibrio* sp. (DSM 2056) oxidizes the fatty acids butyrate through stearate (71).

Simple sugars and other carbon compounds can undergo chemical changes when autoclaved with other media components. Amino acids and organic acids, though heat stable at growth factor levels, may degrade at substrate concentrations. The characteristic darkening of autoclaved media containing glucose and peptones, called the Maillard reaction, is caused by an interaction of amino acids with the glycosidic hydroxyl group of the sugar. Darkening of autoclaved media can also be caused by the interaction of mono- and disaccharides, particularly glucose, with phosphates; the reaction is more intense at alkaline pH. Carlsson *et al*. (72) demonstrated that the glucose–phosphate reaction produces hydrogen peroxide at levels toxic to catalase-negative organisms. These types of adverse chemical reactions between nutrient components compromise the performance of a medium and are to be avoided either by autoclaving or filter sterilizing the reactive compounds separately from the balance of the medium. Not all commonly used carbon substrates can withstand autoclave sterilization. In particular, arabinose, fructose, lactose, pyruvate, ribose, and xylose should be filter sterilized. Light-weight alcohols and similar solvents are volatile at autoclave temperatures. Autoclaving of heat-stable alcohols can be done in tightly stoppered containers; alternatively, these compounds can be sterilized with appropriate solvent-resistant membrane filters. Long-chain hydrocarbons (e.g., oils and waxes) are hydrophobic and are not sterilizable by autoclaving because the sterilant (steam) cannot adequately penetrate the material. A good chemical reference text, such as the *Merck Index* (73), is invaluable for determining the heat stability, solubility, and other important characteristics of many chemical components used in media formulations.

20.4.3 Extracts

Spray-dried powders derived from infusions of meat, yeast, or other chemically complex proteinaceous materials provide a nutritionally useful but undefined source of water-soluble growth factors and sugars. Because they are not subject to the same harsh conditions as those used in the manufacture of peptones, meat or yeast extracts can supply those nutrients lost during the peptone hydrolysis (e.g., vitamins and certain amino acids). Extracts, in themselves, do not contain sufficient concentrations of essential nitrogen or carbon compounds to effectively function as the sole source of these nutrients in a medium. Meat extracts include appreciable amounts of glycolic and lactic acids, as well as creatine. Yeast extract is high in carbohydrates and, therefore, interferes with fermentation studies. The nutritional properties of the fresh yeast extract solution used in many media formulations for the cultivation of mycoplasmas is not replaceable by powdered yeast extract. Malt extract used in some media for fungi is composed primarily of carbohydrates (glucose, fructose, sucrose, maltose, dextrins) and small amounts of nitrogenous matter. Powdered extracts are generally incorporated in media at a concentration of 0.5–1.0%.

Aqueous extracts and infusions of various materials have historically been used to supply undefined nutritional factors in laboratory media. Concentrated liquid extracts generally are used at 10–20% v/v concentration as a medium supplement, whereas infusions will constitute the entire liquid base of a medium to which additional nutrients are added. As already noted, a filtered, aqueous solution prepared from autolyzed baker's yeast (150 g yeast/L) is a necessary ingredient in media for mycoplasmas and other mollicutes. The fresh yeast extract solution is then filter sterilized and incorporated into the mycoplasma media at 10% v/v concentration. Lactic acid bacteria from milk or milk products have been cultivated with infusions prepared from whole milk, whereas tomato juice or other fruit juice extracts have been used at 10–20% v/v in media for lactic acid bacteria isolated from plants. Potato infusions (200–300 g potatoes/L) serve as a nutritional base in many media for the cultivation of bacterial and fungal plant pathogens. Soil extracts prepared from fertile, chemically uncontaminated soils have been used to induce sporulation in many bacteria. Rumen fluid, containing partially digested nutrients from the first compartment of a cow's stomach, is a supplement in media for the cultivation of rumen microorganisms. Rumen fluid contains an undefined mixture of fatty acids, carbohydrates, peptides, vitamins, and metabolites. As rumen fluid is most commonly added to and autoclaved with basal medium components, any heat-labile nutrients are destroyed. Rumen fluid is obtained from fistulated dairy cows and can often be procured gratis from universities with departments of animal or dairy nutrition. Rumen fluid may or may not contain significant amounts of solid material, depending upon the length of time the material has been in the rumen. Centrifugation will effectively remove the bulk of debris; however, a series of filtrations down through 0.2 μm is necessary to remove dead cells of indigenous microflora that can confuse microscopic examinations of the organism being cultured. A defined mixture of fatty acids (Table 20.4) can effectively replace the need for rumen fluid for many bacteria; however, as with most chemically complex, undefined supplements, cell yield is frequently better when it is included in the medium.

TABLE 20.4. Volatile Fatty Mix for Rumen Bacteria and Fungi

Acetic acid	17.0 mL
Propionic acid	6.0 mL
N-Butyric acid	4.0 mL
N-Valeric acid	1.0 mL
Isovaleric acid	1.0 mL
Isobutyric acid	1.0 mL
DL-α-Methylbutyric acid	1.0 mL

Pipette the given volumes of fatty acids into a container that has a tight-fitting closure and mix well. The objectionable odor of the free fatty acids can be reduced by neutralizing the pH of this solution with the addition of NaOH pellets. Use 3.1 mL of the fatty acid mix per liter of medium.

Source: From Ref. 44, p. 162.

20.4.4 Buffers

pH buffers are molecules that, in solution, resist fluctuations in hydrogen ion concentration. Weak acids, bases, and their corresponding salts in partial dissociation function as pH buffers. Buffering capacity is greatest when the compound is at 50% dissociation. The pH at which this occurs is equal to the pK_a value of the compound, and greatest buffering capacity falls between ± 1 pH unit of the pK_a. Thus, no one buffer can be used across the entire pH range of 1 to 14 (74). Some acids are zwitterions (compounds that can chemically behave as acids or bases) and have more than one pK_a. In an extreme example, glycine when titrated against HCl has pK_a 2.3; titrated against NaOH, pK_a 9.6. Other zwitterions include citric acid (pK_{a1} 3.06, pK_{a2} 4.74, pK_{a3} 5.40), succinic acid (pK_{a1} 4.19, pK_{a2} 5.57), and the Good buffers (see later). The perfect media buffer would be (*1*) completely effective at poising a desired pH throughout the metabolic flux of a culture's growth cycle, as well as any other chemical or environmental changes that may affect pH (e.g., metal ion interaction, temperature), (*2*) resistant to microbial enzymatic activity, (*3*) chemically inert with respect to other medium components, and (*4*) inexpensive. The perfect buffer does not exist.

Lacking perfect buffers, in vitro microbial cultivation relies, for better or worse, upon a standard array of buffering systems. Nevertheless, the choice of buffer must not be made haphazardly. No discussion of buffers could be complete without N. E. Good's comment: "It is impossible even to guess how many exploratory experiments have failed, how many reaction rates have been depressed, and how many processes have been distorted because of imperfections of the buffers employed" (75). The capacity to buffer well at a particular pH is only one of many criteria in the determination of an appropriate buffer for a particular application. Chemical interaction with other media components or culture metabolites will compromise both the buffering capacity as well as the nutritional balance of a medium. The effectiveness of a microbially metabolized buffer diminishes with culture growth. The pH of some buffers can vary, sometimes considerably, with concentration or temperature. Synthetic buffers, while very effective for bench-top laboratory needs, may become prohibitively expensive upon scale-up.

20.4.4.1 Natural Buffering Agents. Natural buffering agents are those compounds most frequently encountered in microbiological media; they are also the buffers subject to the greatest drawbacks in their use. Carboxylic acids (e.g., acetate, citrate, succinate) are effective buffers for the lower ranges (<pH 6) of biological activity. These compounds are metabolically catabolized for carbon and energy by many microorganisms. Also, at the concentrations needed for buffering, carboxylic acids can become cation chelators. The mixtures of amino acids in protein hydrolysates and extracts have significant buffering capacity. Thus, peptone-based complex media frequently do not require additional buffering agents when used at or about the initial pH of the medium. Many peptones are adjusted during manufacture to pH 6.8–7.0. Peptone solutions are stable to sterilization at 121°C; however, they adversely interact at elevated temperatures with other medium components such as glucose, phosphates, and polyvalent cations. In addition, because peptones are nutrients, buffering capacity diminishes or shifts as the amino acids are microbially consumed.

Sodium bicarbonate–carbon dioxide buffers can maintain pH in the range 6.0–8.0. However, when used in conjunction with intrinsically buffered media, bicarbonate buffers have a working range of pH 6.8–7.2. Despite the necessity for closed systems to retain the gaseous CO_2 phase, bicarbonate buffers are widely used in the cultivation of anaerobic bacteria and eukaryotic animal cell lines. Bicarbonate buffers are nutritionally consumed. Also, carbon dioxide has minimal solubility in aqueous solutions, which somewhat limits its buffering capacity. Solid calcium carbonate (powdered) is used in various media for strongly acidifying organisms such as *Acetobacter, Clostridium*, and *Lactobacillus*. Ethanol-tolerant, acid-producing acetobactors can be isolated and differentiated from mixed-culture fermentations using a carbonate-ethanol medium (yeast extract, 3%; calcium carbonate, 2%; agar, 2%; filter-sterilized ethanol, 2%). Strongly acidifying acetobacter isolates able to grow in the presence of ethanol will also dissolve the carbonate and form a zone of clearing around the colony.

Although widely used in media formulations at pH 6–8, phosphate buffers suffer from a great number of drawbacks. Unless a medium is carefully designed and prepared with respect to metal speciation and concentration, phosphates will adversely bind to and precipitate polyvalent cations and proteinaceous material at neutral to alkaline pH.

This chemistry creates two problems: (*1*) buffering capacity is diminished as cations complex with the phosphate anion, and (*2*) cations bound as precipitates are unavailable as nutrients. These unwanted chemical interactions are intensified by heat. The problem can be reduced by autoclaving the phosphate buffer separately from the balance of the medium and then combining both solutions when cooled to room temperature after autoclaving. The addition of a chelator such as EDTA may retard trace metal precipitation; however, overchelation will also restrict the availability of trace metals from the nutrient pool. Above pH 7.2, with poorly designed media formulations, precipitation can become spontaneous even at room temperature; the reaction may be immediate or may slowly develop over time and is often misinterpreted as bacterial contamination. Balanced phosphate-buffered salines (e.g., Dulbecco's, Hank's) containing calcium and magnesium salts are filter sterilized to avoid precipitation of the salts. When autoclaved together, phosphate and glucose will also adversely react at neutral pH and above; trace metals will intensify the reaction. Because soluble phosphates are nutrients, the effectiveness of these buffers can diminish with culture metabolism. Finally, phosphate buffers exhibit a concentration effect characterized by a rise of 0.2–0.3 pH unit with each 10-fold dilution.

20.4.4.2 Synthetic Buffers. Synthetic buffers were developed to alleviate the many problems encountered with the earlier generations of natural buffers. Tris [Tris(hydroymethyl)aminomethane; pK_a 8.3 at 20°C] was the first organic compound widely utilized for its improved buffer characteristics. Tris and Tris HCl can be combined for buffering between pH 7.0 and 9.0, with strongest activity between 7.2 and 8.0. Tris can also be paired with other acids such as acetate, borate, or phosphate for specific buffering applications. Tris does not precipitate calcium ions and helps to maintain the solubility of magnesium salts. Tris is, however, a chemically reactive amine and can penetrate cell membranes; some microorganisms (e.g., *Sporocytophaga myxococcoides* ATCC 10010) have shown growth inhibition by the compound. Tris exhibits marked concentration and temperature effects that can limit its effectiveness for certain biological purposes. Tris buffers fall approximately 0.1 pH unit per 10-fold dilution. At 0.05 M, a Tris buffer at 25°C will be pH 7.20; at 5°C, pH 7.76; at 37°C, pH 6.91. Therefore, when used in culture media, Tris buffers should be constructed with the incubation temperature of the culture in mind and not upon the pH of the buffered medium at room temperature.

During the 1960s Good *et al*. (75) developed a number of zwitterionic compounds for use in biological systems to include as many as possible of the following desired buffer characteristics: (*1*) freely soluble in aqueous solutions to permit preparations of concentrated stock solutions, (*2*) buffering optima within the range of most biological systems, (*3*) biochemically nonreactive and chemically stable, (*4*) inert to microbial or other enzymatic attack, (*5*) minimal temperature and ionic effects upon buffer pH, and to further enhance their versatility to include postculture analytical procedures, (*6*) insoluble in organic solvents and (*7*) transparent to the ultraviolet wavelengths used in many biological spectrophotometric assays. Collectively these compounds have come to be known as the Good buffers, of which, HEPES (pK_a 7.5 at 25°C) is most commonly recognized due to its prevalence in media formulations for the cultivation of animal cell lines. Other Good buffers useful for microbial media formulations include ACES (pK_a 6.8 at 25°C), which is a component in the recommended cultivation medium for *Legionella*; buffered charcoal yeast extract (BCYE) (2p.518); MES (pK_a 6.1 at 25°C), PIPES (Pk$_a$ 6.8 at 25°C), and TES (pK_a 7.5 at 25°C).

HEPES has been implicated in the phototoxicity of RPMI medium for the cultivation of eukaryotic cells; however the effect was eliminated when sodium pyruvate was added to the culture medium (76). Other Good buffers have also shown various types of inhibition in certain cell lines (77). As with any buffering system or other media component, the Good buffers should be evaluated for applicability against the microorganism under study.

Biological buffers for cell growth purposes are commonly used at 0.01–0.05 M; chemical effectiveness of the buffer, initial pH of the medium without the buffer, production of acid or basic metabolites during culture growth, and enzymatic or other reagent optima are considerations in determining appropriate buffer ion concentration. Buffer tables can be found in numerous publications. Lacking a table, buffer solutions can be prepared with either of the two following methods and a calibrated pH meter:

1. Prepare a 2× solution of the buffer compound. Using HCl or NaOH, titrate the solution to the desired pH. Bring the solution to 1× volume with deionized or distilled water.
2. Prepare equimolar solutions of the acidic member and the basic member of the buffer pair. The molarity of these solutions is that of the final concentration needed for the working buffer. Choosing the solution of the buffer pair with a pH closest to that needed for the working buffer, titrate the solution to the desired pH with the equimolar solution prepared with the remaining component of the buffer pair.

20.4.5 Gelling Agents

Many microbial applications, such as strain isolation and purification, necessitate the use of solid media. Growth of aerobic organisms, in addition to specific morphologies, are often enhanced on solid media providing unrestricted gas exchange. The different gelling agents available

to microbiologists each have attributes and drawbacks that one must consider before choosing a particular gelling agent to include in a medium formulation. Although agar is the most frequently encountered gelling agent in microbial culture media, it must be properly used in order to maintain the chemical and nutritional integrity of a formulation. Many chemolithotrophic organisms are inhibited by organics and will not grow on media solidified with agar. Conversely, a number of marine bacteria are agarolytic and can quickly dissolve or soften this support matrix. Other gelling agents, including carrageenan and Gelrite, are alternatives to agar, but each has its own chemical peculiarities that must be understood before they can be effectively used.

20.4.5.1 Agar. Agar is a polysaccharide complex extracted from a number of species of red algae (*Gelidium, Gracilaria*, and others) found in the Pacific and Indian Oceans and the Japan Sea. The agar complex can be separated into (*1*) agarose, a neutral gelling fraction, and (*2*) agaropectin, a sulfated, nongelling fraction. Depending upon the purity and gel strength of the agar, and also upon the chemical composition of the medium in which the agar is used, a molten 1.5% agar solution will set at temperatures between 32 and 39°C. However, agar media with high concentrations of salt (e.g., those for the extreme halophiles, which contain >18% NaCl and 0.5% each of $MgSO_4$ and KCl) gel quickly at temperatures above 55°C. The gelling capacity of agar is thermally reversible, however, repeated remelting of agar-containing media is not recommended because the chemical stability of many nutrients cannot withstand repeated exposure to elevated temperatures. Agar is subject to acid hydrolysis, which destroys the gelling capacity of the polysaccharide; the phenomenon is intensified by heat. Agar-containing media autoclaved at less than pH 5.0 will not gel when cooled. If a low-pH agar is required, it is advisable to prepare and sterilize the medium in two separate solutions: For 1 L of low-pH agar medium, (*1*) heat and dissolve agar, with stirring, in 500 mL water; (*2*) dissolve remaining medium components in 500 mL water; (*3*) sterilize each solution separately at 121°C; (*4*) cool each solution to approximately 50°C; (*5*) aseptically combine both solutions, mix well, and dispense into containers as required.

Agar products vary with respect to nitrogenous and inorganic salt contaminants. A number of manufacturers feature agars purified though repeated water and solvent washes. Some agar products contain significant amounts of metals that can bind to and precipitate with phosphates in the medium, resulting in diminished growth yield with the solid medium as compared with that of the corresponding liquid medium. Similarly, autoclaving any agar in the same solution with the carefully balanced nutrient salts of a chemically defined medium, particularly at neutral to alkaline pH, will frequently give rise to a pronounced darkening or haze that can compromise the effectiveness of the medium. Under chemically defined conditions, component integrity is best preserved by autoclaving a purified agar separately from the autoclaved or filter-sterilized chemical portion of the medium, as already outlined for preparation of a low-pH agar medium. The use of electrophoretic grades of agarose would be more suitable than purified agars for gels in which a minimal level of trace metal contamination is required.

As with all gels, agar exhibits syneresis in that it will squeeze out solute as it contracts. The small puddle of liquid at the bottom of a freshly prepared agar slant is an example of this phenomenon. The amount of syneresis is dependent upon the concentration of the agar in the gel. Agar media can also lose water through desiccation during storage. Once water has been eliminated from the agar gel, it will not reenter the matrix unless the gel is remelted; however, melting of solid media for the purpose of rehydration not recommended because performance of the medium will be markedly reduced.

Agar is normally used at concentration from 1.0 to 2.0% for solid media; at 0.075 to 0.2% to create a viscosity that retards oxygen diffusion in media such as fluid thioglycollate medium U.S.P. and the classical oxidation–fermentation (O-F) medium of Hugh and Leifson (78); and at 0.5 to 0.75% for soft, top-layer agars in media for bacteriophage propagation.

20.4.5.2 Agarose. Agarose, the purified gelling fraction of agar, is used in some formulations for organisms that are inhibited by agar. Purified agarose products, particularly those grades used for electrophoretic work, are low in inorganic and organic contaminant and, therefore, react less with the phosphates present in a medium. Gel clarity is greater than for agar. Low gelling temperature agaroses melt above 65°C and form gels at less than 30°C. Agarose will form solid gels at 0.75–1.0%.

20.4.5.3 Gellan Gum. Gelrite, a gellan gum, is a heteropolysaccharide composed of glucuronic acid, rhamnose, and glucose, produced by bacterial fermentation, and commercialized as a gelling agent by Kelco (Merck & Co., Inc., Kelco Division, San Diego, Calif.). Sigma Chemical Co. (St. Louis, Mo.) distributes the material under the trade name Phytagel. Under either name, this gellan gum is somewhat difficult to work with for routine media solidification purposes, but nevertheless, its unique characteristics make the material the most practical solution to some unusual microbial cultivation requirements. Gelrite/Phytagel is a high-melting-temperature (~70°C) gel, which makes it useful for the cultivation of thermophilic bacteria and fungi at 45–50°C, temperatures at which agar shows considerable syneresis and softening. The gel is generally thermally reversible, although under some conditions,

such as the elevated soluble salt concentrations of marine media, gelling can become permanent. Gelrite/Phytagel is subject to acid hydrolysis when autoclaved at low pH. The gellan is resistant to microbial attack by most organisms and so proves useful in the isolation of organisms such as the marine cytophagas, a group in which many strains characteristically possess the ability to degrade other biopolymer gels including agar, algin, carrageenan, and gelatin. Many chemolithotrophic organisms (e.g., *Nitrobacter*, spp. and *Thiobacillus ferroxidans*), although inhibited by agar and other organic gelling agents, can be grown successfully on a solid medium using the gellan. Full gelling capacity of this polysaccharide is cation dependent, and media formulations may need amending to include at least 0.1% $MgSO_4 \cdot 7H_2O$, or other magnesium salt to permit sufficient gelling. Under chemically defined media conditions, further chemical adjustments to other components may be necessary to retain chemical balance because of a modification in cation level. Recommended concentrations for Gelrite/Phytagel are in the 0.1–0.2% range, however experimentation will probably be needed to select the appropriate concentration for one's own needs. Table 20.5 provides a media formulation that has been successfully used as a solid medium for the cultivation of laboratory strains of *T. ferroxidans* (ATCC 21834 and others); the gel is rigid enough for the isolation and picking of colonies, and growth is rapid (3–5 days) at 20–30°C. Preparation methods for this particular formulation illustrate many of the topics discussed in this chapter with respect to treatment of chemically incompatible salts, acid hydrolysis, and heat instability of media components.

20.4.5.4 Alginic Acid and κ-Carrageenan. Alginic acid (79) and κ-carrageenan (80,81) have been used microbiologically for specialized gelling needs. Gelling efficiency of alginate is Ca^{2+} dependent, whereas κ-carrageenan is K^+ or Na^+ dependent. Since all of these substances are easily degraded by assorted bacteria and fungi, their use as gelling agents is restricted. Microbial degradation of these substances is used for taxonomic purposes.

20.4.5.5 Silica Gel. A final solid substrate for the laboratory cultivation of obligate chemolithotrophic organisms is silica gel, first used by Weintraub and Hanks (82) in 1936 for the isolation of ammonia-oxidizing bacteria. Many authors have since attempted improvements on the tedious method (83–86). Preparation of any quantity of plates is laborious. Briefly, sodium silicate is reacted with strong HCl to produce silicic acid, NaCl and almost immediate gelling. Nutrient salts may be included in the formulation, or the surface of the silica gel may be later flooded with nutrients, with some absorption. Because the amount of NaCl is high (~8–10%), the gel may first need clearing of the salt, with repeated washings with water prior to flooding with a nutrient solution. Silica gels are translucent and rigid with a high degree of syneresis. The gels are autoclavable, with a tendency for cracking, and are not reversible. Table 20.6 provides simplified instructions for silica gel preparation adapted from Ref. 82.

TABLE 20.5. Solid Medium for *Thiobacillus ferroxidans*

Solution A	
$(NH_4)_2SO_4$	0.08 g
$MgSO_4 \cdot 7H_2O$	0.20 g
K_2HPO_4	0.04 g
Trace elements (see Table 20.1, mix A)	0.5 mL
Distilled water	40.0 mL
Adjust Solution A to pH 2.3 with concentrated H_2SO_4. Filter sterilize.	
Solution B	
Phytagel (Sigma P-8169)	0.5 g
Distilled water	40.0 mL
With constant stirring, heat Phytagel to boiling to dissolve. Sterilize at 121°C for 15 min. Cool to no less than 80°C.	
Solution C	
$FeSO_4 \cdot 7H_2O$	2.0 g
Distilled water	20.0 mL
Quickly dissolve ferrous sulfate with constant stirring. Immediately filter sterilize.	
Complete medium	
Warm solution A to about 50°C. Add solution C to solution A and immediately combine with solution B. Mix well and pour plates. As this medium must be poured at a rather high temperature to avoid premature gelling of the Phytagel, it will be necessary to dry the plates before use by leaving the lids ajar in a sterile environment or by incubating them at 37°C overnight to eliminate excess condensation.	

20.5 MEDIA STERILIZATION

With few exceptions, media and buffers used for microbial cultivation must be sterilized as soon as possible after preparation to limit proliferation of environmental contaminants that will alter the nutritional characteristics of the medium either by consumption of nutrients or by production of metabolites. Even nonnutritive buffers or trace metal stock solutions can give rise to unwanted fungal growth if stored unsterilized for any length of time at room or refrigerator temperatures. Sterile media and buffers are necessary for culture propagation; the presence of microbial contaminants, even at a low level, can invalidate any study or production process. The physical stress of sterilization, however, can compromise the nutritional and physiological characteristics of a medium or buffer. Consequently, one must choose a sterilization method that has the least negative impact upon the material being sterilized. Although steam sterilization had historically

TABLE 20.6. Simplified Silica Gel Plates

Stock solutions

Solution 1	
Concentrated HCl (~l37%)	14.5 mL
Distilled water	to 100.0 mL
Solution 2	
$Na_2SiO_3 \cdot 9H_2O$	20.0 g
Distilled water	100.0 mL

Use slight heat and constant stirring to dissolve sodium silicate. Filter out any particulates or colloidal material with Whatman #1 paper.

Preparation of silica gel plate

1. Volumes given are for one 20 × 100 mm petri dish. Gelling will occur within 10–15 s of mixing solutions. Be prepared to work quickly.
2. Add 14.5 mL solution 1 to a 100-mL beaker and stir continuously. (A magnetic stirrer will work best.)
3. Quickly add 19.0 mL solution 2 into the beaker and mix well.
4. As soon as effervescence stops, quickly pour contents of beaker into a 20 × 100 mm petri dish. Use a glass dish if subsequent autoclaving is required.
5. Initial gelling will occur almost immediately. Gel strength will increase slightly over a half-hour period, at which time the gel may be washed to remove excess NaCl and then flooded with nutrient solution.

been the only form of sterilization accessible by many laboratories, the widespread availability and diversity of reasonably priced and reliable disposable filtration units offer more appropriate choices for media sterilization, even for small laboratories.

20.5.1 Steam Sterilization (Autoclaving)

Steam remains the most widely used sterilization method for rugged, heat-stable media and has the advantage of often being the terminal step in media preparation. With no additional manipulation of an uninoculated medium post-sterilization, possibility of inadvertent introduction of contamination is reduced. The term *autoclaving* is often used synonymously for the definitional procedure: "sterilize at 121°C for 15 minutes." This phrase *must* be applied in context to the volume of the medium being sterilized as well as to the efficiency of the autoclave being used. The precise meaning of the phrase infers that the contents of each container within an autoclave cycle must achieve an uninterrupted exposure to 121°C for 15 min; it does not mean that the autoclave itself was set for that temperature and time. From a practical laboratory standpoint, this means that small volumes (e.g., test tubes) will require the minimal amount of autoclaving time, whereas large volumes (e.g., one or two flasks) will require additional autoclaving time. Fully loaded autoclaves may require longer run times. Under laboratory autoclave conditions, a 30–35 min sterilization cycle for 0.5 L liquid medium in a 1-L flask is a practical guideline; agar media that have been allowed to solidify before sterilization may require longer autoclave times. Large-scale fermentation volumes can require hours to sterilize; media processed in poorly maintained autoclaves might never be adequately sterilized. Where mechanical agitation of a medium is not possible during the autoclave cycle, maximum container volumes of media should not exceed the ratio of >1 L media in a 2-L vessel because the prolonged autoclave times required for heat conduction to raise the innermost portions of large volumes of media to 121°C will subject the outer portions of the media to extreme overheating.

Autoclaves and their cycles should be validated for media sterilization. Ideally, this would include replicate autoclave run data from multiple thermocouple probes spaced strategically within the autoclave chamber and load configurations. While this technological expense is beyond the budget of many small research laboratories, quantified preparations of *Bacillus stearothermophilus* sterilization indicators, such as the Verify Biological Indicators (Steris Corporation, Mentor, Ohio), can indicate general "121°C, 15 min" parameters. Chemical indicator strips or labels are not reliable indicators of sterilization and should be used only as visual aids to indicate that a particular item has been run through an autoclave cycle. Under the most elemental quality control conditions, media samples should be held at least 2 weeks at 26°C and 37°C, and also at conditions and temperatures conducive to the growth of the types of environmental bioburden normally encountered during media preparation and sterilization, to ensure that latent contamination does not subsequently proliferate. Unusual media formulations (e.g., extremes in pH, chemolithotrophic conditions, unusual energy sources) that may not allow proliferation of common microorganisms may require inoculation of lot samples into more conventional heterotrophic media (e.g., tryptic soy broth) to encourage the growth of common environmental contaminants.

Steam at pressures below 15 psi (121°C) are used for sterilization of many media components not stable at 121°C. Skim milk (used as a cryoprotectant in lyophilization and as a substrate in phenotypic characterization) is best sterilized at 116°C for 20 min; the lower pressure reduces carmelization of indigenous lactose. Powdered sulfur (S^0) used as an energy source for microorganisms can be treated with Tyndallization (100°C for 30 min for 3 consecutive days) to avoid melting the element into a solid mass that physically limits its availability to organisms. Tyndallization is also used as a method of bioburden reduction (it is *not* a sterilization process) for other extremely heat-labile media. In theory, vegetative cells are killed by the first day's boiling; quickly germinating spores are killed the second day; by the third day, late-germinating spores are killed, leaving a relatively clean preparation.

20.5.2 Filter Sterilization

Heat-labile media components should be filter sterilized. Any chemically balanced liquid buffer or medium can also be filter sterilized to ensure that chemical integrity will not be compromised by the elevated heat and pressure of steam sterilization. Membrane filters, rather than depth filters, are preferred for sterilization purposes because their uniform pore size permits absolute retention of particles down to a specified pore diameter when the membranes are stored, sterilized, and used according to manufacturer's instruction. Depending upon the polymer composition, membrane filters are available in porosities from 10 μm down through nominal molecular weight limit used for ultrafiltration. For general microbiological purposes, 0.2-μm filtration is used for sterilization of media and buffers because this porosity effectively traps many vegetative bacteria and spores. However, in serum-based media, because mycoplasmas are not always held back at 0.2 μm, filtration through a stack of three 0.2-μm membranes rather than a single membrane will increase the probability of retention of these common serum contaminants. In addition, membranes are now available in 0.1-μm porosity that can retain smaller-sized microbial contamination, but flow rates are slower and rate of membrane clogging increases as porosity decreases. In any event, the filtration method selected for sterilization should be challenged against the smallest microbial contaminants known to be present in the working environment and production stream (87). As pore size decreases to submicron diameters, there is the possibility of holding back large molecular weight nutritional components and aggregates.

Water-soluble hydrophilic microbial media, stock solutions, and buffers are most commonly filter sterilized with membranes composed of cellulose acetate or nitrate esters. Fastidious cultures may require initial washing of the membranes with hot water to remove residual organics prior to media filtration; filters and membranes specified for tissue-culture applications are also recommended for sensitive organisms. Nonaqueous media components such as ethanolic concentrates of antibiotics or dimethyl sulfoxide (DMSO) must be filter sterilized with hydrophobic polymer membranes designed to withstand organic solvents. Nylon and Teflon membranes are suitable for many organic-solvent based biological applications. These types of membranes can require initial washing with a weak nonpolar solvent such as methanol to condition them for filtration. Some membranes, such as Nylon, are protein binding; if specific proteins are key media components, choose a membrane specifically identified as low protein binding.

Membrane filters have limited loading capacity and will quickly clog. Consequently, effective membrane filtration with any large volume, especially with particulate-laden preparations, requires sequential filtration from larger through smaller porosities to clarify the medium of debris, as much as possible, prior to the final filtration step. Low-speed centrifugation may also be used to first clarify crude media preparations. Glass fiber depth filters are efficient prefilters for many media applications because they have great loading capacity; however, they do not always eliminate the need for sequential membrane clarification steps prior to sterilization. Sterile filtration can be a slow process. It may be necessary, for critical applications, to perform the entire operation in a cold room to retard environmental microbial or other denaturing activity upon the raw material.

Positive-pressure filtration with an inert gas such as nitrogen is used in most large-scale filtration applications. Positive pressure reduces foaming of the filtrate and possible denaturation of any essential protein components. For critical and regulatory applications, the gas supply must also be sterile filtered before it reaches the medium reservoir. In many laboratories, filter sterilization with vacuum is the only available option. With vacuum, foaming of proteinaceous material will be best reduced with sequential prefiltration through larger membrane porosities as well as with minimal vacuum applied to the process. For most bacterial applications, serum foaming is not a deleterious nutritional problem. However, do note that media foaming can be a serious source of environmental contamination if the foam is not trapped and collected before passing into the laboratory vacuum line.

Disposable, presterilized filtration systems are offered by a number of manufacturers (e.g., Falcon, Corning, Gelman, Millipore, Nalge) in small- to large-volume capacities. Capsule filters are available for small to medium in-line batch processing (20–60 L). Filter/storage systems in the 200-mL to 1-L sizes offer the ease of vacuum-operated membrane sterilization and storage with minimal preparation and clean up. Syringe filters are most used for volumes of less than 50 mL; however some types can sterilize volumes up to 1 L without clogging.

20.5.3 Dry Heat Sterilization

Some materials with microbiological applications require dry heat sterilization. Whereas autoclaving is suitable only for heat-stable aqueous material, and filter sterilization is amenable to those materials capable of passage through membranes, dry heat is used for sterilization of nonaqueous, heat-stable material such as oils and waxes. It is also used for glassware or equipment depyrogenation and enzyme (RNase) elimination in many production as well as research protocols. A minimal standard for dry heat sterilization is 350°C for 30 min, or 121°C for 6 h (88). As with autoclaving, the time can vary considerably with the efficiency of the sterilization oven as well as with the volume and

kind of material being sterilized. Sterilization oven validation is required for many production process. However, for basic laboratory needs, biological dry-heat spore indicators (*Bacillus stearothermophilus* and *B. subtilis*) such as Spore-O-Chex (PyMaH 00190) will give a better indication of actual oven operation than will chemical indicator strips that show only that a particular temperature has been reached, but not for how long, nor if any temperature interruptions occurred. Oils and waxes are best heat sterilized in shallow volumes in large containers to permit rapid and thorough heat penetration of the material because temperature lag is much longer with nonaqueous than with aqueous materials.

20.6 MEDIA STORAGE

Prepared microbial media should stored refrigerated at 4–8°C and in the dark. Containers should be tightly sealed or, in the case of petri dishes, packaged in plastic bags to retard evaporation. Desiccated agar media are characterized by surface cracking and pulling of the agar away from container walls. Water evaporation from liquid or solid media concentrates solutes, which can result in permanent precipitation of some components, alters concentrations of critical nutritional factors or substrates, and increases osmolarity to possibly growth-limiting levels. The ability to freeze media is entirely dependent upon the formulation. As water freezes and concentrates the solutes, poorly soluble chemicals, such as tyrosine, or chemicals, such as phosphates, prone to complexing may not go back into solution when the medium is subsequently thawed. Phototoxicity of media can develop when light activates the glass or plastic containers, as well as media components, and initiates formation of free radicals; aerobic conditions intensify these deleterious reactions as do the blue wavelengths of light emitted by fluorescent tubes (89). The effects of light and free radical formation with respect to tissue culture media have been well studied. In one such mechanism, light at 360 nm and 450 nm activates riboflavin, resulting in a transfer of energy to tryptophan or tyrosine and the formation of cytotoxic free-radical products (90). Similar hydrogen peroxide formation in RPMI medium has been shown to be intensified by the presence of HEPES buffer. With bacteria, an inhibitory effect of light on growth-supporting properties of eosin methylene blue agar has been demonstrated (91). It is recommended that tissue culture media and media for those microorganisms sensitive to the presence of hydrogen peroxide or free radicals (e.g., anaerobic bacteria) be stored and cultured in the dark or in yellow wrappers to reduce the inhibitory effects of light on the media and growth of the organisms.

21

MICROSCOPIC CHARACTERIZATION OF CELLS

Erwin Huebner
University of Manitoba, Winnipeg, Manitoba, Canada

21.1 INTRODUCTION AND PERSPECTIVE

The awe and excitement that cell biologists and biotechnologists experience as they probe the inner secrets of cells with the diverse types of microscopy available today are akin to that felt by mankind seeing dramatic images from distant planets and stars from astronomical telescopes and space exploration.

Microscopy opens vistas not possible with the naked eye and allowed early pioneers like Antoine Leuwenhook, Robert Hooke, and the early giants in cell biology to discover that living organisms are composed of cells thus creating the field of cell biology.

For almost 400 years, microscopes have revealed the microcosm of the cellular world. The revealing of this "inner universe" from the 16th century until today has impacted on virtually all facets of humanity as it probes the essence of life itself. Those of us working in cell biology, biotechnology, and developmental biology have the good fortune of sharing and experiencing the incredible wonder past microscopists, like Hooke, Abbe, Zeiss, Zernicke, Nomarski and the many others who developed and used the new advances of their eras, must have felt.

The spectrum of types of light microscopy and electron microscopy that have become available through the genius and creative efforts of the myriad of scientists since Zacharias Jansen made the first two-lens light microscope in 1595 in Holland is astonishing. The renaissance and revolution in light microscopy we are now experiencing has and continues to generate new technologies and new ways of seeing, measuring structures, and characterizing events in living cells. Images now attainable would have been considered science fiction, even 10–20 years ago. So as we enter the new millennium, we can visualize structures in cells with light microscopy and allied methods that were deemed impossible 50–60 years ago when electron microscopes were being brought to bear to resolve the fine structure of cells. The frontiers have been pushed to where we can now see structures like single microtubules, centrioles, pinocytotic vesicles, live organelles; localize gene sequences; observe biochemical processes *in situ* in living cells, see dynamic changes in ions like calcium; and map intracellular pH, to cite a few. Microscopy continues to be a problem-solving tool that is yielding significant benefits in biomedical research, particularly in cell biology. These benefits are being reaped because rapid advances during the past decade have occurred with spectacular advances in optical systems and components, the inclusion of lasers and scanning devices in optical systems, the marriage between microscopes and electronic imaging devices and detectors, the utilization of computers and image processing, as well as the continual introduction of new fluorescent dye molecules to characterize and highlight cellular components and processes.

In view of the enormity of the field of microscopy, past and present, the many excellent research papers, reviews, and books, as well as informative web sites available, it would be presumptuous to do justice to the topic in as short an chapter as this. Thus the aim is to provide a selective perspective, including a cursory coverage of the historic aspects, an overview of some basic information on microscopy in general, and to follow this with highlights of the range of light microscopes from bright-field microscopy to the newest multiphoton microscopy, scanning probe

Upstream Industrial Biotechnology: Expression Systems and Process Development, Volume 1, First Edition. Edited by Michael C. Flickinger.

and scanning near-field optic microscopes, electronic imaging and image processing; laser tweezers, and electron microscopy, including TEM, SEM, and freeze-fracture.

21.2 DEVELOPMENTS AND MILESTONES IN MICROSCOPY

The following highlights some of the milestones in microscopy beginning with invention of a two-lens microscope by Jansen in 1595. The term microscope was coined by Giovani Faber in 1625. Subsequently, cells were observed by Robert Hooke in the mid 1660s, and Malpighi visualized blood capillaries. The Dutch draper Leeuwenhoek built many single lens microscopes in the late 1660s and 1670s with which he observed protozoa, bacteria, sperm, and other cells. The eighteenth century yielded advances in mechanical design of compound microscopes and notably the improvement of lenses particularly by the British scientist Lister in 1829 who developed achromatic lenses by using flint glass. Nicol prisms important for polarizing microscopy were introduced in 1829 by Fox-Talbot as was the first use of reflecting microscopy in the 1820s. A watershed in the improvement of microscopy, key to the advances in cell biology from the 1850s to the turn of the century, was the contributions of Abbe in the 1870s–1880s in providing an understanding of image formation and the importance of the collection angle of light received by the objective. The concept of numerical aperture and its relationship to resolution is expressed by the Abbe formula: $d = \lambda/\text{NA}$ where $\text{NA} = n \sin \alpha$. n is the refractive index of the medium between the object and the objective, and α is one-half of the collection angle of the objective. Abbe with Zeiss was instrumental in bringing about major improvements in objectives, so by the 1880s objectives of the highest NA (1.4) were reached and structures 0.2 μM apart could be resolved. Subsequently, there has been a plethora of advances in corrected objectives to this day with computer designed optics. A key advance in the efficient use of microscopes was the consideration of uniform illumination and alignment of the optical components. In 1894 Köhler (1) introduced an illumination alignment system still central to microscopy today, namely, Köhler illumination. For in-depth coverage of resolution, optical pathways, and alignment procedures, the reader is referred to Inoué and Spring (2), Keller (3), Lacey (4), Spencer (5), and Bradbury (6), as well as the various web sites noted at the end of this review.

During the twentieth century there was a blossoming of various types of microscopy including a variety of contrasting approaches (dark-field, phase-contrast, interference-contrast, asymmetrical-illumination, etc.), the application of polarizing microscopy, and the introduction of fluorescence microscopy. More recent advances in light microscopy include confocal and multiphoton microscopy, the use of video and image processing, and allied methods. The 1980s saw the introduction of scanning tunneling microscopy (STM) and atomic force microscopy (AFM), as well as scanning near-field optical microscopy (SNOM). The past few decades are also marked with the imaging of cells using acoustic microscopy, Doppler–shift microscopy, X-ray microscopy, NMR, and others.

The first electron microscope (EM) was built in Germany by Ruska in 1931 (7–10) and rested on the prior findings of de Broglie in 1924, who showed that electrons travel in waves, and those of Busch in 1926 who showed they could be focused with electromagnetic lenses. With the short wavelength attainable in an EM, particularly at higher electron gun accelerating voltages, resolutions of 1–2 Å (10^{-10} m) are possible. Advances in the design and construction of EMs coupled with the advancement of improved fixation, initially due to osmium tetroxide and subsequently glutaraldehyde, made possible the high resolution of cell ultrastructure and descriptions of cell organelles. The 1950s to 1980s are replete with EM studies that characterized hundreds of cell types. Scanning EM (11) made possible three-dimensional viewing of cells, as well as cell interior components when appropriately prepared. The use of ultracryofreezing methods combined with carbon/platinum replica freeze-fracture methods made it possible to visualize the molecular architecture of membranes, cell junctions, and macromolecular arrays such as F-actin filaments and microtubules. Analytical methods have also been incorporated into EMs making possible molecular characterizations using X-ray microanalysis, energy loss spectroscopy, or electron spectroscopic imaging, and other approaches. The combination of immunogold-labeling techniques and the resolving power of EM has impacted significantly on the characterization of cell components, receptor sites, etc. In the 1990s the emphasis has shifted back to light microscopy, in particular with confocal and multiphoton microscopy and the emerging areas of atomic force and scanning near-field optic microscopy. The ability to visualize structures and processes in live cells with fluorescent probes and to utilize digital imaging methods has supplanted electron microscopy in many areas of cell biology. For additional information and perspectives on new developments in microscopy, the reader is referred to Refs 12–19, Ref. 20 (Vol. 3), and the various microscopy web sites.

21.3 LIGHT MICROSCOPY

21.3.1 Basic Concepts, Microscope Components and Principles

A superb up-to-date reference source that is comprehensive in coverage of fundamental principles and practical aspects

of basic microscopy, as well as specialized types, is by Inoué and Spring (2). This is an invaluable resource in any cell biology lab that uses microscopes. Definitions of the terminology used in microscopy are available in the Royal Microscopical Society Dictionary (21).

The essential components of a light microscope are as follows:

21.3.1.1 Illumination Source. A light source which usually is built-in and includes a collector lens, a diaphragm, and has focusing and centering capabilities. The specific type of light source will vary depending on the type of microscope and application. Light sources could be tungsten filament lamps (usually 12 V), quartz-halogen lamps (often 12 V 100 watts), high-pressure arc lamps HB0 100 or 50 mercury or XB0 75 Xenon that are operated with a DC power supply, or various high-intensity laser light sources depending upon which wavelengths are needed. Some setups may have more than one light source fitted for multiple applications.

In most microscopes, the light is introduced directly into the optical path via a collector lens, but increasingly fiber optic light guides are being used to bring the light path to the condenser or other optical components. Where a single fiber optic fiber is being used, improved images are attained if the light field is made uniformly homogeneous with minimal loss of luminance by using a "light scrambler" (2,22). A field diaphragm in the illumination pathway is essential for setting up Köhler illumination and centering the condenser.
