It is usually convenient and appropriate in macroscopic models to lump two or more of the phases together as a pseudohomogeneous subsystem having the mass or volume-averaged properties of the individual phases (Table 64.1). Most commonly, a substrate bed consisting of the moist solid particles and the interparticle gases is defined as a single subsystem. In the pseudohomogeneous matrix that comprises this system, the temperatures and water potentials of the gas and solid at the same location are assumed to be the same. The validity of this assumption depends on whether the bioreactor operation allows the gas and solid to approach equilibrium. In addition, note that the temperature and water potential of this pseudohomogeneous matrix can vary from position to position.

Depending on how well subsystems are mixed, macroscopic models may only need to describe transfer between subsystems, or they may also need to describe transfer within subsystems. If a subsystem is well mixed, then there will be no thermal and concentration gradients across the subsystem, and there will only be transfer equations to describe the transport between subsystems. Therefore the spatial coordinate does not appear in the transfer equations for such subsystems. For subsystems that are static or poorly mixed, there will also be transfer equations to describe the transfer processes within subsystems. For example, equations incorporating the spatial coordinate may be required to describe solid or gas flow patterns in the bioreactor, and to describe temperature and concentration gradients within the substrate bed. Such models can be used to explore bioreactor design and operation strategies to minimize these gradients.

64.7.2 The Bulk Transport Phenomena Occurring in SSF Bioreactors

Through their interactions with local transport processes, bulk transport processes determine the local environment experienced by the microorganism and therefore influence the performance of SSF bioreactors. Macroscopic models predict bioreactor performance by combining empirical descriptions of growth kinetics with expressions describing bulk transport between and within the subsystems (solid,

TABLE 64.1. Subsystems in SSF Bioreactors and Their Simplification

Subsystem and References	Detailed view of the System (Macroscopic Viewpoint)	Simplification of the System Appropriate for Modeling	Mixing
Trays: may be stirred (the whole room is the bioreactor) (10,15,24)	Headspace gas (flowing around tray)	Headspace gas	Assume headspace infinite and well mixed, such that one tray represents all trays
	Solid particles (static) Interparticle gas (no forced flow)	Assume the bed consists of a pseudohomogeneous matrix	May be intermittently mixed, but usually not appropriate to assume that the bed is well mixed; gradients will exist
Packed beds and similar stirred reactors (3,38,39)	Solid particles (mostly static) Interparticle gas (flowing due to movement within bed)	Assume the bed consists of a pseudohomogeneous matrix	If mixed, usually intermittently; therefore will still have end-to-end gradients within the bed
Rotating drums and similar stirred reactors (21,40)	Headspace gas (flowing) Solid particles (flowing) Interparticle gas (flow depends on movement within bed)	Headspace gas Assume the bed consists of a pseudohomogeneous matrix	Depending on operation may assume these two subsystems are each well mixed, or may allow for axial variation; if well mixed, may assume that headspace and bed are in equilibrium (i.e., 1 subsystem)
Air–solid fluidized beds (growth in this bioreactor has not yet been modeled)	Solid particles (flowing) Interparticle gas (flowing)	Assume a pseudohomogeneous matrix, with mixing keeping the whole bed homogeneous, and that aeration air is moist so that system is close to moisture equilibrium	Typically well mixed

Note: Subsystems are in addition to the bioreactor wall itself.

gas, and bioreactor wall), and between these subsystems and the surroundings. Local transfer mechanisms are currently ignored in these models. Momentum transfer, heat transfer, and mass transfer may be involved, and any of these may potentially limit the performance of an SSF bioreactor. Table 64.2 indicates the mechanisms for these phenomena in various SSF bioreactor types. Of these phenomena, heat transfer has received the most attention.

Conversely, there is very little information regarding momentum transfer processes, that is, those processes involving material flow and that affect mixing and shear phenomena. Within bioreactors, both mixing of gas molecules within the gas phases in the bioreactor and mixing of solid substrate particles may be important. To date, the mixing of solids in agitated SSF systems has not been studied, and there are only two investigations of gas mixing and flow behavior (40,42). Residence time distributions for gas molecules indicate that operational parameters such as the gas velocity and solids loading affect the presence and extent of stagnant gas regions within the substrate bed and the homogeneity of the headspace gas phase (40,42). Further, such investigations are crucial because these flows underlie the other transport phenomena, such as heat and mass transfer. Due to the paucity of information, current macroscopic models assume ideal flow behavior such as plug flow of gases in packed beds or perfect mixing of the solids and gases in rotating drums.

The flow of solids leads to shear forces due to interactions of the solid substrate particles with each other and with the bioreactor wall. These shear forces are complex and therefore difficult to characterize. Thus, despite their potential to affect substrate characteristics and adversely affect microbial growth, and significant speculation regarding their importance in SSF systems, shear forces are not described in any macroscopic model of SSF.

Heat transfer processes have received attention because overheating due to release of metabolic waste heat is a very significant problem in SSF even at small scales. Rates of metabolic heat production reported in SSF range from about 3 to 330 kJ (kg dry matter)$^{-1}$ h^{-1}. Removal of metabolic heat is more difficult in SSF than in liquid fermentation

TABLE 64.2. Important Transport Phenomena within SSF Bioreactors

Bioreactor and Subsystem	Heat Transport Phenomena	Mass Transport Phenomena	Momentum Transport Phenomena
All bioreactor systems: the microscopic phenomena within the substrate particle are usually greatly simplified in macroscopic models describing bioreactor performance. Also, as noted in Table 64.1, *the solid and gas subsystems are often assumed to form a single pseudohomogeneous matrix.*			
Within the solid particle	This is the site of heat generation by the microbe growing at the surface of the solid particles.	Diffusion of enzymes and nutrients within the solid particle (6,11,33,34)	
Between the solid and gas subsystems within the substrate bed	Conduction, evaporation of water, and free or forced convection (depending on bioreactor operation) from solids to interparticle air	Evaporation of water, and transfer of O_2 and CO_2 between the solid particles and the interparticle air (15)	
After assumption of a pseudohomogeneous matrix	Solid and gas in thermal and moisture equilibrium	Transfer of O_2 and CO_2 between solid particles and interparticle air Transfer of water to maintain saturated air (38,39)	
Trays: the solid particles and interparticle air may or may not be considered as a single pseudohomogeneous substrate bed. The whole room is taken as the bioreactor. Individual trays are assumed to be open at the top and to have perforated bases.			
Transfer across the substrate bed	Conduction (15) and natural convection within the bed, leading to spatial gradients	Diffusion (10,15) and free convection of gases and water vapor within the bed, leading to spatial gradients	
Involving the tray wall or the headspace gases	Conduction to the tray walls, conduction within the tray wall, and then convection between the tray wall and the headspaces	Convection of gases (15) from the exposed bed surfaces into the headspace	Flow of headspace gases around the trays (15)
	Evaporation and free or forced convection (depending on airflow), between the exposed bed surfaces and the headspace gases	Evaporation of water from the substrate into the headspace at the exposed bed surfaces	
At inner surface of the room walls	Convection to the tray room walls Condensation on room walls		
Packed beds and similar stirred reactors, assumed to be vertical cylinders			
Transport through the pseudohomogeneous matrix	Conduction, convection and evaporation axially along the substrate bed (38,39) Conduction radially within the substrate bed (3,38) Both axial and radial gradients may exist (38)	Convection of air in the axial direction due to the forced aeration of the bed. Although axial O_2 gradients occur, they are usually not as important as the temperature gradients Radial mass transfer should be negligible	Gas flow patterns through the bed (plug flow without dispersion is often assumed) (3,38,39) Pressure drop between the bottom and top of the substrate bed (40)
At the inner surface of the bioreactor wall	Conduction radially between the substrate and the inside surface of the bioreactor wall (3,38)		

(*continued*)

TABLE 64.2. ***(Continued)***

Bioreactor and Subsystem	Heat Transport Phenomena	Mass Transport Phenomena	Momentum Transport Phenomena
Rotating drums and similar stirred reactors, assumed to be horizontal cylindrical drums			
Transport through the pseudohomogeneous matrix	The role of conduction depends on the degree of mixing; may assume that bed is well mixed (21,41) Convective flow within the bed due to mixing Usually well mixed radially, but axial gradients may exist	The role of diffusion depends on the degree of mixing Convection of gases within substrate voids due to mixing Axial O_2 gradients may occur but are usually not important	Mixing and flow of the solid substrate Shear forces; impact and abrasion due to solids interacting with each other
Between the bed and the headspace	Convection between the substrate bed surface and the headspace (41) Evaporative cooling at the surface of the substrate bed (41) Bulk flows of gases between the interparticle voids and the headspace carry sensible energy	Gas and water vapor exchange between the substrate bed and headspace gases (41).This may involve bulk flows exchanging gas between the headspace and interparticle voids.	Bulk gas flows between the interparticle voids and the headspace
Within the headspace	Convective flow of the headspace gases, carrying sensible energy (41)	Convective flow of the headspace gases (41)	Flow patterns of the headspace gases (41)
At the inner surface of the drum wall	Conduction from the substrate to the drum wall and convection between the headspace gases and the inside surface of the drum wall (41)		Shear forces, impact, and abrasion due to solids interacting with the drum wall
Air–solid fluidized beds, assumed to be vertical cylinders. The aeration air is assumed to be moist so that the bed is close to moisture equilibrium. Growth in these bioreactors has not yet been modeled.			
Within the well-mixed substrate bed	Whole bed well mixed such that there are no thermal or moisture gradients	Whole bed well mixed, such that there are no water vapor, CO_2, or O_2 gradients	Pressure drop across the bed itself, fluidization phenomena Shear, impact, and abrasion due to interactions between particles in the bed
At the inner surface of the bioreactor wall	Convection from the bed to the bioreactor wall		Shear, impact, and abrasion due to interactions between the solid particles and the wall
All bioreactors			
Involving the entry and exit of the airstream	Energy enters and leaves the system in the airstream blown through the bioreactor (3,21,38,41).	Gases and water vapor enter and leave the system in the airstream blown through the bioreactor (21,41)	Pressure drop between air pump and air exhaust
Within the bioreactor wall and between the wall and the surroundings	Conduction through the wall (the room wall for the tray system) and loss to the surroundings, often by free convection to air (21,41) or forced convection to cooling water (3,38)		

Note: These are phenomena that should be considered in the construction of mathematical models of bioreactor performance. As discussed in the text, most models greatly simplify the system by including only the most important transport phenomena or lumping phenomena together. In this table not all phenomena have been mentioned. In some places where transport processes occur in parallel, minor contributors have been ignored. In addition, the importance of the transport phenomena mentioned will depend on how the particular bioreactor is designed and operated. After identifying the phenomena to be modeled, the next task in modeling is to find appropriate expressions to include in the mass and energy balances that describe the system. Expressions that have been used to date in macroscopic models of SSF bioreactors are discussed in the text. Numbers in parentheses indicate references.

processes for a number of reasons. First, compared to liquid media, solid substrates have low heat capacities and low thermal conductivities, which means that although less heat is required to raise the temperature of the solid substrate by the same increment, the solid substrate loses heat less readily than liquid media. As well, due to the concentrated nature of SSF systems, biomass concentrations are higher and heat production on a volumetric basis is therefore also correspondingly higher. Heat removal in SSF system occurs by convection, conduction, and evaporative cooling, with the contributions of each mechanism depending on the bioreactor design and operation.

The important bulk mass transfers in SSF bioreactors involve the gas phase: oxygen supply and carbon dioxide removal for aerobic processes, and the removal of water vapor during evaporative cooling. The transfer processes described by macroscopic models may include transfer across interfaces, diffusion within stagnant gas regions, and convection by bulk gas flow. As noted in Table 64.1, it may be appropriate to divide the gas phase into a headspace gas phase and an interparticle gas phase. The degree of continuity between these phases depends on the type of bioreactor and how it is operated.

Solid-state bioreactors differ in the types of mixing that they provide and in the relative importance of flow and diffusion processes in the bulk transport phenomena that occur. This section discusses mathematical modeling of bulk transport in tray, packed-bed, and rotating drum bioreactors. Models have not been developed to describe transport phenomena within other bioreactor types. The following sections discuss, for each bioreactor, the approaches to modeling the transport phenomena identified in Table 64.2. Although these transport phenomena have also been studied in non-SSF systems, the discussion is limited to SSF itself.

64.7.3 Macroscopic Transport Phenomena in Tray Bioreactors

Tray bioreactors often consist of a large number of individual trays incubated within a room in which the temperature and the humidity of the air may be controlled. However, mathematical models of trays usually describe only a single tray, assuming homogeneous conditions within the headspace surrounding the multiple trays in the bioreactor. This single tray comprises either an intact or a perforated tray on which rests a thin layer of static solid substrate. Two distinct gas phases exist in tray SSF systems: the first is the interparticle voids within the substrate itself; the second is the bulk gas phase, which consists of the headspaces above and below the tray.

64.7.3.1 Heat Transfer in Tray Bioreactors. Only Rajagopalan and Modak (15) have described heat transfer during tray SSFs. In their model, sensible heat transfer occurs in the vertical direction by conduction through the substrate,

$$\frac{\partial T}{\partial t} = \frac{k}{\rho_s C_p}\frac{\partial^2 T}{\partial y^2} + \frac{\Delta H r_g}{C_p} \tag{64.20}$$

and by convection from the substrate surfaces to the headspaces above and below the substrate bed (the base of the tray was assumed to be open),

$$-k\frac{\partial T}{\partial y} = h(T_0 - T) \tag{64.21}$$

where T is the temperature of the bed; t is time; k, C_p and ρ_s are the thermal conductivity, heat capacity, and density of the bed, respectively; ΔH is the enthalpy of the growth reaction; y is the spatial coordinate; T_0 is the temperature of the surrounding air, and h is the heat transfer coefficient between the bed and the surroundings. The model predicted that substrate temperatures would be highest in the center of the tray, and that the incubation temperature and substrate depth were critical to the success of tray SSFs. For a tray bed 6.35 cm high, an incubation temperature of 30°C produced the greatest total biomass, although the maximum specific growth rate occurred at 40°C. Likewise, substrate depths of 3 cm and under gave significantly better growth when incubated at 38°C than when incubated at 40°C. Simulations involving simultaneous changes of incubation temperature and substrate depth indicate that, as the bed height decreases, the incubation temperature supporting optimal growth increases and overall growth is optimal in trays less than 1 cm high. Clearly, such shallow trays would not be practical at large scales. Gas flow velocity around the trays had little effect on heat transfer between the gas phase and the bed. This model did not describe evaporative cooling, convective heat transfer through the substrate bed due to free convection, or heat removal through the tray material.

64.7.3.2 Mass Transfer in Tray Bioreactors. A number of workers (10,15,24) have modeled mass transfer in trays. All of these models describe mass transfer within the interparticle voids; however, only the model of Rajagopalan and Modak (15) describes mass exchange between the interparticle voids and the bulk headspace.

In describing mass transfer within the interparticle voids, all three models consider transfer by diffusion in the vertical direction only. The models consider transfer of either oxygen only (10) or both oxygen and carbon dioxide (15,24). None of the models describes the mass transfer of water. All three models neglect the possibility of convective mass transfer due to thermal gradients within the substrate. The equations used in these models for mass transfer within the

substrate bed take the general form of a balance of compound A (either O_2 or CO_2) in the interparticle gas phase,

$$\frac{\partial \varepsilon C_a}{\partial t} = D_a \frac{\partial^2 C_a}{\partial y^2} - R_a \tag{64.22}$$

where t is time, y is vertical distance within the bed, ε is the porosity, and D_a and C_a are the diffusivity and the concentration, respectively, of A in the bed. In the case where A is oxygen, R_a is the rate of oxygen consumption (10,24) or the rate of oxygen dissolution into a liquid film layer on the substrate particles (15). For film transfer, $R_a = K_a(C_{o_2} - HC_{o_2,F})$, where K_a is an overall gas side mass transfer coefficient, H is Henry's constant for oxygen and $C_{o_2,F}$ is the oxygen concentration in the film liquid. In the case where A is carbon dioxide, the minus sign in front of R_a in the previous equation is changed to a plus sign, and R_a is the rate of carbon dioxide production (15,24).

The porosity in the previous equation is an important term and received further attention within the models of Rajagopalan and Modak (15) and Auria *et al*. (24). Rajagopalan and Modak (15) calculated D for the oxygen and carbon dioxide gases as

$$D_i^b = \frac{\varepsilon}{\tau} D_i' \tag{64.23}$$

where ε is the porosity of the substrate bed, τ is the tortuosity factor (taken to equal 1.7), i is the gas (either carbon dioxide or oxygen), and D^b and D' are the diffusivities in the bed and in air. However, the porosity was held constant for any one simulation; therefore porosity changes caused by growth were neglected. Auria *et al*. (24) used their model to estimate the diffusivity within static beds consisting of *A. niger* growing on beads of ion exchange resin impregnated with a nutrient medium. The diffusivity decreased with increasing biomass concentration, and at high biomass concentrations of 27 mg g^{-1} dry matter, the diffusivities of oxygen and carbon dioxide were less than 5% of their bulk diffusivities in air. The effect of growth on porosity and gas diffusivity deserves further attention.

The tray models of Auria and Rajagopalan are dynamic models. The model developed by Ragheva Rao *et al*. (10) is different in that it consists of only a single pseudo-steady-state equation. From a balance for oxygen within the bed, they developed an equation for the maximum thickness, H_c, that a tray could be without becoming depleted of oxygen at any depth within the substrate layer during the fermentation,

$$H_c = \sqrt{\frac{2D_e C_{O_2} Y}{\mu_m X_m}} \tag{64.24}$$

where μ_m and X_m are the maximum specific growth rate (h^{-1}) and maximum biomass concentration (mg cm^{-3}), respectively. Use of μ_m and X_m represents the worst case scenario for which the rate of oxygen demand would be greatest. This model has a number of implications for the design and operation of tray SSFs. First, with the use of perforated rather than unperforated trays, the critical bed thickness, H_c, could be increased by a factor of up to two, depending on the fraction of the area of the underside of the bed exposed to air. Second, greater substrate depths can be used if the air above the bed is oxygen enriched or if the headspace is continually replenished during operation (thereby keeping C_{o_2} as high as possible). This model is one that could be readily applied in practice, requiring only values of the D and kinetic parameters μ_m and X_m, although it has not yet been tested experimentally.

The model of Rajagopalan and Modak (15) goes further than the other models in not only describing diffusion within the bed, but also the convection of gases from the upper and lower bed surfaces into the headspaces. Headspace air is assumed to move horizontally across the substrate surface, being well mixed normal to the flow direction but with no axial dispersion. At the plane of contact with the substrate, gases diffuse into or out of the bed. The balance of oxygen or carbon dioxide at the bed surface is given by

$$\frac{\partial C_a^h}{\partial t} = -v_x \frac{\partial C_a^h}{\partial x} - \frac{D_a}{z} \frac{\partial C}{\partial y}\Big|_{y=L} \tag{64.25}$$

where A is either carbon dioxide or oxygen, x is the horizontal coordinate, y is the vertical coordinate, L is the thickness of the substrate, z is the thickness of the headspace above the bed, C_a^h is the headspace concentration, and v_x is the headspace gas flow velocity. Model simulations showed that substrate depth and porosity greatly affected mass transfer within the bed; however, the gas flow velocity around the trays had little effect on mass transfer between the headspaces and the bed. These predictions can guide design and operation of tray bioreactors.

64.7.3.3 Combined Heat and Mass Transfer in Tray Bioreactors. Finally, both heat and mass transfer processes may be important at different times during SSFs in trays. Therefore, mathematical models describing these systems will need to describe both transport mechanisms. Currently, only the model by Rajagopalan and Modak (15) does this. The phenomena described by their model are shown in Figure 64.4. The predictions of this model for substrate temperature, biomass, and gas phase concentrations of oxygen and carbon dioxide showed trends similar to those noted experimentally by Rathbun and Shuler (43) during the tempe fermentation of soybeans by *R. oligosporus*.

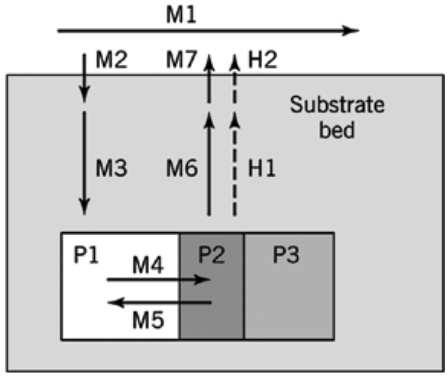

Figure 64.4. Diagrammatic representation of the tray bioreactor as modeled by Rajagopalan and Modak (15), indicating the three phases within the substrate bed. P1, Interparticle gas phase; P2, thin water film on the surface of substrate particles, which is the location of oxygen consumption, carbon dioxide production, and generation of waste metabolic heat; P3, solid substrate particle. The heat and mass transfer processes occurring are M1, bulk flow of air above the tray surface; M2, transfer of oxygen into the bed; M3, diffusion of oxygen within the bed; M4, transfer of oxygen from the interparticle air phase to the liquid film; M5, transfer of carbon dioxide from the liquid film to the interparticle air phase; M6, diffusion of carbon dioxide within the bed; M7, transfer of carbon dioxide from the bed to the surrounding air; H1, conduction of heat through the bed; H2, convective removal of heat at the bed surface.

The model predicts that the substrate temperature is the dominant influence on growth in the initial and final stages of the fermentation. During intermediate stages of the fermentation, oxygen has a large effect at the bottom of the bed (in an unperforated tray), whereas temperature effects are more important in the center of the bed.

64.7.4 Macroscopic Transport Phenomena in Packed-Bed Bioreactors

64.7.4.1 Heat Transfer in Packed-Bed Bioreactors. Heat transfer in packed beds has received most modeling attention because the temperature gradients obtained are more important than the gas concentration gradients, and if aeration satisfies the heat removal requirements it will also satisfy aeration requirements (44,45). In bioreactors of different designs and operated under different conditions, both axial and radial temperature gradients have been observed (45–47). Under some operating conditions, temperatures in the middle of the bed can be over 20°C higher than the temperature of the inlet air, leading to large variations in growth and product formation across the bioreactor (46).

Saucedo-Castaneda *et al*. in 1990 (3) modeled radial heat transfer in an experimental packed bed in which *A. niger* was grown on cassava meal. This model was later extended by Sangsurasak to describe both axial and radial heat transfer (38). A general expression for heat transfer in a pseudohomogeneous substrate bed within a cylindrical packed-bed bioreactor, which takes into account the heat transfer processes shown in Figure 64.5, can be expressed as (38)

$$\rho_b C_{pb}\frac{\partial T}{\partial t} + (\rho_{ma}C_{pma} + \rho_a f \Delta H_v)V_z\frac{\partial T}{\partial z} = \frac{k_b}{r}\frac{\partial T}{\partial r} + k_b\frac{\partial^2 T}{\partial r^2} + k_b\frac{\partial T}{\partial z^2} + r_Q \qquad (64.26)$$

where ρ_a, ρ_{ma}, and ρ_b are the densities of air, moist air, and the bed, respectively; C_{pma} is the heat capacity of moist air; C_{pb} the heat capacity of the bed; f describes the relationship between saturation humidity and temperature; ΔH_v is the enthalpy of vaporization of water; k_b is the thermal conductivity of the bed; V_z is the superficial air velocity; z and r are the axial and radial spatial coordinates; and r_Q is the rate of heat generation from the growth reaction. The factor $\rho_a f \lambda$ arises because the equilibrium assumed between the substrate and air means that the evaporation of water to keep the air saturated as the air temperature increases gives the air a higher apparent heat capacity. This is a simplified approach to handling evaporative cooling, which can contribute as much as 65% of the heat removal from a packed bed (47).

For thin packed-bed bioreactors of about 6 cm diameter, operated with low superficial air velocities (e.g., 0.01 m s^{-1}), radial conduction is the major heat removal mechanism (3). In this particular case the terms for convection and evaporation and axial conduction can be omitted.

In addition to transfer phenomena within the bed, the other important transfer process is from the outer edge of the substrate bed to the surroundings (the bioreactor wall itself has been assumed to offer negligible resistance to heat transfer). Convective cooling at this boundary has been assumed (3,38):

$$\left.\frac{\partial T}{\partial r}\right|_{wall} = \frac{ha}{k_b}(T_{surr} - T_{wall}) \qquad (64.27)$$

Overheating problems occur at the top of the column when it is aerated from the bottom because the air reaching higher regions has been prewarmed in the lower regions and therefore does not cool the top as effectively. Even for quite small columns, when they are operated with the cross-sectional airflow rates of 0.01 to 0.025 m s^{-1} that are commonly used in packed-bed bioreactors, temperatures that can cause significant microbial death are predicted. The model of Sangsurasak (38) can be used as a tool in bioreactor design, operation, and scale-up. Sangsurasak used the model to explore strategies for minimizing the overheating problem at large scale. Higher aeration rates and lower height-to-diameter ratios appear to be the best strategies. However, the model has not yet been used in the actual construction of a larger-scale packed bed.

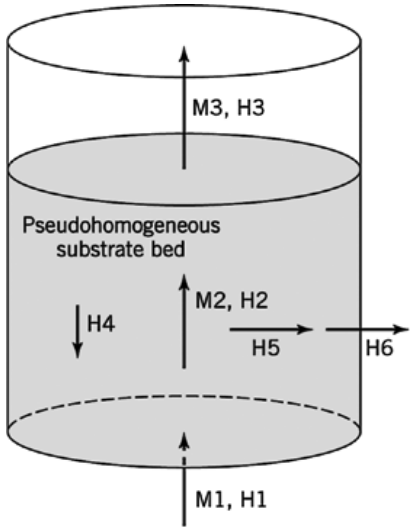

Figure 64.5. Diagrammatic representation of the packed-bed bioreactor as modeled by Sangsurasak (38). The substrate bed is treated as a single pseudohomogeneous phase. The microbe grows in the bed and releases waste metabolic heat. The heat and mass transfer processes occurring are M1, flow of moist air into the pseudohomogeneous bed; M2, flow of moist air within the bed, with the air being saturated at the bed temperature; M3, flow of moist air out of the pseudohomogeneous bed; H1, bulk transfer of energy into bioreactor with airflow; H2, convective heat transfer within the bed; H3, bulk transfer of energy out of bioreactor with airflow; H4, axial conduction within the bed (opposes the temperature gradient caused by convection); H5, radial conduction within the bed; H6, conduction across the bioreactor wall and convective removal by cooling water.

Gutierrez-Rojas *et al*. (17) used a different approach to modeling heat transfer during growth of *A. niger* in a packed bed on beads of ion exchange resin impregnated with nutrient medium. They defined an "elementary representative volume" of 20 mL, over which scale variations in the process variables were assumed to be negligible. However, they modeled only an individual elementary representative volume, and although their model was able to describe the experimental results obtained in a 20-mL packed bed, it is not able to describe the gas concentration and temperature profiles that occur across larger-scale packed-bed bioreactors (46).

64.7.4.2 Heat and Mass Transfer in Packed-Bed Bioreactors. The reliance on evaporative cooling means that water balances over the bed are important (45). A combined heat and mass transfer model is required to take these into account. Such a model, considering only gradients in the vertical direction, was proposed by Van Lier *et al*. (39), who modeled the composting of a mixture of wheat straw and horse manure. The energy balance is similar to that used by Sangsurasak (38), but because a material balance was also done for water, a simplified description of evaporation was not required. The equation was of the form

$$\rho_b C_{pb}\frac{\partial T}{\partial t} + \rho_{ma} C_{pma} V_z \frac{\partial T}{\partial z} = k_b \frac{\partial^2 T}{\partial z^2} - h(T - T_0) - \Delta H_v r_w + r_Q \quad (64.28)$$

where h is the heat transfer coefficient for conduction through the side wall to the surroundings at temperature T_0, and r_W is the rate of evaporation of water from the solid phase into the gas phase.

A general mass balance equation for compound A in the gas phase, for example, oxygen or water, can be written in the following form with terms for axial convection, axial diffusion, and exchange with the metabolizing organism attached to the solid phase:

$$\frac{\partial(\varepsilon C_A)}{\partial t} = -V_Z \frac{\partial C_A}{\partial z} + \frac{\varepsilon}{\beta^2} D_A \frac{\partial^2 C_A}{\partial z^2} + r_A \quad (64.29)$$

where C_A is the concentration of A at a location, D_A is the diffusivity of A in air, ϵ is the bed void fraction, β is the tortuosity and r_A is the rate of exchange of A with the solid phase. In the water balance Van Lier *et al*. assumed that the vapor phase remained saturated with water at the local temperature in the bed, and used this equation to calculate the evaporation rate (r_W). Film transfer of oxygen was not incorporated into the equations.

Solution of the equation set was complicated because the porosity and height of the bed changed during the composting process. However, good agreement was achieved between the model predictions and measured temperatures and bed heights. In composting, unlike other SSF processes, some self-heating is desired, and this reduces problems with overheating. Despite this, the aeration rate required to remove excess heat is still about 10-fold greater than that required to supply oxygen (39).

64.7.4.3 Other Phenomena in Packed-Bed Bioreactors. As air flows through the porous bed in a packed-bed bioreactor, there are viscous and kinetic phenomena (5). Substantial pressure drops can occur in packed-bed bioreactors (5,18,41). To date characterization of this phenomenon has been limited to demonstrating the relationship between pressure drop and the bed void fraction, which decreases as the microbe fills in the interparticle spaces. At high biomass densities, the microorganism can occupy up to 34% of the free interparticular space, reducing the relative permeability of the bed to around 1% of the original value (40). In the future, such considerations could be built into momentum balances to describe how the flow through the bed changes during the fermentation.

64.7.5 Macroscopic Transport Phenomena in Rotating-Drum Bioreactors

Only heat transfer phenomena (and the related mass transfer of water) have been modeled in rotating-drum bioreactors and the related rocking-drum bioreactor (RDBs). As in packed-bed systems, it is likely that in order to achieve adequate heat removal in RDBs, aeration requirements will already be met. Neither of the models developed so far (21,40) describes all of the heat transfer processes mentioned in Table 64.2.

Sargantanis *et al*. (21) modeled heat transfer during growth of *R. oligosporus* on corn grit in a rocking-drum bioreactor with a 1.2-L working volume. They described heat removal very simplistically by assuming equilibrium between the headspace and the substrate bed; in essence, this was a single homogeneous subsystem. The model was useful for determining better operation of their rocking-drum bioreactor system; however, it is not very versatile and can not readily be adapted to describe larger-scale SSFs in RDBs, where the assumption of thermal and moisture equilibrium between the solid substrate and the headspace could be unreasonable, particularly if high aeration rates are used. For such cases a model predicting heat removal in terms of heat transfer rather than equilibrium relationships is likely to be more useful.

Stuart (41) modeled heat transfer in a 20-L rotating-drum bioreactor in which *A. oryzae* was grown on both an artificial gel substrate and on wheat bran. The model is more mechanistic than that of Sargantanis *et al*. (21) and considers several of the heat transfer processes listed in Table 64.2. As shown in Figure 64.6, it simplifies the bioreactor system into three subsystems: the two internal subsystems, the fermenting substrate and the headspace gas, which are contained by the third subsystem, the fermenter wall. Each subsystem is assumed to be homogeneous with respect to composition and temperature in both the radial and axial directions. The model, therefore, does not describe heat transfer processes within any of the subsystems, and the temperature of each subsystem is represented by a single time-dependent value. Stuart (41) neglected water mass transfer within the substrate bed by assuming that water at 25°C is added to maintain the water activity within this pseudohomogeneous subsystem close to unity. Mass transfer from this bed to the headspace gas is assumed to be limited by the rate at which water vapor in the gas sublayer of the substrate bed diffuses into the bulk headspace gas.

Three energy balance equations, one for each subsystem, describe heat transfer phenomena within the RDB system, and heat exchange between the RDB system and the surroundings (41). Metabolic heat is generated within the substrate and then dissipated by conduction to the bioreactor wall and by convection and evaporative cooling to

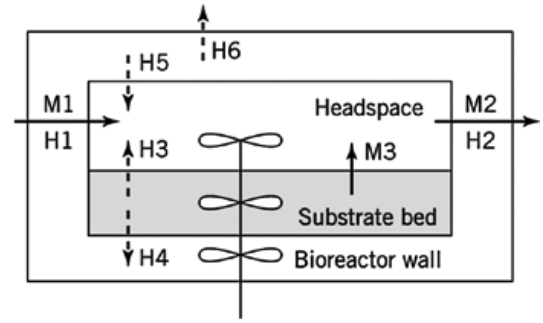

Figure 64.6. Diagrammatic representation of the rotating-drum bioreactor as modeled by Stuart (41), showing the three subsystems that were assumed. The pseudohomogeneous substrate bed is the site of generation of water and waste metabolic heat during growth. The mixer indicates that each subsystem is assumed to be at the same temperature at all locations within the subsystem. The heat and mass transfer processes occurring are M1, flow of moist air into the headspace; M2, flow of moist air out of the headspace; M3, transfer of water from the substrate bed to the bioreactor headspace; H1, bulk transfer of energy into bioreactor with airflow; H2, bulk transfer of energy out of bioreactor with airflow; H3, convection from the substrate bed to the headspace; H4, conduction from the substrate bed to the bioreactor wall; H5, convection from the bioreactor wall to the headspace; H6, convection from the bioreactor wall to the surroundings.

the headspace gases. The overall energy balance for the substrate is

$$\begin{aligned}\frac{d[T_s M(C_{pm} + C_{pw}W)]}{dt} &= r_Q - h_{sf}A_{sf}(T_s - T_f) \\ &\quad - h_{sa}A_{sa}(T_s - T_a) \\ &\quad - (1.2 \times 25)C_{pw}(W_i - W)M \\ &\quad - kA_{sa}(C_I - C_B)[T_s C_{pw} + \Delta H_v \\ &\quad - (T_s - T_a)C_{ph}] \qquad (64.30)\end{aligned}$$

Energy enters the headspace gas with the evaporated water from the substrate and with incoming aeration gases, and through convection from the substrate and from the bioreactor wall:

$$\begin{aligned}\frac{d[T_a G(C_{pg} + C_{ph}H)]}{dt} &= T_i F_i(C_{pg} + C_{ph}H_i) \\ &\quad + kA_{sa}(C_I - C_B)T_a C_{ph} \\ &\quad - T_a F_o(C_{pg} + C_{ph}H) \\ &\quad + h_{sa}A_{sa}(T_s - T_a) \\ &\quad + h_{fa}A_{fa}(T_f - T_a) \qquad (64.31)\end{aligned}$$

The exiting air flow carries energy out of the headspace and thereby away from the RDB system. During fermentation, the bioreactor wall heats up due to its contact with the

substrate. Energy, when it leaves the bioreactor wall, passes either to the surroundings or to the headspace gas inside the RDB:

$$\frac{d(T_f V_f \rho_f C_{pf})}{dt} = h_{sf}A_{sf}(T_s - T_f) - h_{fa}A_{fa}(T_f - T_a) - h_{fe}A_{fe}(T_f - T_e) \quad (64.32)$$

Thus there are two overall routes by which metabolic heat is removed from the substrate subsystem to the surroundings: with the exiting air stream or as heat lost through the bioreactor wall.

In these equations, T is temperature, M is the mass of dry solid, W is the mass of water per mass of dry solid, G is the mass of dry gas, H is the mass of water per mass of dry gas, V_f and ρ_f are the volume and density of the bioreactor material, respectively, C_P is a heat capacity, r_Q is the rate of production of metabolic heat, h is a heat transfer coefficient, A is an area of heat or mass transfer, k is a mass transfer coefficient, C is a concentration of water at either the interface (subscript I) or within the headspace bulk (subscript B), ΔH_v is the heat of vaporization of water, F is a flow of dry gas either entering (i) or leaving (o) the bioreactor system during aeration. The subscripts S, A, and F denote the three subsystems: the substrate, headspace gas, and fermenter wall, respectively. Combinations of these subsystem subscripts indicate heat or mass transfer between these materials, for example, the subscript combination "SF" represents heat transfer from the substrate to the bioreactor wall. The other subscript terms denote dry solid matter (m), dry gases (g), liquid water (w), water vapor (h), and the external surroundings (e).

Estimation of the coefficients and areas involved in the heat and mass transfer processes during SSF in RDBs is difficult, Stuart (41) used empirical equations to estimate transfer coefficients and assumed that the substrate and headspace gas subsystems occupy constant volumes throughout the fermentation. Likewise, transfer areas were assumed to be constant and were calculated based on the interfacial areas between the substrate, headspace gas, and the bioreactor wall, when the surface of the substrate bed forms a flat plane. Heat and mass transfer coefficients and interfacial areas of contact urgently require experimental attention in SSF systems.

In order to incorporate evaporative cooling into a model of heat transfer during SSF, water balances must be determined over the substrate and headspace gas subsystems. Stuart (41) assumed that the substrate and headspace gas subsystems each consist of a water component and a dry component. Therefore four material balance equations were written, two equations to describe each subsystem.

- Balance of dry matter in the substrate:

$$\frac{dM}{dt} = r_m \quad (64.33)$$

- Balance of liquid water in the substrate:

$$\frac{d\,(MW)}{dt} = -kA_{sa}(C_I - C_B) + r_w + 1.2(W_i - W)M \quad (64.34)$$

- Balance of dry gas in the headspace gas subsystem:

$$\frac{dG}{dt} = F_i - F_o + r_{dg} \quad (64.35)$$

- Balance of water vapor in the headspace gas subsystem:

$$\frac{d\,(GH)}{dt} = F_i H_i - F_o H_o + kA_{sa}(C_I - C_B) \quad (64.36)$$

In these equations, r_m, r_w, and r_{dg} are the net rates due to microbial metabolism of substrate dry matter consumption, water production, and dry gas production, respectively.

Due to consumption of substrate dry matter during microbial growth in SSF and loss of water from the substrate to the headspace gas, the flow of gases out of the RDB ($F_o[1 + H]$) will often be greater than the air flow into the RDB ($F_i[1 + H_i]$). Because RDBs are open systems and large pressure variations in the headspace are unlikely, ideal gas behavior and a constant pressure within the headspace gas are assumed. This gives an equation (not shown) for the flow of gas out of the bioreactor (F_o) and enables the calculation of C_B (the headspace concentration of water vapor).

This model was used to explore SSF performance in RDBs over a range of scales, operations, and designs. The model predictions of temperature profiles for the substrate, bioreactor wall, and headspace gas agreed reasonably well with experimental results for SSFs in real small-scale RDB systems (41). Model simulations indicate that, whereas at small scales heat removal from the substrate bed through the bioreactor wall is most important, the required contribution of evaporative cooling increases with scale. This requires very high aeration rates with relatively dry air: simulations showed that the aeration rate in air volumes per bioreactor volume per minute (vvm) required to achieve adequate heat removal from the substrate might increase by a factor of 25 over a scale change of 1,000. Such high aeration rates would be costly. Therefore heat transfer through the bioreactor wall should be maximized to minimize reliance on evaporative cooling and to limit the amount of water that needs to be added to the system during the fermentation. At all scales, heat removal from the substrate to the headspace gases by sensible heat transfer was insignificant compared with heat transport from the substrate subsystem

by conduction and evaporative cooling. However, sensible heat transfer to the headspace gases was always indirectly important in the model predictions because it affected the temperature of the headspace gases and thereby determined the amount of moisture that the headspace could hold and the driving force for evaporative cooling. This investigation of RDB performance demonstrates how models can be used as tools to explore interactions between important processes occurring during SSFs as well as operation and control options for the design of larger-scale bioreactors. This model, with its mechanistic basis, represents a first step toward developing semifundamental scale-up criteria for SSF in RDBs.

64.8 PARAMETER ESTIMATION

As highlighted in the introduction to this chapter, much more attention needs to be given to the estimation of the parameters involved in models of SSF systems. Models involve four main types of parameters: operational and design parameters, microbial parameters, transport parameters, and thermodynamic parameters. In the modeling work to date, many of these parameters have not been independently determined. In some cases parameters have been allowed to vary to enable the model to fit the experimental data. In other cases parameters have been borrowed from other systems involving different substrates and microorganisms, and even from work done in submerged liquid culture. Even physical parameters may depend on the substrate and its preparation and the bioreactor and how it is operated, making it important for parameters to be measured in the actual system studied. This section describes the work that has been done to determine model parameters in SSF systems.

64.8.1 Operational and Design Parameters

Operational and design parameters come directly from the experimental system being modeled. They include bioreactor geometry, air temperatures and flow rates, and rotation or mixing rates. These parameters are important in optimizing bioreactor performance, but these considerations are beyond the scope of this chapter. For modeling purposes, these parameters are easy to obtain because they are determined by the operator.

64.8.2 Microbial Parameters

Microbial parameters include specific growth and death rates, saturation constants, yields, activation energies, lag periods, and biomass composition. Ideally these parameters should be measured in SSF systems, although this is difficult for those parameters requiring direct measurement of biomass because it is usually impossible to remove the biomass from the substrate particles. Parameters such as specific growth rates and yields are often based on indirect indicators of growth, such as oxygen uptake or protein content, but the relationship of these indicators to growth can often vary during the growth phase. In other cases, parameter values determined in liquid culture have been used, but due to the different physical environment in SSF, these values may not be appropriate for SSF.

Specific growth rates depend on the particular system used. A wide range of values have been reported, from very low values of 0.05 h^{-1} to values as high as 0.5 h^{-1} (45). In some modeling work the specific growth rate has been used as one of the fitting parameters (3,6). The stoichiometry of growth will also be highly variable, and most models consider overall yields and do not balance elements. Only Larroche and Gros (22) have done detailed stoichiometric analyses (for growth and sporulation of *Penicillium roqueforti* on buckwheat seeds). For the anabolic reactions during biomass production from starch they obtained

$$1.104CH_{1.667}O_{0.833} + 0.087NH_3 \rightarrow CH_{1.882}O_{0.603}N_{0.087} + 0.014CO_2 + 0.109H_2O \quad (64.37)$$

Because a range of different empirical equations have been used to describe the effect of temperature on growth, the values of the parameters do not have general significance. In any case, these parameters are typically determined by incubating cultures at different temperatures, but with any one culture being held isothermally throughout the whole growth phase. The models of Stuart (41) and Saucedo-Castaneda *et al*. (3) suggest that the relationships obtained from such experiments may not describe the situation in SSF where the organism is subjected to high temperatures after an initial period at the optimum temperature for growth, because their models could describe their data only if the specific growth rate was maintained unchanged at the value for the optimum temperature as the temperature increased.

64.8.3 Transport Parameters

Transport parameters include heat and mass transfer coefficients, diffusivities, and thermal conductivities. Relatively few efforts have been made to determine these in SSF systems. With respect to mass transfer, Auria *et al*. (24) estimated the diffusivities of oxygen and carbon dioxide within substrate beds as 2 to 25% of their diffusivities in air, with the values decreasing with increasing biomass content. For transfer of oxygen into the moisture films on substrate surfaces, values of $K_L a$ have been estimated by a sulfite oxidation method to range from 1,140 to 3,050 h^{-1}, with the value increasing with increasing airflow rate (48). For

nutrient diffusion within particles, Mitchell *et al*. (6) estimated the diffusivity of glucose at 37°C as 8.2×10^{-3} $cm^2\ h^{-1}$ compared with a bulk diffusivity in water of $2.5 \times 10^{-2}\ h^{-1}$. However, because they used an artificial gel substrate, this value is not of general applicability. They were not able to measure glucoamylase diffusivity using their experimental system. Diffusion has not been investigated for real SSF substrates containing structures such as fibers and cell walls.

With respect to heat transfer, coefficients for heat transfer between subsystems in SSF bioreactors have typically been estimated from literature values for non-SSF systems. However, because these coefficients can depend strongly on bioreactor design and operation, they need to be determined experimentally for the particular system used. Thermal conductivities of composts varied from 0.25 $W\ m^{-1}\ K^{-1}$ at 20% moisture content to 1.0 $W\ m^{-1}\ K^{-1}$ at 70% moisture content (39).

64.8.4 Thermodynamic and Physical Parameters

Thermodynamic parameters include enthalpies of vaporization and saturation humidities that are usually straightforward to obtain from thermodynamic databases. However, it may be difficult to estimate other parameters such as the heat capacities of substrates with complex compositions, and therefore experimental measurements should be made. Physical parameters such as substrate densities and bulk packing densities are readily measured experimentally. They vary widely between different systems.

64.9 SUMMARY AND NEEDS FOR THE FUTURE

Growth in SSF results from the interaction of three types of phenomena: microbial growth, local transport, and bulk transport. This chapter has surveyed the ways in which these phenomena have been described in mathematical models of SSF processes. In these models, many simplifications are made, reducing both the complexity of the system and the complexity of the processes occurring within the system. Despite these simplifications and assumptions, the usefulness of the models has been identified. Microscopic models give insights into how diffusion of enzymes, their hydrolysis products, and oxygen can limit growth. Macroscopic models give insights into how interparticle oxygen transport, and more importantly, how heat transport can limit growth within bioreactors.

SSF and traditional liquid culture systems are quite different: compared with liquid culture systems, in SSF systems water availability is more restricted, and diffusional limitations play a greater role. It is these differences that can give SSF advantages over liquid culture in certain cases; the unique SSF environment can stimulate certain products, and the low water content can lead to higher concentrations and therefore higher volumetric productivities and reduced recovery costs. These differences also lead to some differences in approaches to modelling SSF and liquid culture. Due to the heterogeneity of SSF systems, differential equations must often be formulated and solved for each of several subsystems, and due to the importance of transport processes, many of the equations involve partial differential terms. Also, due to diffusional limitations within substrate particles, it is not simple to measure the substrate concentration experienced by the microbe. For this reason, growth kinetic expressions for the majority of models in SSF will continue to be substrate independent. This is in contrast to liquid culture, where even simple models usually take substrate concentration into account, often assuming a Monod-type relationship. However, in the future, some models will be developed that integrate the microscopic- and macroscopic-scale processes occurring within SSF. These models will give interesting insights into how the interactions among the various phenomena control growth at various stages during SSF.

More work needs to be done in establishing the validity and flexibility of current models. Due to the difficulties of measuring key process parameters in SSF, many of the parameters used in these models have been estimated, or borrowed from other systems. Therefore, more effort is required to measure model parameters in SSF systems. More attention must be paid to microbial physiology. Current expressions describing the effect of elevated temperatures on microbial growth are based on experiments where a number of cultures have been incubated isothermally at a range of temperatures. Better expressions will be developed from experiments that mimic the temporal temperature profiles characteristic of SSF systems. In addition, product formation is usually the main objective of an SSF process. Accurate description of product formation kinetics will require an understanding of how the SSF environment influences microbial product formation.

Our current ability to apply SSF technology at large scale is limited by our relatively poor knowledge of the basic engineering principles underlying SSF bioreactor performance. Rational rules for the design and operation of large-scale SSF bioreactors are crucial to the future commercial success of SSF technology, and mathematical models of bioreactor performance will be essential tools in the development of such rules. The power of the modeling approach is obvious. Modeling is a more cost-effective way of searching for optimal bioreactor designs than building large bioreactors and encountering problems experimentally. It does not replace the need to experiment, but can reduce the experimental program by avoiding poor designs and can guide the program by raising questions about the dominant mechanisms and the key process

variables. However, because the models to date have been based on laboratory-scale systems, work needs to be done to confirm that the mechanisms incorporated into the models remain dominant at large scale. Several of the bioreactor designs, such as stirred bioreactors and air solid fluidized beds, have not received any modeling attention. Air solid fluidized beds have the potential to overcome many of the problems faced in other SSF bioreactors, and therefore urgently need modeling attention.

65.1 INTRODUCTION

Solid substrate fermentations (SSF) normally refer to processes where microorganisms grow in beds of water-insoluble moist solid particles, where the interparticle space is filled with a gas phase, and almost no visible liquid water (1,2). The gas phase is usually humid air that flows through the solid bed, providing oxygen and removing heat and carbon dioxide, whereas the solid particles provide the necessary nutrients for growth and metabolite production. The microorganism grows over and inside the support covered by a liquid film, and in the interparticle free space.

SSF has been used by man since ancient times (3,4) to produce fermented foods, such as bread and cheese all around the world, or typical oriental foods and alcoholic beverages, such as "koji" in Japan and China, "tempeh" and "ontjom" in Indonesia, "shao-hsing" wine and "kao-liang" liquor in China, and "ragi" in India. In addition, SSF has been used to produce vinegar, to preserve meat and fish, and for composting. More recently, SSF technology has been applied to bioremediation and to produce antibiotics, aromas, biofuels, biopesticides, enzymes, organic acids, mycotoxins, and secondary metabolites (3–6).

It is usually argued that in many cases SSF is superior to submerged fermentation (SmF) (5,7,8). Commonly mentioned advantages of SSF are its use of low cost agroindustrial wastes, low capital and processing costs, low demand on sterility, good oxygen circulation, differential expression of certain microbial metabolites with respect to SmF, high volumetric yields, high end-concentration products, lower catabolic repression, and simpler to carry out mixed cultivations (3,4,6,9). However, only few large-scale applications of SSF processes are currently running in industry.

Most of the advantages above are evident at laboratory scale but not at large production scales, where heat and mass transfer are insufficient, resulting in bed overheating, bed drying, and nutrients and oxygen limitations (3,10). For example, in fungi cultivation (2), fungal hyphae can dry out when they are exposed to unsaturated air streams. In addition, bed temperature during cultivation can vary widely and take on high values, far beyond those for optimum growth or production, or ultimately high enough to damage the microorganism. Finally, diffusion of oxygen and nutrients through the liquid film to supply the microorganism is very slow and sometimes insufficient to ensure optimum growth or viability. Other important factors that complicate the design and operation of large-scale SSF bioreactors are the lack of affordable and readily available sensors appropriate for monitoring this type of process, limited availability of experimentally validated SSF reactor models, and the need for robust and generally applicable control strategies that take into account the heterogeneous characteristic of this type of cultivation (9,11,12).

This chapter will focus in the latter topics, which we think are unavoidable for large-scale SSF processing. First, the most critical operating variables in SSF bioreactors and how we can measure them are discussed. Then, a brief description of SSF bioreactors commonly used for commercial-scale production together with suggested

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

control strategies is provided. Finally, the production of gibberellic acid by the filamentous fungus *Gibberella fujikuroi* is used to illustrate the design and performance of an automated SSF bioreactor.

65.2 MEASUREMENT AND CONTROL OF CRITICAL OPERATING VARIABLES

To build and put in operation an industrial-scale SSF bioreactor is challenging, mainly due to its complex dynamic behavior and the lack of affordable and reliable instrumentation for measuring key variables inside the solid bed. These hinder the development of supervision and automatic control systems to operate the bioreactor efficiently. Most of the instrumentation used in SSF bioreactors up to now is associated with the gaseous phase, whereas there is very little for the solid phase.

Measuring microorganism environmental variables such as temperature, water content, and pH of the solid bed is critical to ensure optimum growth and production. In addition, effective supervision and control of the bioreactor require measurements of inlet and outlet air condition (temperature and humidity) and composition (O_2 and CO_2), air flow rate, and bed pressure drop (13).

Next, each of them is briefly analyzed. Measurement of nutrients, biomass, and product composition would be beneficial; however, measuring them on-line is very difficult. For example, biomass sensors have been developed, but tested in small scale only (14). We have not found reports of applications of on-line biomass sensors in large-scale SSF bioreactors.

Possible measurements inside the solid substrate are as follows:

1. *Temperature.* Microorganism's growth produces metabolic heat. If this is not dissipated effectively, high temperatures (over 40°C) and significant temperature gradients will be developed (up to 3°C/cm). High temperatures reduce growth and production rates, and in extreme cases can cause loss of microorganism viability. In turn, temperature gradients impede optimum growth all over the bed. These phenomena can be observed in practically all static large-scale SSF bioreactors (15). Measuring bed temperatures is relatively simple in SSF bioreactors by means of thermocouples or resistance temperature detectors (RTDs) such as PT-100 (13,16,17). It is advisable to measure the temperature at different heights and radius to detect and control hot spots (18–20). If this is the case, the problem then is deciding which temperature to control. Reasonable choices are the maximum or average temperatures (19,21). In addition, an auctioneering control scheme (22) can be used. In this case, the average temperature is controlled during normal operation. However, the maximum temperature (hot spot) becomes the controlled variable when it surpasses a given threshold.
2. *Water Content.* Solid's bed water content directly affects growth and production rates; hence, it must be carefully controlled to achieve optimum bioreactor performance. Still, it is difficult to control the water content of the solid bed, since available on-line sensors are expensive and unreliable for SSF applications. Although TDR (time domain reflectometry) (23) has not been used in SSF bioreactors, there are many successful applications in porous solids (13); therefore, this kind of sensors may be a good option. Alternatively, water content can be estimated through soft-sensors (see below) (11,12,21,24) using other related measurements, such as bed weight or air measurements (13). The simplest option to measure water content, although not necessarily the best, is periodic sampling in different points of the bed followed by dry weight determination in the laboratory (19).
3. *pH.* It is rather difficult to get a good on-line measurement of the pH of the solid bed in SSF bioreactors. Although there are sharp or flat end (17,25) probes, specially designed for solids, it is not possible to ensure a good contact with the type of substrate normally used in SSF. This prevents a suitable diffusion of the ions through the sensible membrane of the probe. Experimental tests at laboratory (26) and pilot (19) scales have not been encouraging with these probes; on-line pH measurements in the solid phase were significantly different from those obtained from extracts of the solid samples. Despite this, pH control in SSF bioreactors is not that difficult due to the large buffer capacity of the solid bed. In standard practice, pH is initially adjusted to the optimal growth value (27) and then measured periodically from samples taken from the bioreactor. It is also possible to incorporate, initially or sporadically during the cultivation, nutrients like mixtures of ammonium salt and urea to keep the pH of the solid substrate at optimum values (4,28). Additionally, optic pH sensors that have been applied successfully in SmFs (29) could be adapted to SSF bioreactors in the future.
4. *Biomass.* Even though this is perhaps the most important variable, it is not measured in large-scale SSF bioreactors. In recent years several innovative sensors for biomass measurement have been developed. Although these are too expensive, not sufficiently reliable for large-scale commercial application or have been tested in SmF bioreactors only; a review on some of these sensors can be found in Ref. 30. Available biomass probes make use

of electric impedance (31–33), electric capacitance (14), and redox potential (34). Soft-sensors (see below) are a good option for now.

Variables that are not measured in the solid bed, but are relevant to monitor the state of the process are discussed next:

1. *Gas Flow Rate.* Bed aeration is required for microorganism's respiration, for removal of CO_2 and metabolic heat, and for bed humidity regulation (35). Therefore, measuring airflow rate is crucial for bioreactor monitoring and control. The diversity of probes available measure either the air velocity or the airflow rate (mass or volumetric) (13). It is rather difficult to select an appropriate airflow rate instrument. A detailed guide is provided in Ref. 36 to ensure that, for a given application, an accurate, reliable, and reasonable cost instrument is chosen.
2. *Relative Humidity of Inlet Air.* When the evaporative cooling strategy (see below) is used to control the bed temperature, it is advisable to measure and manipulate the inlet air humidity (19). Capacitive instruments that comprise a dielectric hygroscopic membrane are frequently used for this purpose (17). Air is assumed to be saturated when leaving the bioreactor, therefore it is usually not measured.
3. *Pressure Drop.* When flowing through the bioreactor, air suffers a pressure drop that depends on how compact the solid bed is, which in turn is affected by the growth of filamentous fungi. Therefore, differential pressure measurements have been used to estimate the permeability or porosity of the bed (1,37) and the biomass concentration (13,38,39). In addition, these measurements have been used to decide when to agitate in intermittently mixed bioreactors (25,40) or to detect gas channeling when the differential pressure falls without apparent reasons. Piezoelectric sensors are recommended for SSF applications, since they are fast, insensitive to temperature, and measure over a wide range (41).
4. *Off-Gas Analysis.* The analysis of the outlet air provides significant information regarding the state of the cultivation. For example, by measuring CO_2 and O_2, important respirometric parameters can be calculated on-line, like CO_2 production rate (CPR), oxygen uptake rate (OUR), or respiration quotient (RQ). These, in turn, can be used to infer the amount of viable biomass (17,42–44) and to assess the physiological state of the culture (25,45,46). The production of aromas and volatile metabolites can also be tracked through off-gas analysis (47). Measurements can be carried out using different techniques, such as gas chromatography (13,17,48), infrared spectroscopy (46), special sensors for respirometric gases (49,50), and tailor-made sensors called *electronic noses* for specific metabolites (13,51), which have been tested in fungus cultivations (52).
5. *Soft-Sensors.* These are computer algorithms that use a process model and auxiliary measurements (usually corrupted with noise) to infer the value of an unmeasured variable of interest. All kind of models, such as static or dynamic, empirical (black box), purely phenomenological (first principles) or hybrid models (gray box) have been applied in soft-sensors. One of the most widely used soft-sensor algorithms in fermentation biotechnology is the Kalman filter (KF) state estimator (53). Here, a dynamic phenomenological mathematical model, typically derived from mass and energy balances, is required. The KF algorithm uses feedback to provide reliable estimations of the real values of the unmeasured variables, taking into account both, model predictions and process measurements. The KF has been successfully used for many years in SmF bioreactors, and has been applied in a laboratory-scale SSF bioreactor (54) and in realistic simulations with a pilot-scale SSF model (55). Details of this algorithm are beyond the scope of this chapter, but a simplified description can be found in Ref. 55 and a detailed description in Ref. 56.
   Table 65.1 provides a quick reference for instrumentation useful in large-scale SSF bioreactors.
6. *Signal Processing.* All measurements have associated errors, which may prove detrimental for the operation and control of SSF bioreactors. High and medium frequency noise, systematic bias, and outliers (or gross errors) are the most common type of measurement errors found in this process (16). Systematic bias can be minimized by periodic calibration of the instruments, while noise and outliers should be reduced with analog circuits (usually incorporated in the instruments) or digital algorithms (when on-line data is stored in a computer). In the latter, signal processing techniques, such as digital filtering and peak shaving, are typically applied (57).
7. *Control Algorithms.* Automatic control involves a measurement (controlled variable), comparison with a predefined optimum value (set point), and implementation of a corrective action (manipulated variable). Several mathematical procedures (control algorithms) can be used to compute the corrective actions in terms of deviations (errors) from the set point. The easiest algorithm is on–off control, applicable when the corrective action can take only two possible states, such as "open/closed" or "high/low", like a thermostat for example. This algorithm is useful when the controlled variable just

TABLE 65.1. Instrumentation for Large-Scale SSF Bioreactors

Measured Variable	Sensor Type	Main Characteristics of the Method	Application and References
Temperature	Thermocouple	Seebeck effect produced in two different joined wires	Solid bed, inlet and outlet air (on-line), all scales (13,16,17)
	RTD (Pt100)	Variation of electrical resistance of a long wire	Solid bed, inlet and outlet air (on-line), all scales (58,59)
Water content	Dry weight	Weight difference between a wet and a dried sample	Solid bed samples (off-line), all scales (25,60)
	Capacitance	Variation of dielectric property	It must be used carefully in porous medium (61). No application in SSF bioreactors was found
	Conductivity	Variation of electric conductivity	Applications in solid medium (62). No application in SSF bioreactors was found
	TDR	Variation of the travel time of a high frequency, electromagnetic pulse	This technology has been used to measure soil (63) and substrates (64) water content. No application in SSF bioreactors was found
pH	Combination electrode	A pH electrode and a reference electrode, built into a single body or housing. Sense H^+ ions concentration	To correct solid medium pH, taking samples at the beginning or during a fermentation run (27). It is also used on-line to establish the fermentation state (26)
	Optic sensors	Fluorescent dyes immobilized in a water-permeable polymer layer inside an optical fiber	Used only in SmF (30,65). No application in SSF bioreactors was found
Biomass	Electric impedance	Measure the electric impedance of a given medium at different frequencies	Applied in SmF (31–33). No application in SSF bioreactors was found
	Capacitance and conductivity	Dielectric and conductivity measured at different frequencies (Aber Instrument Ltd)	Good results in Petri dishes (14,60,66). No application in SSF bioreactors was found
	Redox potential	Measure the relative affinity for electrons of a given substance compared with hydrogen	Applied in SmF (34). No application in SSF bioreactors was found.
Gas flow rate	Velocity sensors	Measure gas velocity in a representative point inside a duct	Air flow rate in pilot-scale SSF bioreactor (49). Applicable at all scales
	Flow sensors	Many options; see a selection guide in Ref. 67	Applicable at all scales. No application in SSF bioreactors was found
Relative humidity	Hygrometers sensors	A capacity sensor with a hygroscopic dielectric film	Commonly used in SSF bioreactors (49,68,69). Applicable at all scales
	Wet and dry bulb temperatures	Wet bulb temperature is a measure of relative humidity	Indirect measurement. Has been used in SSF bioreactors (19). Applicable at all scales
Pressure drop	Piezoelectric sensor	Deformation, produced by applied pressure, induces an electrical potential.	Used in SSF bioreactors to estimate the state of the fermentation (70), bed compactness (1,37) and biomass (13,38,39). Applicable at all scales
Off-gas analysis	Concentration of respiratory gases	Gas chromatography, mass spectrometry, infrared spectroscopy, optical sensors, paramagnetic, and electrochemical cells	Used to measure CO_2 and O_2 in exit gas in SSF bioreactors. Useful to assess state of the culture. Commonly used in SSF (46,71,72). Applicable at all scales (13,17,46,48–50,73–76)
	Electronics noses	Adsorption of some volatile metabolites of the exit gas produces an electrical signal	Used in SmF (52). No application in SSF bioreactors was found
Soft-sensors	Kalman filter, neural nets, fuzzy models, etc.	Also known as *virtual sensor*. Relate measured with unmeasured variables using a mathematical algorithm	Useful to estimate water content, biomass and fermentation products (11,12,19,21,24,55,77). Applicable at all scales

need to be near the set point. A more sophisticated algorithm is PID (proportional integrative derivative) control; a standard in the process industries. Here, the control action (u) is proportional to the error (e), the derivative of the error, and the integral of the error:

$$u(t) = P \cdot e(t) + I \cdot \int_0^t e(t)\ \mathrm{d}t + D\frac{\mathrm{d}e(t)}{\mathrm{d}t}$$

The parameters P, I, and D should be "tuned" to ensure stability, fast response, and no steady-state error (offset) (78). Many advanced control algorithms make use of process models to compute the corrective actions. For example, model predictive controllers (79) are widely used in the process industries and have been applied in pilot-scale SSF bioreactors (80). These controllers predict future values of the controlled variables and use an optimization algorithm to compute control actions that minimize set point deviations subject to constraints on controlled and manipulated variables.

65.3 AUTOMATIC CONTROL STRATEGIES FOR COMMERCIAL-SCALE SSF BIOREACTORS

To achieve optimum performance, the microorganisms in the solid bed should face a favorable environment. High temperatures, inadequate water content, and low available oxygen are common limitations that preclude optimum growth and production in large-scale SSF bioreactors. Next, control strategies that can be applied to minimize the impact of such limitations in the performance of the most common types of commercial-scale SSF bioreactors are described.

65.3.1 Tray Bioreactors

This is the first kind of SSF bioreactor used for commercial production and has been employed in the Far East for many years. In these bioreactors, individual trays are arranged one on top of the other with sufficient space between them to allow free circulation of air (81). Tray bioreactors have evolved from very simple designs, where an air-conditioned chamber contains several stacks of trays and solids handling is manual. In these, trays are normally open at the top and made of wood, bamboo, or plastic, with solids layers of 5 cm height or less (82) due to heat transfer limitations. More advanced designs consider heat exchanger surfaces and perforated metal trays to improve heat dissipation and aeration. Even more sophisticated designs nowadays comprise closed columns and complete automatic operation, including solids handling (47).

A reasonably good control strategy for tray bioreactors involve temperature regulation in predefined "hot spots" by manipulating inlet air temperature or flow rate, keeping the inlet air saturated to minimize evaporation from the solid bed. If that is not good enough to avoid overheating or over drying, other options for manipulation are air recirculation, vapor addition, cooling water flow rate and temperature, or periodic mixing of the solid layer in the trays. In addition, it has been shown that air pulsation is extremely effective to control solids temperature in industrial-scale tray bioreactors (83). Using this technique, the solids layer were increased to 9 cm height, the maximum temperature in the trays were reduced to 20°C, and the temperature gradient were reduced to one-third (18).

If temperature can be controlled effectively with just one operating variable, on/off or PID algorithms should suffice. However, if many operating variables need simultaneous manipulation to avoid overheating, model predictive control (MPC) is better. Mathematical modeling, as described in Ref. 27, can be useful to design a proper control strategy before building the bioreactor.

65.3.2 Packed Bed Bioreactors Without Mixing

These are cylindrical or rectangular tanks, filled with a solid substrate suspended on a perforated surface. Traditionally, air is forced through the perforated surface from the bottom, but to improve aeration air may be forced from either ends or perforated tubes can be immersed in the solid bed (84). Metabolic heat dissipation can be enhanced with a cooling jacket or immersed cooling plates (85) or tubes. In most cases, the main limitation for optimum performance in packed bed SSF bioreactors is temperature, since the high aeration rates required for heat removal ensure sufficient oxygen supply to solid particles (35). In some cases, though, this rule does not apply. For example, in bioremediation applications, where temperature control is not a concern, oxygen supply may affect bioreactor performance (86).

To regulate temperature, many probes can be inserted in the solid bed; however, we are concerned with the maximum temperature, which is normally found in the top of the bed. In addition, the outlet air is in equilibrium with the solids in the top; therefore, the outlet air temperature is a good candidate for control. In traditional designs (no inner tubes or plates), the only useful manipulated variables are aeration rate and inlet air temperature. In extreme cases, when temperature gradients can be as much as 20°C, pulsed aeration may be as effective here as in tray bioreactors. It is not advisable to manipulate inlet air humidity, since this will lead to bed drying and there is no effective way to replenish evaporated water without bed mixing. Therefore, inlet air should be saturated to minimize water loss from the bed. In addition, manipulating flow rate or temperature of the cooling water in the jacket is useless in large-scale bioreactors, since these will influence at most the solids within 20 cm from the wall (35).

Using a packed bed bioreactor model (87) have shown that manipulating either inlet air temperature or flow rate with a proportional control algorithm is effective to minimize the outlet air temperature. Using inner cooling plates makes bed temperature control much easier. It was found by simulations that a simple proportional control, manipulating cooling water temperature in a bioreactor with a 6 cm gap between plates, achieved almost optimal performance (87).

65.3.3 Packed Bed Bioreactors with Periodic Mixing

These are probably the most widely used type of SSF bioreactor at industrial large scale of production. Here screws, blades, or other mechanical devices agitate the solid bed. Agitation is intermittent, and its frequency, intensity, and duration can be varied during the process. These bioreactors may be either vertical or horizontal. Among the former, the most popular are the Japanese Fujiwara bioreactors (88). These are specifically designed and mostly used for Koji production in the Far East and United States. Among the latter, the best known is the INRA-Dijon bioreactor (89) that has been used in France for the production of enzymes and biopesticides. This open and rectangular reactor is based on a design for a barley malting process. The solid bed rests on a perforated plate through which air is forced. Rotating screws mounted on a conveyer that moves back and forth across the main axis of the tank provide agitation. The shape and size of the screws need to be designed specifically for each substrate and microorganism, in order to minimize abrasion and breakup damage. Both bioreactors have been redesigned for aseptic operation (88,90), and some applications of pilot stirred bioreactors with aseptic operation have been published (25,91,92). Packed bed bioreactors with periodic mixing require a high degree of automation. This complex engineering problem has to be resolved satisfactorily before scaling up the process.

In these bioreactors, addition of water, nutrients, and preservatives can be done by aspersion over the solid mass. Air can be conditioned at the inlet, while the temperature and pH of the solid may be measured at several places within the tank. Many of the difficulties complicating the operation and control of these bioreactors concern the regulation of temperature and water content in the solid bed. Especially hard is the ability to overcome the limited dissipation capacity of the metabolic heat generated during the cultivation. For example, temperature gradients can be as high as 20°C during the exponential growth period. The main manipulated variables for temperature control are flow rate, humidity, and temperature of the inlet air. Although bed agitation can reduce temperature gradients, metabolic heat cannot be removed by vigorous or frequent agitation, as it has a negative impact on microbial growth.

Perhaps, evaporative cooling is the most effective strategy to control bed temperature in periodically stirred bioreactors. In this technique, inlet air temperature or relative humidity (or both) is manipulated to control the rate of evaporation from the solid bed, thereby governing the amount of heat removed by the air stream. At certain point of the process, however, very dry inlet air may be required. This prompts the main drawback of this method—its excessive drying of the solid bed, necessitating the inclusion of efficient water content regulation in the control system. However, control of the water content is difficult since on-line sensors are scarce, expensive, and unreliable. This results in water content regulation being difficult, slow, and imprecise. However, this limitation can be overcome using soft-sensors based on secondary on-line measurements (12). Periodic samples could also be taken manually and analyzed in the laboratory to define the addition of fresh water based on the water balance or heuristics (25). Full details regarding automation of a pilot packed bed bioreactor with periodic mixing are given below.

65.4 CASE STUDY: AUTOMATION OF A PILOT PACKED BED BIOREACTOR WITH PERIODIC MIXING

65.4.1 General Features of the Process

Since most systems proposed in the literature to control SSF processes have been developed at lab scale, they do not take into account the complexity of the dynamic behavior of large-scale SSF bioreactors, such as bed heterogeneity, steep temperature gradients, limiting cooling capacity, multiple sensors and noisy measurements. Consequently, these lab-scale control systems are hardly applicable at industrial scale. In order to develop control systems suitable for commercial scale, we built and put in operation two pilot SSF bioreactors, one of 50 kg dry mass nominal capacity and then one of 250 kg capacity. The control system was similar in both reactors; therefore, only the large bioreactor is described here. The control system of the 50-kg bioreactor is described in Ref. 25.

The bioreactor and its control system consist of (Fig. 65.1) (a) a bioreactor chamber, (b) an air preparation system, (c) a power cabinet, (d) an instrumentation and control cabinet, (e) and a control room with a PC for remote monitoring and control. The bioreactor is made of stainless steel with a perforated base revolving body that can contain up to 250 kg of substrate (dry base). The bioreactor was designed to operate aseptically; hence, the upper and lower parts of the revolving body contain water seals. A hermetic lid supports two motor drives, a spray feeding system (fresh water, nutrients, and inoculation), and solid bed thermocouples. Below the revolving body, there is an air-mixing chamber to homogenize the air before passing through the solid bed.

In the mixing chamber, we placed the inlet air temperature and relative humidity probes. Additional type K thermocouples measure the temperature distribution (six) inside the solid bed and the temperature of the outlet air. The pressure drop through the solid bed, the outlet airflow rate (off-line), and the outlet air composition (O_2 and CO_2)

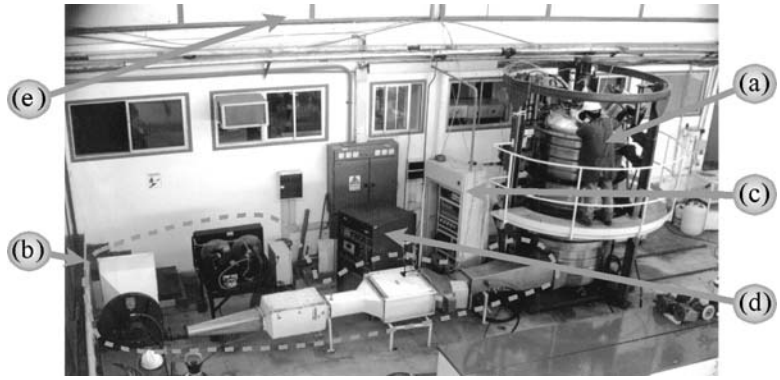

Figure 65.1. General view of the bioreactor and control system: (a) bioreactor chamber, (b) air preparation system, (c) power cabinet, (d) control cabinet, (e) control room.

are also measured. An electric fan drives the air through the preparation system duct containing a pre-filter, an absolute filter, ultraviolet (UV) radiation lamps, cooling fins, electric heaters, and a steam addition system. In this duct, a hot wire probe measured the air velocity.

65.4.2 Control System

As stated above, the main control goals in SSF bioreactors are temperature and water content of the solid bed. In large-scale bioreactors, we should try to minimize bed compactation and temperature gradients. An evaporative cooling strategy (25,93,94) with a cascade configuration was used to control the average bed temperature in this bioreactor. A discrete PID algorithm, based on the average bed temperature, defines the set point for the inlet air humidity. In turn, an on–off algorithm drives a solenoid valve that feeds steam into the air duct (Fig. 65.2). To enhance bed cooling, the inlet air temperature and the air flow rate were also manipulated at the peak heat generation

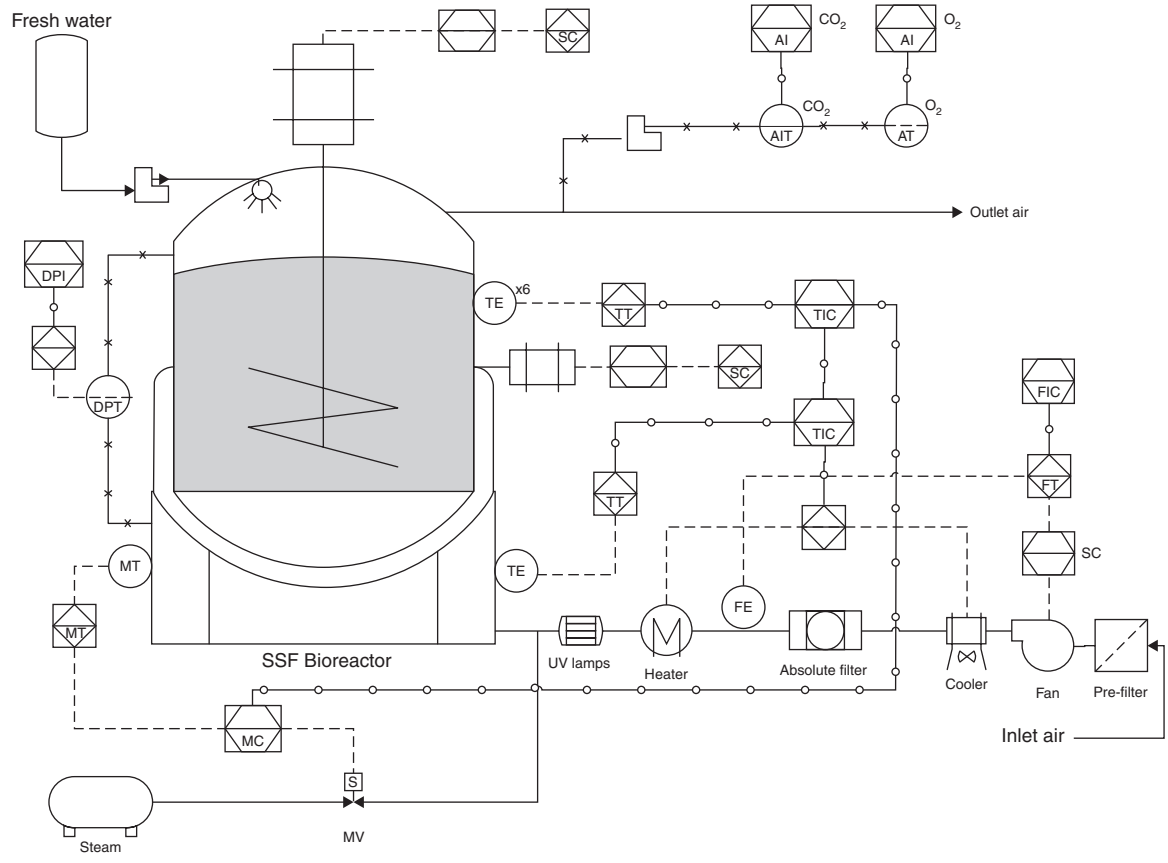

Figure 65.2. Process and instrumentation diagram (P&ID) of the system (Abbreviations are related to ISA 5.1 and ISA 5.3 standards, see Ref. 36).

period. Air flow rate was manipulated by changing the fan speed through an inverter drive, while air temperature was controlled with a split range arrangement that commanded two on–off algorithms; one for the cooling system and the other for the electric heaters.

The main drawback of the evaporative cooling strategy is that the solid bed gets dry. Therefore, we had to add fresh water periodically to replenish that lost by evaporation. It is important to agitate the bed during water addition to ensure good distribution of the water through the bed. The required amount of water was computed based on manual water content measurements and a water balance. In addition, bed agitation was turned on to reduce temperature gradients and bed compactation. A special purpose software with a graphics interface was developed to monitor, operate, and control the process from the PC.

65.4.3 Control Performance

Figure 65.3 shows the performance of the control strategy just described during cultivations of the filamentous fungus *G. fujikuroi* to produce gibberellins. During the first 80 h, the PID controller drove the relative humidity set point and the operator manipulated the inlet air temperature set point. After that, the PID loop manipulated the inlet temperature set point and the operator the relative humidity set point. In turn, both manipulated variables were adjusted to their respective set points by on–off algorithms, explaining the highly oscillatory behavior and offset shown in Fig. 65.3a. Despite this, a reasonably good bed temperature control was obtained most of the time with both configurations (Fig. 65.3b). However, a significant bed temperature gradient is observed along the whole fermentation, where for long periods the differences surpassed 15°C. It should

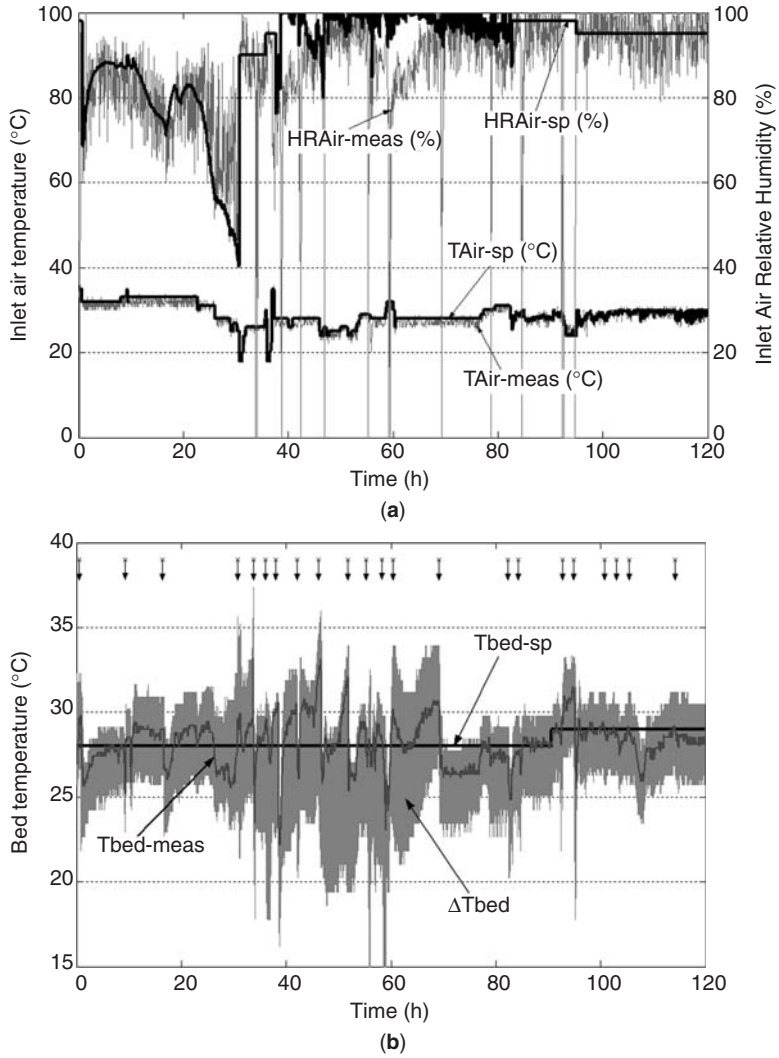

Figure 65.3. Main variables involved in bed temperature control: (a) manipulated variables and (b) bed temperature (↓ mixing events).

be noted, however, that the large temperature peaks that appear during mixing are not due to bad performance of the control system. To avoid damaging the probes during mixing, they are taken out of the bed; thus, in these instances they measure the headspace air temperature instead of the bed temperature. The figure also shows that at the peak of the metabolic heat generation (20–40 h), both manipulated variables saturate at their minimum (19°C, 40%) to achieve maximum heat removal rate. This means that, in this bioreactor, we could not achieve the required cooling by just inlet air temperature manipulation.

As Fig. 65.4 shows, the control system described above allowed us to operate the bioreactor reproducibly since four fermentation runs presented almost the same performance in terms of GA3 production. It is worthwhile noting that the performance shown in the figure does not differ much from that obtained at lab-scale cultivations (not shown here).

In conventional feedback algorithms, such as PID, control loops include one input and one output only (single input single output, SISO). Nevertheless, many large-scale processes need more complicated control configurations. For example, in the pilot bioreactor just described, manipulating the relative humidity was not enough to ensure good bed temperature control along the whole fermentation run. Consequently, the operator had to manipulate the inlet air temperature and sometimes the flow rate to aid the automatic bed temperature control.

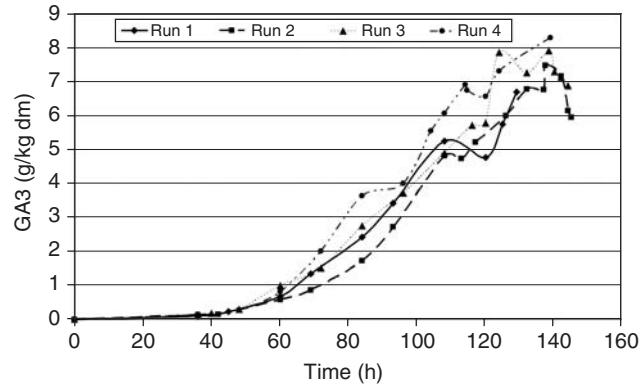

Figure 65.4. Production of GA3 in fourth different SSF cultures.

Figure 65.5 shows a typical 24-h bioreactor operation, where the inlet airflow rate was kept constant, while the

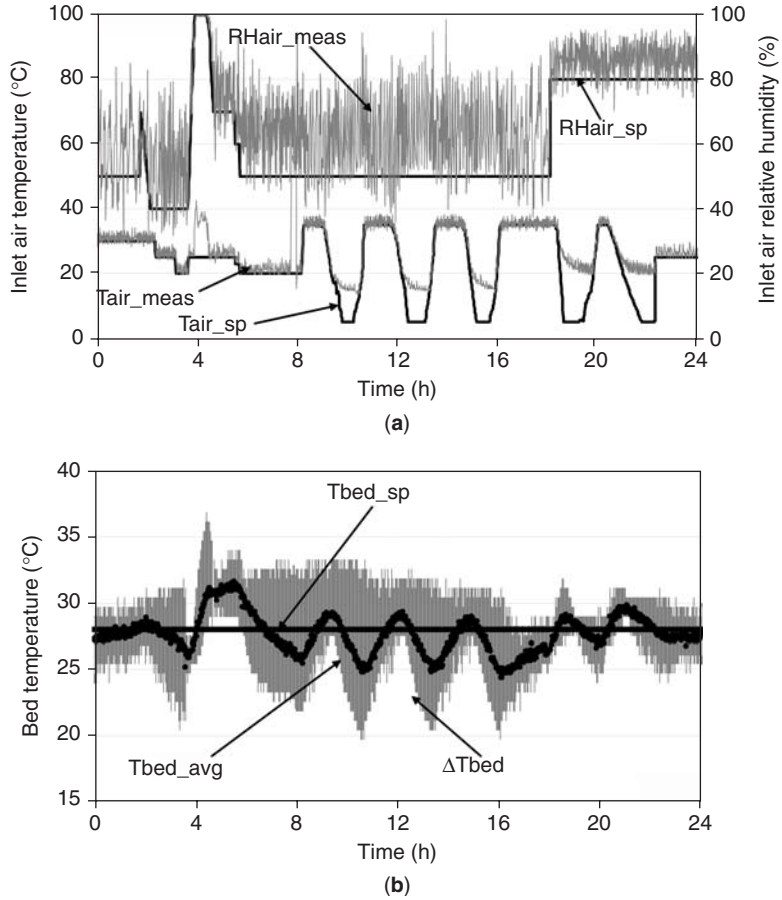

Figure 65.5. Bed temperature control using cascade-PID algorithms: (a) fixed and manipulated variables and (b) controlled variable.

operator manipulated the inlet air relative humidity when needed and the PID algorithm, based on average bed temperature measurements (Fig. 65.2), set the inlet air temperature. The first 8 h the bioreactor was operated manually, that is, the operator established both the inlet air temperature and relative humidity. Large temperature deviations are observed, revealing how difficult controlling this process is. Then, the relative humidity was set at a minimum value (50%) and the control loop was closed. In this case, the loop behaved extremely oscillatory, although temperature deviations were smaller than before. The figure also shows the limitation of the air cooling system that cannot achieve the low temperatures required by the control loop. When the operator set the inlet air humidity at a larger value (80%), the control performance improved significantly, showing smaller bed temperature deviations and finally achieving a steady condition. It is worthwhile noting also the large temperature gradients observed when the relative humidity was set to 50%. Saturation and interaction among different manipulated variables, as shown in Fig. 65.5, make automatic SISO control difficult, calling for manual intervention. At commercial production scale, this is undesirable since the result of each fermentation run will depend on the respective operator skill, affecting the reproducibility of the processes.

A good option is MPC algorithms that can deal with control saturations and inputs interactions easily. One of the simplest and most used at industrial-scale MPC algorithms is dynamic matrix control (DMC) developed by Shell Oil in the 1970s (95). DMC uses a dynamic linear model of the process and minimizes, without constraints, the sum of the square deviations between the set point and the controlled variable. This results in an analytical solution that can be coded in few lines in a standard computer language. To illustrate the potential benefits that DMC can provide in developing a control system for a large-scale SSF bioreactor, Fig. 65.6 shows a 24-h fermentation run controlled with DMC. In this run, the inlet air temperature and relative humidity were manipulated simultaneously, but the algorithm was tuned to manipulate the temperature more strongly. It is clear that DMC achieved a better performance; most of the time significantly smaller bed temperature deviations and temperature gradients are observed. It is important to mention that this was the first

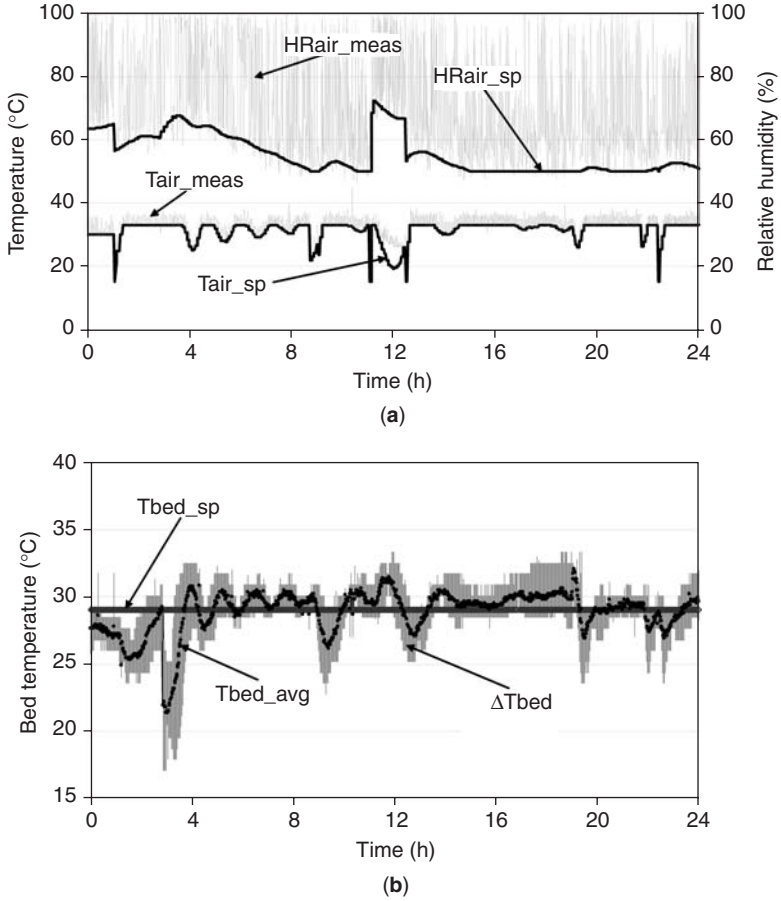

Figure 65.6. Bed temperature control using a DMC algorithm: (a) manipulated variables and (b) controlled variable.

fermentation run with DMC in this bioreactor therefore its performance was not optimized, whereas the PID fermentation runs shown here are the result of a thorough and time consuming tuning exercise.

Without doubt, optimizing the design and performance of a control system for commercial-scale SSF bioreactors is difficult, costly, and time consuming. Computer simulation provides a convenient option. In turn, this requires reliable mathematical models that are able to reproduce the main dynamic features observed in industrial-scale SSF bioreactors. One such model that represents the bioreactor described above has been recently presented by Fernández-Fernández and Pérez-Correa (56) and used to design, tune, and compare different MPC algorithms (96). The model can be adapted to reproduce the dynamic behavior of other kind of SSF bioreactors.

STAINLESS STEELS

C.P. Dillon
C.P. Dillon & Associates, Hurricane, West Virginia

Stainless steels offer an unusual combination of strength, ductility, formability, weldability, corrosion resistance, and amenability to cleaning that makes them uniquely suitable for pharmaceutical and bioprocessing operations. This chapter discusses the origin and nature of stainless steels, the several groups and many grades of stainless steels, together with the fundamentals of the metallurgical differences. Specific corrosion phenomena that pose potential problems, together with preventive and remedial measures, are presented. I explain the basic nominal workhorse compositions, together with their potential weaknesses, and discuss the possible utilization of other more highly alloyed substitute alloys. Particular emphasis is laid upon measures for quality assurance, postfabrication cleanup procedures, and passivation treatments to ensure improved resistance toward specific types of localized corrosion.

66.1 THE NATURE OF STAINLESS STEELS

As a whole, stainless steels and similar chromium-rich alloys are characterized by their *passivity*. Passivity is a condition in which a base metal, such as iron, exhibits the corrosion behavior of a more noble metal or alloy. As described further here, passivity cannot be maintained under some specific conditions.

Steel is an alloy of iron and carbon plus other minor elements and is notorious for susceptibility to rusting. With even minimal corrosion, it is a source of iron contamination and is therefore objectionable in many services. However, when a minimum of 12% chromium (Cr) is alloyed with steel, the resulting metal is generally not susceptible to rusting under ordinary circumstances of exposure to the atmosphere or in substantially neutral aqueous solutions. (Certain exceptions, however, are described further here.) Actually, several types of stainless steels, which are characterized by specific properties, have been developed.

66.2 TYPES OF STAINLESS STEELS

The 12% Cr grades of stainless steels are predominantly "martensitic." Martensite is a needlelike structure resulting from heating and quenching iron-base alloys, which gives increased hardness and strength with a concurrent diminution of ductility. (A certain amount of ductility is restored by tempering, i.e., heating to some intermediate temperature.) The martensitic grades are exemplified by Type 410 (UNS S41000) (1) and are characteristically magnetic.

When the chromium is increased to about 17%, the material is magnetic but not amenable to hardening by heat treatment. Such alloys, exemplified by Type 430 (S43000), are classified as "ferritic" and are more corrosion resistant than the martensitic grades by virtue of their higher chromium content, although they have lower strength than heat-treated martensitic grades.

The "workhorse" materials for the process industries, however, are the "austenitic" grades, often loosely called "18-8" stainless steels. When about 8% nickel (Ni) is added to an 18% Cr steel, a face-centered crystal structure called austenite is formed that is characteristically nonmagnetic. (This structure exists only at elevated temperatures with steels and the straight chromium grades.) Austenitic stainless steels, exemplified by Type 304 (S30400) and Type

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

316 (S31600), have in general a remarkable combination of properties that occasion widespread use in the process industries as compared with the martensitic and ferritic grades, which are used much less frequently.

Stainless steels that contain 18% Cr or more are also alloyed with a lesser amount of nickel (about 5%) to form "duplex" grades, which are about 50:50 austenite and ferrite. This method results in alloys of higher strength than Types 304 (S30400), 316 (S31600), and so forth, with an improved resistance in aqueous environments of high chloride content. The newer duplex grades are exemplified by Alloys 2205 (S31803) and 255 (S32550).

Finally, there are "superferritic" grades such as Alloy 26-1 (S44626) and several "superaustenitic" alloys, exemplified by Alloys 254SMO (S31254) and 6XN (N08367). The superaustenitic grades have superior resistance to localized corrosion such as pitting, crevice corrosion, and stress corrosion cracking (SCC) in chloride-bearing environments. Also, they are as strong as duplex grades by virtue of nitrogen addition.

The compositions of some typical specific grades in these basic categories are given in Table 66.1, wherein the midrange of major elements is given with the maximum allowable concentration for minor elements. More detailed listings of stainless steel types and compositions are available (2–4).

66.3 CORROSION MECHANISMS

Corrosion of metals is electrochemical in nature, metal ions being formed at anodic sites by oxidation, accompanied by a discharge of electrons through the external (metallic) circuit. At cathodic sites, electrons provide reduction of specific species (e.g., dissolved oxygen, cations) in the electrolyte to complete the reaction equilibrium. This change is most apparent in galvanic (i.e., bimetallic) corrosion in which the anodes and cathodes are different materials (e.g., the galvanic corrosion of steel by contact with copper, or of zinc by contact with steel). However, it also occurs in monometallic corrosion, such as steel in water, wherein discrete local anodes and cathodes of a transient nature provide the reactions.

$$Fe^{\circ} \rightarrow Fe^{2+} + 2e \text{ (anodic)}$$

$$2H^{+} + 1/2O_2 \rightarrow H_2O \text{ (cathodic)}$$

The formation and dissipation of discrete anodes and cathodes cause the general, uniform corrosion typical of base metals.

When a metal or alloy is protected by a superficial layer of a composition different from the substrate (mill-scale on steel; oxide films on copper-, nickel-, or chromium-bearing alloys), anodic sites may be relatively stable at defects in the otherwise protective film, causing a more localized type

TABLE 66.1. Composition of Typical Stainless Steels

Grade	UNS #	C	Cr	Ni	Mo	Other
			Martensitic grades			
410	S41000	0.15	12.5	—	—	1 Si
420	S42000	>0.15	13.0	—	—	1 Si
			Ferritic grades			
409	S40900	0.08	11.0	—	—	1 Si, Ti 6 × C
430	S43000	0.12	17	—	—	1 Si
444	S44000	0.025	18.5	1.0	2.0	Ti, Nb, N
			Austenitic grades			
304	S30400	0.08	19	9	—	1 Si
304L	S30403	0.03	19	10	—	1 Si
316	S31600	0.08	17	12	2.5	1 Si
316L	S31603	0.03	17	12	2.5	1 Si
317L	S31703	0.03	19	13	3.5	1 Si
Duplex grades						
329	S32900	0.08	25	3.5	1.5	0.75 Si
2205	S31803	0.03	22	5.5	3.0	0.08–0.20 N
255	S32550	0.04	25	5.5	3.0	1.5–2.5 Cu
			Superaustenitic grades			
254SMO	S31254	0.02	20	18	6.0	0.8 Cu, 0.20 N
367XN	N08367	0.03	21	24.5	6.5	1 Si
28	N08028	0.03	27	31	3.5	1.0 Cu
20Mo6	N08026	0.03	26	35	5.5	0.5 Si

of attack. This reaction is somewhat analogous to galvanic corrosion, the film acting as a cathode to the more anodic substrate.

66.4 CORROSION SUSCEPTIBILITY OF STAINLESS STEELS

The stainless steels in general resist corrosion because of the formation of an invisible oxide film that renders them passive in oxidizing environments. The semipermanent surface passive film is very thin (about 0.1 nm), analogous to ice on a pond. This passive film of chromic and silicon oxides plus adsorbed oxygen can be increased in thickness by exposing it to oxidizing solutions or by anodic passivation using an electrochemical technique. (Note: Electropolishing is followed by another electrochemical treatment to reform and enhance the passive film following anodic dissolution of the alloy. If the film is solubilized, as by reducing acids such as hydrochloric or dilute sulfuric, stainless steels change from a passive to an active state and are actually less resistant than ordinary iron and steel.) Most applications of stainless steels are in air, aerated water, and other oxidizing media wherein the passive film is retained. It should be noted that stainless steels are *autopassivating*; the film reforms immediately if removed by mechanical means (e.g., abrasion) when the alloy is subsequently exposed to air, water, or other oxidizing environments. They do not demonstrate the active state except under continuous abrasion or conditions of immersion in reducing environments.

Stainless steels are resistant to general corrosion in most applications, with corrosion rates <4–5 mpy. When data are reported showing general corrosion rates of 10, 20, or 50 mpy, this indicates that the alloy is fluctuating between an active and a passive state and should not be used in that specific environment. Unfortunately, despite their passive nature, stainless steels are subject to several forms of localized attack. These are described further for the austenitic grades, which are the primary alloys for bioprocessing applications (5).

66.5 FORMS OF LOCALIZED CORROSION

66.5.1 Pitting

Pitting can occur on boldly exposed surfaces in high-chloride environments, such as brackish cooling waters or dilute hypochlorite solutions (e.g., during sanitizing operations). The molybdenum-free alloys such as Type 304L (S30403) are more susceptible to pitting than molybdenum-bearing alloys in chloride-bearing environments, and the problem is combated by specifying successively higher grades, that is, Type 316L, Type 317L (S31703), and the 6% Mo grades as required by the severity of the environment.

66.5.2 Crevice Corrosion

Crevice corrosion is a special form of pitting occurring in physical or mechanical crevices (e.g., flanges, threaded fasteners) or under surface films. When it occurs under calcareous deposits, biomasses, or other foreign material, it is known as "under-deposit corrosion" or UDC. Typically, crevice corrosion is driven by a dissolved oxygen (DO) cell, the oxygen-starved crevice functioning as an anode to the boldly exposed cathodic area where the DO constitutes a cathodic depolarizer. However, the cell can also be driven by dissolved sulfur (DS) or by differences in metal ion concentrations. Crevice corrosion is aggravated by chloride contamination, the chlorides being attracted to the anodic sites and producing a locally low pH (e.g., pH 2) from acid chlorides within the crevice.

66.5.3 Sensitization

When the regular carbon grades such as Types 304 (S30400; 18 Cr–8 Ni–0.08 C maximum) or 316 (S31600) are heated in the temperature range from about 800° to 1,500°F (as by slow cooling from the annealing process or from thermal stress-relieving treatment, or in the heat-affected zones of welds), carbon migrates to the grain boundaries and precipitates as chromium carbides. This leaves a chromium-depleted zone around each grain and causes a susceptibility to intergranular corrosion (IGA) in many environments. When IGA is observed in the heat-affected zone of welds, it is commonly called by the misnomer "weld decay," although it is not the weld itself that suffers corrosion. Sensitized areas are also more prone to chloride pitting than are unaffected areas such as those at some distance from welds.

Conventional sensitization by chromium carbide precipitation was originally combatted by addition of stabilizing elements, that is, columbium (niobium) or titanium, to an 18-8 alloy such as Type 304 (S30400). When stabilizing elements are present in concentrations several times the carbon content, it is their carbides that precipitate, thereby avoiding chromium depletion. The stabilized grades such as Types 321 (S32100) and 347 (S34700) are therefore derivatives of Type 304 containing Ti and Cb, respectively, and are still used in some special applications. It should be noted that titanium-stabilized grades such as S32100 require a stabilizing anneal at about 1,600°F to tie up the carbon in the form of titanium carbides before welding. IGA may occur

even in stabilized or low-carbon grades if weldments are carbon-contaminated by oil or grease.

The stabilized grades can themselves become sensitized by multipass welding or cross-welding, causing knife-line attack (KLA); this is caused by a resolubilizing of the columbium or titanium carbides by the heat of welding, followed by slow cooling. This step requires about 1,250°C (2,300°F) reheating in 18-8 grades, moving the susceptible area to the fusion zone, and permitting a very narrow band of corrosion immediately adjacent to the weld (KLA). With higher nickel content, the resolubilization temperature drops; Alloy 20Cb3 (N08020) and Alloy 825 (N08825) with nickel contents in the 35% range are more easily sensitized to KLA (about 980°C or 1,800°F) than is type 347.

In modern practice, the problems of sensitization have been largely alleviated by use of low-carbon grades (Type 316L, S31603; 17 Cr–12 Ni–2.5 Mo–0.030 C maximum), although sensitization will occur with very prolonged exposure in the sensitizing range (e.g., in long-time service >800°F or when stainless steel–clad vessels are thermally stress relieved). Modern-day steel-making practice using argon–oxygen decarbonation (AOD) makes very low carbon grades of stainless steels routinely available.

IGA may also occur due to mechanisms other than carbide precipitation. A ferrite phase, if present for any reason, may be selectively attacked by reducing acids such as hydrochloric or sulfuric; its thermal conversion product, sigma phase, is selectively attacked by oxidizing acids (e.g., nitric). Chi phase can form in molybdenum-bearing grades (S31603) as the result of prolonged heating in the sensitizing range (e.g., thermal stress relief of clad-steel vessels), producing IGA in alloys of <0.030% carbon in certain aggressive environments.

66.5.4 Selective Weld Corrosion

Selective or preferential attack is sometimes encountered in weldments, particularly in the molybdenum-bearing grades. This can occur either in conventional welds or autogenous welds (i.e., welds made without the addition of filler metal) in some environments. This type of attack is ascribed to microsegregation, which causes a maldistribution of the molybdenum component of the alloy.

Selective weld corrosion is the reason for the cold-work requirement for welded stainless steel condenser tubes (see ASTM A249). Cold-working to minimum requirements before the final anneal allows the weld to recrystallize and homogenize, alleviating the microsegregation.

For butt welds in piping and fabrication welds in tanks and vessels, no such cold-work is feasible. Instead, an overmatching rod is used to confer higher resistance to the weld itself, for example, alloy 254SMO (S31254) to weld S31603 or S31703 or alloy 625 (N06625) to weld S31254.

66.5.5 Stress Corrosion Cracking

The predominant form of environmental stress cracking (ESC) in the 18-8 varieties of stainless steels is anodic stress corrosion cracking (SCC) under either applied or residual tensile stress. Compressive stress will not cause SCC, and indeed application of *compressive* surface stress, as by shot-peening, is sometimes used as a palliative surface treatment against SCC. Only the martensitic grades are subject to hydrogen-assisted cracking (HAC), a form of ESC found, for example, in "sour" service due to hydrogen sulfide effects.

The most common form of SCC of 18-8 austenitic grades is caused by chloride contamination. The ubiquitous chloride is sodium chloride (NaCl, table salt), as found in water and atmospheric exposures. NaCl usually causes SCC only between about 50°C (120°F) and 200°C (390°F). However, SCC can occur at room temperature and even at cryogenic temperatures in the presence of other chlorides, such as ferric chloride, sulfuric–NaCl mixtures, aqueous solutions of hydrogen sulfide–NaCl, and hydrogen chloride (HCl). For boldly exposed surfaces, there are rough correlations between pH and chloride concentration at which SCC may be anticipated. There is no minimum chloride concentration below which SCC will not occur if there is any possibility of concentration, either by evaporation or by occlusion or adsorption in films adhering to the stainless surface (e.g., mill scale, heat tints, welding slag, rust deposits, calcareous deposits, biomasses).

External stress corrosion cracking (ESCC) occurs when chlorides from the atmosphere, water leaks, or insulation concentrate on the surface of an 18-8 type stainless steel pipe or vessel. This is best combatted by coating vessels and piping that are more than 4 in in diameter and that operate between 60 and 200°C, using a zinc-free and chloride-free paint system (6,7).

Hot caustic can also cause SCC of 18-8 stainless steels, as frequently happens when high-pressure steam is contaminated by carryover of alkaline boiler-treating chemicals. This is a potential problem in steam lines and during sterilization procedures. Use of nickel-base alloys such as N06625 or better (but not N08800 or N08825) is effective against caustic SCC.

66.5.6 Rouging in High-Purity Water

Austenitic stainless steels are subject to superficial rusting under some circumstances, either because of tramp iron embedded in the surface or from chloride contamination by corrosive atmospheres or water environments. The former problem is addressed through standard cleaning and passivation techniques described further next.

An apparently separate problem, "rouging," is sometimes observed with clean stainless steels in high-purity water at about 80°C (175°F) (8). Strictly speaking, rouge

consists of a thin red deposit of α-Fe_2O_3 which is usually loosely adherent, wiping off easily. Generally, very little corrosion of the surface is evident. Typically, rouging is experienced in high-purity deionized water such as WFI ("water for injection") in the pharmaceutical industry, and UHPW ("ultrahigh-purity water") in the electronics industry and in nuclear reactor systems. When the U.S. Food and Drug Administration and solutions for human injection are involved, the presence of red-colored oxide on the surfaces of stainless steel equipment is not acceptable. Also, the standards for ultrahigh-purity water in the electronics industry do not permit this sort of condition.

One explanation that has been advanced to explain the fairly recent development of this phenomenon relates to modern steel-making processes. The AOD process itself gives a precise control that permits the manufacturer to work at the lowest ranges permissible for alloying elements, for example, chromium, within the nominal range specified. During long-time hot-working and annealing, the stainless steels form a chromium oxide scale that depletes the metal substrate of Cr. Modern short-time "spray pickling" may not be adequate to dissolve the depleted layer, leaving a surface of somewhat lesser corrosion resistance than the nominal analysis. However, even minor mechanical abrasion restores the proper surface chemistry, and electropolishing, although not simple nitric acid "passivation," which does not attack alloys with as little as 11% Cr, also does so.

A rouge of loose ferric oxide has been developed on Type 304L in laboratory tests in deionized water at 250°C, simulating a reactor loop. When the water was cooled for sampling and filtered through a 0.1-μm PTFE filter supported on a 0.2-μm silver filter, no deposits were found on the PTFE but large crystals of spinel ferric oxide (with traces of Cr and Ni) had developed on the silver filter and grown back into the PTFE from the backside. This reaction suggests either soluble or colloidal iron in the nearly supercritical (288°C or higher) water. Loose rouge has also been observed in hot aggressive waters (e.g., WFI) as low as 80°C (175°F) from sterilizing procedures with stainless steels in the pharmaceutical industry. Some operators have used solutions of sodium hydrosulfite ($NaHSO_3$) to reduce and remove rouge from their systems.

Some authorities state that the term *rouging* is a misnomer because the films may be either the powdery red iron oxide or adherent films of various colors including gray, black, purple, blue, and even yellowish green. In practice, it is often difficult to distinguish between superficial corrosion (involving a black substrate under a reddish-brown crust, associated with craters and white debris) and extraneous deposits (9). Heat tints and similar films exhibit colors related to their thickness and, although they can occlude and concentrated corrosive species such as chlorides, should not be considered rouge.

In one case, an electropolished Type 316L filter plate developed a blue-black tint, with no apparent corrosion of the parent metal, in ultrahigh-purity water of reportedly ambient temperature or at least not more than about 55°C (130°F). Analysis determined that the film contained more than 85% iron as a black oxide, probably derived from equipment upstream and entering the system, perhaps during regeneration of the mixed ion exchange beds.

66.6 FACTORS CONTRIBUTING TO LOCALIZED CORROSION

Some factors that contribute to the occurrence of localized corrosion in the stainless steels are surface defects or foreign matter. Surface defects are undercut welds, scratches, and grinding marks, which can initiate localized attack.

Foreign matter constitutes embedded iron or iron oxides (usually from mill or shop contamination of the stainless steel surface), the bluish heat tints adjacent to welds, weld splatter or arc strikes, and paint or crayon markings. Iron oxides and heat tints can occlude and concentrate chlorides and are themselves susceptible to corrosive attack. Weld splatter and arc strikes weaken the surface film and may constitute crevices for the initiation of attack. Paints and crayon markings may contain organic chlorides, which can hydrolyze or thermally degrade to release traces of hydrochloric acid and promote localized attack.

Bacterial effects in unsterile water, for example, residual hydrotest water, can also cause localized attack. The production of traces of hydrogen sulfide by sulfate-reducing bacteria (SRBs) and the excretion of iron or manganese oxides by aerobic strains can cause serious pitting in a very short time. Sulfides compete with oxygen and weaken the passive film, contributing to pitting and SCC. Microbiologically induced corrosion (MIC) has attracted increasing interest in the process industries.

66.7 PREVENTION OF LOCALIZED ATTACK

To prevent or minimize the possibility of localized corrosion, a specific sequence of events must be established. The methodology for this starts with proper materials and design and the establishment of certain procurement details in the materials selection, specification, and inspection phases, plus postfabrication cleanup and preservice sanitizing or other preparatory steps.

66.7.1 Materials

Materials must be properly chosen for the expected conditions of fabrication and service. The alloys chosen should be indicated by the proper alloy designation or

corresponding UNS number, and these should be allied with an appropriate ASTM or ASME specification and any necessary supplements.

For best results, cast components, such as pumps and valves (which are predominantly CF8M and CF3M, the cast equivalents of types 316 and 316L), should be purchased to ASTM A743 with a special annealing temperature requirement. Annealing at about 1,120°C reduces the tendency toward molybdenum gradients within the casting, ensuring a more uniform corrosion resistance.

To avoid materials mixups, such as may occur either at the manufacturer's plant or in warehousing, the composition of the alloy should be verified not only by checking the mill analysis but also by spot-test or nondestructive metal identification procedures; this is particularly necessary when a molybdenum-bearing alloy has been chosen. Inadvertent substitution of Type 304L for 316L has caused many problems in process applications. The fact that a piece of stainless steel is clearly marked as Type 316L, Heat No. *X*, is not a guarantee.

Finally, special finishes may be required. The several commercial finishes (in decreasing order of surface roughness) are numbered 1 (hot-rolled, annealed, and pickled) through 8 (a mechanically polished and buffed specular finish, with no visible abrasive scratches). For bioprocessing applications, a number 2B finish (cold-rolled, annealed, pickled, and temper-rolled) or a number 4 (which adds a 150-grit abrasive belt grinding to the 2 B finish) is usually specified.

For extra smoothness in special nonstick applications or to facilitate removal of bacterial contaminants, stainless steel may be electropolished to a mirror finish in lieu of a number 8 finish. Electropolishing aids surface homogenization and autopassivation, and an actual anodizing can be added as the final step to enhance the passive film.

66.7.2 Design

Because localized corrosion causes about 90% of the failures experienced with stainless steels in process applications, vessels, piping, and ancillary equipment must be designed, purchased, and maintained to minimize the risk of such attack. This requires that crevices, pockets, and traps should be avoided, thereby minimizing the probability of localized corrosion.

All fabrication steps, such as bending, forming, and welding, should conform to standard procedures. The welds must be full penetration to prevent crevice corrosion in incompletely fused joints. Fillet welds should be smooth and continuous, with no undercutting. Butt welds should be smooth and corner welds should be avoided if possible; side-wall welds in tanks are preferable. Lines and vessels should be sloped and self-draining, and top nozzles, side ports, and bottom nozzles must be accessible for cleaning.

A postweld chemical cleaning with an ammoniated citric acid solution, as described next, will remove the heat tints from the welded heat-affected zones (HAZ).

66.8 REMEDIAL MEASURES

66.8.1 Pickling

Because stainless steels are chosen for appearance, corrosion resistance, and freedom from product contamination in storage and shipment, pickling (to remove contaminants) or passivation (to augment the naturally occurring surface film) is often required. A surface of assured cleanliness, uniformity, and corrosion resistance is desirable and, in some services, absolutely required.

During fabrication, stainless steels are subject to contamination by embedded steel particles or iron oxides, as well as heat tints caused by welding. The alloy surface may be cleaned with acid solutions or pastes, mechanically cleaned with a stainless steel wire brush or a clean abrasive disk, or hydroblasted with high-pressure water of potable water quality (i.e., <250 ppm Cl^-). ASTM A 380, "Cleaning and Descaling Stainless Steel Parts, Equipment, and Systems," provides detailed procedures. Demineralized water is usually specified for critical services, but a 25-ppm maximum chloride limit should be adequate.

Embedded iron is subject to air oxidation to hydrated ferric oxide ($Fe_2O_3 \cdot H_2O$). Foreign rust particles or mill scale (Fe_3O_4) may also be present. "Pickling" (see following) is intended to effect the desired cleanliness while simultaneously homogenizing the surface. A solution of 10–15% nitric acid and 1–3% hydrofluoric (HF) acid has been used as a "bright pickle" to remove visible oxides, while pastes of similar composition are available for localized application. Such solutions and pastes constitute somewhat of a safety hazard to personnel, as well as potential disposal problems, but are very effective. (Note: There is increasing resistance to using HF mixtures today because of the safety concerns and disposal problems related to environmental considerations.)

A HNO_3–HF mixture, unlike nitric acid itself, is a reducing acid intended to remove iron oxides and other metallic oxides by chemical reduction. This mixture is not a passivating medium, and corrosion rates are high during the actual exposure. However, a uniform passive oxide film will reform over the freshly cleaned surface after removal of the pickling environment by autopassivation.

Heat tints from welding tend to adsorb chlorides, with attendant pitting or stress corrosion cracking. They may be removed by abrasive disks or with a nitric–HF paste. Citric acid solutions, such as a 5% solution adjusted to pH 3.5 with ammonia and used at about 80°C, are very effective and are to be preferred for removing heat tint from bioprocessing equipment. This solution is a chelating agent

as well as an acid cleaning medium. Unlike the nitric–HF materials, citric acid solutions are benign and quite readily disposable from the environmental standpoint. However, chelants incorporate the metal ions within a clawlike ringed structure that may pass through conventional waste treatment systems. When heavy metals (i.e., chromium, copper, nickel, and zinc) are involved, special waste treatment systems, rather than simple sanitary drain systems, may be employed.

Antisplatter pastes are sometimes used to minimize weld-splatter sticking. If such splatter has adhered to the adjacent areas, it should be removed by a flapper wheel, wire-brushing, or hydroblasting. A cleaning operation with organic reducing acids may be followed with an alkaline sodium nitrite neutralizing–oxidizing rinse. (Note: Adequate provision must be made for proper disposal of the chemical solutions in accordance with environmental regulations.)

Electropolishing, in which the work serves as the anode during electrochemical dissolution to produce a highly polished nonstick and uncontaminated surface, is a specialized form of chemical cleaning in which the surface is actively corroded during the operation. Although the stainless steel surface will passivate on rinsing and exposure to air, many users specify a final anodizing step, which is tantamount to chemical passivation.

66.8.2 Passivation

Cleaning and pickling, as described, and passivation of stainless steels, particularly in the widely used austenitic 300 series, for example, Types 304 (S30400), 304L (S30403), 321 (S32100), 347 (S34700), 316 (S31600), 316L (S31603), and 317L (S31703), are widely misunderstood.

Cleaning and pickling are intended to remove foreign materials and permit the surface to equilibrate or homogenize, effecting an electrochemically uniform surface for resistance to localized corrosion. Passivation has been defined as a reduction in the rate of the anodic reaction of an electrode involved in corrosion, as by formation of a protective oxide film.

As previously noted, stainless steels are self-passivating on exposure to air and moisture as the result of their high chromium content (i.e., >11%). Passivation treatment consists of augmenting the naturally occurring protective oxide film by chemical or electrochemical methods. The enhanced passive film is somewhat thicker and more persistent than that formed by autopassivation. For example, in some iron-sensitive organic chemicals (e.g., acetoacetanilide, glyoxal), stainless steel vessels are specially passivated and repassivated at intervals thereafter whenever chromophoric corrosion products are detected in the chemical product. This practice suggests a gradual diminution in thickness (or localized weakening of) the passive film with time in some services. Passivating is accomplished by treatment with oxidizing solutions, such as warm dilute nitric acid (not nitric-HF), ammonium persulfate (which is very safe to handle), dilute hydrogen peroxide, and citric acid–sodium nitrate mixtures.

Table A2.1 of ASTM A 380, Part II, recommends passivation with 20–50% nitric acid at 49–71°C (120–160°F) for 10–30 min or 21–38°C (70–100°F) for 30–60 min for dull or nonreflective surfaces. In the latter case, a 10% caustic–4% potassium permanganate solution is suggested for smut removal after the final rinse. A 20–40% nitric acid with 2–6% sodium dichromate is suggested for bright-machined or polished surfaces, instead of straight nitric acid. Such solutions are also used for precipitation-hardening (PH) grades, 12–14% chromium grades, and high-carbon martensitic grades, such as Type 440 (S44000). However, chromates are not compatible with pharmaceutical products. (Note: In chemical plants, large tanks or vessels are usually passivated with 10–15% nitric acid at 66°C (150°F) for about 4 h.) A 1% citric acid–1% sodium nitrate solution at 21°C (70°F) is discussed in ASTM A 380, Part III. The dairy industry has used a 0.5–1.0% nitric acid for 10 min at 65–82°C (150–180°F).

A special sequence of alkaline–acid–alkaline (A-A-A) treatment is recommended for free-machining grades (10). Because oil or grease interferes with passivation and because attack on sulfur or selenium inclusions in Type 303 (S30300) and its variants can leave minute pits with residual corrodents on the metal surface, the machined parts are (*1*) degreased for 30 min in 5% sodium hydroxide at about 70–80°C (160–180°F) and rinsed, (*2*) immersed in 20% nitric plus 3 oz. per gallon sodium dichromate at 50–60°C (120–140°F) for 30 min and rinsed, and finally (*3*) neutralized in the original caustic solution.

Because oil or grease can interfere with self-passivation by preventing ready access of water and oxygen to the metal surface, degreasing may be required. Such contamination occurs primarily from machining operations and should be removed by degreasing with nonchlorinated solvents before passivation is attempted. (Note: Chlorinated solvents may introduce inorganic chloride ions, Cl^-, by hydrolysis or by thermal degradation, and are proscribed.)

Note that nonoxidizing solutions, such as ammonium citrate, hydroxyacetic–formic acid mixtures, and EDTA (ethylenediaminetetraacetic acid) instead of a nitric acid passivation are described in ASTM A 380, Part III. The dairy industry uses a 0.5–1.0% phosphoric acid solution at 65–82°C (150–180°F) for 10 min. These nonoxidizing solutions used to remove iron or iron oxides only equilibrate the surface, facilitating autopassivation. They do not actually enhance the film as do the true passivation procedures.

66.8.3 Sanitizing

As a final step (or between batch operations), it is frequently desirable or even necessary to sterilize stainless steel equipment. Sodium or calcium hypochlorite is most frequently utilized, but the oxidizing capacity and chloride content pose serious potential dangers for pitting or crevice corrosion. The conditions and time of exposure and the proper steps to flush the hypochlorites from the system, including low spots, is of paramount importance. Serious failures have occurred in numerous stainless steel installations when adequate measures to preclude attack during treatment or by residual hypochlorites were not taken. Treatment with ozone or dilute hydrogen peroxide, as well as by ultraviolet light, seems to provide useful alternatives.

66.9 STANDARD OPERATING PROCEDURES

To summarize, the recommended sequence of treatment of fabricated stainless steel equipment for pharmaceutical applications should embrace the following steps:

1. A pretreatment with solvent or detergent to remove oil, grease, and the like
2. A rinse with water of suitable quality (deionized water being preferred)
3. Necessary pickling or other cleaning operations
4. Passivation
5. Water rinsing
6. Sanitizing
7. Final water rinse; drain and dry

A proper understanding of service conditions and requirements is essential if the several possible cleaning, pickling, and passivation treatments are to be successfully employed for their respective end purposes.

The most valuable resources for practical information on corrosion and corrosion prevention of stainless steels are as follows:

- NACE International (standards and publications), Houston, Tex.
- The Nickel Development Institute (AISI, INCO, and NiDI publications), Toronto, Ontario, Canada
- ASTM International (specifications), Barr Harbor, Pa.
- The Materials Technology Institute of the Chemical Process Industries, Inc. (publications), St. Louis, Mo.

STATIC MIXING, FERMENTATION PROCESSES

Radu Z. Tudose
Technical University Gh.Asachi Iaşi, Iaşi, Romania
Maria Gavrilescu
Research Centre for Antibiotics, Iaşi, Romania

67.1 INTRODUCTION

The intensification of transfer processes in bioreactors using techniques that do not require additional energy costs is of great interest in biotechnology. Traditionally, most bioprocesses, especially aerobic fermentations, are conducted in stirred-tank bioreactors, which require considerable power input to attain adequate oxygen transfer rates. Besides the conventional mechanically agitated fermenters, other types of gas–liquid contactors are used, as pneumatic or jet bioreactors with or without a loop. Advantages of these nonmechanically agitated bioreactors are known to include efficient use of energy for aeration, simple design, and construction. To improve transfer processes in these bioreactors, considerable efforts have been made to study all the essentials of the major relationship for flow, mass and heat transfer over plates, cylinders, baffles, and spheres as well as through sieves and trays. These are the simplest and the oldest contacting bodies, and also are the basic shapes for other contacting devices of practical interest. Both theoretical and experimental studies on flow around these internals together with heat and mass transfer approaches are available (1–4).

Recently, new constructive types of internals known as static mixers or motionless mixers have been developed that supply spectacular effects concerning transfer rate increase. The first of these unconventional mixers was developed for viscous fluids about 30 years ago (5). After a slow start, the development of static mixers has been proceeding since 1970. Static mixers are applied in many operations in heterogeneous systems that require larger contact areas, thermal homogenization, and mass transfer. Today, these devices placed in column bioreactors are increasingly considered for use in fermentation industries, sometimes replacing the traditional mechanically agitated bioreactor design. Static mixers are suitable particularly for use in shear-sensitive cell cultures because of their lower shear rates, compared to those in mechanically agitated bioreactors. They proved to consider some specific criteria in the design of a bioreactor system for a definite process: population damage, energy distribution, and oxygen demand of a culture. The relatively numerous investigations and works that refer to static mixers are concerned with their influence on different process transfer parameters not only in fermentation systems, most of them being performed in model systems, in monophasic and polydispersed laminar or turbulent flow (usually gas–liquid dispersions), using low and viscous liquids, with Newtonian or non-Newtonian rheological behavior.

Static mixers frequently require no additional space (in-line assembly) and can be used as compact inserts or with a distance between the elements. They act on hydrodynamic conditions for turbulence development, the increase of contact areas, or the intensification of driving forces, separately or simultaneously. In all cases, the energy for process intensification is extracted from the fluid flowing through the mixers.

67.2 STRUCTURAL TYPES AND CONSTRUCTION

Static mixers can be of numerous constructive types, made of tubes, sheets, helixes, or wire matrix. They can be manufactured by steel, ceramic, or plastics. Their effect depends on the construction of the mixing element and the capacity to produce continuous separation, distribution, and reuniting the fluid stream. Besides their multiple advantages, static mixers often have the difficulty of a complicated structure. At the present time, most of the problems in the construction of static mixers have already been solved, and a number of different types of static mixing systems are being manufactured on an industrial scale, so that about 30 types of static mixers are known today. One of the most important moments in static mixing presentation was the ACHEMA '79 Exhibition in Frankfurt/Main (5). This section discusses some of the most interesting, familiar and, at the same time, most structurally dissimilar static mixers.

67.2.1 Static Mixers from Tubes or Short Pipes

Static mixers from tubes or short pipes generally affect the spatial distribution of the fluid by twisting, distorsion, and expansion of fluid elements in specially designed flow arrangements. For instance, the Ross-ISG static mixer (Aachener Misch- und Knetfabrik) is made by elements turned through 90°, placed one behind other. Over the cross-section of an element there are four obliquely sloped channels twisted with an angle of 120° (Fig. 67.1a), forming a tetrahedral space between elements. The PRM mixer (Prematechnik, Frankfurt/Main) consists of a tubular packet containing obliquely arranged partial tube sections (Fig. 67.1b), which change the direction of the fluid stream (5). Another static mixer used in laminar flow conditions, especially to equalize the distribution of the flow residence time, consists of six guiding holes, directed in the direction of flow (Fig. 67.1c). A portion of the fluid stream, which flows through the central section in front of the device, has a higher mean velocity and crosses the channels that direct it to a zone with a low mean velocity. Other parts of the fluid stream that flow near the pipe wall cross over the channels that direct them to the central zone of the pipe behind the static mixer. Therefore, the positions of the fluid streams that flow with different velocities are inverted (6–8).

67.2.2 Static Mixers of Plates or Sheets

The effects of these static mixers depend on the continuous cutting, subdividing, distribution, and reuniting the stream of fluid. The PSM mixer (Petzhold, Frankfurt/Main) (Fig. 67.2a) contains rectangular and conical channels combined with conical holes resulted from a special arrangement of

individual plates. The fluid flows from the entry to the exit of the static mixing element, being subdivided through a central hole, a conical space created by tangentially arranged slots and furthermore through other channels and openings (5). Sulzer mixers (Sulzer Brothers Ltd., Switzerland) are adequate for both laminar and turbulent regimes. They are constructed in many different ways (SMV, Fig. 67.2b; SMX, Fig. 67.2c) from stacks of corrugate sheets with open crossing channels. The SMX mixer consists of strips inclined to one another that form frameworks with the axis perpendicular to the column axis. The mixing elements are arranged successively in the column turned through 90° one to another. The SMLX mixer type is constructed from corrugate sheets with a distance between the strips increasing in the flow direction. The crossing angle of the sheets is 60°. These static mixers made of corrugate sheets can be mounted in packed form in compact arrangement or with distance between packets in different nonmechanical bioreactors (9). The Komax mixer (Long Beach, Calif.) contains triangular-shaped channels, made by the bent ends of the slotted sheets that form the mixing element (Fig. 67.2d). The Koch mixer (10,11) contains a numer of in-line elements mounted alternately at right angles to each other. The mixing elements are made from layers of corrugate metal sheets joined one to another, forming opened intersecting channels. C_1 and C_2 mixer types (12) (Figs. 67.2e and f, respectively) developed in the Central Institute of Physical Chemistry of the German Academy of Sciences and the Pyrapak 480 type developed at the CLG Leipzig-Grimma were also manufactured out of metal sheets.

67.2.3 Helical Static Mixers

The Kenics mixer (Ott Vertriebsgeselschaft, Leonberg) is made of counterclockwise and clockwise rotational elements twisted at 180°, being mounted in tubes alternating left and right with perpendicular leading edges (Fig. 67.3a). A particular form of this helical static mixer consists of an unbroken continuous helical surface that may have the diameter of a screw identical or smaller than the inner diameter of the tube (13) (Fig. 67.3b). Helical static mixers can be disposed in columns as in-line elements or in packed form (14). The Erestat mixer (Yxzet, Dr. Karg GmbH, Affalterbach) consists of four baffles twisted in an alternate manner arranged in a left- or right-handed arrangement on an inner support (Fig. 67.3c). This assembly creates various flowing channels. The N-shaped mixer (Bran and Lübbe, Norderstadt) consists of twisted mixing elements (Fig. 67.3d) that determine variable cross-sectional areas, owing to the formation of variable channels. The Lightin type (Lightin, Rochester, NY) combined in-line mixers obtained by assembling three-bladed elements to form helixes with different senses of rotation (Fig. 67.3e).

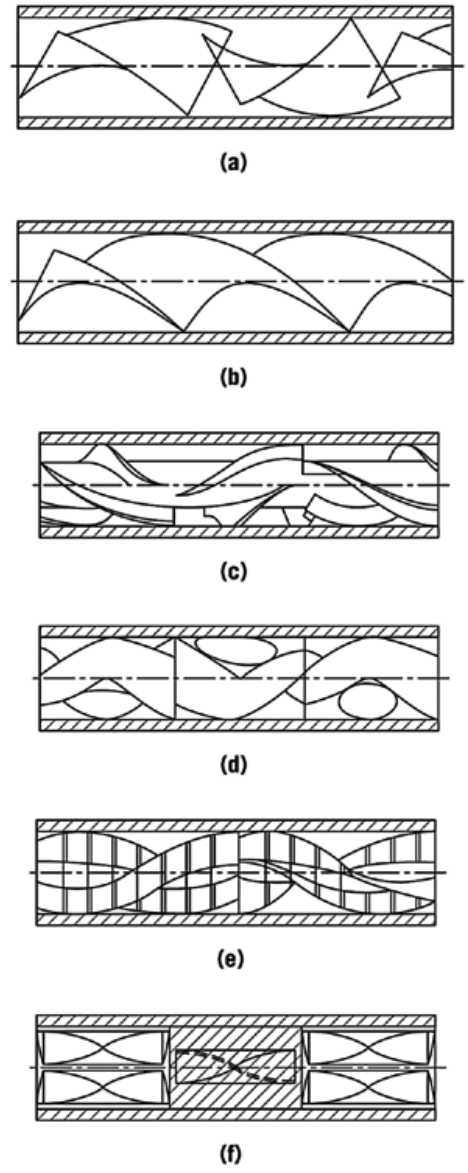

Figure 67.3. Helical static mixers. *Source*: Reprinted from Ref. 5, with permission from VCH Verlagsgesellschaft mbH, and from Ref. 7, with permission from Wiley-VCH.

The HI mixer (Toray, Tokyo) is constructed by helixes twisted at 180°, fitted into holes performed parallel to the axis in a solid cylinder (Fig. 67.3f).

67.2.4 Wire Matrix Turbulators

The Heatex inserts (15) consist of a central wire core onto which are wound a series of wire loops. Each loop is inclined at a certain angle to the core. These inserts are pulled into a tube, the loops being so inclined as to be oversized for the tube and come into a close contact with the tube wall in the form of an arc (Fig. 67.4). A degree

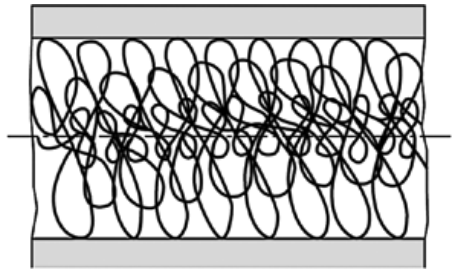

Figure 67.4. Static mixers of wire matrix. *Source*: Reprinted from Ref. 7, with permission from Wiley-VCH.

of resistance is offered as the insert is pulled into the tube, indicating that some wall contact is achieved and that the insert is self-supporting. Heatex inserts may have different loop densities, characterized by the number of tube wall contacts achieved per unit insert length.

67.3 EFFECTS OF STATIC MIXERS ON MOMENTUM TRANSFER

67.3.1 Flow Structure

Static mixers produce variations in the flowing cross-sectional area that result in modifications of velocity profiles. The fluid is split into individual streams at the open intersecting channels of the mixing element. At each intersection, a partial quantity is sheared off into a crossing channel and stagnant zones are usually eliminated. Also, most of the static mixers divide and reunite continually the main fluid stream and give rise to the formation of elementary layers of fluid. The number of n elementary layers or partial streams produced in laminar flow over a static mixer resulted through assembly of N mixing elements can be calculated from the following expression (16):

$$n = ca^{\mathrm{N}} \tag{67.1}$$

where c and a are parameters characteristic for the static mixer in discussion that are usually given in the literature (16). In the laminar regime, the flow profiles are modified by cutting and twisting, displacement and distortion, or separation and expansion. In the turbulent flow, additional effects occur (5). For instance, the fluid streams are alternating directed from the center to the wall of the column and from the wall to the center in the Ross-ISG mixer (Fig. 67.1a) or in the static presented in Fig. 67.1c. The presence of Heatex inserts (Fig. 67.4) causes a tube wall–fluid disturbance, and radial mixing is expected to be produced as the fluid flows through the mesh of loops nearer the pipe axis (15). In a Kenics mixer (Fig. 67.3a) a tracer injected below the first element in a certain point can perform a helical rotation strictly geometrically and reach the element edge in an opposite point situated on the same diameter, or it flows along a shortened path after a distortion and arrives at the end of the helix in a intermediate position on the diameter (5). The flow pattern in a Sulzer SMV mixer was presented by Pahl and Muschelknautz (5) using a model that consists in two triangular opened ducts crossing at 90° (Fig. 67.5) forming two intersected channels. Tracer introduced at the entrance of the channel I flows up to the intersection of the channels, and then about two-thirds of the tracer stream takes the shortest path flowing into duct II owing to the displacement that is produced at the crossing point. The trajectory of the tracer is also distorted; the fluid that exists along the left cathetus of the triangle representing the cross-section of the duct I shifts to the right side of duct I at the exit, performing a rotation. Also, the stream that starts from the opposite position at the entrance of duct I is greatly distorted at the crossing point and flows into both ducts I and II. In gas–liquid dispersions, a reasonably uniform distribution of the gas velocity over the cross-section of a column with static mixers is one of the favorable results. An equalizing effect is achieved by the resistance to flow, which forces the gas to spread out gradually in the direction of flow. This fact is very important in bioreactors with viscous non-Newtonian fermentation fluids, where the bubbles coalesce in the sparged vertical columns, leading to the formation of large bubbles, even at very low gas flow rates. In absence of static mixers, these bubbles rose with large velocities and their size distribution is controlled by bubble coalescence. The velocity profile of a fluid flowing through a tube containing motionless mixers is also considerably altered. There are some works in the literature that give information about radial and axial velocity profiles in the presence of static mixers (13,17,18). The axial

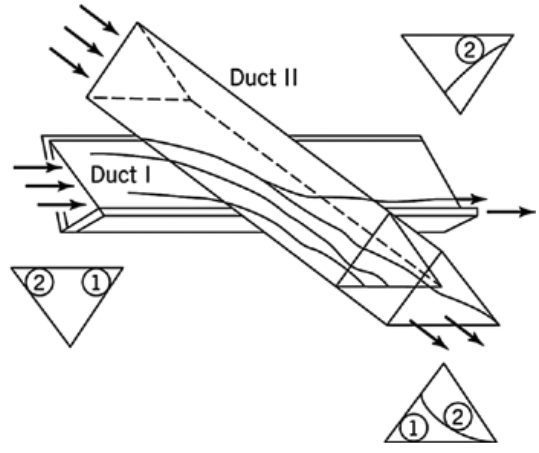

Figure 67.5. Flow path in a Sulzer-SMV static mixer (two triangular channels crossing at 90°). *Source*: Reprinted from Ref. 5, with permission from VCH Verlagsgesellschaft mbH, and from Ref. 7, with permission from Wiley-VCH.

and radial velocity profiles in a Kenics mixer change periodically owing to the use of alternating elements of right- and left-hand pitch that results in more intensive mixing of fluids. The screw having the form of a continuous helical surface divides the inside of the tube into two parallel channels, which causes a secondary motion of the fluid in the tube (13). In these motionless mixers, circulating flow occurs in the r-θ plane (r and θ being radial and tangential coordinates, respectively), which is caused by a slow twist in the partitioning chord so that it forms a helix. The actual velocity profiles can be calculated using a complex procedure (17), but an approximation can be made, leading to the following expressions:

$$\upsilon_r = \frac{dr}{dt} = \beta r(1 - r^{\upsilon}) \sin 2\theta \tag{67.2}$$

$$\upsilon_\theta = \frac{d\theta}{dt} = \beta[2 - (2 + \upsilon)r^{\upsilon}] \sin^2\theta \tag{67.3}$$

where

$$\upsilon = \left(\frac{11}{3}\right)^{0.5} - 1 \tag{67.4}$$

and β is a parameter that governs the intensity of circulation (17).

67.3.2 Pressure Drop

The changes in the velocity field caused by the static mixers cause modifications in the pressure loss as well. The pressure drop in static mixers depends very strongly on the geometrical arrangement of the packed elements, the nature of the flowing fluids, and the flow regime (19,20). A simple form representing the pressure loss equation can be referred to the empty tube, together with a geometrical correction factor (5,7,13). For Newtonian media, the equation for calculating the pressure drop is in the following form:

$$\frac{\Delta p_M}{\rho \upsilon_{SL}^2} \frac{2D}{L} = f_D(Re_D, \text{ geometry}) \tag{67.5}$$

The mean liquid superficial velocity υ_{SL} can be calculated on the basis of the empty tube cross-section as follows:

$$\upsilon_{SL} = \frac{4\dot{V}_L}{\pi D^2} \tag{67.6}$$

In laminar flow, $f_D\, Re_D =$ constant. Rearranging equation 67.5, a relationship is obtained whose denominator becomes the pressure drop for laminar flow through an empty pipe:

$$\frac{\Delta p_M}{\Delta p_L} = \frac{\Delta p_M}{32\eta\upsilon/D^2} \tag{67.7}$$

Defining a pressure drop factor as

$$z = f_D \frac{Re_D}{64} \tag{67.8}$$

it follows that

$$\Delta p_M = z\Delta p_L \tag{67.9}$$

In Figures 67.6 and 67.7, the pressure drop and friction factors for different static mixers are presented (5,7). The plot $f_D - Re_D$ could be also used for comparing static mixers in the turbulent flow regime, since f_D is then approximately independent of the Reynolds number

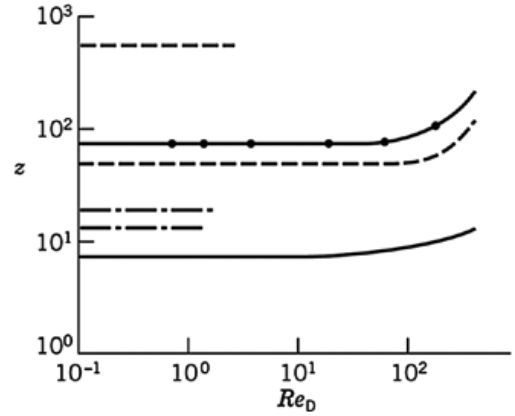

Figure 67.6. Relative pressure drop for different static mixers versus Reynolds number. — = Kenics; —·— = Erestat; —··— = N-shaped; — — — = HI; — □ — □ — = Sulzer-SMX; - - - - - - = Ross-ISG. *Source*: Reprinted from Ref. 5, with permission from VCH Verlagsgesellschaft mbH, and from Ref. 7, with permission from Wiley-VCH.

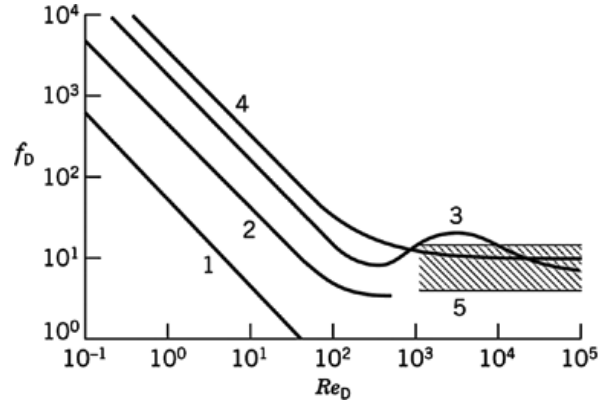

Figure 67.7. Friction factor as a function of Reynolds number for some static mixers. 1 = empty pipe; 2 = Kenics; 3 = HI; 4 = Sulzer-SMX; 5 = Sulzer-SMV. *Source*: Reprinted from Ref. 5, with permission from VCH Verlagsgesellschaft mbH, and from Ref. 7, with permission from Wiley-VCH.

(Fig. 67.7). Compared with an empty tube, the pressure drop in static mixers is 7 to 200 times greater for laminar flow and 100 to 600 times greater for turbulent flow. Kenics mixers show the smallest pressure drop, and the Ross-ISG affords the largest pressure drop (5,16). Also, the pressure losses in a tube containing continuous screws calculated using equation 67.5 are lower than those corresponding to a tube containing Kenics mixers for the same value of the parameter h/d. The following analytical expressions were developed for the different types of helical static mixers (13). For Kenics type (for $15 \leq Re_D \leq 1{,}200$):

$$f_D = \frac{213.5 + 224.0(h/d)^{-1}}{Re_D} + \left[-0.549 + 4.775(h/d)^{-1}\right] \quad (67.10)$$

For static mixer with a continuous screw surface for $15 \leq Re_D \leq 90$,

$$f_D = \frac{191.3 + 229.0(h/d)^{-1}}{Re_D} \quad (67.11)$$

for $90 \leq Re_D \leq 5{,}000$,

$$f_D = \frac{79.8}{Re_D^{0.839-0.454(h/d)^{-1}}} \quad (67.12)$$

With increasing of h/d, the pressure loss decreases for any given type of fittings (Fig. 67.8). The specification of notation is given in Table 67.1.

Figure 67.8. In Newtonian liquids, the presence of wire matrix turbulators caused an increase in pressure drop by factors up to 20 compared with the empty tube case (15). In non-Newtonian fluids, the pressure drop in a static mixer assembly can be correlated as follows:

$$\Delta p_M = \frac{A}{Re_D} + \frac{B}{Re_D^m} \quad (67.13)$$

where the values of A, B, and m are dependent on rheological behavior of the liquid phase (7,21). Olivier and Oosterhuis (22) studied the pressure drop in the laminar flow regime for a Sulzer-SMV-type in the xanthan fermentation and found that the pressure drop is approximately 15 times greater than that in an empty tube. Fan *et al*. (23) studied the pressure drop in a gas–liquid system in a bubble column packed with Sulzer-Koch mixing elements and observed that the ratio of the pressure drop through the packed column to that of the empty one was slightly greater than 1. Data referring to the pressure drop in a column equipped with a static mixer of the Kenics type were obtained for a single (gaseous) phase and two-phase countercurrent flow, respectively (14,24). For one mixing element, the pressure drop, which is a function of the Reynolds number for the gaseous phase, Re_G, is assessed as follows:

$$\Delta p' = \frac{\Delta p_M}{N} \quad (67.14)$$

The pressure drop in the system was calculated using the gas dynamic pressure for the single phase as

$$\Delta p' = f_{Do}\,\rho\,\frac{v_{SG}^2}{2} \quad (67.15)$$

and for the diphasic flow:

$$\Delta p'_{TP} = f_{DTP}\rho\,\frac{v_{SG}^2}{2} \quad (67.16)$$

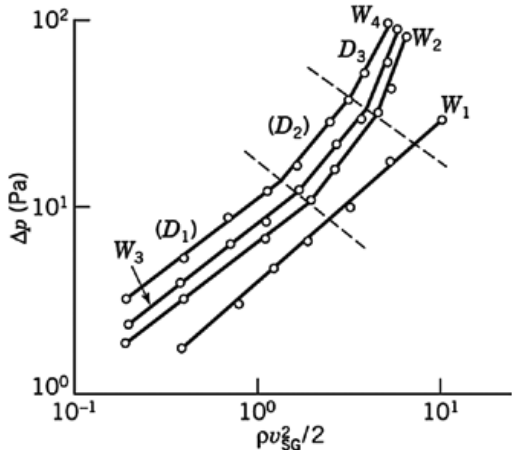

Figure 67.9. Pressure drop through a single static mixing element as a function of the dynamic pressure of the gaseous phase for different spraying intensities. $W_1 = 0$; $W_2 = 60.93$ m^3/m^{2}h; $W_3 = 81.24$ m^3/m^{2}h; $W_4 = 101.56$ m^3/m^{2}h. *Source*: Reprinted from Ref. 7, with permission from Wiley-VCH.

The plots show three domains with different slopes (Fig. 67.9). The friction factor also differs in the domains. For a single phase flow, it was correlated as follows:

$$\text{Domain D}_1: \quad f_{\text{Do}} = 12.86 Re_{\text{G}}^{-0.1708} \tag{67.17}$$

$$\text{Domain D}_2: \quad f_{\text{Do}} = 1.039 Re_{\text{G}}^{0.1062} \tag{67.18}$$

$$\text{Domain D}_3: \quad f_{\text{Do}} = 0.9742 Re_{\text{G}}^{0.1137} \tag{67.19}$$

For a diphasic flow, the following relation was established (24):

$$\frac{\Delta p'_{\text{TP}}}{\Delta p'} = B'^{\text{W}(1+b' Re_{\text{G}})} \tag{67.20}$$

The values of the spraying intensity, B', and of the parameter b', are different in the three domains of the curves (Table 67.2) (24).

For a two-phase flow, Shah and Khale (21) applied a correction factor for the manometer reading, assuming the gas holdup to be proportional with $\dot{V}_{\text{G}}/(\dot{V}_{\text{G}} + \dot{V}_{\text{L}})$. For an empty tube, the correction factor was found to be 0.83. They presented their data in the form of a Lockhart-Martinelli correlation for three types of static mixers, Kenics, Sulzer, and Komax, for two-phase non-Newtonian liquid–air systems in the following form:

$$\Delta p_{\text{TP}} = \varphi_{\text{L}}^2 \Delta p_{\text{L}} = \varphi_{\text{G}}^2 \Delta p_{\text{G}} \tag{67.21}$$

$$\varphi_{\text{L}}^2 = 1 + (c'/X) + (1/X^2) \tag{67.22}$$

$$X = (\Delta p_{\text{L}}/\Delta p_{\text{G}})^{0.5} \tag{67.23}$$

with $c' = 2.5 \pm 0.3$ for glycerol solution–air and $c' = 3.27 \pm 0.1$ for CMC solution–air diphasic systems, respectively. Generally speaking, the pressure drop in the gas–liquid systems decreases as the gas flow rate increases (10).

67.3.3 Gas-Holdup

In tower bioreactors with or without a loop (bubble columns, airlifts, jet contactors), liquid flow and gas holdup are of basic importance in the determination of their performance (25). Because microbial aerobic cultures often behave as non-Newtonian fluids, much attention was directed toward the performance of these gas–liquid contactors equipped with static mixers, especially when they handle non-Newtonian fermentation liquids. The rheological behavior of biofluids plays an important role in bubble coalescence and breakup, because the large velocities of coalesced bubbles lead to gas holdup decreasing (26). The presence of static mixers in diphasic flow diminishes the bubble coalescence rates owing to their shear effect. Therefore, the average bubble size should decrease and gas holdup is enhanced (7,10) (Fig. 67.10). The results of MacLean *et al*. (27) confirm these findings, suggesting that the motionless mixers help to retain more gas in the column. Similar effects can be obtained in triphasic sparged reactors (28). By using Ross-LPD and Sulzer SMV static mixers, larger gas holdup values resulted, compared with the empty contactor (Fig. 67.11). Kenics mixers mounted in an airlift bioreactor contribute to increase gas holdup values during the batch fermentation of a yeast culture (29). Gas holdup in downcomer (annular section) decreased because of a lower liquid recirculation rate, which implied a more intense gas disengagement at the upper part of the bioreactor, reducing the quantity of the recirculated gas. In the region of greater airflow rates (the riser), gas holdup values are, however, improved. This

behavior had a favorable influence on oxygen transfer rates (29,30). The presence of static mixers does not change the correlation between gas holdup and gas superficial velocity, which was established in the following form:

$$\varepsilon_G = a\upsilon_{SG}^{b} \tag{67.24}$$

For example, static mixers manufactured through assembly of corrugated stainless steel sheets and mounted in the riser section in an external-loop airlift bioreactor can contribute to gas holdup intensification at any given gas flow rate and liquid phase properties, relative to bioreactor configuration without static mixers (Fig. 67.12), also proved by the modified values of the parameters a and b in equation 67.24. This effect is found in low-viscous Newtonian and viscous non-Newtonian liquids as well (Table 67.3) (25). It is evident from Table 67.3 that static mixers show an increased efficiency in more viscous

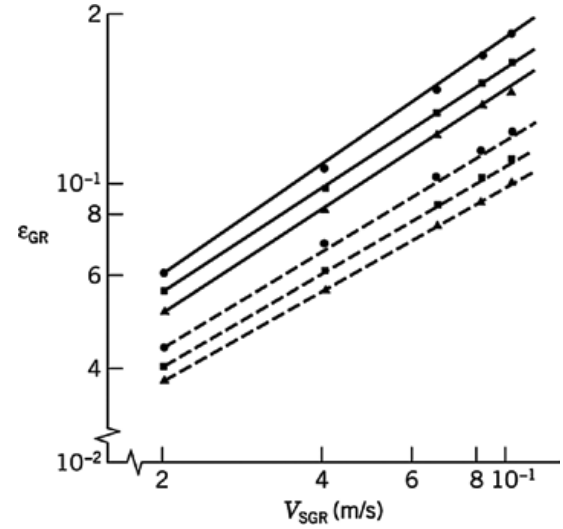

Figure 67.12. Gas holdup in an external-loop airlift bioreactor without (--------) and with (——) static mixers, in non-Newtonian starch solutions. ● = 0.5% w/v × 2.5 w/v; ▲ = 4.0 w/v. *Source*: Reprinted from Ref. 25, with permission from Springer-Verlag, Germany.

TABLE 67.3. Ratios Between Parameters a and b in Equation 67.24 in the Configuration with and without Static Mixers for an External-Loop Airlift Bioreactor

liquids. Also, they affect the values of the coefficient a in equation 67.24 in a greater measure than those of b. Therefore, larger values of gas holdup in columns with static mixers resulted because of smaller bubble sizes and hindering action of the packing, which contribute to increasing the gas phase residence time (21,31).

67.3.4 Liquid Velocity

The presence of static mixers changes the liquid circulation rates, because they act as supplementary resistances in the flow path. Besides changes in gas flow pattern, the presence of static mixers in gas–liquid contactors having a net liquid flow (continuous bubble columns, airlifts, contactors with a liquid jet) changes the liquid circulation velocities, their effects being complementary to those of several other parameters, including gas superficial velocity, gas holdup, liquid phase viscosity, pressure drop along the flow path, reactor geometry. For instance, the static mixers mounted in an external-loop airlift bioreactor diminish the liquid

superficial velocity in the riser section both in Newtonian and non-Newtonian liquids. The parallel lines in the diagram presented in Fig. 67.13 show that in all cases the liquid velocity increases with gas superficial velocity. This behavior can be expressed by the following mathematical expression as:

$$\upsilon_{SL} = f\upsilon_{SG}^{m} \tag{67.25}$$

In non-Newtonian liquids, it was found that the presence of static mixers affects f and m values, dependent on consistency index values (25) (Table 67.4).

The relationship between the ratio of f values with and without static mixers, respectively, and the consistency index in an airlift contactor can be represented by the following relationship (25):

$$\frac{f_M}{f} = 0.85K^{0.008} \tag{67.26}$$

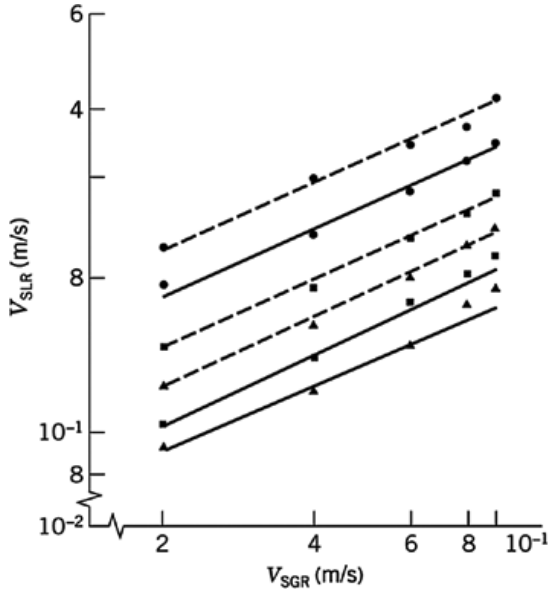

Figure 67.13. Liquid superficial velocity versus gas superficial velocity in an external-loop airlift bioreactor without (--------) and with (——) static mixers. Symbols as in Figure 67.12. *Source*: Reprinted from Ref. 25, with permission from Springer-Verlag, Germany.

The effects of the consistency index on the liquid velocity could be considered as being less significant proving that static mixers are effective in viscous liquids. Popovic and Robinson (32) found that the circulating liquid velocity in the riser section of an airlift reactor is dependent mainly on the downcomer-to-riser cross-sectional areas ratio, A_D/A_R, the apparent viscosity, η_{ap} and gas superficial velocity, as described by the following correlation:

$$\upsilon_{SLR} = c'\upsilon_{SGR}^{0.32}(A_D/A_R)^{0.97}\eta_{ap}^{-0.39} \tag{67.27}$$

Considering that equation 67.27 correlates well a large number of experimental data, it was found that the differences in the values of υ_{SLR} should be treated as particular cases of diminuation up to 40% of the geometrical parameter A_D/A_R, as a result of the presence of static mixers (25).

67.3.5 Mixing

As shown, homogenization in static mixers is attained by means of motionless elements using the flow energy of the fluids. The mixing effect depends on the continuous separation, distribution, and reuniting streams of material (5,7). The energy requirements of static mixers when used for mixing are lower than those of conventional dynamic mixers and, moreover, they are of simple construction. In the case of two components, the two quantities are related to each other by the volumetric flow rate ratio, $\dot{V}_2/\dot{V}_1$. The degree of mixing may be described using the variation coefficient $s/\overline{C}_V$ or the relative standard deviation s/τ_0 (5). For component 1, the following expression held:

$$s_1/\overline{C}_V = \sqrt{\dot{V}_2/\dot{V}_1}s_1/\tau_0 \tag{67.28}$$

where

$$s_1^2 = \frac{1}{n-1}\sum_{i=1}^{n}(C_{V_i} - \overline{C}_{V_1})^2 \tag{67.29}$$

$$\tau_0 = [\overline{C}_{V_1}(1 - \overline{C}_{V_1})]^{0.5} \tag{67.30}$$

$$\overline{C}_{V_1} = \frac{1}{n}\sum_{i=1}^{n} C_{V_{1,i}} \tag{67.31}$$

$$C_{V_{1,l}} = \dot{V}_{1,i}/(\dot{V}_{1,i} + \dot{V}_{2,i}) \tag{67.32}$$

The degree of mixing is strongly dependent on the static mixer type and normalized mixing length, L/D (Fig. 67.14). It can be seen that the Sulzer-SMX mixer and HI-mixer require shorter homogenization lengths. Also, the degree of mixing is dependent on the entry point

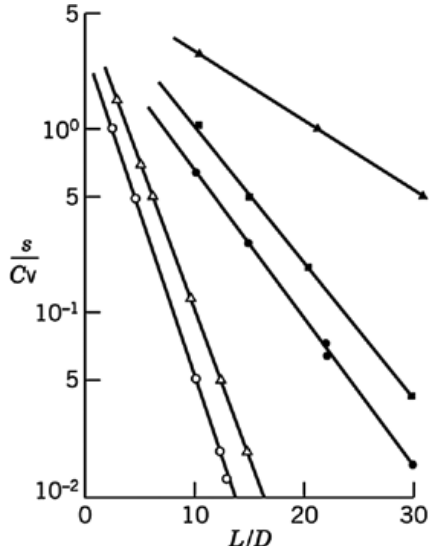

Figure 67.14. Variation coefficient as a function of the normalized mixing length for various static mixers. ● = Kenics; ◯ = Sulzer; ■ = Komax; ▲ = Lightin; △ = HI. $C_{V_1}^{-} = 0.1$; $Re_D < 1$. *Source*: Reprinted from Ref. 5, with permission from VCH Verlagsgesellschaft mbH, and from Ref. 7, with permission from Wiley-VCH.

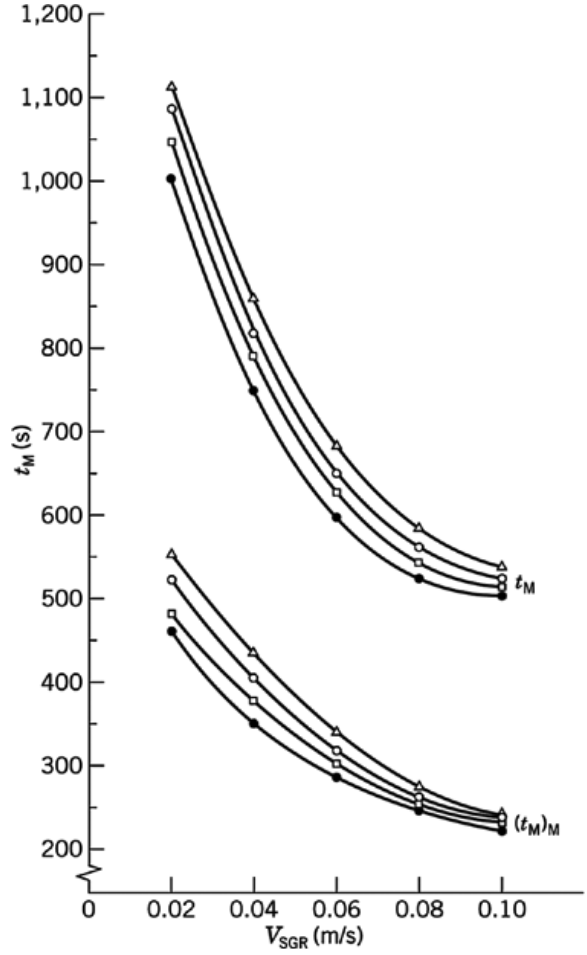

Figure 67.15. Mixing time versus gas superficial velocity in an external-loop airlift bioreactor without and with static mixers, operating with starch non-Newtonian solutions as liquid phase. ● = water; Starch solutions: □ = 0.5% w/v; ◯ = 2.5% w/v; △ = 4% w/v; *Source*: Reprinted from Ref. 34, with permission from Wiley-VCH.

of fluids to be mixed as well as by the operation scale (5). Static mixers achieve rapid mixing of fluids with low energy requirements, and the fluids may have either similar or different viscosity. Operation in fermentation processes involves very viscous fluids, and the flow will be predominantly in the laminar region for both liquid and gaseous phases. Suitability of static mixers to mix fluids of different viscosities was investigated in the literature (12,22,33,34).

Mixing behavior is usually described by mixing time, t_M, which is defined as the time required to achieve a definite degree of homogeneity after a trace pulse has been injected into the reactor (35). The mixing time is highly dependent on the presence of static mixers (34). In gas–liquid dispersions, the mixing time is dependent to a great extent on the gas superficial velocity and the presence of static mixers and to a low extent on the liquid phase properties. In Figure 67.15 the mixing time in water and starch solutions is plotted against superficial velocity. With static mixers, mixing times at a given superficial velocity are essentially up to 50% shorter than in the reactor without static mixers. The dependence of mixing time on gas superficial velocity can be expressed by the following equation:

$$t_M = k\upsilon_{SG}^{q} \tag{67.33}$$

The presence of static mixers does not affect q very much, but significantly influences k. Mixing times increase with increasing pseudoplasticity, but not very greatly (Fig. 67.15). In non-Newtonian systems, the consistency index had no significant influence on these parameters in the presence of static mixers (Fig. 67.16).

Other properties of a suitable static mixer are good radial mixing on as short as possible flow path and as low as possible axial mixing. Some static mixers contribute to diminish axial dispersion and influence the residence time distribution in laminar monophasic liquid flow, dependent on the Reynolds values (6). In the presence of static mixer seen in Figure 67.1c, the pulse response at the tube exit indicates a smaller axial dispersion (Fig. 67.17) (6). Also, the dead zones are diminished, and the distribution function of the elements of fluids with ages less than the residence time indicates an evident equalization of the residence times in laminar flow (Fig. 67.18) (6). In turbulent flow regimes, this effect is not very important. A good radial mixing

of a static mixer does not imply in all cases also low axial mixing. The individual static mixers display a different dependence of the axial dispersion on the flow rate of the phases both for single and two-phase flow system. A good static mixer from the standpoint of axial dispersion in single-phase flow does not necessary display a low axial dispersion in two-phase flow (12). Data on axial mixing for the individual types of static mixers are usually missing in the literature. Fialova *et al*. (12) presented the value of the Péclet number given by Sulzer for its SMX product ($Pé > 110$, $d = 0.1$ m; $L/D = 22$). These properties can be ascertained by experimental means.

67.4 MASS TRANSFER IN PRESENCE OF STATIC MIXERS

The application of the static mixers built in nonmechanically bioreactors, especially in aerobic bioprocesses, should

Figure 67.18. lead to attain the most extensive transport rate of oxygen into the liquid phase at the low possible energetic requirement. The influence of static mixers on hydrodynamic behavior has an important impact on mass and heat transfer characteristics and transfer rate intensification. The improvement of the oxygen mass transfer in bioreactors depends on a number of factors, such as bubble formation, bubble size distribution, bubble shear, gas holdup, rate of coalescence, and breakup. Also, bubble or drop coalescence behavior in gas–liquid dispersions, especially in viscous fluids, demonstrates the necessity for redispersing the gaseous or liquid phase to prevent the reduction of interfacial areas and mass transfer rates. A general solution to the mass transfer problems that appear in gas–liquid systems can be the use of static mixers installed at different intervals for increasing the degree of the gas dispersion and mass transfer rates (7,33,36). Usually, the intensity of oxygen transfer is characterized by its volumetric mass transfer coefficient, *Kla*. Static mixers improve *Kla* at any given gas flow rate relative to the bioreactor configuration without static mixer (7). The mass transfer rates are very high during bubble formation, and the values of mass transfer coefficient vary significantly being associated with large surface renewal rates. Coalescence and break-up, bubble formation, bubble shear, and turbulent liquid surface are examples of conditions where mass transfer coefficient is large. The introduction of static mixers has two important roles in *Kla* enhancement:

1. Bubble redispersion produces increased values of interfacial areas, a.

2. The interfacial turbulence during bubble coalescence and redispersion increases Kl.

At low gas flow rates, the latter mechanism becomes important (37). Small bubble size can be obtained with a homogeneous bubble distribution over the column cross-section and with a narrow size distribution. However, small rigid bubbles less than 2 mm in diameter have frequently been found to have much smaller mass transfer coefficients (38). Several studies were presented concerning the influence of the Sulzer type (22,33,36,39), Koch (10,11,20,24,40), Kenics (29,30) on *Kla* in bubble columns and external-loop airlift bioreactors in waterlike fluids as well as in non-Newtonian pseudoplastic media. Static mixers significantly enhance the mass transfer rates in waterlike fluids (Fig. 67.19). In non-Newtonian systems, the improvement in *Kla* due to static mixers depends on the rheological parameters. Stejskal and Potucek (30) and Chisti *et al*. (39) mounted static mixing elements in the risers of internal- and external-loop airlift reactors that enhanced mass transfer in viscous pseudoplastic CMC aqueous solutions that simulated the rheological behavior of filamentous biofluids. In pseudoplastic liquids, the thicker the fluid was, that is, the higher its value of the consistency index, K, the greater the effect of the static mixer was on *Kla* (36,39). Usually, the accumulation of biomass or product in the culture medium leads to increased viscosity and non-Newtonian flow characteristics that contribute to diminish *Kla* (26). This leads to a drastic decrease in oxygen transfer capability, and the aerobic culture eventually becomes oxygen limited (33,41). The significant decrease in *Kla* is mainly attributed to the formation of large bubbles and a decrease in specific interfacial areas that can be counterbalanced by the static mixers presence. The values of *Kla* can be correlated with the gas superficial velocity, v_{SG}, in tower bioreactors as

$$Kla = u v_{SG}^{t'} \tag{67.34}$$

The presence of static mixers affects u and t' values. They do not affect t' very much, but significantly enhance u dependent on the consistency index (Fig. 67.20) (36). The degree of *Kla* enhancement depends on the fluid viscosity and the pattern of fluid circulation through the reactor. The results of Hsu *et al*. (20) also show that mass transfer coefficient in a bubble column in the presence of Koch type static mixers is improved. A comparison of the oxygen transfer efficiency in terms of kilograms of oxygen transferred per kilowatt hour consumed at low flow rates indicated that the Koch mixed column was almost twofold as efficient as the empty column. However, at high gas flow rates, the efficiency was about the same for the two columns. Also, the ratio Kla/P_G can be used to characterize the efficiency of energy utilization for mass transfer per unit volume of the liquid phase or dispersion. Potucek (29) found that an airlift bioreactor with static mixers showed higher Kla/P_G values for absorption of oxygen in water or polyacrylamid solutions in the region of gas velocities of $v_{SGR} = 0.01 - 0.06$ m/s. Also, in the batch yeast cultivation, Kla/P_G was larger than in the witness bioreactor; gas superficial velocities ranged from $v_{SGR} = 0.03 - 0.06$ m/s, whereas with $v_{SGR} = 0.01 - 0.03$ m/s, lower values of Kla/P_G were obtained. As energy costs increase, more capital should be allocated to motionless mixers that increase the mass transfer efficiency. Olivier and Oosterhuis (22) considered that by keeping liquid and gas velocities as well as the volume ratio of empty tube parts and internals constant, the oxygen transfer would be higher and nearly independent on the scale. They also considered that oxygen transfer takes place not only in the internals, but also in the empty tube parts, and correlated the overall oxygen transfer coefficient as (22):

$$Kla = \frac{(Kla\, V_M)_{\text{internals}} + (Kla\, V_E)_{\text{empty tube}}}{(V_M)_{\text{internals}} + (V_E)_{\text{empty tube}}} \tag{67.35}$$

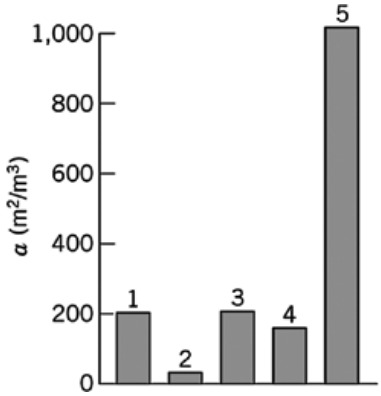

Figure 67.21. Comparison of specific interfacial areas in different gas–liquid contacting devices. 1 = Baffled agitated tank; 2 = bubble column; 3 = packed tower; 4 = plate tower; 5 = static mixers. *Source*: Data from Ref. 42.

The results obtained in different gas–liquid contactors show larger interfacial areas in the systems with static mixers (42) (Fig. 67.21). Data also indicate that the static mixer contactors are superior to other nonmechanically contacting devices, regarding mass transfer coefficient. Hsu *et al*. (20) investigated mass transfer in a bubble column with Koch mixers comparative to that with sieve trays. They found a different dependence of *Kla* on gas superficial velocity:

$$\text{for KOCH mixed column} : Kla \approx \upsilon_{SG}^{0.95} \tag{67.36}$$

$$\text{For sieve-tray bubble column} : Kla \approx \upsilon_{SG}^{0.89} \tag{67.37}$$

Also, data presented by Atkinson and Mavituna (42) show that in static mixed gas–liquid contactors a larger range of high Kla/V values was obtained, compared to those resulted in other gas–liquid contacting devices (Fig. 67.22).

The optimization of the number of motionless mixing elements and their positioning can enhance the mass transfer rates.

67.5 HEAT TRANSFER USING STATIC MIXERS

The role of the static mixers in heat transfer to flowing homogeneous or heterogeneous or heterogeneous fluids consists in fetching fresh fluid to the surface of the heat exchanger by promoting secondary flow, mixing, and turbulence (15). Most heat exchanger performances depend on hydrodynamics, and there are evident advantages that heat transfer may be enhanced by using built-in elements that change the velocity fields inside the tubes. Several studies investigated the heat transfer enhancement by using twisted strip inserts (43), helical static mixers (44,45), and wire matrix (15). The static mixers mostly used for heat transfer enhancement were helical static mixers,

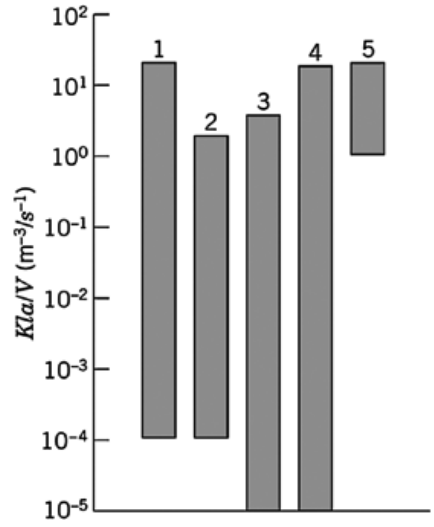

Figure 67.22. Comparison of different gas–liquid contacting devices regarding Kla/V values (significance of numbers as in Figure 67.21. *Source*: Data from Ref. 42.

which promote a secondary motion in the fluid, increasing the heat transfer between the fluid and the tube wall by convection.

The heat transfer performances of a given piece of equipment is usually estimated in terms of a Nusselt number, *Nu*, which is then related to the fluid properties and the Reynolds number, *Re*, characterizing the fluid environment. For instance, the individual heat transfer coefficient α_1 for the inside surface of a tube equipped with a helical static mixer is assessed from the following expression (44):

$$Nu_1 = \frac{\alpha_1 D}{\lambda_1} = \phi(Re_1, Pr_1, h/d, \eta W_1/\eta_1) \tag{67.38}$$

with

$$Re_1 = \frac{D\upsilon_1\rho_1}{\eta_1} \tag{67.39}$$

$$Pr_1 = \frac{c_{p1}\eta_1}{\lambda_1} \tag{67.40}$$

The overall heat transfer coefficient, K_T, of a tubular heat exchanger is related to the individual coefficients as follows:

$$K_T = \frac{1}{\frac{1}{\alpha_1}\frac{D_e}{D} + \frac{D_e}{2\lambda_s}\ln\frac{D_e}{D} + \frac{1}{\alpha_2}} \tag{67.41}$$

The values of K_T in a double-tube heat exchanger with hot water flowing through the annular space and cold water–glycerol solutions circulating through the inner tube containing helical static mixers were determined

using the individual heat transfer coefficients calculated with the following equations (67.44): For the tube ($90 \leq Re_1 \leq 5800$; $6 \leq Pr_1 \leq 5800$);

$$\mathrm{Nu_1} = 1.86\left(\mathrm{Re_1 Pr_1}\frac{\mathrm{d}}{\mathrm{L_T}}\right)^{0.33}\left(\frac{\eta_1}{\eta_{\mathrm{W_1}}}\right)^{0.14} \tag{67.42}$$

For the annular space ($Re_2 = 1520$):

$$Nu_2 = 1.02 Re_2^{0.45} Pr_2^{0.50}\left(\frac{D_e - D}{L_T}\right)^{0.40} \cdot \left(\frac{D_e}{D}\right)^{0.80} Gr^{0.05}\left(\frac{\eta_2}{\eta_{W_2}}\right)^{0.14} \tag{67.43}$$

Lecjacks *et al*. (44) reported the following relationship for helical elements of continuous and Kenics type:

$$Nu_1 Pr_1^{-1/3}\left(\frac{\eta_{W_1}}{\eta_1}\right)^{0.14} = \alpha_1 Re_1^{n_1} \tag{67.44}$$

with

$$\alpha_1 = \phi_a\left(Re_1, \frac{h}{D}\right) \tag{67.45}$$

and

$$n_1 = \phi_n\left(Re_1, \frac{h}{D}\right) \tag{67.46}$$

Also, they extended their investigations in the turbulent flow regime, which allowed them to assess the favorable effect of the built-in elements on heat transfer, especially in the laminar regime, for low values of h/d in Kenics static mixer. In the continuous helical static mixer, an increase in friction factor and heat transfer coefficient of 4.4% and 5.3% was obtained, whereas in the Kenics insert this increase was of 19.3% and 10.2%, respectively, comparative with the empty tube (45). Therefore, the heat transfer coefficient was found to be dependent on the flow conditions and geometrical properties of the internals. Olivier and Aldington (15) found a noticeable heat transfer enhancement by factors up to five in round tubes containing wire matrix turbulators, comparative to the empty tube, in laminar regime. Also, the wires caused the falling of the effective viscosity in non-Newtonian solutions at high liquid flow rates. Static mixers are used for thermal homogenization when a breakdown can occur on the heat transfer surface, especially in viscous media. Shear-thinning fluids should give good heat transfer/pressure drop behavior in the presence of tube inserts because the viscosity is reduced in the higher shear rates that are obtained. Static mixers are insensitive and nonresponsive to temperature. They can be well sealed against the surroundings. Maintenance and wear are small, and they are very economical, because they do not require additional space (in-line disposed).

67.6 SCALE-UP CONSIDERATIONS

Static mixers are used for many monophasic or gas–liquid, two-phase operations, which involve momentum, mass, and heat transfer. They are largely used in biotechnology and other applications such as processing of natural gases, wastewater treatment, dissolution of gases, continuous mixing of mutually soluble fluids of different viscosities, and so on. It is widely agreed that static mixers are suitable to mix fluids of very widely different viscosities, being especially effective for use with highly viscous fluids. They also could remove any mistakes made by the equipment designed for heat and mass transfer.

As shown in the fermentation field, factors taken into consideration on the choice and the design of an equipment for a definite process, besides the general factors, should include the population safety and damage, the uniform distribution of the phases and energy in phase transfers, the oxygen demand of the aerobic cultures, and so on (4,7). Static mixers can fulfill these objectives. Their action gives rise to elementary fluid layer formation. The maximum thickness of an elementary layer is given by the following expression (16):

$$\delta = \frac{D}{n} = \frac{D}{ca^{\mathrm{N}}} \tag{67.47}$$

As in the case of any apparatus, the static mixer behavior is tested first in small-scale equipment and then designed for large-scale operation, on the basis of the experimental data acquired for the model. For geometric similarity between the model and the actual mixer, the same degree of mixing means that (16):

$$\delta_m = \delta_a \tag{67.48}$$

or

$$\frac{D_m}{ca^{N_m}} = \frac{D_a}{ca^{N_a}} \tag{67.49}$$

Boss and Czastkievicz (16) introduced a linear scale-up coefficient, expressed as follows:

$$S = \frac{D_m}{D_a} \tag{67.50}$$

when equation 67.49 becomes

$$N_a = N_m + \frac{lgS}{lga} \tag{67.51}$$

This reasoning is valid in the laminar flow regime. For constant physicochemical properties of the fluids that flow through the model and the actual mixer, the changes in Reynolds number for the actual mixer relative to the model can be attributed to modifications occurring in the flow rate of the fluids or in the diameter of the static mixer. The relationships between the volumetric flow rates and Reynolds numbers in the model and the actual mixers, respectively, are as follows (16):

$$\dot{V}_a = \frac{z_m}{z_a} \frac{S^3}{1 + \lg S/N_m \, lga} \dot{V}_m \tag{67.52}$$

$$Re_a = \frac{z_m}{z_a} \frac{N_m}{N_a} S^2 Re_m \tag{67.53}$$

These general equations, applicable to scale-up of mixing processes in static mixers, are inferred starting from the pressure drops associated with laminar flow of a Newtonian fluid through circular pipes, which are taken into account by the pressure drop coefficient z, defined in equation 67.9. Boss and Czastkievicz (16) gave several examples of scale-up calculations for some types of static mixers, namely Kenics, Ross-ISG, and Sulzer.

67.7 CONCLUDING REMARKS

An overview of the published results on transfer processes in fluid flow through static mixers has been presented in the preceding pages. The velocity fields inside a tube containing motionless mixers can be modified using static mixers. As a result, a significant enhancement in mixing, mass, and heat transfer are achieved. Static mixers can be used in chemical and biochemical processes to perform a rapid mixing of monophasic, diphasic, and poliphasic systems with low energy requirements, and the fluids may have similar or different viscosities. The energy for mixing is extracted from the fluid flowing through the mixers. Static mixer effects result from specially designed flow arrangements, cutting and twisting, displacement and distortion, or separation and expansion. Significant efforts are devoted by specialists for developing new static mixers and optimal strategies for using minimum number of static mixers located at different positions in tubes, to ensure greater efficiency on transfer processes intensification, especially mixing and oxygen transfer in aerobic fermentation processes.

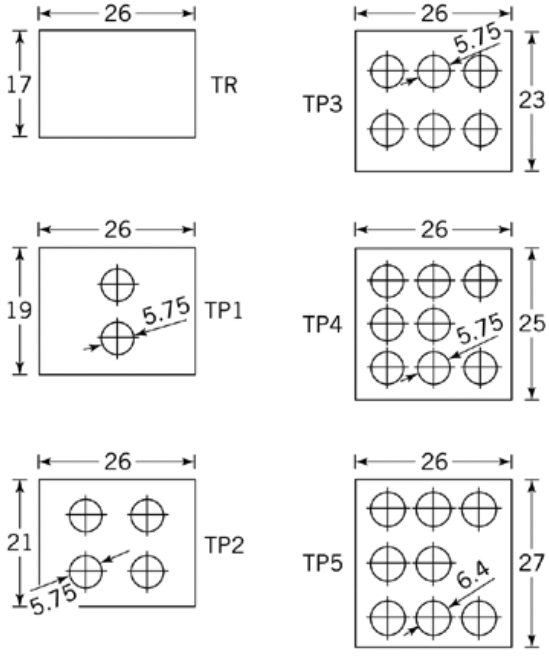
TRANSFER PHENOMENA IN MULTIPHASE SYSTEMS

RODICA-VIORICA ROMAN
Chemical Pharmaceutical Research Institute, Iaşi, Romania

68.1 INTRODUCTION

The dispersion of gases and solids in liquids is one of the most commonly applied processes of chemical engineering, and the fully baffled stirred vessel is one of many types of equipment used for this purpose. The hydrodynamic regime of the impeller controls the mixing performance of the whole reactor, as is reflected in phases of homogenization, the intensity of local energy dissipation distribution in the region of severe shear conditions, the retained gas fraction, bubble size, solid concentration distribution, mass transfer, and heat transfer (1–3). Good understanding of the dispersion mechanism of the impeller is indispensable for a reliable prediction of the behavior of the multiphase system flow in the reactor as a whole.

In multiphase processes carried out in stirred vessels, interphase mass transfer is often an important step and may be rate determining for the overall process. In aerobic fermentation systems, the oxygen transfer from the gas phase to the surface of the microbial cells is of primary importance, especially at high cell densities when microbial growth is likely to be limited by the availability of oxygen in the liquid phase (4–6). For many years, a set of radial flow Rushton disk turbine impellers of roughly one-third of the standard reactor diameter has been considered the optimum design for the multiphase system mixing, including fermentation processes. Mass transfer cannot be improved by increasing the specific power consumption or the aeration rate above certain limits, both of which lead to increased overall costs, but only by a modification of the blades of the impellers or by the development of impellers that allow a better bulk mixing with a minimum power consumption.



It has been reported (7) that a simple modification of the blades of a Rushton turbine through increase in the blade height simultaneously with perforation of the blade surface could significantly diminish power consumption and improve oxygen transfer efficiency in either a nonbiological system or in an antibiotic biosynthesis process.

68.2 DESCRIPTION OF THE MODIFIED RUSHTON TURBINE AGITATORS

The modified blades were obtained by increase in the conventional (standard) blade height simultaneously with perforation of the blade surface. Five modified blade turbine types (denoted TP1–TP5) were investigated; these are characterized by the fact that the number of perforations and their size varied and that the filled surface of the modified blades is equal to the blade surface of the standard Rushton turbine (TR) (Fig. 68.1) (7,8).

The application of perforations to the modified blades decreases the pathway between successive shearing actions on the liquid streams, increasing the number of times that the fluid is sheared. This effect has direct implications on local bubble size distribution in a gas–liquid mixture, which develops as a result of the balance between the complementary processes of dispersion and coalescence. The surface fraction of the perforations, defined as the ratio between the area S_G of the perforations on the surface and the full surface area S_C of the blade is in the range of 0 to 0.588. The

modified blade turbines do not require any modification in the electrical motor and drive assemblies and are simple to manufacture. The experiments were carried out in a transparent vessel of inside diameter $D = 0.25$ m, with a flat bottom and four symmetrical wall baffles of width $w = 0.1\,D$. Fluid mixing was carried out by conventional and modified blade turbines, positioned singly (1TR, 1TP1–1TP5) or doubly (2TR, 2TP1–2TP5) on the same shaft.

68.3 MULTIPHASE SYSTEM HYDRODYNAMICS

68.3.1 Gas–Liquid Dispersing Characteristics

The hydrodynamic regimes were defined by reference to the distribution of the gas phase in the vessel. For an air–water system, the flow regimes were detected through visual observation of the zone close to the outer edge of the TR and TP1–TP5 turbines (8). In the single-turbine configurations, the three classical regimes (9,10) were observed: flooding (F), loading (L), and complete dispersion (CD). For a double-turbine system, two hydrodynamic configurations were defined in the upper zone: ineffective dispersion (DI) and effective dispersion (DE), respectively; the transition between the hydrodynamic regimes corresponds to the rotational speed at which the bubbles have a radial velocity sufficient to reach the vessel wall. The gassed power consumption, P_g, is usually determined by varying the operational parameters: the volumetric flow rate, Q_g, and the impeller speed, N.

The curve representing the ratio P_g/P as related to the gas flow number presents maximum and minimum points when the volumetric gas flow rate is kept constant. Each of these extreme points corresponds to a gas–liquid hydrodynamic regime in the impeller region. The power curves change notably when the power consumption is expressed as a power number. Interesting results were obtained by plotting the gassed power number $(\mathrm{Ne})_g$ against the impeller speed N, when the aeration rate Q'_g, expressed as volumetric flow rate of gas per minute/volume of liquid (vvm) was kept constant. These results are presented in Figures 68.2 and 68.3 for mixing systems having one or two turbines, respectively. Table 68.1 explains the symbols used in Figures 68.2 and 68.3.

In the range of low N values, the power number for a single turbine decreased with increasing impeller speed until a certain point: subsequently, it increased suddenly in the case of the standard blade turbine and slowly in the case of the modified blade turbines. The impeller speed at which the transition between these two zones occurred was very close to the transition impeller speed between flooding and loading of the turbine. For two turbines on the same shaft, clear delimitation between the two zones of the impeller speed was not apparent (Fig. 68.3). The $(\mathrm{Ne})_g$ values decreased slowly with increasing impeller speed until the agitation system exceed the flooding state of the bottom turbine. In the range of large N values, when the gas dispersed uniformly through the entire vessel section, the gassed power number became independent of the impeller speed, as it was a function of aeration rate and geometrical configuration of the mixing system only. The variation in the power number depending on the surface fraction of the perforations, which indicates the geometry of the mixing system, is presented in Figure 68.4.

The range of power number for an individual Rushton turbine reported in the literature (11) is $\mathrm{Ne} = 4.8 - 6.3$ for

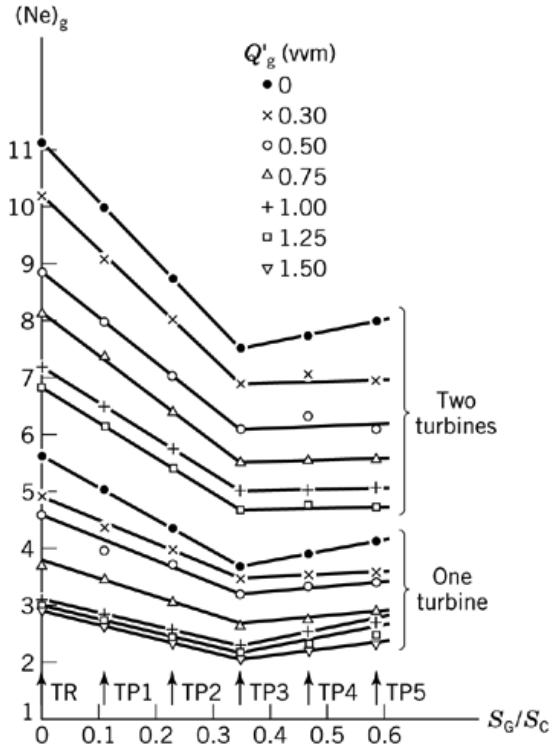

Figure 68.4. Variation in the power number depending on the surface fraction of the perforations (S_G/S_C) at various aeration rates ($Q_g^{'}$). (*Source*: From Ref. 8, with permission.)

$Q'_g = 0$. In our case, the value Ne = 5.5 for a single Rushton turbine is in good agreement with these data. The Ne values for Rushton turbines are dependent on a scale (12), and for a mixing system in which the geometrical symplexes deviate from the standard values, the introduction of a correction factor of the power number is recommended (13,14). The Ne and $(Ne)_g$ values for all the modified blade turbines are smaller than those for the Rushton turbine, as a result of the change in fluid flow around and over the blades and of the minimization of the drag forces associated with the motion of blades such that the energy losses due to form drag are very low. These results imply that it is possible to rotate the modified blade turbines much faster than the standard Rushton turbine at an equal specific power consumption. The TP3 modified blade turbine, with the surface fraction S_G/S_C of the perforations equal to 0.353, has the smallest gassed and ungassed power number values, these being reduced by approximately 50% in comparison with the standard Rushton turbine. The increase in the surface fraction of the perforations over $S_G/S_C = 0.353$ is not justified on the basis of the power consumption.

For double turbines, the power number values are approximately twice those obtained for the single turbines, irrespective of the turbine type, at constant aeration rate Q'_g. This shows that, in the case of two identical turbines, the power consumption P_g is twice that obtained using a single turbine: this is possible because, if Q'_g is kept constant, the volumetric gas flow rate, Q_g, ($m^3\ s^{-1}$) is 60% higher when the liquid volume is higher (Table 68.1). Also, the power consumption of two TP3 modified turbines is reduced by 50% in comparison with the double standard Rushton turbines. Because the surface of each modified blade increases simultaneously with the S_G/S_C ratio, it is to be expected that a larger gas volume is retained in the ventilated cavities behind the modified blades and dispersed afterward. Therefore, the modified blades have a greatly increased gas-handling capacity: the TP3 turbines handle more than 35% more gas than do the standard Rushton turbines at the same specific ungassed power consumption, before flooding or ineffective dispersion.

68.3.2 Suspension of Solid Particles in Liquid

Three suspension states can be defined, as follows (15):

1. Incomplete suspension, in which a part of the solid phase is deposited on the bottom of the vessels
2. Complete suspension, in which all particles are in suspension
3. Homogeneous suspension, in which the particle concentration is uniform throughout the vessel

Many earlier investigations concentrated on the impeller speed for complete suspension, when the maximum surface area available for processing is achieved (15–18). The most widely used criterion to describe solids suspension in mechanically agitated vessels is the just-off-the-bottom suspension condition, first described by Zwietering (19).

In this section, an attempt is made to understand the effects of the physical and rheological properties of the suspensions and number and turbine types on the complete suspension speed and on the power dissipation at complete and homogeneous suspension states of the solid particles (20). The solid particles used are $CaCO_3$, a cation exchange resin (Amberlite IR-120 type), and an anion exchange resin (Amberlite IRA-410 type). A range of density differences $\Delta\rho = (\rho_s - \rho_L)$ between 150 and 1,200 kg/m^3 was examined. The ion exchange resin particle shape is spherical, the particle size distribution being measured by a microscopic method. The change in particle size during the experimental run was negligible. The surface-to-volume (Sauter) mean diameter of the particles, d_p, was calculated for the ion exchange resin particles. In the $CaCO_3$ suspension, the mean diameter of the particles was 15 μm (21). The particle concentration, X, was between 20 and 150 kg/m^3 for each particle type used. The physical properties are given in Table 68.2. The suspensions used are pseudoplastic in behavior. The rheological properties of suspensions depend

Source: Ref. 20.

on the particle size and the concentration of solids. Rheological data of the suspensions were obtained with a rotational cylinder viscosimeter (Rheotest-2.1) and were fitted according to the power law model (22). The rheological parameters, consistency index, K, and flow behavior index, n, are also presented in Table 68.2. The definition of complete suspension speed, N_{js}, was taken as the speed at which no particles were visually observed to remain at rest on the vessel bottom for more than 1 or 2 s (19). The last particles to be suspended were located near the center of the vessel base and also behind the baffles. The experimental relationships between complete suspension speed and solid concentrations are shown in Figure 68.5 for each of the five particle types and for modified and standard turbines positioned singly or doubly on the same shaft.

For the same operation conditions, the N_{js} values for the TP3 modified turbine are slightly higher than those for the standard turbine. Also, Figure 68.5 shows that, independent of the agitator type, N_{js} actually is increased when two turbines are used, as was also observed by Armenante (23). Although the phenomenon of solid suspension off the vessel bottom is largely dominated by the lower impeller, the presence of two turbines modifies the flow pattern in the vessel.

In all geometrical systems, the N_{js} values are found to increase with solid concentration. This increase of the N_{js} value may result from an increase of probability to find particles at rest on the bottom as the number of particles in suspension increases. It was observed that at N_{js} the concentration of the solid particles in the zone near the bottom is considerably higher than the average value in the vessel. The physical background of the concentration effect is the increased power dissipation by presence of solid particles in the turbulent field (24). The particles can interfere with the turbulent field via two routes. (*1*) Because of their inertia, particles do not follow the motion of the liquid. Consequently, the kinetic energy of a particle changes continuously. Acceleration of a particle occurs at the expense of energy from the turbulent eddies, whereas deceleration leads to energy dissipation in the form of heat. (*2*) At high solids concentration, the particles will also interfere with each other (collison and/or hindrance). In a similar way, this will lead to increased dissipation of the energy of the turbulent eddies. Thus, for the point of complete suspension to be maintained, a higher solid concentration requires a higher power input to the systems.

Figure 68.6, where the power consumption expressed as power number for complete suspension condition $(Ne)_{js}$, is plotted against the Reynolds number Re, demonstrates that in the vessel equipped with the modified blade turbines, single or double, the $(Ne)_{js}$ values are approximately 30% lower than those in the standard vessel. In these plots, $(Ne)_{js}$ and Re numbers are calculated using the properties of the suspensions. The $(Ne)_{js}$–Re representation based solely on liquid properties is inadequate (25), because at the highest solids concentration laminar or transition range appear to persist up to very high Reynolds numbers. By using a suitable apparent viscosity for the solid–liquid suspension, it is possible to condense all the data in the adequate range. In our case, the Reynolds number values

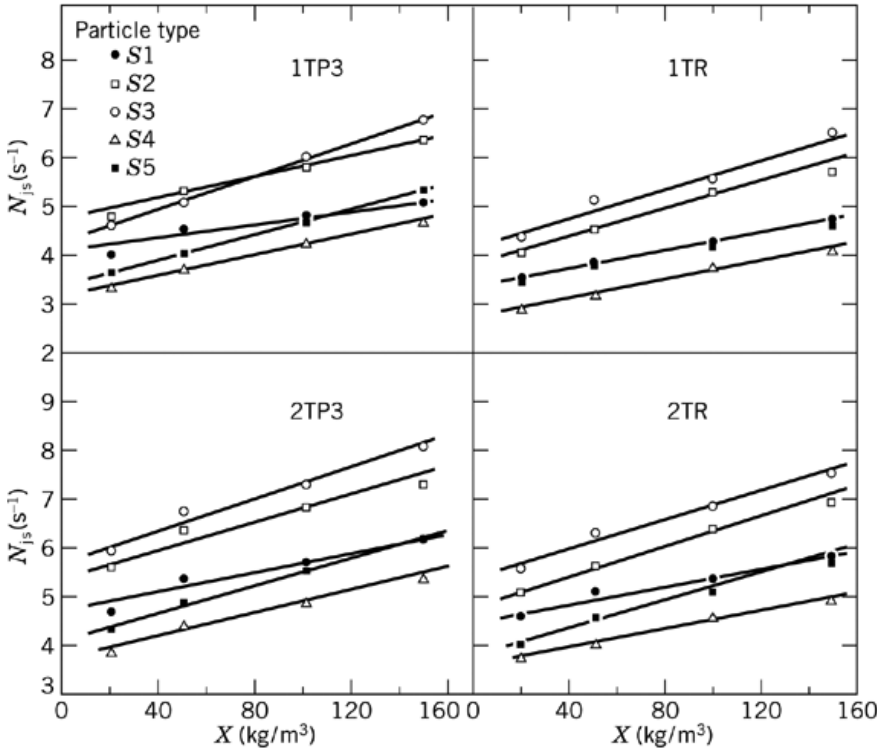

Figure 68.5. Effect of solid concentration on complete suspension speed for standard and modified Rushton turbines, positioned singly or doubly on the same shaft. S1–S5, particle types (see Table 68.2). (*Source*: From Ref. 20, with permission.)

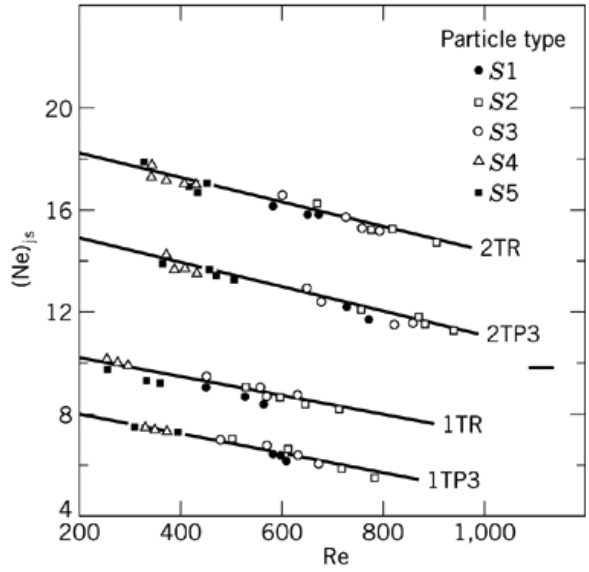

Figure 68.6. Relation between the power number and Reynolds number (Re) at the complete suspension state, for standard and modified Rushton turbines, single or double. (*Source*: From Ref. 20, with permission.)

for complete suspension condition are in the transition range ($Re < 1000$); the $(Ne)_{js}$–Re dependency has a negative slope.

The main reason for the smaller power number of modified blade turbines is the change of suspension flow around and over the blades. The fluid flow around the blades of the standard Rushton turbine was studied by Vant' Riet (26). Dead zones behind each turbine blade are formed. From these dead zones with the stagnation lines, the trailing vortex pair originates as a combined effect of the vortex motion at the rear of the vertical inner edge of the blade and the wrapping of the vortex sheets behind both horizontal edges. In the case of the modified blade turbines, the fluid jets penetrating the perforations, eliminate the stagnation lines and change the conditions of the trailing vortex formation.

When all the observation are combined, the following correlation is evident between complete suspension speed and the physical and rheological properties of the solid particles:

$$N_{js} = c d_p^{0.2} \Delta\rho^{0.45} X^{0.13} K^{0.1} \tag{68.1}$$

The exponents of d_p, $\Delta\rho$, and X are essentially the same as those reported by Zwietering. The correlation, equation 68.1, includes the consistency index K as a pseudo-viscosity of the suspensions. The value of the dimensionless constant, c, is specific for each of the geometrical configurations studied. The influence of the turbine type and number of the turbines on N_{js} can be

expressed by incorporation of two dimensionless groups, namely $(1 + S_G/S_C)$ and $n_p/6$ (S_G/S_C is the surface fraction of the perforation and n_p is the number of blades of the mixing system). Using nonlinear least squares regression, the following correlation was established:

$$N_{js} = 1.1 d_p^{0.2} \Delta\rho^{0.45} X^{0.13} K^{0.1} (1 + S_G/S_C)^{0.2} (n_p/6)^{0.25} \quad (68.2)$$

In the turbulent range (Re > 1000), when $N > N_{js}$, the particle concentration is uniform throughout the vessel, and power number in solid–liquid system, $(Ne)_s$, is constant.

In the vessel equipped with a standard turbine, the maximum value of the Reynolds number is 1,800; for the modified blade turbine, the maximum Reynolds number is 2,400. This is possible because the modified blade turbine rotates much faster than the standard turbine at an equal specific power input (11). The relation between the mean values of the power number and the physical properties of the solid particle, in the turbulent range, is

$$(Ne)_3 = 5.6175(n_p/6)(1 + S_G/S_C)^{-1.3867} \cdot (1 + 10 d_p^{0.2} \Delta\rho^{-0.45}) \quad (68.3)$$

The estimated error using equations 68.2 and 68.3 lies within ±10%.

68.3.3 Effect of Particles on Gas–Liquid Hydrodynamics

Establishment of the major interactions between gas dispersion and particle suspension mechanisms is a basis for examining in detail the effect of the major variables on the minimum agitator speed for particle suspension under gassed conditions and on the minimum agitator speed for gas dispersion to all parts of the vessel in the three-phase systems.

The manner in which the presence of the particles affects the gas dispersion is inferred from the variation of the relative power consumption P_{gs}/P_s (P_{gs} and P_s are power consumption in gas–liquid–solid and solid–liquid systems, respectively), with gas flow rate, Fl, which is associated with different stages of cavity growth behind the impeller blades. In the curves presented in Figure 68.7, for various volumetric gas flow rates and concentrations of the S5 type solid particles for 1TR and 1TP3 turbines, the transition to complete gas dispersion is obtained when a minimum occurs in P_{gs}/P_s and the cavity sizes are maximum (27). For the 1TR turbine, the maximum values of P_{gs}/P_s are between 0.5 and 0.3 for all solid concentrations and depend on the volumetric gas flow rate. The 1TP3 turbine shows a behavior similar to that of 1TR turbine but only at $X = 20$ kg/m^3 and $X = 50$ kg/m^3. At $X = 100$ kg/m^3 and $X = 150$ kg/m^3, the minimum values of the P_{gs}/P_s for 1TP3 are approximately 0.5, irrespective of the volumetric gas flow rate. This confirms previous observations (8) as regards the fact that the modified blades have a greatly increased gas-handling capacity.

Effect of particle concentration on power number in a three-phase system, $(Ne)_{gs}$, at constant superficial gas velocity is presented in Figure 68.8 for the S2 type ion exchange resin, in modified turbines, single or double. A decrease in power number at $N < N_{jsg}$ (jsg is the moment of complete solid suspension) is due to the "false bottom" formed by the particles effectively reducing impeller clearance at low speeds. As the agitator speed N tends to N_{jsg} (as indicated in Fig. 68.8), the particles were suspended, the false bottom removed, and the power number tended to the common value. The power number generally increased as particle concentration increased before complete particle suspension had been obtained.

In the case of the 1TP3 turbine, the moment of the complete gas dispersion N_{CD} shifts into the range of smaller gas flow rates when the particle concentration increases. For two turbines (2TP3), the variation $(Ne)_{gs} = f$ (Fl) showed the following transition points: the transition to effective dispersion of the gas at the upper impeller (minimum point of the each curve) and also the flooding–loading transition of the bottom impeller (maximum point of each curve). The transition at complete gas dispersion does not show in Figure 68.8, probably because, once the particles are suspended, the increasing suspension density in the impeller region (and of the power consumption) compensates the decrease in power consumption because of large cavity formation.

The examination of the experimental data in correlation with the Reynolds number shows the following (27):

- For Re < 1,000, mixing is in the transition range, in which the $(Ne)_{gs}$–Re dependence has a negative slope.
- In the range 1,000–1,400 of the Reynolds number, the $(Ne)_{gs}$ values for 1TR attain a minimum point more pronounced for the lower solids concentration. In the case of the 1TP3 turbine, the variation of $(Ne)_{gs}$ with Re is negligible, as a result of the change in fluid flow around and over the perforated blade. The formation of the ventilated cavities behind the modified blades was influenced by the impact of the jets that come through the blade perforations.
- For Re > 1,400, $(Ne)_{gs}$ becomes independent of the Reynolds number, but depends on particle and agitator types. The mixing is in the turbulent range and the phases are uniformly dispersed within the entire vessel section.

The relation between the power number and the physical and rheological properties of solid particles is presented in Figure 68.9 for the 1TR turbine at various aeration

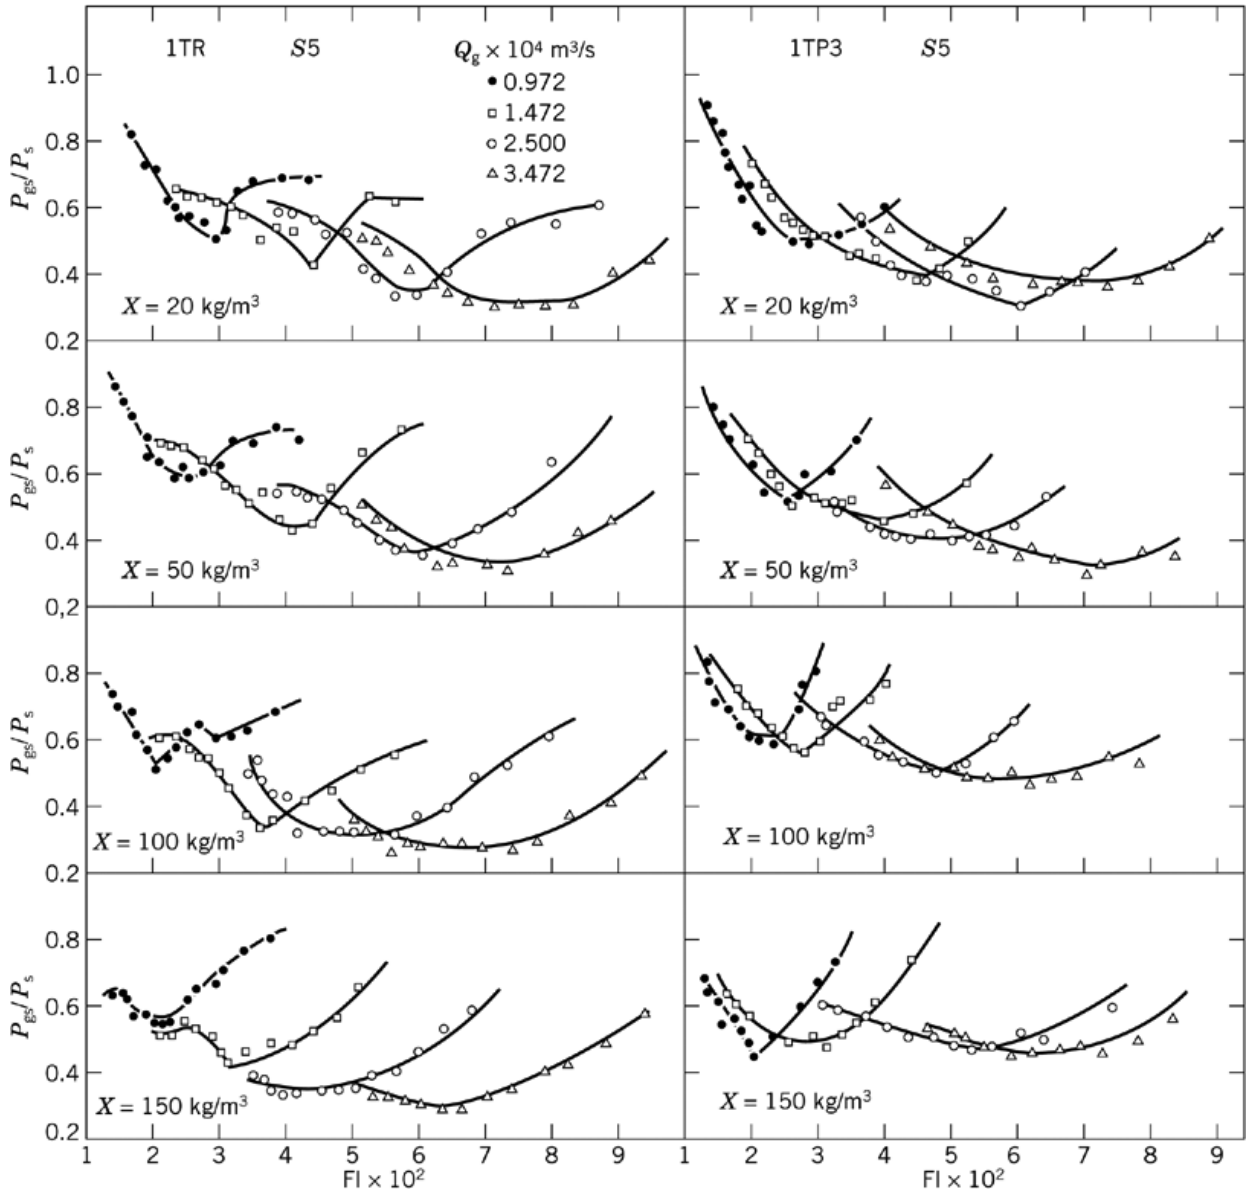

Figure 68.7. Relation between relative power consumption (P_{gs}/P_s) and gas flow number (Fl) for the S5 particles using single standard and modified turbines. (*Source*: From Ref. 27, with permission.)

conditions and for 1TP3, 2TP3, and 2TR turbines at constant aeration rate. For the same operation conditions, the modified blade turbines are more efficient, the power number $(Ne)_{gs}$ being reduced by 50% in comparison with the standard Rushton turbine.

68.3.4 Effect of Gas on Solid–Liquid Hydrodynamics

The effect of gas on solid–liquid hydrodynamics in mixing vessels was studied to determine the agitation speed required to just completely suspend all the particles under gassed conditions, N_{jsg} (28). The introduction of a small amount of gas into a solid–liquid system, for the just-suspended condition, causes slight sedimentation such that, for the same impeller speed, the particles were no longer just suspended (i.e., $N < N_{jsg}$). Further increases in the volumetric gas flow rate led to more sedimentation because the pumping capacity and ability of the impeller to circulate fluid and the power input decrease. Any decrease in pumping capacity and power input will decrease all the parameters that cause particle suspension: drag forces, energy dissipation, and associated turbulent eddies. An increase of the agitator speed to N_{jsg} ensured complete resuspension. Similarly, under gassed

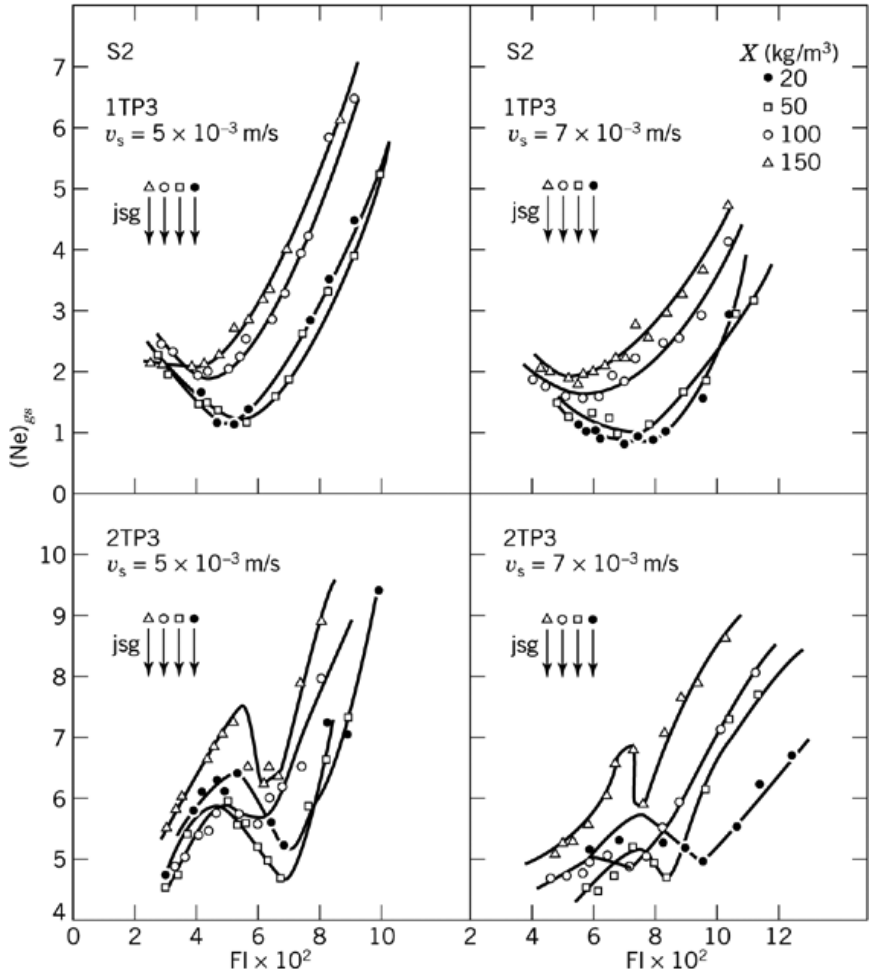

Figure 68.8. Variation of the power number with gas flow number for the S2 particles using modified turbines, single and double. (*Source*: From Ref. 27, with permission.)

conditions, if $N < N_{jsg}$, a reduction in volumetric gas flow rate gave complete resuspension. In fact, there is a unique combination of gas rate and impeller speed at which the just-suspended condition is achieved and which depends on the agitator type used.

If N_{jsg} is plotted against superficial gas velocity, v_s, the form of the curves is slowly parabolical, for any particle concentration (Figure 68.10). At superficial gas velocity of approximately 4×10^{-3} m/s, the slope of the dependence $N_{jsg} = f(v_s)$ decreases, demonstrating that the mechanism of the solid suspension changes. Indeed, this value of the superficial gas velocity is found around a gas flow number Fl = 0.03, when in gas–liquid systems, transition occurs between the clinging cavity regime and the large cavity regime (29,30). The presence of particles has no measurable effect on the formation of the gas-filled cavities.

As showed previously, for complete suspension to be maintained, a higher solid concentration requires a higher power input to the systems. The presence of the gas amplifies the effects mentioned, such that with increasing aeration rate, associated with increasing particle concentration, the agitator speed N_{jsg} must be larger (Fig. 68.11). The relationship for evaluation of the agitation speed required to just completely suspend all the particles under gassed conditions, N_{jsg}, takes into account the physical and rheological properties of suspensions, the aeration rate, and the equipment configuration (28).

68.4 MASS TRANSFER

The mass transfer process from the gas phase to the liquid phase is usually expressed in terms of the volumetric mass transfer coefficient, Kla. The determination methods of the volumetric oxygen transfer coefficient are divided by Rainer (31) into indirect methods, applied without biological system (gassing-out, electrode momentum, sulfite oxidation, carbon dioxide, and glucose oxidase

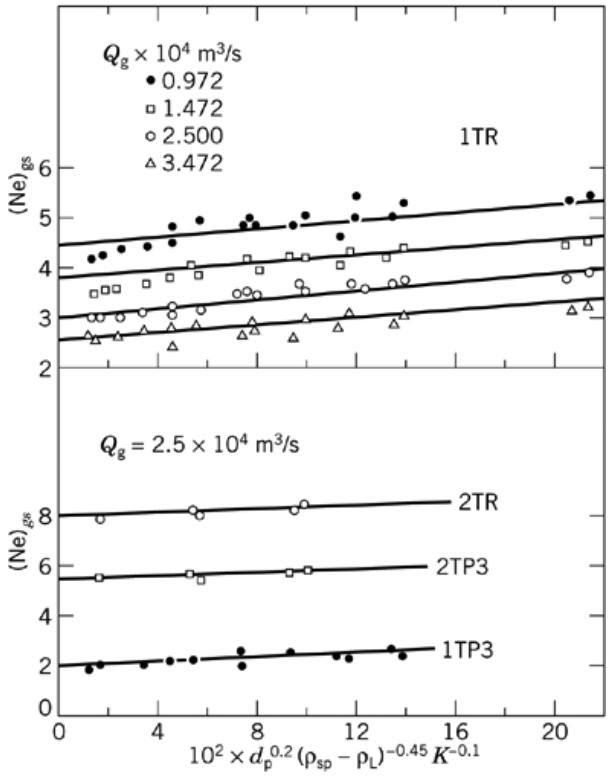

Figure 68.9. Relation between the power number and the physical and rheological properties of the suspension agitated by various agitator geometries. (*Source*: From Ref. 27, with permission.)

methods), and direct methods (method of gas balance, dynamic method, continuous culture method). The Kla values in mechanically agitated reactors depend on various parameters such as system properties, vessel and stirrer dimensions and arrangement, and operating conditions (32). To examine the behavior of the modified turbines regarding mass transfer, the Kla coefficients were determined in the presence and absence of the solid particles by the sulfite oxidation method.

68.4.1 Gas–Liquid Mass Transfer Characteristics

Figure 68.12 shows the measured Kla values as a function of gas flow number, Fl, for single and double turbine agitator of TP3 type, having as parameter the agitator speed (curves indicated in Figure 68.12 by the continual line) or the aeration rate (curves indicated by the dotted line). The same variation, Kla $= f$(Fl), was also observed for the other modified turbines and the Rushton turbine (33). The dependence of Kla on Fl, when N is constant, is greater at lower gas flow rates (lower gas flow numbers). At higher gas flow numbers, the curves tend to constant Kla values for all agitator speed values and single turbine types (Fig. 68.12a). In the case of double turbines (Fig. 68.12b), this tendency of the curves Kla $= f$(Fl) appears only at values $N < 10$ s^{-1}. This dependence of Kla on Fl can be explained by the prism of various hydrodynamic regimes, considering the value Fl $= 0.03$ as the transition point between the vortex-clinging cavity regime and large cavity regime (33). When the Kla values are represented depending on the gas flow number at a constant aeration rate (curves indicated by the dotted line in Figure 68.12), these increase slowly once with increasing the rotational speed when the agitator works in flooding regime (below line noted F/L in Figure 68.12). When the agitator works in the loading regime (over line F/L), the volumetric oxygen mass transfer coefficient increases considerably with the decreasing gas flow number.

One procedure for evaluating the volumetric oxygen mass transfer coefficient is based on knowledge of the specific power consumption (P_g/V) and the superficial gas velocity (v_s) (34):

$$\text{Kla} = c(P_g/V)^{0.95}(v_s)^{0.67} \tag{68.4}$$

The relationship between Kla and the product of the variables $(P_g/V)^{0.95}$ $(v_s)^{0.67}$ for all turbine types and their geometrical disposition is linear, the average value of the dimensional constant c being specific for each of the geometrical configurations studied.

The influence of the mixing system geometry on gas–liquid mass transfer is quantified by including, in equation 68.4, the geometrical elements $(n_p/6)$ and $(1 + S_G/S_C)$, which indicate the number of turbines and their type. The following correlations were obtained for the evaluations of the volumetric mass transfer coefficient:

$$\text{Kla} = 7.2202 \times 10^{-4}(1 + S_G/S_C)^{1.753}(n_p/6)^{-0.126} \cdot (P_g/V)^{0.95}(v_s)^{0.67} \text{ for } S_G/S_C \leq 0.353; r = 0.9843 \tag{68.5}$$

$$\text{Kla} = 2.721 \times 10^{-3}(1 + S_G/S_C)^{-2.73}(n_p/6)^{-0.141} \cdot (P_g/V)^{0.95}(v_s)^{0.67} \text{ for } S_G/S_C)0.353; r = 0.9629 \tag{68.6}$$

To obtain the same value of the volumetric mass transfer coefficient, the power consumption in the vessel equipped with the TR agitator is higher than that in the vessel equipped with the TP3 agitator. Therefore, the oxygen transfer efficiency E (m^3O_2/W h) (the oxygen volume transferred into the liquid phase for 1 W h of energy consumption for mixing) for one and two TP3 modified Rushton turbines, for any value of the aeration rate (Fig. 68.13), is more than 30% higher than those obtained with the TR turbines. The TR and TP5 turbines are similar as regards mass transfer efficiency.

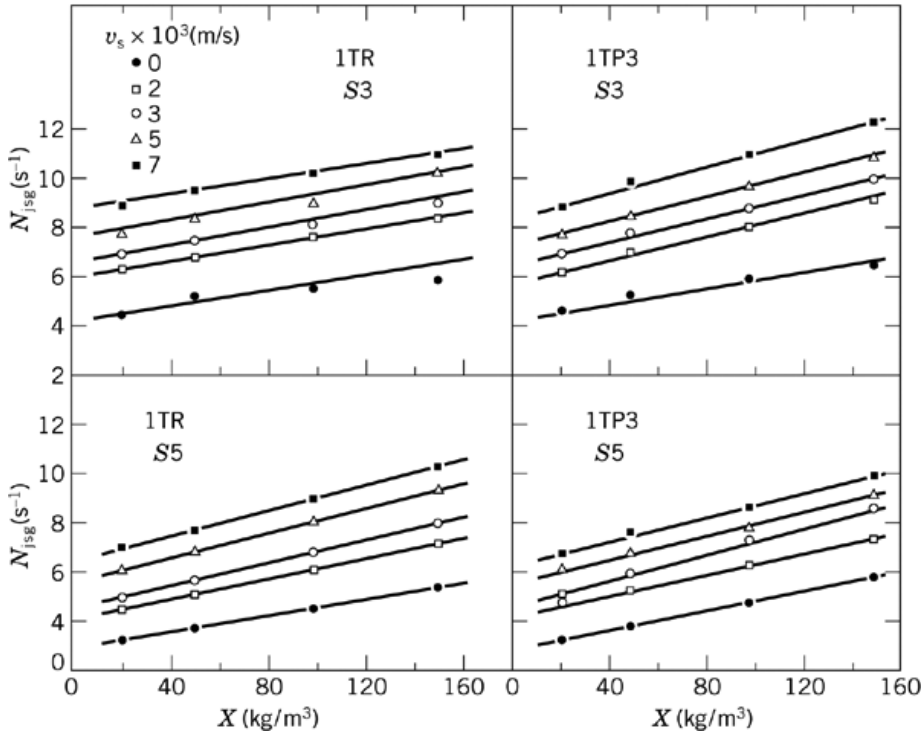

Figure 68.11. Relation between N_{jsg} (jsg, moment of complete solid suspension) and the solid concentration for various values of the superficial gas velocity. (*Source*: From Ref. 28, with permission.)

68.4.2 Effect of Particles on Gas–Liquid Mass Transfer

It has been observed that the addition of solids has an influence on gas–liquid mass transfer characteristics, even if these particles are not reactive and do not show increased adsorption of dissolved gases. The inert solid particles used in our work are $CaCO_3$ (S1) and cation exchange resin Amberlite IR-120 type (S3) (35). The experiments were carried out in the range of three-phase homogeneous mixing. The presence of the solid phase, with the concentration between 20 and 50 kg/m^3, influences the gas–liquid mass transfer as shown in Figure 68.14 for the standard (TR) and modified (TP3) turbines, single or double, at various values of superficial gas velocity. All curves show the same general trend.

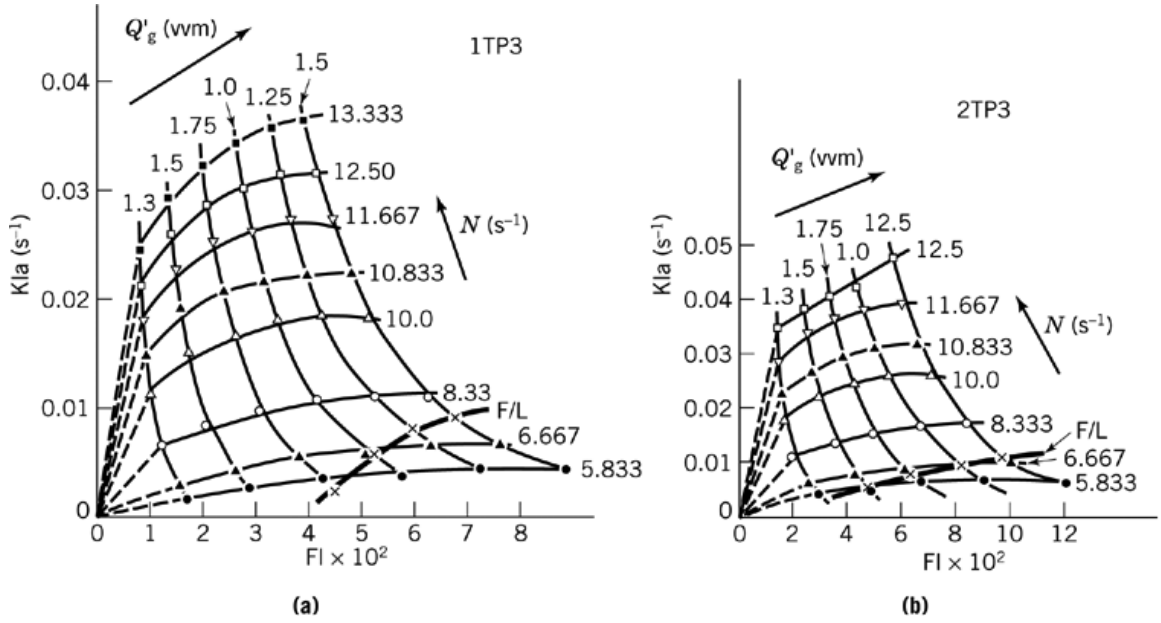

Figure 68.12. Variation of the volumetric mass transfer coefficient (Kla) depending on the gas flow number: (**a**) single TP3 modified Rushton turbine; (**b**) double TP3 modified Rushton turbines. (*Source*: From Ref. 33, with permission.)

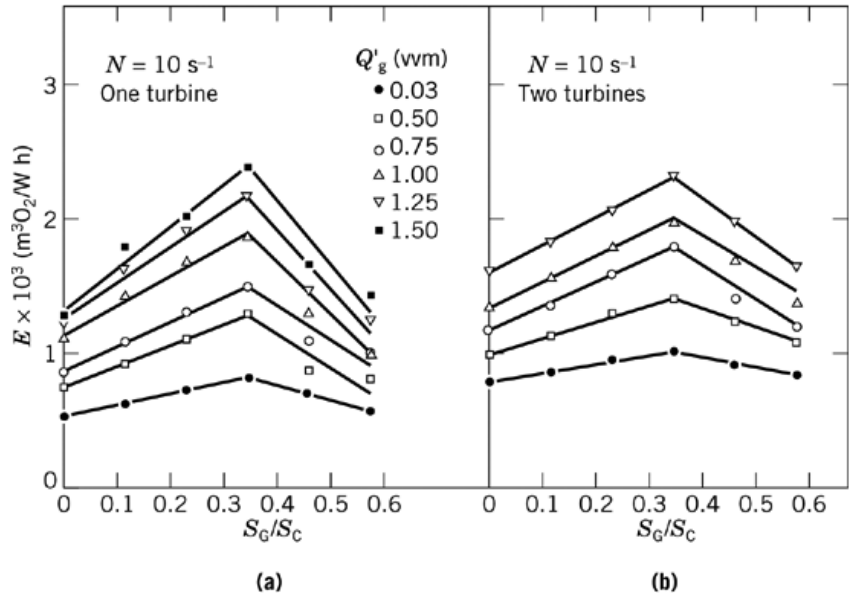

Figure 68.13. Variation of the oxygen transfer efficiency (E) depending on the surface fraction of the perforation at various values of the aeration rate: (**a**) single turbine; (**b**) double turbines. (*Source*: From Ref. 33, with permission.)

For $CaCO_3$ particles (S1 solid), a very slight increase of the Kla coefficient is observed until $X = 50$ kg/m^3, while the addition of the cation exchange resin in a proportion of 20 kg/m^3 leads to a pronounced increase of the Kla value, particularly at $N = 11.667$ s^{-1} and at higher values of the superficial gas velocity. This trend of the Kla coefficient to increase in the range of small solid concentration was explained by Brehm (36) that at the moderate agitator speed ($N < 15$ s^{-1}) the solid particles can move independently of fluid elements and break up the gas–liquid interface, which leads to decreasing thickness of the boundary layer. When increasing the solid concentration beyond the values

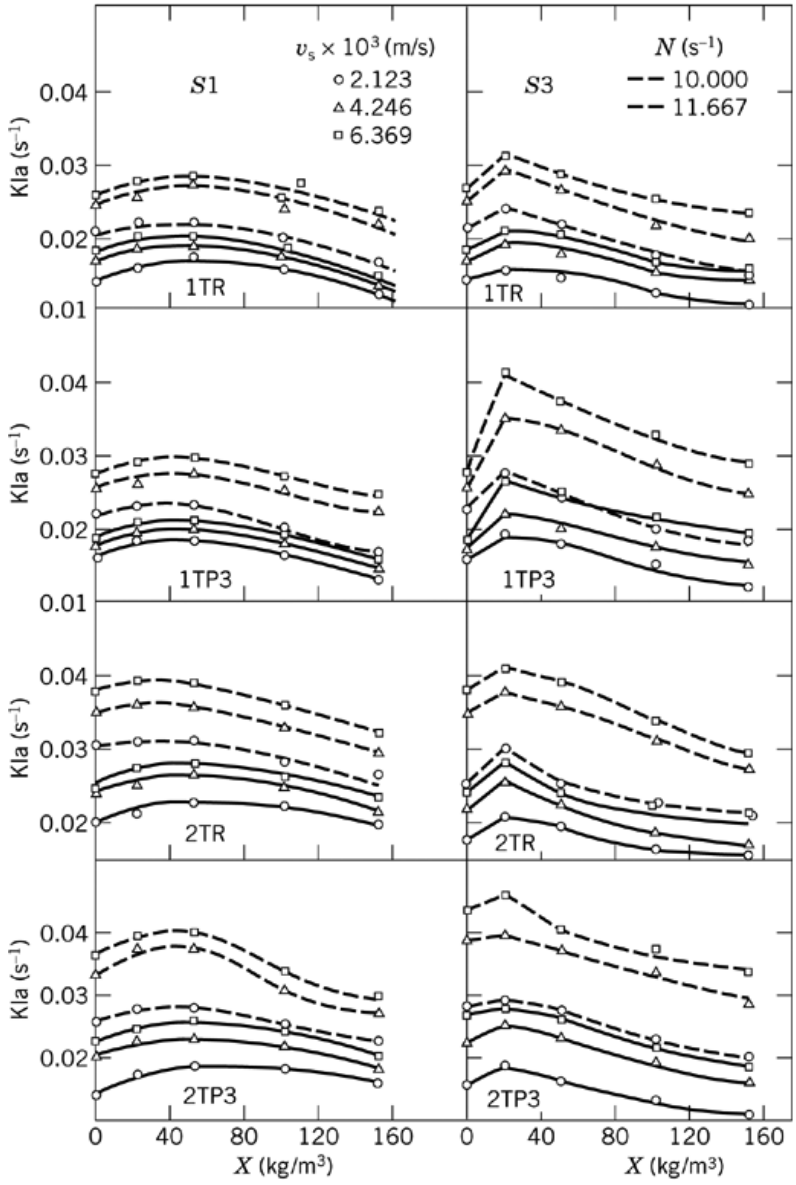

Figure 68.14. Effect of solid concentration on volumetric mass transfer coefficient for standard and modified Rushton turbine, positioned singly or doubly on the same shaft. (*Source*: From Ref. 35, with permission.)

mentioned, the Kla coefficient gradually decreases toward values smaller than those obtained in gas–liquid systems.

Two main factors are responsible for this reduction of the Kla values (37): one factor is the change of the rheological properties of the suspensions and the other is enhanced bubble coalescence, which is caused by turbulence intensity damping. The higher Kla values for mixing with two turbines (Fig. 68.14) are due to the their higher power consumption for the same operation conditions.

In the three-phase system, the oxygen transfer efficiency, E, decreases with increase of solid concentration, irrespective of the agitator type (Fig. 68.15), but for mixing with the TP3 modified turbines, the E values are more than 45% higher than those obtained using TR turbines. The experimental data regarding the mass transfer in gas–liquid suspensions demonstrate that the Kla values depend on the physical and rheological properties. The effect of the solid particles on Kla value is given by the group $K^{-0.15}X^{-0.1}$, which includes the consistency index K as a pseudo-viscosity of the suspensions. Therefore:

$$\text{Kla} = 7.2202 \times 10^{-4}(1 + S_G/S_C)^{1.753}(n_p/6)^{-0.126} \cdot (P_g/V)^{0.95}(v_s)^{0.67}K^{-0.15}X^{-0.1} \qquad (68.7)$$

Equation 68.7 describes the experimental data with an average error of 20%.

68.5 PERFORMANCE OF THE MODIFIED AGITATORS IN BIOSYNTHESIS OF ANTIBIOTICS

The transport phenomena in submerged aerobic fermentation involve mixing and mass and heat transfer in three-phase systems consisting of gas bubbles and suspended microorganisms in a liquid phase and are strongly influenced by the rheological properties of the medium used. The rheology of the broth is affected by the composition of the original medium and its modification by the growing culture, the concentration and morphology of the biomass, and the concentration of microbial products. Complex interaction between transport phenomena and reaction kinetics characterizes bioreactors and determines their performance. The modified turbine TP3 with the surface fraction S_G/S_C of perforations equal to 0.353, considered an optimum in dispersion of the gas and solids in liquid, was investigated in antibiotic biosynthesis liquids in semiindustrial and industrial bioreactors.

68.5.1 Biosynthesis of Antibiotics in Semiindustrial-Scale Bioreactors

The experiments were carried out in two 20-m^3 stainless steel stirred tank bioreactors, equipped with three modified Rushton turbines (TP3) (blade width × blade length = 0.306 × 0.225 m), and three witness Rushton turbines (TR) (blade width × blade length = 0.225 × 0.225 m), respectively, having the same diameter and rotating with the same agitator speed (38). The experimental data in the biological systems were obtained using four different microorganisms: *Streptomyces erithreus*, *S. griseus*, *S. noursei*, and *Nocardia mediterranei*, producing erythromycin, streptomycin, nystatin, and rifamycin, respectively. During the four parallel fermentations, the specific power consumption, the volumetric oxygen mass transfer coefficient, the oxygen transfer efficiency, and the antibiotic concentrations were investigated. For each fermentation type, the power consumption for the TP3 agitator is diminished by a factor of 1.18 (streptomycin) to 1.6 (erythromycin) compared to that for the TR agitator (Fig. 68.16). Therefore, in the viscous mycelial fermentation, the TP3 agitator minimizes the drag forces associated with the motion of the blades, confirming the observations presented for a nonbiological system.

The Kla values, as measured by the dynamic method, decrease during the fermentation processes, depending on the microorganism growing in the liquid (Fig. 68.17). The fermentation media for *S. erithreus* and *S. noursei*, producing erythromycin and nystatin, respectively, contain starch as a degradable component (22,39), which confers a high

viscosity on the initial medium; thus, Kla is smaller at the beginning of biosynthesis, compared to the initial medium for *S. noursei* and *N. mediterranei* without this component. The Kla values obtained under mixing conditions with the TP3 agitator are 25% (streptomycin) to 50% (nystatin) higher than those obtained by using the TR agitator. This effect can be explained by the improvement of the dispersion of the gas bubbles as a result of the impact of the jets that come through the perforations in the TP3 blades onto the relatively surface in the back of large cavities.

Because the TP3 blades are higher by 36% in comparison with the witness blades, the size of the well-mixed, low-viscosity, and high-Kla region is effectively increased. In the micromixing region, excellent bubble breakup and shear thinning of the viscous medium occurs, which results in oxygen transfer improving in accordance with the concepts of Bajpai and Reuss (40). Also, the macromixing region, away from the impeller where the oxygen transfer is relatively poor, is much smaller.

In the investigated biological systems, for 1 W h of energy consumption (for agitation and air compression), the oxygen volume transferred into the liquid phase is approximately 30% higher in the bioreactor equipped with a TP3 agitator (Fig. 68.18). The oxygen transferred into the medium is consumed mainly in the combustion reaction that takes place within the biomass, on which the antibiotic production depends. The relative antibiotic concentrations measured over the entire course of the fermentations are plotted in Figure 68.19.

The efficiency of the TP3 agitator was confirmed in that antibiotic production increased up to 35% in nystatin biosynthesis, as much as 9% in rifamycin biosynthesis, and up to 20% in streptomycin biosynthesis as well. No difference in erythromycin production was observed between the two parallel fermentations, but efficiency occurs from the energy savings. Therefore, using the TP3 agitator in the biosynthesis of antibiotics, it is possible to minimize the power consumption and to increase the antibiotic production for the same operating conditions as well as the TR agitator.

68.5.2 Biosynthesis of Antibiotics in Industrial-Scale Bioreactors

In the biosynthesis of antibiotics in semiindustrial-scale bioreactors, it was demonstrated that when the modified agitator has the same diameter and rotates with the same

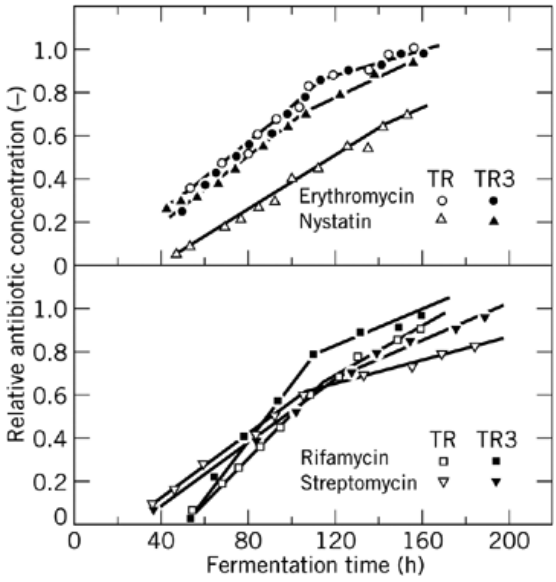

Figure 68.19. Relative antibiotic concentration profiles during the biosynthesis process using the TP3 and TR agitators in semiindustrial-scale bioreactors. (*Source*: From Ref. 38, with permission.)

agitator speed as the standard agitator, the power consumption is reduced by a factor of 1.18 to 1.6 (38). Therefore, the use of a modified agitator in biosynthesis of the antibiotics may improve the productivity for a given power input by increasing the TP3 impeller diameter and keeping the agitator speed as high as for the TR agitator, and by increasing the TP3 agitator speed and keeping the impeller diameter as large as for the TR agitator.

The improved agitation performance by modified Rushton turbine agitators corresponding to the two aforementioned cases (if the specific power consumption is constant) was verified experimentally in industrial-scale bioreactors, as follows (41):

- In parallel fermentations of *S. aureofaciens* and *S. rimosus*, producing tetracycline and oxytetracycline, respectively, in two 100-m^3 stainless steel stirred tank bioreactors equipped with four modified impellers (TP3) and four standard impellers (TR), respectively (first case)
- In parallel fermentations of *Penicillium chrysogenum* producing penicillin, in two 63-m^3 stainless steel stirred tank bioreactors equipped with three modified impellers (TP3) and three standard impellers (TR), respectively (second case)

The morphology of molds is a function of shear stresses in the bioreactor. The growth rate and partial pressure of oxygen, and the following elements, play a role: the growth of hyphae, the branching of hyphae, the dispersion (breakup) of hyphae caused by the shear stress in the vessel, and the tensile strength of hyphae. The breakup frequency (λ/k_o) is proportional to the frequency that a particle will have in the so-called dispersion zone (V_{disp}), that is, the volume at which the turbulent shear forces are greater than the forces necessary to break the hyphal cell wall (42). The λ/k_o and V_{disp} values for the agitators investigated are presented in Table 68.3.

Therefore, by using the TP3 agitators, the size of the well-mixed region is effectively increased up to 27% and the breakup frequency of the mycelial hyphae is increased up to 75%. The relative antibiotic production and variation of the specific antibiotic production rate, Q_p, during the cultivation time, are plotted in Figures 68.20 and 68.21, respectively. The improvement in antibiotic production by more than 30% by using modified agitators can be explained by creating a better hydrodynamic microclimate, and effectively increasing the well-mixed region, oxygen mass transfer, discharge efficiency, and the breakup frequency of mycelial hyphae.

The Q_p values reach a maximum in the early exponential phase of batch growth, although the cell mass concentration is small. The maximum values of the specific antibiotic

production rate and the fermentation time at which these maximum points are reached depend on the type of producing microorganism and the type of agitator. Therefore, the standard and modified agitators create various types of environmental conditions under which the cells appear to adapt by structural and functional changes.

69.1 INTRODUCTION

The monitoring and control of processes is of key importance in all industries. Effective methods of monitoring are required to develop, optimize, and maintain processes at a maximum efficiency and desired product quality. Biotechnological processes are no exception to this (1,2).

Biotechnology processes are used to produce a large variety of products, such as primary and secondary metabolites, cells, tissues, vaccines, and therapeutic proteins (2). Different host cell systems are used in the modern biotechnology, for example, bacterial cells, plant cells, and eukaryotic cells, with specific requirements for bioreactor design, media composition, and process control. Especially the production of recombinant proteins and antibodies has become a major source of revenue during the past 30 years, which are typically produced by genetically engineered mammalian cells. The cultivation of mammalian cells requires, among other factors, complex media composition, specialized bioreactor design, and the control of various parameters in narrow ranges to obtain the desired productivity and product quality. Therefore, more research has been devoted to develop specifically designed sensors, sampling strategies, and integrated data management systems to allow better and more detailed process monitoring (3). Advanced analytical technologies are required in all phases of a product and process life cycle. During the development stage, it is needed to create knowledge and understanding of the process and therefore optimize the process with accelerated timelines (e.g. high throughput screening and design of experiments). During process characterization and validation, it is essential to understand and determine control limits, set points, and critical process parameters, which have an influence on process performance and, more importantly, affect product quality. In routine production, it is essential to control the process at the set points within the operating ranges. These process parameters are defined during process development and characterization to achieve the desired product quantity and quality and support ongoing process monitoring/validation as required by the health authorities.

The process analytical technology (PAT) framework published by the Food and Drug Administration (FDA) in 2004 describes PAT as a mechanism to design, analyze, and control pharmaceutical manufacturing processes through the measurement of (critical) process parameters that affect quality attributes of the product (4). The concept is based on building quality through deep understanding and control of the process, especially critical quality attributes and their interactions/dependencies to other parameters. This requires a comprehensive detection system to measure, analyze,

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

monitor, and control all important attributes of a bioprocess and the employment of feedback-based control systems, including integrated data management and analysis. Over the past several years, there has been a lot of effort in analytical technologies to enable these stringent controls (5).

The chapter describes general operational aspects of sensors, sampling technologies, and methods of process monitoring, examples for different controls and advanced applications such as soft sensors and metabolic controls. Some aspects are based on a previous article published in 2010 (1).

69.2 GENERAL ASPECTS OF SENSORS AND MONITORING

Several bioprocess sensors have been designed and are employed for routine applications. For bioprocesses monitoring, the following areas for physical, chemical, and biological parameters are commonly monitored (Fig. 69.1).

For any measuring technique, there are a number of criteria that the measuring device must satisfy to enable its deployment in commercial bioprocess manufacturing. The following list of characteristic is not exclusive, but does cover the main aspects of sensor attributes and characteristics (see also Ref. 1 for more details).

69.2.1 Measurement Frequency and Costs

In most cases—especially in context of the PAT initiative—real-time measurements at a high frequency are highly desirable. However, in some cases, this is not necessary and the kinetics of the reaction, consumption, and evolution must be considered in determining the frequency of measurements. In addition, differences in the life cycle of the process and cost aspects must be evaluated during the selection of one or more monitoring techniques. For research and development (R&D) purposes, in general, more data are obtained and collected to gain deeper process understanding and optimize process robustness and yield. At this stage, higher costs are often more acceptable compared with commercial bioprocessing. For routine operations, critical and important variables must be monitored and controlled within predefined intervals. A secondary aspect is cost; measurements that are resource and time intensive, but not critical to the process from a product quality and quantity perspective, may not be implemented. In general, high frequency at low costs, time, and resource consumption is desired, including automated data handling and analysis.

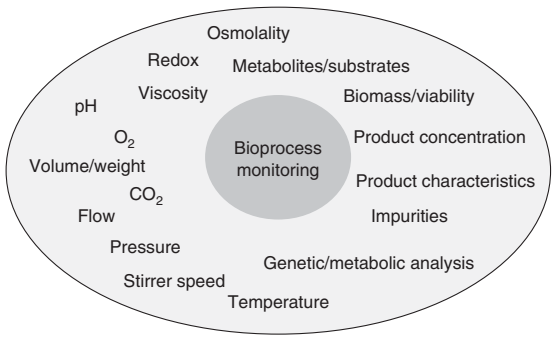

Figure 69.1. Major areas for bioprocess and fermentation monitoring.

For biological processes, the growth rates, substrate depletion rates, and evolution rates of products, by-products, and impurities are most relevant for the measurement frequency. Animal cells, for example, display a doubling time of approximately 1/ day. Bacterial cultures such as *Escherichia coli* display a doubling time of 20–30 min, also reflecting their metabolic activities. It becomes obvious that the measurement frequency to control feed rates and other physical parameters has to be much higher in bacterial cultures compared with animal cell cultures. Therefore, some fully automated systems have been developed for off-line or online analysis. *In situ* probes (discussed later) with fully automated analysis, such as spectral analysis, *in situ* microscopes, and off-gas analysis, have also been established.

69.2.2 Ease of Validation and Implementation

If operated in a regulated environment, the method and sensor should be easy to validate and qualify. Efforts required to validate and implement the sensor should not be complex as this could also affect project timelines, for example, implementation of a new sensor during a technology transfer project. Standard platforms that have been assessed toward this factor are often used for bioprocess operations at a large scale. In recent years, the aspects of leachables and extractables have become more important in the industry and should be considered as well because these can affect cells or even product quality attributes.

69.2.3 Easy to Use and Maintain

A sensor should be easy to maintain and easy to use (e.g. calibration and exchange of membranes). This may not be a primary focus during research and development. However, for routine operations, this is an important factor in terms of reliable execution: manufacturing schedule impacts for planned and predictable performance of operations. In general, calibration of the sensor and other preventive maintenance activities should be part of routine operations with intervals: calibration ranges and other requirements specified in operating procedures.

69.2.4 Cleaning Aspects and Sterility

When operated in an aseptic or sterile environment, the sensor must be amenable to clean in place (CIP) and steam

in place (SIP) without nonpredictable effects to performance of the sensor. This can be a threat because aggressive chemicals as well as high temperatures may be used to obtain sufficient cleaning and sterility/aseptic conditions. In biotech processes, temperatures in the range of 121–130°C are common for sterilization, and treatment of surfaces with hot base or acid is common for cleaning. The general acceptance and impact on lifetimes and performance for various probes can be found in vendor recommendations. Nevertheless, the standard probes currently applied in most routine (GMP) production biotech processes, such as pH or dO_2, are able to cope with these conditions quite well. Sensor drifts affected by caustic solution or heat treatment my occur, but are usually not an issue because most often these probes are operated in a single-use mode or at least only for a few batches with appropriate calibration cycles that assure the desired sensor performance.

Beside, the possibility of *in situ* sterilization probes and their fittings into the bioreactor are a critical point with respect to the sterile boundary. This is one of the key aspects, which has to be considered when introducing new probes into a (GMP) manufacturing environment.

69.2.5 Reliability, Accuracy, and Reproducibility

A sensor, especially when used online, has to provide reliable performance over a large span of time. Mammalian cell culture processes, for example, have operating times of up to several weeks (or months in perfusion systems) and therefore the probe/sensor has to deliver reliable performance to avoid failures and batch losses. The sensor should always provide sufficient accuracy in the desired control range. A low error between actual value and measured value is a prerequisite for adequate control. Measurement should be reproducible and drift only in an acceptable range for the measurement.

69.2.6 Linearity, Sensitivity, and Specificity

A measurement signal in most cases is directly proportional to the concentration of the component. Sometimes, there need to be corrections, and sample dilution has to be performed to overcome the effect of nonlinearity. A sensor has to deliver appropriate sensitivity to measure changes in the concentrations. The lowest level of detection is related to the sensitivity and the signal-to-noise ratio. Specificity is a statistical measure of how well a test correctly identifies the negative cases or those cases that do not meet the condition under study. Specificity is defined as the number of true negatives divided by the total sum of true negatives and false positives. A sensor with high sensitivity and specificity is capable of identifying and possibly quantifying a small signal, while still differentiating between a true signal and noise.

69.2.7 Response Time

The measurement of any process variable will entail a time delay between change in the parameter and display of the measured value. The response time should be appropriate for the progress of the bioprocess, particularly if the measurements are linked to a control action. For tight control limits and fast reaction times, an off-line sensor may not be appropriate. *In situ* measurement or online monitoring might be more appropriate. The response time of the sensor also depends on the control requirements of the bioprocess. For example, in a high cell density culture, dissolved oxygen (DO) will be depleted in a few minutes. Hence, DO is almost always monitored using an *in situ* sensor with a response time in seconds.

The importance of these aspects and factors varies and is different from R&D to a routine manufacturing application (6). Table 69.1 shows the importance of different aspects during the life cycle of a process (+ = low; ++ = medium; +++ = high).

69.3 METHODS OF MONITORING

In principle, analytics can be performed in two ways: withdraw a sample and perform off-line analysis or by integrating the sensor in the process, for example, bioreactor, peripheral equipment, and external loops, to enable online or *in situ* monitoring (Fig. 69.2). In some cases, a combination with auto sampling devices can lead to an "*in situ* sampling and *ex situ* sensor" (3,5).

TABLE 69.1. Aspects of Sensor and Their Importance During the Life Cycle of a Process from Research to Commercial Manufacturing (6)

Factors/Aspect	Research	Process Development	Manufacturing
Reliability, accuracy, reproducibility	+++	+++	+++
Selectivity, sensitivity, linearity	+++	+++	+++
Calibration	+/++	++	+++
Ease of validation and implementation	++	++	+++
Cleaning aspects and sterility	+/+++	+/+++	+++
Analysis frequency and costs	++	++	+++
Robust and easy to maintain	+	++	+++

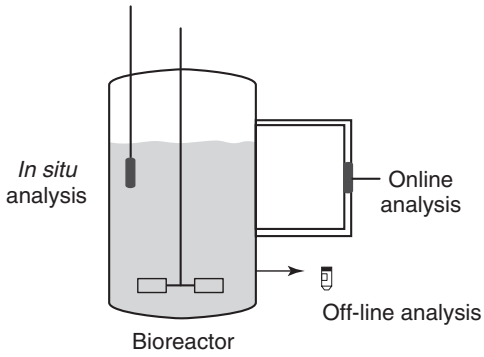

Figure 69.2. Different methods of monitoring and sensor interfaces with the process.

69.3.1 Off-Line Monitoring

For off-line monitoring, a sample is withdrawn from the bioreactor/vessel and analyzed after sample preparation in a suitable device. The preparation and handling of the sample is of crucial importance because it may affect the accuracy of the measurement. For example, for cell counts, homogeneous mixing after sampling and short lead times can be important. For pH and CO_2, rapid measurement is needed to avoid drifting due to off-gassing. This is especially important for pH to avoid offsets between *in situ* and off-line control measurements because pH is often controlled in a narrow range for bioprocesses. An important aspect (especially for bioburden monitoring) can be the aseptic treatment of the sample. For all off-line samples, detailed procedures, trained staff, and suitable laboratory are required. Off-line analytics always has a delay and affects the frequency of the measurement.

69.3.2 *In situ* or In-Line Monitoring

In Situ and in-line monitoring involves the use of sensors placed directly in the vessel or the flow lines associated with it or the unit operation (e.g. conductivity or pH monitoring in purification steps). The use of *in situ* sensors are well established, especially for chemical or physical parameters (pH, redox potential, O_2, CO_2, conductivity, and turbidity) (7). *In Situ* monitoring allows rapid measurement in high frequency and therefore enables real-time measurement and direct control. Robustness, long-term stability, aseptic design, and SIP/CIP capability are a prerequisite (and sometimes a pitfall) for these sensors and probes. Sometimes, *in situ* probes can be placed in external loops. The use of bypasses and additional peripheral equipment always adds potential risks to the process (e.g. sterile barriers, pumping of cells and protein and associated shear force, and cells outside a controlled environment) and therefore need to be carefully considered.

69.3.3 Online Monitoring

A compromise between *in situ* and off-line monitoring can be found with online monitoring, where a sample is automatically withdrawn and analyzed. One example of this has been the development (since the early 1980s) of flow injection analysis (FIA). This is a liquid handling technique that has proved flexible and adaptable to most chemical and biochemical reaction procedures (8), representing an effective compromise between the desirability of *in situ* monitoring and the technical ease of off-line measurements. The principal advantages of online methods are that sensor sterilization can be readily accomplished, sample pretreatment (e.g. gassing, dilution, and removal of interferences) is readily achievable, and sensor calibration can be built into the system. The main disadvantages are a need for an effective and reliable sampling system and the fact that the signal is discontinuous; the frequency of measurement is determined by the overall FIA design and the inherent limitation of the approach (3).

69.4 SENSOR, DEVICES, AND TECHNOLOGIES

69.4.1 pH Measurement

pH is a critical factor in most bioprocesses (5,6). As the impact on performance and in some cases impact on product quality has been described, an *in situ* monitoring and control is needed. In addition, a risk mitigation strategy is widely used by comparing *in situ* measurement with periodic off-line measurements. The most common form of pH sensor used for fermentation monitoring is based on the electrode design introduced by Ingold in 1947. The detailed design of a pH electrode and functional principles can be found elsewhere (1). A large variety of pH probes based on the electrochemical design are commercially available. pH probes can be autoclaved and cleaned in place. However, a reduction in lifetime and robustness needs to be taken into account. Steam sterilization can affect the glass membrane potential, thereby adversely affecting the robustness of these conventional pH probes (9). Also, optical pH sensor, which uses pH indicators immobilized on waveguides such as optical fibers, is available. Measurement of pH changes can be detected with a good precision by the change in absorption or in fluorescence. With the development of disposable bioreactors, the need for disposable sensors has also evolved. Several companies have developed disposable sensors for pH, DO, and dissolved CO_2 (DCO_2). In these sensors, a fluorescence dye sensitive to the analyte is immobilized in a matrix or patch, which can be miniaturized to a few millimeters. This enables monitoring and control with presterilized/γ-irradiated systems, even of miniature system (e.g. shake flasks and microplates) (1,5,6)

TABLE 69.2. Types and Principals of Temperature Probes

Type	Principle
Thermistors	Type of resistor measuring the change in resistance. The output response from thermistors is of a nonlinear temperature versus resistance curve, with the resistance decreasing as the temperature increases
Resistance thermometer	Based on the changes in the electrical resistance of metallic conductors (mostly platinum), with changing temperature (10). A platinum wire of 100-Ω resistance at 0°C is typically used—platinum sensors are stable under both sterilization and fermentation conditions
Bimetallic thermometers	Consist of a bimetallic helical coil surrounded by a protective tube or wall. The coil winds or unwinds with changes in temperature and causes movement of a fixed pointer (11)

69.4.2 Temperature

Temperature is a well understood and a well-controlled parameter in bioprocesses. Bioprocesses are monitored and controlled usually in a tight range of 0–121°C, including sterilization cycles. Several devices and principles are available to control temperature. Table 69.2 shows three of the most common applications.

Other applications and more details can be found in Refs 1 and 11.

69.4.3 Pressure

Pressure is an important control parameter because it affects not only the bioprocess but also safety. Pressure, in general, influences the saturation concentration of gases dissolved in the liquid phase. Therefore, the conditions for calibration (if not automatically pressure corrected) need to be taken into account. In some bacterial fermentations, pressure increase is sometimes used to enable higher mass transfer. For cell culture applications, this can lead to higher carbon dioxide levels, which can negatively influence the process. Pressurizing the fermenter also mitigates the risk of undesired contaminations. Pressure monitoring is also essential for sterilization of bioreactors. Several devices and principles are described (e.g. Bourdon tube pressure gauge and strain gauge). Most common applications are piezoelectric manometers and diaphragm-type sensors.

69.4.4 Viscosity

Information on rheology, or viscosity, can help in ensuring the efficiency of a biological process and understanding the behavior of mixture, flow, mass transfer, and heat transfer. Animal cell culture media are mostly Newtonian fluids. However, for high protein concentrations in formulation processes and bacterial fermentations for the production of polysaccharides and DNA, the liquid can depict non-Newtonian characteristics. These can have severe inputs on power characteristic, mass transfer, shear stress, pumping, bioreactor design, and so on. The viscosity can be determined by using commercial available viscometers, for example, cone and plate viscometers, coaxial cylinders viscometers, and impeller viscometers. Viscosity is especially important in the production of high protein concentration, for example, in *subcutaneous* formulation of antibodies (12).

69.4.5 Redox Potential

Monitoring the redox potential of a bioprocess medium can provide information about the equilibrium between oxidizing and reducing species (electron acceptors and donors, respectively) present. The redox potential plays a significant role in understanding and optimizing secretion of proteins from mammalian cells (13,14). Typically, the metal electrode can be gold, iridium, or platinum; with platinum being the usual choice. The reference electrode is either Ag/AgCl or calomel. The redox sensor is linked to a pH meter that is fitted to provide readout in millivolts. During operations, the redox potential (measured between the metal and reference electrodes) varies as the logarithm of the ratio of oxidizable and reducible components in the media. The redox value varies linearly with the pH of the media and with the logarithm of DO tension via chemical reactions of the media components or culture components. This can lead to complication when trying to interpret the readout from the sensor. A full description of the use and problems associated with the redox sensor was outlined by Kjaergard (13). New and more reliable sensors have been published by Pluschkel and Flickinger (14), including a case study on mammalian cells.

69.4.6 Osmolality

Osmolality is a measure to describe the solute concentration defined as number of osmoles per liter of solution. The osmolality is therefore a result of dissolved components in a media. Freezing point depression, a phenomenon where the freezing point of a solvent decreases due to the presence of a non-volatile solute, is the commonly used method to

determine the osmolality of culture broth in bioprocesses. Mammalian cells are typically cultured in conditions where the osmolality is in the range of 300–450 mOsm/kg. Higher osmolality can increase the specific productivity of recombinant proteins in mammalians (15). However, this is often accompanied by an impact on cell growth. Although not directly controlled, osmolality is an important parameter for monitoring mammalian bioprocesses.

69.4.7 Oxygen

Oxygen is an essential control parameter for all aerobic bioprocesses and can have influence on culture performance—the oxygen demand of cultures varies significantly. For cell culture, ranges from 20 to 200 mg/L/h have been reported (20). Impacts on metabolism and effects on cell culture have been described in high and low oxygen concentration—as well as on recovery process steps (21–24).

The control of oxygen is a simple feedback loop. DO is measured by an *in situ* oxygen probe in most cases. Mammalian cell culture processes are typically robust to changes in DO in the range of 20–60% of air saturation. Transient low (<10%) as well a high (>60%) perturbations are also well tolerated by Chinese hamster ovary (CHO) cells, the commonly use host cell line for production of recombinant proteins. DO is typically controlled at 30–40% of air saturation to ensure sufficient "driving force" for oxygen transfer. The driving force is determined as the difference between saturation concentration (in equilibrium with the gas phase) and the control set point of DO (20).

The control is based on the set point, and therefore, (dissolved) mass transfer for oxygen is controlled by gas flow rate, power input, and/or changes in gas composition. For cell cultures, the common practice is to keep gas flow constant at low power inputs and add more oxygen to the gas flow—this is feasible due to the low oxygen uptake rates (OURs) of mammalian cells. For bacterial fermentations, this is not the case. Here, high power inputs (>1 kW/m^3) and high gas flow rates are used (combined with overpressure) to achieve high mass transfer characteristics in the bioreactor. Most differences for cell culture bioreactors and bacterial bioreactors are driven by this unit operation. Although high power inputs and high shear is desired in bacterial fermentations to achieve high mass transfer and low mixing times, this is the opposite in cell culture processes due to their shear sensitivity (lack of cell wall). In cell culture processes, power inputs between 10 and 100 W/m^3 are typically used. In addition, several low shear–high mixing impeller types have been developed by retrofitting bacterial bioreactor operations. For high density cell cultures, often pure oxygen is used to achieve the necessary mass transfer rates without high power inputs. Specific sparger types (e.g. microsparger and open pipe sparger) are also used to avoid CO_2 build up and high shear force due to bursting of gas bubbles at the air–liquid interface (16–19).

Oxygen (and carbon dioxide) can also be measured in the vent lines at the exit of bioreactors. This "off-gas" measurement can be used to decipher the metabolic state of the cell. The difference in the oxygen and carbon dioxide level between the inlet and the outlet of a bioreactor can be utilized to estimate the OUR and carbon dioxide production rate (CPR) in real time. These parameters, especially OUR, can be used to adapt feed rates (21,22). In general, off-gas analysis requires a certain change in gas concentration in order to estimate the consumption of oxygen and buildup of carbon dioxide. For bacterial cells the difference between inlet gas concentrations and off-gas concentration is big enough for differential measurement using mass spectrometers. For mammalian cells this is not the case. Therefore, off-gas analysis is not common in mammalian cell culture processes. Recently, due to availability of more sensitive detectors, examples of off-gas analysis have been reported for mammalian cells (21,22).

Table 69.3 shows the most common methods to determine oxygen (dissolved as well as off-gas oxygen levels). A large variety of oxygen probes are available. The probes are easy to maintain and reliable, with sufficient specificity and reliability. The probes can be used in sterilization processes. Sometimes, long-term use after CIP/SIP can be an issue. Therefore, redundant electrodes are often used in processes to provide backup. However, preventive maintenance and preventive exchange of the *in situ* probes has been successfully applied of the past few years. For disposable application also, sensors are available based on fluorescence as described earlier (see pH).

Beside, the critical role of oxygen in aerobic fermentation, impact of dissolve oxygen on product quality in downstream processing has also been reported. Pizarro et al. (23) describe the relevance of DO concentration during a refolding process of recombinant human vascular endothelial growth factor (rhVEGF). Kao *et al*. (24) described the reduction in interchain disulfide bonds in a therapeutic antibody, in a CHO-based manufacturing process after the harvest operations, resulting in observation of antibody fragments in protein A pool. As a result, certain measures were introduced, one of which was air sparging of the harvest tank (24).

Despite their differences in operation and measurement principles, there are some constraints for electrodes. All electrodes need to have sufficient movement at the surface, including movement of oxygen through the bulk of the fermentation media and diffusion across the membrane and through the supporting electrolyte. An incorrect placing of the electrode in a highly viscous media displaying non-Newtonian characteristics might be an issue. If the electrode is situated in an area of quiescent fluid, the received signal may not be an accurate representation of oxygen partial pressure throughout the bioreactor. Pressure difference might play a significant role, as well

TABLE 69.3. Device and Principle for Oxygen Measurement

Type	Principle
DO Probes	Based on galvanic or polarographic principle. Measurement of partial oxygen pressure (19,26–28)
Optodes (DO)	Optical sensors for oxygen are constructed using an immobilized fluorophore that undergoes dynamic quenching of the luminescence of a ruthenium complex. The change in fluorescence signal is measured by optical measurement device. Also available as single-use sensors
Exit gas analysis	There are a number of methods available for determining the oxygen concentration of exit gas from a bioreactor. Several of these are based on exploiting the strong affinity shown by oxygen to a magnetic field. Paramagnetic gases, such as oxygen, display a positive magnetic susceptibility. There are two types of detectors based on this phenomenon: the magnetopneumatic and thermomagnetic analyzers consist of a bimetallic helical coil surrounded by a protective tube or wall. The coil winds or unwinds with changes in temperature and causes movement of a fixed pointer (11)

as temperature control and compensation. Fouling of the sensor membrane surface by components of the bioprocess media can lead to erroneous signals. With continued use, this could include the growth of microorganisms on the membrane surface, especially when cultivating adherent cell lines. DO electrodes are also susceptible to signal drift during operation. In addition, gas bubbles and restricted flow toward the sensor can affect the received signal. Other important considerations are the effect of sterilization on the sensor and its calibration. Typically, calibration is carried out after sterilization, using medium gassing to obtain the full range of sensor values. However, in some cases, this might lead to excessive foaming or reduction/oxidation of media components and therefore needs to be considered carefully. For fast reactions, especially with high mass transfer and oxygen consumption rates, the response time of the probe and potential calculation need to be taken into account as well.

69.4.8 Carbon Dioxide

For many bioprocesses, the measurement of CO_2 is an important feature. Media in bioprocesses is typically buffered by CO_2/bicarbonate buffer in addition to other buffers such as HEPES (16,20,21). Carbon dioxide is utilized for pH control in mammalian bioprocesses. In addition, carbon dioxide is also required for cellular processes such as fatty acid synthesis. At smaller scales, such as spinners and shake flasks, mammalian cells are typically cultured in incubators with 5% CO_2. However, increased levels of dissolved carbon dioxide can inhibit growth and reduce the production of secondary metabolites. Especially in cell culture processes, carbon dioxide is critical at certain concentration and has demonstrated impacts on product quantity and process performance. Hence, DCO_2 is typically maintained between 5% and 10%.

Cells produce CO_2 during respiration, which is stripped off by air (or oxygen) sparged in the bioreactor. Carbon dioxide build up must be considered carefully during scale-up. Due to geometric similarity during scale-up, the surface-to-volume ratio decreases. Hence, the volumetric air/oxygen flow rate is reduced to avoid excessive foaming. For oxygen supply, this is addressed by supplying oxygen-enriched air or pure oxygen. However, this causes a reduction in CO_2 stripping rate, resulting in an increase in DCO_2 concentration. DCO_2 levels above 20% are often growth inhibitory for mammalian cells. Hence, the aeration strategy should be carefully considered during scale-up of bioprocesses. In addition, the concentration of bicarbonate in the medium will affect the DCO_2 levels.

Carbon dioxide probes are commercially available. In principle, these are steamable and cleanable as described for pH and DO probes. These function in a similar way to oxygen probes and are based on a pH sensor immersed in a saturated bicarbonate buffer, separated from the bioreactor fluid by a hydrophobic membrane. DCO_2 gas molecules diffuse from the bioreactor media, through the hydrophobic membrane into the carbonate buffer (e.g. InPro 5000i by Mettler Toledo). *In situ* fiber optic probes are also available for DCO_2 measurement (e.g. YSI 8500 by YSI Life Sciences).

69.4.9 Weight and Liquid Levels

Weight and liquid levels are widely used to measure contents, nutrient additions and consumptions for mass balances, addition of base, flow rates, and so on. In most cases, load cells (measuring the strain on the device) or direct liquid level measurements are applied. The liquid level is also important from several perspectives (e.g. safety and total mass of product). In addition to load cells, several methods to determine liquid levels are known (e.g. measuring hydrostatic pressure) (29).

If the culture media shows excessive foaming, the exhaust filters may foul. Hence, conductivity sensors are widely used to monitor foam formation. If liquid or foam levels rise and contact the nonisolated tip of the probe,

the liquid or foam acts as an electrolyte—in most cases, this is used to control foam by addition of antifoam. Capacitance sensors detect the relative dielectric constant of the media compared with air. Acoustic sensors operate via transducers that generate and detect ultrasonic waves. Guided wave radar technologies are used as well. Guided wave radar is based on the principle of time domain reflectometry (TDR). TDR is a measurement technique used to determine the characteristics of electrical lines by observing reflected waveform pulses of electromagnetic energy that are transmitted down a probe and the pulse is reflected when it reaches a liquid surface. The distance to the reflecting surface is determined by the return time of the pulse to the source (30). Also, techniques of measuring temperature differences in the vessel can be applied (1).

69.4.10 Flow Measurement and Control of Liquids and Gas

Flows need to be measured at the inlet and the outlet of a bioreactor, vessel, filter, or column. Flow control is important for process robustness and safety. In upstream processes, flow control is applied, for example, in fed-batch processes (potentially combined with weight measurements) or the control of airflow. In recovery operations, it is important to maintain flow rates in chromatography and filtration operations—especially viral validations and filter integrity might be affected because flow can be correlated to pressure and therefore in most cases is controlled. Calibrated rotameters or flow meters are typically used for flow measurement. Also, thermal mass flow controllers play an important role. For liquids, the characteristics of liquid (especially viscosity and conductivity) and the process requirements (sensitivity, accuracy, sterility, etc.) are used to determine the measurement device.

69.4.11 Biomass

In bioprocesses, the monitoring of biomass, cell densities (or cell volumes), is of crucial importance for the process. A wide array of techniques are available, usually carried out using microscopic method, volume measurements, dry weight, and so on (31,32). These are routinely performed off-line. *In situ* or online methods have been described as well (turbidity, *in situ* microscopes, capacity probes, etc.) for direct measurement of cell counts, and so on. Of particular interest is the development of real-time online methods. Generally, methods for determining biomass concentration can be divided into two classifications: direct and indirect. The former is based on determining the physical properties of the cell and its components. In contrast, indirect methods measure factors related to the cell and its activity (e.g. respiration, electrochemical behavior, and nutrient fluctuation).

Quantification of cell number concentration is performed ubiquitously in cell culture operations. Trypan blue exclusion method is most commonly used to differentiate between viable and dead cells, although other staining methods that use ethidium bromide or propidium iodide can also be used. Viable cell density (VCD) and viability (percentage of total cells that are viable) can be measured either manually (using hemacytometer) or using automated cell counters (e.g. Bioprofile® CDV from Nova Biomedical or the Cedex HiRes Cell Analyzer from Roche Innovatis), although the latter results in greater consistency. Automated cell counters can also provide statistics related to cell size and cellular aggregation levels. Cell concentration can also be measured indirectly by cell volume. A fixed volume of cell culture fluid is typically centrifuged in a graduated tube at a predetermined gravitational force for 5–10 min to estimate the volume of packed cells, referred to as the *packed cell volume* (PCV). In exponential growth phase, when cell viability is high, PCV is strongly correlated with VCD. However, due to the inability of PCV to differentiate between alive and dead cells, the correlation between PCV and VCD is weak at low cell viabilities.

A primary disadvantage of these methods is their off-line nature. For mammalian cell culture process, a culture sample is drawn, typically every 12–24 h for each measurement. This limits the frequency at which cell growth can be monitored. Developing technologies to monitor cell growth in real-time has been an aggressive pursuit in the past two decades. Methods based on nuclear magnetic resonance spectroscopy, conductivity, capacitance, fluorescence, and optical absorbance have been tested in bioprocess (for review see Refs 5 and 32).

Among these methods, capacitance-based cell density measurement appears promising. Cells behave as capacitors due to the presence of charged molecules both inside (cytoplasm) and outside (culture broth), separated by a plasma membrane. Capacitance, measured by application of an electric field, is directly proportional to the cell concentration. An important advantage of the method is its ability to differentiate between live and dead cells, because dead cells without intact membranes do not contribute to charge polarization. Good correlations between VCD and capacitance measurement have been demonstrated in several reports (reviewed in Ref. 33). Real-time viable cell mass estimation was used to optimize the perfusion rates in CHO-based recombinant protein production process (34). For large-scale applications, the sensitivity, especially at low cell densities, and linearity of capacitance-based cell density measurements should be carefully considered, because nonlinear correlations between capacitance and cell mass have also been reported in the fermentation of yeast (35). In-line optical density probes have also been employed to monitor total biomass concentration in

TABLE 69.4. Examples for Optical Probes Used in Mammalian and Bacterial Fermentation Processes (5)

Sensor	Mechanism	Application
Aquasant AF44 SIR	Back scattering	Bacterial and mammalian

Optek	Forward scattering	Not specified

bioprocesses. Table 69.4 shows the examples of optical probes in bacterial and mammalian fermentations. These probes rely on light scattering and absorbance properties of cells to estimate cell concentration. However, their application is limited due to their inability to distinguish between viable and dead cells. An *in situ* microscopic system was also developed for CHO-based process in a feasibility report (36). Despite its distinct advantage to enable real-time microscopic examination, a staining method could not be used with this technique to measure cell viability. Cell concentration can also be measured real time indirectly using indicators of cellular metabolism such as oxygen consumption rate, ATP production rate, or CO_2 production rate (32). Among these indirect methods, oxygen-consumption-based estimate is most promising because DO probes are routinely used in cell culture unit operations. Empirical correlations of oxygen transfer coefficient ($k_L a$) in stirred-tank bioreactors can be used to estimate approximate OUR. OUR can also be estimated periodically in the bioreactor by ceasing oxygen supply for short durations. Alternatively, the output of DO controller can be correlated to VCD (or PCV) in a bioreactor. As the cells divide and consume more oxygen, the output of the DO control will increase to maintain a constant DO level in the bioreactor, as shown in Fig. 69.3. However, DO-based methods assume that the specific oxygen update rate is relatively constant. Although this parameter depends on the physiological state of the cells, it is likely to be relatively constant during growth phases in seed and inoculum trains. Care should be taken, however, as these correlations may be cell line specific. Exit gas analysis can be applied as well, while using OURs displaying more accuracy.

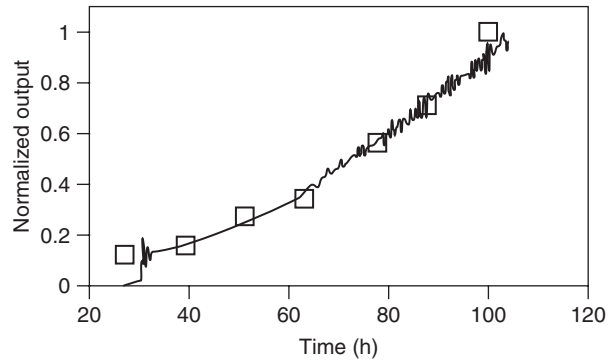

Figure 69.3. Robust correlation between DO controller output (black line) and PCV (open black square) for a CHO process. The *Y*-axis is normalized. DO output is represented as the ratio of the controller output (%) and the maximum output recorded at this bioreactor stage based on more than 100 batches. PCV is represented as percentage of the total volume.

The "health" of a cell culture operation can be monitored by other indicators such as viability and apoptosis. Assays based on extracellular quantification of lactate dehydrogenase (LDH), the reversible enzyme that converts pyruvate to lactate, is a commonly used method to estimate viability indirectly. Viability is measured from the extracellular levels of LDH in membrane-compromised, damaged cells. However, this is a very indirect measure for viability. Programmed cell death or apoptosis can also be used to understand the physiological state of mammalian cells. High recombinant antibody production levels, often accounting for more than 20% of cellular protein levels, can result in stress responses that induce apoptosis. A variety of colorimetric assay kits are available to detect early as well as late apoptotic cells. Many of these assays quantify the active levels of one of the many caspase enzymes that are activated during apoptosis. These assays can be used in conjunction with a flow cytometry device (such as a Guava Easycte) to observe distribution of cell populations. A flow injection instrument used in conjunction with flow cytometry allows real-time monitoring of cell subpopulations (38). Broger *et al*. (37) characterized different high and low EGF-producing populations of *Pichia pastoris* in small-scale bioreactors using real-time flow injection flow cytometry. Flow cytometry is a measuring technique based on the irradiation of a flowing sample solution (containing a cell population) with a suitable light source, followed by monitoring of the scattered or adsorbed light. In addition, fluorescence can be used as the measuring parameter. This technique can be used to ascertain a number of cellular features, such as the accumulation of cellular components (e.g. DNA, RNA, and proteins) and cell dynamics (e.g. cell size distribution). Furthermore, flow cytometry can be used to differentiate and quantify a range of species populations present in a mixed medium. Although such process

instrumentation can be very valuable to further our understanding of cell population heterogeneity in bioprocesses and its impact on process variability, their use in large-scale manufacturing processes has been limited thus far. Their use is often limited to screening and selection of high protein producing cell lines during cell line development.

69.4.12 Monitoring of Other Process Indicators and Product

Measuring and analyzing various metabolic parameters during fermentation is crucial for process control, to achieve and maintain a reproducible fermentation process, and to gain a deep process understanding to characterize, validate, and further improve fermentation processes. Conventionally, substrates, specific proteins, and the metabolites of fermentation media are analyzed using different methodologies depending on the nature of the analyte: that is, amperometric (enzyme membrane based), enzyme linked immunosorbent assay (ELISA), and/or high performance liquid chromatography (HPLC). For mammalian cell culture processes, the parameters typically monitored are glucose, lactate, ammonium, and glutamine. Glucose, lactate, glutamine, and glutamate are commonly measured using an enzyme-based biosensor that converts the substrate to hydrogen peroxide, which is oxidized to produce an amperometric signal proportional to substrate concentration. Examples include Nova Bioprofile Flex (Nova Biomedical) and YSI biochemistry analyzer (YSI Life Sciences). These bioprocess analyzers are most commonly used as off-line, standalone instruments for periodic nutrient measurements. However, autosampling technologies have been developed and successfully applied for cell culture. For bacterial fermentations, autosampling is challenging due to high viscosity, cleaning requirements, and so on. In all cases, comparable performance and reliability needs are to be demonstrated.

The Nova Bioprofile Flex has been applied with autosampling technologies. It can combine three analyzers (metabolite—glucose, lactate, glutamine, glutamate), cell counter, as well as gases and electrolytes (pH, PO_2, pCO_2, ammonium, potassium, sodium) by using a reactor valve module. Details can be found in Refs 5 and 39.

Methods based on photometric quantitation of nutrients such as glucose, glutamine, and other parameters have recently been commercialized (e.g. Cedex Bio by Roche Diagnostics GmbH Germany) to overcome potential disadvantages of other technologies. The Cedex Bio is shown in Fig. 69.4.

In addition to the already mentioned substrates and metabolites, the Cedex Bio can analyze IgG concentration from cell culture broth without any small-scale purification. LDH activity can also be determined using Cedex Bio. LDH is a cytosolic protein released on the lysis of cells, which can be representative to the amount of released proteases, glucosidase, nucleases, or host cell protein (HCP) detrimental to product.

Other chemical parameters such as sodium and potassium concentration are also periodically monitored. As all these parameters are only measured once every 12–24 h, it is desirable to have a high degree of accuracy and precision in their measurement. However, the level of accuracy necessary for process control is different for different parameters. For example, if feed addition is based on controlling glucose at low concentrations, then the instrument must be capable of measuring glucose concentration in the low range (e.g. 0.1–2 g/L) accurately. On the other hand, parameters such as sodium and potassium concentration are typically not utilized for processing decisions, but are useful for troubleshooting purposes. A high degree of accuracy may not be necessary for such parameters.

69.4.13 *In Situ* Process Monitoring Using Spectrometry

Autosampling can minimize disadvantages associated with off-line analysis and sampling procedures. However, this poses risks to sterility and robustness, while increasing complexity. *In Situ* sensors are therefore more advantageous. Several technologies are being developed for real-time estimation of nutrient levels. Technologies including Raman spectroscopy (41,42), infrared spectroscopy (43), UV spectroscopy (42), and fluorescence spectroscopy can monitor a wide array of species, including glucose, lactate, various amino acids, and NAD(P)H. Near infrared (NIR), mid infrared, and Raman spectroscopy have demonstrated successful applications in mammalian cell culture, yeast, and bacterial fermentations (5). In most cases, multivariate data analysis of large data sets from historical fermentations, model evaluation, and training were necessary to establish suitable models. Among all these technologies, NIR spectroscopy offers practical advantages with respect to cost and ease of use (for review see Ref. 44). However, interpretation of NIR absorbance spectra is rendered difficult due to the overlapping spectra of multiple species and the absorption of water in the NIR spectrum. Dimensionality reduction methods such as principal component analysis (PCA) and partial least squares (PLS) are commonly used to identify spectral correlations and express them as linear combinations of a small number of orthogonal dimensions. Pattern recognition methods [e.g. artificial neural network (ANN)] are also necessary to generate calibration or training data sets.

69.4.14 DNA Microarrays

The technology to examine the gene expression level of thousands of genes in a host cell (e.g. *E. coli* and CHO),

Figure 69.4. Cedex Bio by Roche Diagnostics GmbH.

using a single chip called *DNA microarray* was developed less than two decades ago (45). A DNA microarray comprises thousands of probes, each of which is designed to bind with messenger RNA (mRNA) of a particular gene with high specificity. The probe is designed to be complementary to the nucleic acid sequence of the mRNA of a gene. DNA microarrays are commercially available for several species (e.g. mouse and human) from Roche Nimblegen, Affymetrix, or Agilent Technologies. These oligonucleotide microarrays typically comprise 25–60 base pair-long probes that are deposited on the microarray surface by *in situ* synthesis using photolithography

Microarrays provide a valuable tool to decipher the physiological basis of traits that are biopharmaceutically relevant, such as high productivity of recombinant proteins in mammalian cells. Through direct comparison of the host cells under high productivity conditions and control conditions, the genes that are differentially up- or downregulated under the high productivity conditions can be identified. The biological function of the differentially expressed genes (e.g. role in cell cycle and protein synthesis and secretion) facilitates the correlation between the molecular snapshot obtained using microarray and the observed phenotype. Microarrays have been utilized as tools to identify the gene expression signature associated with high recombinant protein producing cells lines (46), as well as high productivity conditions (47). These signatures provide useful targets for engineering cells with relevant traits. The applications of this technology in development of biopharmaceutical processes is reviewed elsewhere (48). Real-time quantitative polymerase chain reaction (Q-PCR) can also be used to quantify the transcript level of genes. Although Q-PCR assay has greater sensitivity and accuracy compared with DNA microarrays, it has significantly lower throughput (e.g. 96-well plate-based assay format). Q-PCR-based expression analysis is often useful when the number of genes are small and known (e.g. all the genes encoding proteins involved in a specific metabolic pathway).

Microarrays can be used as diagnostic tools in cell culture processes. For example, investigations associated with lower productivity and adverse product quality trends during scale-up, technology transfer, and routine manufacturing can utilize a genome-scale survey tool such as microarray to facilitate product and process understanding, leading to possible corrective actions. Recently, the entire 2.45-Gb genome CHO-K1 parental cell line has been sequenced, which is publicly available (49,50). This development is likely to accelerate the use of whole-genome "omics" tools (e.g. a commercially

available DNA microarray for CHO) in a wide array of bioprocess applications.

Advent of massively parallel sequencing technologies has promoted development of several sequencing-based high throughput assays such as detection of noncoding microRNAs (79) and ChIP-Seq for detection of DNA sites that interact with proteins. As the cost of high throughput sequencing plummets, additional applications in cell engineering and bioprocessing will emerge.

69.4.15 Chromatography and Recovery Operations

After production in the fermentation process, the desired product has to be purified. The major goal of the recovery operations is to remove impurities (DNA, HCPs, etc.), potential viruses, and by-products. Therefore, chromatography has been widely used in the industry. The principle is based on the separation of a mixture of compounds by specific interactions with the matrix of a mobile and stationary phase.

Process monitoring for recovery operations is usually made up of two components—in-process analytical tests and real-time measurements via in-line sensors and probes. In-process analytical tests are designed to provide information on product quality attributes at various stages throughout the purification process. Some of these tests (i.e. pH or UV absorbance) can be performed quickly by the operators on the manufacturing floor with little set-up time, while others (i.e. bioburden) may take several days to obtain results and usually require the expertise of a separate analytical group. Currently, most real-time measurements are designed to provide information about the process. With modern manufacturing control systems and data historians, large amounts of continuous data can be collected during a purification process. Sensors located on the process equipment provide information about key process indicators such as pH, conductivity, pressure, and UV absorbance. These process indicators can be visualized during the process itself or examined retrospectively and provide information on the performance of chromatography steps or filtration operations. They can also be trended versus historical limits to identify subtle process changes over time. Although most real-time measurements are currently being used to provide data about the process performance, recent advances in PAT can now allow a direct correlation to product quality as well. To control the process, several analysis and detection methods have been established. Especially the production of therapeutic proteins and antibodies requires a wide range of analytical methods to determine the concentration, purity, identity, integrity, and activity. A large number of operations and detectors have been developed for these purposes (flame, UV detectors, electrochemical detectors, IR and refractive index detectors, conductivity, and mass spectrometry). Also, a large number of chromatographic methods are available for sample analysis. Most of the chromatographic analysis is carried out off-line. Table 69.5 shows exemplary analytics performed in a pharmaceutical antibody production process. Details can be found in the study by Flatman *et al*. (51). A state-of-the-art monoclonal antibody process can be found in the study by Shukla and Thömmes (52).

Some real-time testing of product quantity can be performed online. Other operation monitoring parameters can be performed online as well. For example, one factor that can have a significant effect on chromatographic performance is the quality of the column packing. The current standard procedure for testing the quality of a packed bed liquid chromatography column is to use a nonabsorbed tracer to perform a pulse-injection experiment. The injected tracer solution is assumed to be a Dirac pulse. The pulse exits the column as a peak due to axial dispersion. Plate number, N, describes the degree of the dispersion, which is influenced by the packing quality of the column bed. A related term, Height Equivalent to a Theoretical Plate (HETP), provides a measure of peak broadening in relation to the distance the tracer has traveled in the chromatography column. The mathematical definitions of N and HETP are given by the following equations:

$$N = V_r^2/\sigma^2$$

$$\text{HETP} = L/N$$

where V_r is the retention volume, which is defined as the volume that has passed through the column from the time when half the tracer is applied to the time when half the tracer has exited the column. In other words, V_r is the mean exit volume of the injected tracer, σ^2 the variance of the exit volume distribution, and L the column length.

Based on the normal density function, the width of a curve at half peak height, W_h, is equal to $2\sigma(2\ln 2)^{1/2}$. Because the peak generated by the tracer as it exits the column is assumed to follow a Gaussian distribution, N is usually calculated with the simplified formula shown in Fig. 69.5.

In recent years, efforts have been made to directly use process chromatography data to determine column efficiency to achieve real-time monitoring (53,54). The common approach taken in these studies is to utilize information from step transitions between buffers of different conductivities to describe the same dispersion parameters as the traditional pulse-injection method. One method is to transform a breakthrough curve or a washout curve into a peak by taking the first derivative (53). The dispersion parameters are then derived from the peak position and shape. To avoid the inaccuracy of calculation caused by assuming a normal distribution, algebraic functions other than the normal probability density function were evaluated, and a function that can describe

a large number of step transitions has been identified. However, arbitrarily assigning a predetermined function to represent unknown distributions has disadvantages. Depending on the column packing quality and the running conditions of the chromatography, there are transitions that differ significantly from the chosen function and cannot be adequately represented by it. In these cases, the forced fitting of transitional data to the function would cause loss of information. Another method is to treat the exit volume of the solution that is replacing the original solution in the column as a discrete random variable (54). The incremental change in a response signal, such as conductivity, serves as the frequency of each exit volume. The starting point for the transition occurs when 0 L of the displacing buffer has flowed onto the column. The conductivity recorded at this point corresponds to that of the buffer on the column at that time ($C_{\min}$). After a sufficient amount of the displacing buffer has flowed through the column, the conductivity will reach a new equilibrium ($C_{\max}$).$C_{\max}$ is equal to the sum of $C_{\min}$ and the definite integral of dC, which is integrated from $C = C_{\min}$ to $C = C_{\max}$. To simplify the calculations, C

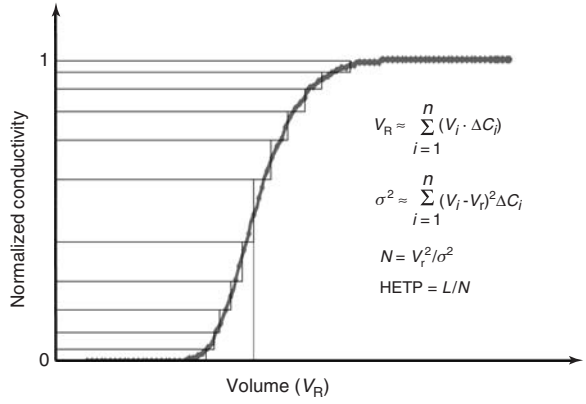

Figure 69.6. Plate calculation via transition analysis method.

may be first normalized using the following equation:

$$C_{\text{normal}} = \frac{(C_i - C_{\min})}{(C_{\max} - C_{\min})}$$

As shown in Fig. 69.6, V_r and σ^2 can be calculated from the transition curve using the rectangular approximations of their integral forms. As the numeric data used in the analysis is discrete, V_r and σ^2 can be calculated using the following equations:

$$V_r = \Sigma(V_i \Delta C_i)$$
$$\sigma^2 = \Sigma(V_i - V_r)^2 \Delta C_i$$

Note that the influence of each V_i on the output values of V_r and σ^2 is weighed by the magnitude of the corresponding ΔC_i. The largest value for ΔC_i usually occurs when its corresponding V_i is close to V_r. The values for N and HETP are calculated using equations shown later. Both breakthrough curves and washout curves can be analyzed in a similar fashion.

Monitoring the integrity of large-scale packed bed liquid chromatography columns using transition analysis can provide useful information about the process. Figure 69.7 provides an example of how the HETP value derived from the transition analysis of a protein A chromatography column changed over multiple cycles of processing. The values increased with time after initial column packing (A). Increased measurement variability was also observed as integrity decreased. This was later determined to be caused by the formation of a headspace on the column. When the top flow adapter was lowered to eliminate the headspace, the HETP values were restored to their original values (B). However, subsequent repacking of the column once again revealed rapid degradation of the column integrity due to insufficient consolidation of the resin during the packing procedure (C and E). The flow adapter was lowered again after the second packing (D) to improve column performance.

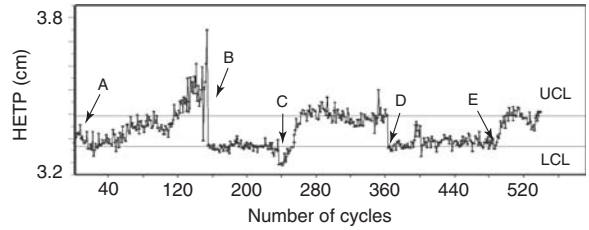

Figure 69.7. Control chart of protein A column HETP derived from transition analysis. UCL, upper control limit; LCL, lower control limit.

69.4.16 Data Technologies and Artificial Intelligence

The data obtained have to be analyzed to derive powerful and scientific sound conclusions, define interdependencies, and derive enhanced control strategies. Several approaches have been discussed in the literature, for example, hybrid modeling (55,56) and multivariate modeling, including principle component analysis, PLS, and ANNs (57,58).

Recent developments in the field of artificial intelligence have led to investigations into the use of such systems for improving bioprocess control, based on the received measurement output signals. This has included the use of both knowledge-based expert systems and neural networks, during bioprocess operation. Robotics is also an important way to manage millions of chemical assays. Undoubtedly, the adaptation of such "intelligent" systems will develop over the coming years and will play an important role in the precise control of bioprocess applications.

Multivariate tools are widely used to increase process understanding and optimization. Application in fermentations (including raw material screening) to analyze metabolic effects, estimations of final productivity in bioreactors, root cause analysis tools, real-time process monitoring, and so on have been described. Also, in recovery processes, this technology has been reported to add value. Chromatographic operations are often characterized by different phases that produce specific patterns and signals. For robust automation, these patterns have to be detected and discrete decisions need to be made at key points. Structured models are frequently used to perform online diagnosis and fault detection, and chromatogram overlays are often used to monitor interbatch performance. Early detection of process perturbations makes it easier to identify root causes and adjust control parameters or correct deficiencies to ensure high product quality and prevent batch loss. One method that has been described frequently in the literature for analyzing production data and gaining process understanding is multivariate statistical process control (MSPC) (59–62). Several papers have described the use of MSPC for monitoring batch processes to not only ensure acceptable product quality but also improve overall process performance and output

(63–65). In MSPC, multivariate models are first developed for "good batches" using PCA and PLS. These models can then be used to evaluate the performance of new batches in real time using commercially available software packages. When applying MSPC to chromatographic process data, a large number of factors can affect when certain events occur. Variations in the mobile phase composition, gradient reproducibility, temperature variations, and column packing variability can lead to shifts in the chromatographic patterns making objective analysis and comparison difficult. The unsynchronized nature of chromatographic data, therefore, implies the need for chromatogram alignment before analysis. Fortunately, most alignment problems can be resolved by normalizing the data based on the cumulative volume of buffer passed through the column. More sophisticated alignment techniques, such as dynamic time warping and correlation optimized warping, have also been used (66,67).

69.4.17 Softsensors

From a process engineering perspective, a software sensor, or in short, a softsensor is an estimation algorithm for a quantity that cannot be easily detected online. Information from other online sensors being utilized in the process can be used to estimate this quantity. Hence, a softsensor associates sensor hardware and an estimation method, that is, a software routine (70). Typically, softsensors were developed for online measurements of biomass concentrations, product concentrations, or specific biomass growth rates. The topic has also been reviewed elsewhere (75). At production scale bioreactors, the options for online measurement devices are rather restricted. Only a few basic devices can be validated such as sensors for pressure, temperature, pH, DO, and the off-gas volume ratios of O_2 and CO_2. Hence, softsensors are essentially a software challenge. Softsensors most often do not take their information from a single sensor. Instead, they pool and condense the information from several ones, thus performing a multivariate analysis of the bioprocess to provide accurate estimates. This gives them a decisive advantage over single sensors: By means of simple balances, data consistency checks can be performed. This is important because decisions can only be made on measurement data that have good accuracy. Thus, it is not only the possibility to measure quantities that cannot be measured directly that makes softsensors attractive, the software can also be employed to perform tasks beyond the actual estimation. For instance, the software can perform fault analysis with respect to the sensor and the process. The complexity of signal processing may vary from simple code conversion to sophisticated extraction of pattern hidden in the data. The focus in this section is the estimation part of softsensor. In this respect, the softsensors are classified by the sophistication of the model relating the available sensor signals to the quantities to be estimated. Two basic categories are distinguished: data-driven and first principle models.

69.4.18 Basic Estimation Models

69.4.18.1 Data-Driven Models

69.4.18.1.1 Utilization of Correlations. Simple engineering correlations are traditionally the first approach when process quantities must be related to each other. For instance, to track the biomass within a bioreactor with quantities that are measured online, a first choice is to look for the respiration rate of the cells.

The OUR or the CPR can reliably be determined from the volume fractions of O_2 and CO_2 in the reactor's vent line. They are related to biomass x by a simple relation similar to Luedeking and Piret's (77) expression:

$$\mathrm{OUR} = Y_{\mathrm{ox}}\mu X + m_0 X$$

This relation can be used to form a softsensor by converting it into an ordinary differential equation in biomass and solving it using a simple Euler algorithm. With an initial biomass $x_0 = x(t_0)$, the final expression to be iteratively determined at each sampling time t_i for OUR and culture mass W measurements:

$$x(t_i) = x(t_{i-1}) + \mathrm{d}t\left(\frac{\mathrm{OUR}(t_i)W(t_i) - m_0 x(t_{i-1})}{Y_{\mathrm{ox}}}\right)$$

An equivalent sensor can also be obtained for the relation between biomass and the CPR, which can be measured online as well.

Computationally, with softsensors we are faced with two different problems, we must distinguish between the computing power required during the online estimations (measurements). For the above example, this is the computing power needed for the stepwise solution of the Euler formula. On the other hand, we must consider the implementation expenses. In this particular case, it is the identification of the parameter values Y_{ox} and m_0 from a set of training data measured beforehand for the process under consideration by means of nonlinear optimization procedures. While the first task is usually time critical, the second is performed off-line using optimization routines and is thus uncritical concerning computing time.

69.4.18.1.2 Polynomials. An improvement can be obtained by pooling the information from several measurements. In the simplest case, the following linear relation can be used:

$$X = a_0 + a_1\mathrm{OUR} + a_2\mathrm{CPR} + \cdots$$

The parameters can simply be determined with multivariate regression algorithms available in all standard software libraries.

Simple improvements of this basic linear approach can be obtained when OUR and CPR are replaced by their cumulative rates cOUR and cCPR. This measure acts as a powerful noise filter. In addition, another cumulative signal that is usually available at fermenters can be added. This is the total mass of base added to the culture during pH control as measured online with a simple balance under the base reservoir. This enlarges the linear equation to

$$x = a_0 + a_1 \mathrm{cOUR} + a_2 \mathrm{cCPR} + a_3 \mathrm{Base}$$

The parameters a_i can be determined in the same way as before using a set of training data.

As the cultivation processes are intrinsically nonlinear, the linear relations can be extended to polynomials. A first approach is

$$\begin{aligned} x = {} & a_0 + a_1 \sum \mathrm{CPR} + a_2 \sum \mathrm{OUR} + a_3 \sum \mathrm{Base} \\ & + a_4 \left(\sum \mathrm{CPR}\right)^2 + a_5 \left(\sum \mathrm{OUR}\right)^2 + a_6 \left(\sum \mathrm{Base}\right)^2 \\ & + a_7 \sum \mathrm{CPR} \sum \mathrm{OUR} + a_8 \sum \mathrm{CPR} \sum \mathrm{Base} \\ & + a_9\ \mathrm{OUR} \sum \mathrm{Base} + a_{10} \sum \mathrm{CPR} \sum \mathrm{Our} \sum \mathrm{Base} \end{aligned}$$

With respect to the parameters a_i, this equation is still linear; hence, the parameters can once again be identified with multiple linear regression routines.

69.4.18.1.3 Principal Components. Another linear technique often applied in multivariate data analysis is PCA. This technique is particularly important when many different measurements are to be exploited within the analysis, because the main idea is to transform the input data matrix composed of the signals from n input variables into a matrix of signals for a lower number of latent variables ($< n$) that essentially carry the same measurement information (62,72,74). As with multiple linear regression, PCA can easily be performed using general PC software. Ready to used subroutines are included in all common software packages (e.g. MATLAB® subroutine *princomp*).

As many online process variables in a fermentation process are correlated (e.g. lactate concentration and base addition), a notable reduction in variables is possible. However, this can only be performed at the cost that the latent variables or scores obtained no longer depict a physical meaning. In fermentation processes where the number of online variables is rather low, the benefit of such an approach is thus questionable.

69.4.18.1.4 Artificial Neural Networks. A general approach of representing nonlinear relationships between several input and output variables is using ANNs. Even simple feed-forward networks with a single hidden layer proved to be able to represent the mappings that are of interest in softsensors.

The term *artificial neural network* can be considered a catchword that is derived from the dataflow in a very simple algorithm. In the case of the simple feed-forward network with a single hidden layer with m nodes, it loses its myth when represented as a simple expression in term of a logistic function $1/[1 - \exp(s)]$. For the biomass x

$$x(t) = w_\mathrm{h} \frac{1}{1 + \exp[-w_\mathrm{i} s(t)]}$$

This is a simple deterministic scalar product. The coefficients w_h, referred to as *weights*, form the first (row) vector, which is multiplied with a second (column) vector composed by elements that are logistic functions with argument $w_\mathrm{i} s$, where w_i is a weight matrix with m rows and n columns and $s(t)$ the n-dimensional input (column) signal vector at time instant t.

The coefficients of this representation, compiled in the vector w_h and the matrix w_i, can be determined in various ways. The easiest way is using the nonlinear optimization routines offered by the various software libraries (in MATLAB® the equation can be fitted to process data with *lsqcurvefit*).

An important point to be considered is that it is not reasonable to feed all available online signals to the input of an ANN biomass estimator. It must be made sure that every input signal will more significantly contribute information to the biomass estimate than just putting noise into the analysis. This requires knowledge about the cultivation process (Fig. 69.8).

More sophisticated versions of ANNs can be constructed by transferring the idea behind PCAs into the domain of nonlinear relationships. This is done in "autoassociative artificial neural networks" (aANNs). As with PCA, a set of $k < n$ latent variables is produced. For this purpose, a regular ANN with n input nodes is used. Then, in addition, these k signals are mapped back into the original data space by means of two further feed-forward network layers. After determining all coefficients or weights, the entire aANN should be able to map all reasonable input vector combinations of the process under consideration onto themselves. In this way, the layer with the latent variables is directly related to the input variables, that is, a nonlinear version of the linear PCA is generated.

Different estimators are often compared in terms of a performance measure, which is usually an average estimation error. Most often, the root-mean-square error (RMSE) is used for this purpose (73). A quantitative

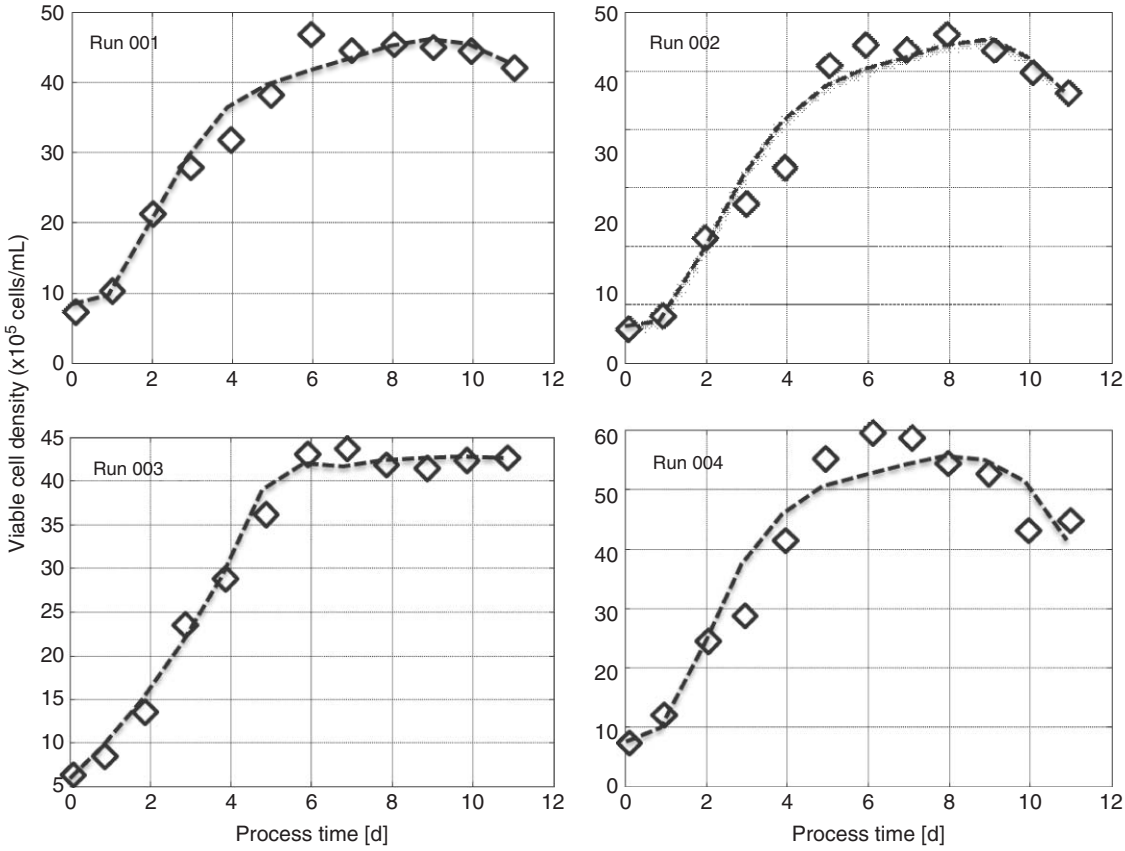

Figure 69.8. Viable cell count off-line data (symbols) from four individual batches of a CHO recombinant protein production process together with the online estimates of an ANN (lines). Input variables are several signals from the DO controller of the bioreactor as well as base consumption and reactor weight.

TABLE 69.6. RMSE Values for the Different Biomass Estimation Methods as Described in Text

Estimation Procedure Applied to VCD Data From a Production Cell Culture Process	Biomass Estimation Error, RMSE (%)
Biomass estimation by a feed-forward ANN	3.24
Polynomial regression	4.76
Multivariable nonlinear regression	4.12
Luedeking/Piret-like relationship and OUR measurements	4.41

comparison of the various approaches discussed here is shown in Table 69.6. All the estimators mentioned can be evaluated online, while the corresponding parameter optimization procedures can be rather time consuming.

The ranking of the methods mentioned clearly shows that the best estimation quality can be obtained with simple feed-forward ANNs with a single hidden layer. This result proved to be valid in microbial and animal cell cultures at various scales from the small liter scale-up to several cubic meters.

69.4.18.1.5 Support Vector Machines. Support vector machine (SVM) is an attractive alternative to ANNs. Compared with ANNs, SVMs find the global minimum, what cannot be guaranteed with neural networks.

The basic idea behind SVM is to map the training data from the input space into a higher dimensional feature space. This transformation allows constructing a separating hyperplane with maximal margins in the feature space. Consequently, although we cannot determine linear function in the input space to decide what class a given data element belongs to, we can easily determine a hyperplane that can discriminate between two classes of data. The accuracy of the SVM regression is at least about the same as the result obtained from the ANNs discussed earlier.

69.4.18.1.6 Bayesian Approaches. As the performance of computers increased significantly over the years, more computationally demanding algorithms can be employed for

analysis of online data. Thus, more practical applications of Bayes statistics (71) appear in the literature.

Instead of looking at single parameter values within an estimation algorithm, it considers probability density distributions of the parameters to characterize the actual knowledge about their values. When the density function is tight, that is, the variance is small; we have a rather concrete knowledge about its value. Bayes' law shows how the current prior knowledge about a parameter θ becomes sharper when we employ concrete measurement data from the process to obtain an improved *a posteriori* density function.

Additional techniques such as clustering, decision trees, and *k*-nearest neighbors can also be employed for mining bioprocess data (reviewed in Ref. 80).

69.4.19 First Principle Models

69.4.19.1.7 Virtual Plant. When there is not enough data available from the process, the measurement information used to estimate the quantity under consideration can be supplemented by a priori knowledge about the process in form of first principle models. Although full dynamic models of the process are an attractive option to relate online signals to key performance parameters of the process, they are not considered to be typical for softsensors as the online solution of the models might be expensive. Moreover, the behavior of the solvers of dynamic equation systems for combination of noisy input signals is difficult to keep under control. Nevertheless, developments of online simulations of the processes are under way and are referred to as *virtual plants*. Versions that are able to simultaneously run with the process are used for process supervision (68).

69.4.19.1.8 Extended Kalman Filters. Simpler first principle models can be employed in softsensors when they are exploited in the so-called observers or filters. The extended Kalman filters (EKFs) are an advanced variant that has been applied to recombinant protein production processes (68,76,78).

EKFs are one-step-ahead predictors: At each data sampling time, the EKF determines a new estimate as a weighted average from the previous estimate, the value predicted by the model and the measurements. When, for example, the measurement values are considered more accurate than the model predictions, they influence the estimate more than the values predicted by the model. A scheme for online estimating the biomass (X) and substrate (S) concentrations as well as the specific growth rates (μ) in a fed-batch process from OUR, CPR, and Base is depicted in Fig. 69.9.

Basis is the first principle model based on the mass balances for X, S, and W, under the assumption that specific growth rate is to be kept constant, is shown on the left. Measurements H performed online are shown on the right. The connection between both is established by means of the measurement equation. The measurement equation transforms the actual state vector c into the measurement vector H. The EKF then provides a weight matrix K_g, referred to as the *Kalman gain*, which determines a correction Δc to state c_{pred} predicted by the model from the difference between the actually measured values H and those (H_{pred}) predicted from the model, to provide a new estimate c_{est}.

An example is shown in Fig. 69.10 for an *E. coli* culture producing a recombinant protein.

69.4.19.1.9 Hybrid Models. A compromise between full dynamic process models and data-driven models can be made by combining the best of both approaches. From the full dynamic models, one can take the basic mass balance equations, which are simple to formulate, while the kinetic

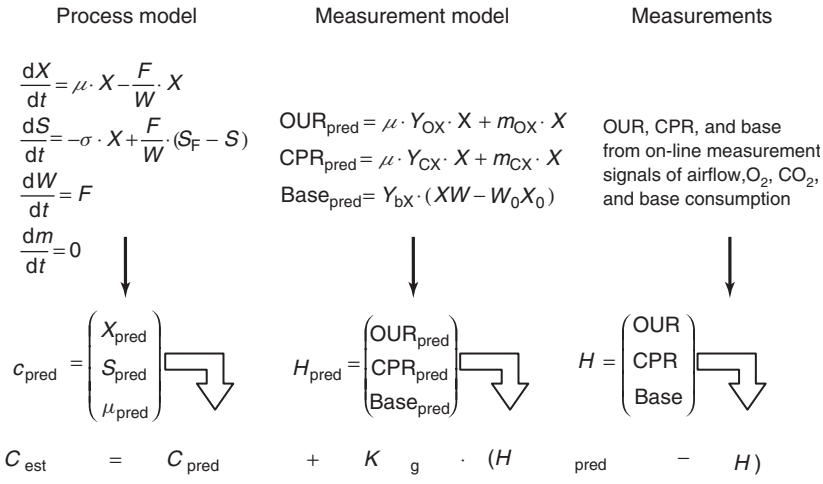

Figure 69.9. Concrete scheme of an EKF estimating biomass and substrate concentrations as well as the specific biomass growth rate from OUR, CPR, and Base consumption measurement values.

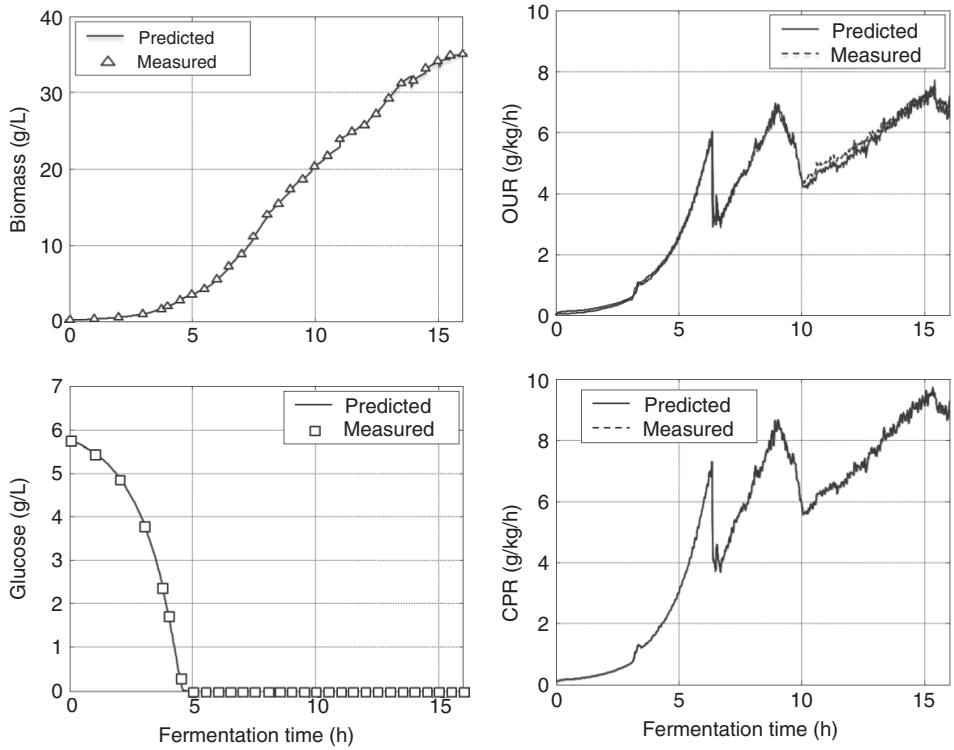

Figure 69.10. Typical example of EKF estimates of the biomass concentration X, the substrate concentration S, the OUR, and the CPR together with measured values.

submodels, which are much more difficult to establish, are represented in a data-driven way (e.g. by means of ANNs; Fig. 69.11.

69.5 CONCLUSION

A wide variety of sensor and instruments for process monitoring are available. Tremendous efforts have been made in the recent years to enable PATs in bioprocesses. Several *in situ* and online technologies and sensor are on their way into commercial manufacturing to enhance processes and enable more advanced control systems. Most of them have been used in other industries for years and have evolved to meet the demands of the biotechnology industry. The application of new sensors, with the right selectivity, robustness, ease of use, and so on, will lead to enhanced process understanding and drive more advanced

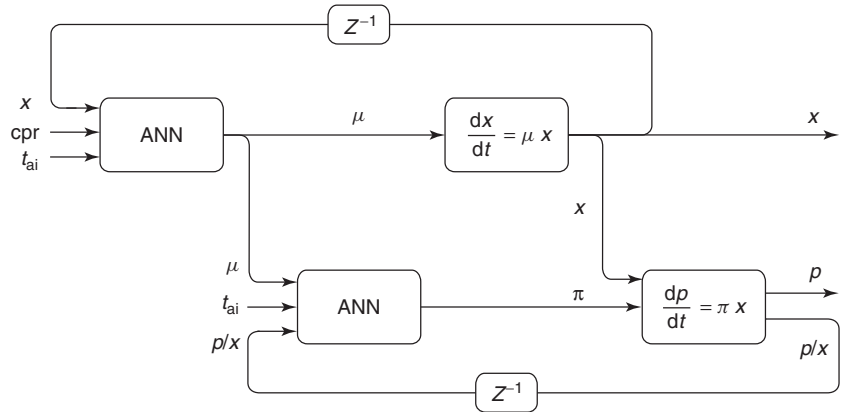

Figure 69.11. Scheme of an ANN-based approach of deriving the $\pi(\mu)$ relationship, that is, the product formation rate π as a function of the specific biomass growth rate μ.

process controls as a PAT application. New and advanced sensors combined with strong data analysis tools will drive toward a next level of process control. Multivariate data analysis techniques and softsensors will provide a valuable toolkit in our efforts to better understand and monitor bioprocess and to improve their consistency. In general, the following trends can be seen in applications of softsensors:

- an available sensor is not fast enough or not sensitive enough or displays adverse signal drifts;
- a sensor allowing direct measurements at sufficient accuracy is not available;
- a direct measurement is physically impossible;
- the employment of a direct measuring device is too expensive; and
- a direct measurement would require too much supervision or maintenance.

The choice of the estimation algorithm depends on the accuracy and the computing time in online applications required for a particular task. For control purposes, smaller response times are mandatory, while for process supervision, usually more time is available.

While the cost of sensing and computation has been decreasing drastically in the past, softsensor systems still require some development expenses. Hence, costs and benefits must carefully be balanced. Finally, it should be stressed that multivariate data mining techniques can discover patterns that are hidden within the process data sets and therefore lead to opportunities to increase robustness and yields. Software estimators do not generate new information. Hence, development and implementation of more accurate and reliable online sensors for production processes will be in important pursuit.

70.1 INTRODUCTION

Introduced in 1975, flow injection analysis (FIA) was an entirely new approach to perform chemical analysis (1). While such assays for centuries had been based on thorough mixing of sample with appropriate reagent(s), and waiting for chemical equilibrium to be obtained (i.e. both physical and chemical homogenization), FIA was, as illustrated in Fig. 70.1(a), founded on injection of a well-defined volume of sample into an inert or reagent-containing carrier stream, to which additional reagents, if called for, could be added downstream, thereby accomplishing partial mixing of the components to promote chemical reaction, the result of which subsequently could be monitored by a suitable flow-through cell, which may continuously observe an absorbance, an electrode potential, or any other physical parameter as it changes on passage of the sample material through the flow cell. Thus, the physical and chemical homogenization, which, in fact, had been the key stones in batch assays and also in the then existing (predominantly clinical) automated analyzers, were not any more necessary, which, in turn, opened up entirely new avenues to perform chemical assays, where non-steady state conditions could be exploited. The ensuing years have amply proven these advantages, as clearly evidenced in the large number of FIA publications which have been published, counting at the beginning of 2008 altogether more than 17,500, to which should be added ca. 20 dedicated monographs and hundreds of Ph. D. theses (2).

During its existence, FIA has undergone certain changes and modifications, that is, it was in 1990 supplemented by Sequential Injection Analysis (SIA), also termed the second generation of FIA (3,4), and in 2000 by the Lab-on-Valve (LOV), the third generation of FIA (5). Thus, the present chapter will focus on these three generations of FIA, their characteristics and their applications, that is, initially outlining the distinctive features of FIA when compared to conventional continuous flow analysis (CFA) and via selected examples demonstrate some of its unique capabilities, while in the following sections emphasis will be placed on the ensuing generations of FIA, detailing their distinct advantages (and limitations) as compared to FIA. In selecting the examples given, attention has been given to show the versatility of FIA and its sequels particularly within the biotechnological field, including process-monitoring. What is of importance in the present context is, to demonstrate that the FIA approach, besides allowing automation of chemical assays with high sampling frequencies and minute consumptions of sample and reagent solutions, offers potentials to implement novel applications. As one of these authors previously wrote in characterizing FIA: "the ultimate test for an analytical approach is not that it can do better what

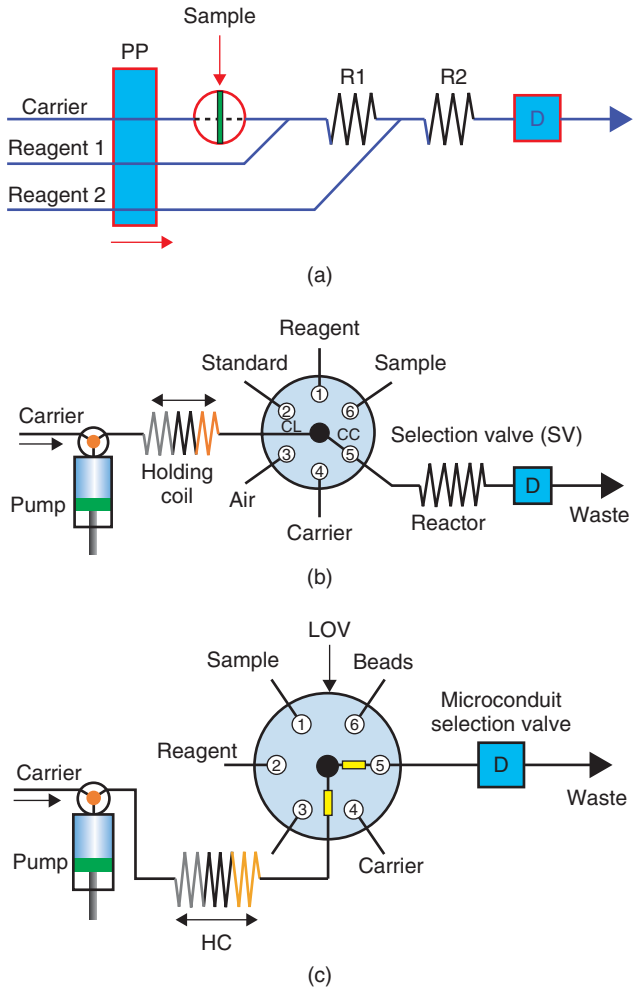

Figure 70.1. (a) Flow injection system, where the sample (S) is injected into a carrier stream as propelled by a peristaltic pump (PP), which downstream is merged with reagent(s), the transient signal from the product generated by passing the reaction coil(s) (R) being measured by a suitable detector (D). (b) Sequential injection system as based on using a selection valve, the central communication channel (CC) of which can be programmed to address each of the external ports. Via the central communication line (CL), sample and reagents can by means of the syringe pump be aspirated into the holding coil and afterwards propelled to the detector which monitors the ongoing chemical reaction. (c) Lab-on-valve (LOV) system, the concept of which is a microconduit placed atop a selection valve (as shown in Fig. 70.5). Ideally containing all means for facilitating the chemical assay, including a flow-through detection cell, the microconduit is also amenable to externally attached components, such as detectors or bead reservoirs for integrating small packed column reactors within the valve. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

can be done by other means, but that it allows us to do something that we cannot do in any other way" (6). And FIA does exactly that. The only limitation is simply our own ingenuity.

70.2 FUNDAMENTALS OF FLOW INJECTION ANALYSIS

As mentioned above, FIA is based on injection, or insertion, of a discrete, well-defined volume of sample solution (usually 20–100 μL) into a flowing carrier stream. Yet as already verbalized in the very first FIA publication, it relies on two additional cornerstones, namely: (i) reproducible and precise timing of the manipulation that the injected sample zone is subjected to in the system, from the point of injection to the point of detection, that is, the so-called controlled, or rather controllable, dispersion, and (ii) the creation of a concentration gradient of the injected sample, providing a transient, but strictly reproducible readout of the recorded signal. The eventual peak-shaped readout, as monitored by a suitable detection device, is therefore always the result of two kinetic processes that occur simultaneously, namely the *physical* process of zone dispersion and the superimposed *chemical* processes resulting from reaction between analyte and reagent species. It is the combination of these features that makes it unnecessary to achieve steady-state conditions, as they are essential in conventional CFA. Any point on the path toward the steady-state signal is as good a measure as the steady-state itself, provided that this point can be reproduced repeatedly, and this is certainly feasible in FIA with its inherently exact timing. This, in turn, has not only allowed to perform chemical assays much faster, and hence facilitate higher sampling rates, than in conventional procedures, but more importantly it has permitted to implement procedures which are difficult, or, in fact, impossible, to effect by traditional means.

Being modular in its operational set-up, virtually any unit operation can be incorporated into an FIA system in order to facilitate the optimal manipulations and ultimate detection of the analyte. Thus, the sample might be subjected to appropriate pretreatments to separate the analyte species from interfering constituents (e.g. by dialysis or extraction). It can be heated/cooled, suitable chemical reagents can be added downstream to facilitate the desired chemical reaction(s) under optimal conditions, and almost any detection device is amenable to be used. In biotechnological applications, sampling is performed by exploiting a sterile barrier for removal of suspended matter, high molecular weight species or cells (7). The immediate consequences of this sample pretreatment is the effective stopping of any further metabolism in the collected sample and the feasibility to inject a preset volume of sample directly into the detection system without the need for further sample clean-up. The sterile barrier is usually composed of a flow-through concentric microdialysis probe operating under convective-controlled transport (8,9). The microdialysis probe can be introduced either directly into the reactor or implemented into an external by-pass loop in order to minimize membrane fouling.

When monitoring parameters in fermentation broths, it is however important to reduce both residence time in the loop and the ratio of loop volume to working volume in the bioreactor to prevent any effect on the performance of the microbial culture in terms of substrate availability (10). It should be borne in mind that yields of flow-through dialysis are frequently below 15% wherefore, dialysis modules/probes have been tailored successfully to bioreactors for in-line dilution of target species (11,12).

Moreover, since only one sample is handled at a time in FI set-ups, the inter-sample washout is efficient and there is no cross sample contamination. In addition, because the wash-to-sample ratio is high, the sample contact time with the detector is short, which is especially advantageous for biosensor applications, as the analytical reaction often reduces the life of the sensor (sensor wear-off) (7).

While much of the attention in using FIA (or just FI, to emphasize that it is a conceptual approach, in addition to a means of performing analysis) initially was set on the feasibility of achieving high sampling rates, as facilitated by exploiting transient rather than conventional steady-state signals, the focus was soon shifted to exploitation of the concentration gradient created, which, as a result of the axial and radial dispersion processes, in reality corresponds to an innumerable number of sequential liquid segments, representing all concentrations from zero to the maximum of the FI peak readout, each of which, as related to a fixed delay time (as measured from the time of injection), potentially can be used for the analytical readout. This, in turn, gave rise to a number of gradient methods (13) as briefly outlined in Table 70.1, among which especially should be highlighted the stopped-flow method (Fig. 70.2), which either can be used to gain increased reaction time without dilution (dispersion) of the injected sample, or, when stopping a part of the sample/reagent mixture within the flow-through cell, for sensitivity improvement as well as for measurement of reaction rates. The second approach has proven to be a very powerful tool in many contexts and implemented in the various generations of flow injection (14). Not the least for bioanalytical assays encompassing investigation of cellular activities (15,16) and enzymatic procedures for determination of both substrates and enzymatic activities (17,18), where the latter one traditionally has been very difficult to execute.

Later followed the introduction of methods relying on detection by bio- and chemiluminescence, allowing to relate the maximum intensity of the generated transient light emission to the analyte concentration (see below). These very sensitive analytical procedures, which prior to the introduction of FI virtually were nonexistent, have blossomed to the extent that more than 2000 publications have emerged in the scientific literature over the years, thus accounting for about 11.5% of all the published FI articles (2). Essentially, these assays are all based on enzymatic conversion procedures, and these types of kinetic *modus operandi* are, in fact, some of the most frequently encountered ones. In the beginning, primarily relying on the use of solubilized enzymes, but later predominantly via immobilized enzymes, taking advantage of the fact that the costly enzymes, even though they are participating in the reactions with the substrate, are not consumed and thus can be reused.

Exploiting the precise and reproducible timing in FI, the formation of intermediate/metastable constituents, which, in contrast to the ultimately generated products, exhibit specifically attractive analytical characteristics, have been utilized to serve for the analytical readout (14), an approach that is totally impossible to make use of in a batch system. Among the many exciting novel techniques are also found the so-called kinetic discriminating schemes, where, even subtle differences in the reaction rates of occurring

TABLE 70.1. Examples of FIA Gradient Techniques

Gradient dilution	
	Selecting and using for the analytical readout specific fluid elements along the concentration gradient, the concentration being $C = C^{o}/D(t_i)$. To be used, for instance, to accommodate the concentration of sample to the dynamic range of a detector.
Gradient calibration	
	Identifying and exploiting a number of elements along the gradient, the concentrations of which are given through the dispersion coefficient of the individual elements. A multipoint calibration curve can be obtained from a single injection of a concentrated sample.
Gradient scanning	
	Combining the use of gradient dilution with the use of a dynamic detector which, for each concentration level, is able continuously to scan a physical parameter, such as wavelength or potential.
Stopped-flow	
	Increase of sensitivity of measurement by increasing residence time, or quantifying sample concentration by measuring a reaction rate under pseudo-zero-order reaction conditions (Fig. 70.2).
Titration	
	Identifying elements of fluids on the ascending and descending parts of the concentration gradient where equivalence between titrand and titrant is obtained, and relating the time difference between these elements to the concentration of injected analyte.
Penetrating zones	
	Exploitation of the response curves from the concentration gradients formed when two or more zones are injected simultaneously. In addition to acting as an economical way of introducing sample and reagent solutions, it can be used for measuring selectivity coefficients, and to make standard addition over a wide, controllable range of standard/analyte concentration ratios.

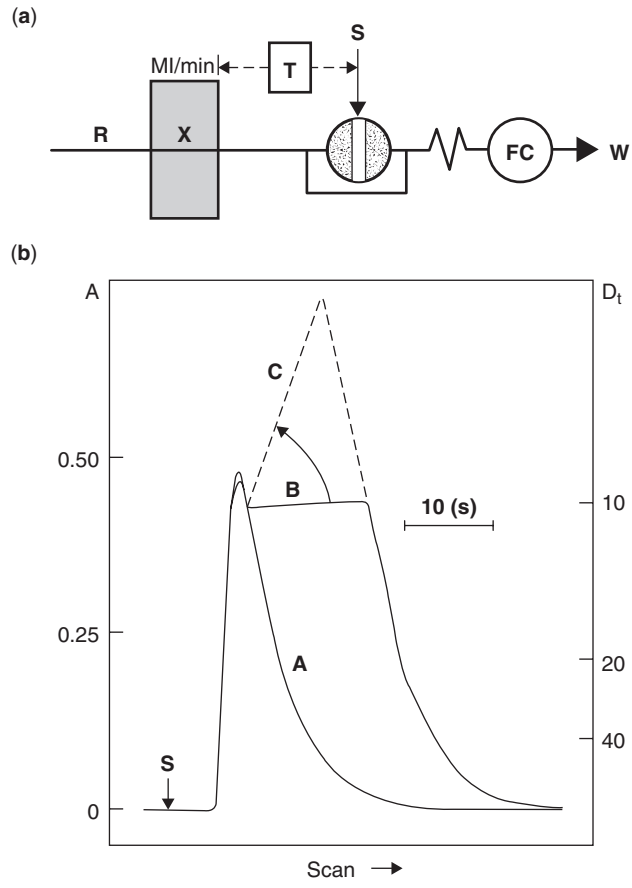

Figure 70.2. (a) Simple stopped-flow FI manifold, where the timer (T) can be set to stop the liquid stream at a preset time. (b) As demonstrated for a spectrophotometric measurement of absorbance, curve (A) shows the signal for continuous pumping, curve (B) for a fast (instantaneous) chemical reaction, while the dashed line (C) indicates the signal output that would be registered if a zero-order or pseudo-zero-order reaction had taken place within the stop interval. (From Ref. 14, courtesy John Wiley & Sons.)

chemical reactions judiciously are exploited (19,20) (see section below).

70.2.1 Dispersion and Dispersion Coefficient

The dispersion in an FI system is quantified by the dispersion coefficient D, which is defined as the ratio of the concentrations of sample material before (C^o) and after (C) the dispersion has taken place in that element of fluid that yields the analytical readout, that is: $D = C^o/C$ (14). The dispersion can be manipulated by the physical dimensions of the FI manifold used (e.g. length and i.d. of tube, pumping rate and number of merging points), as dictated by the analytical task to be fulfilled. Thus, *limited* dispersion ($D = 1-2$) is used when the injected sample is to be carried to a detector in undiluted form, that is, the FIA system serves as a means of rigorous and precise transport and sample presentation to the detection device (such as an ion-selective electrode or an atomic absorption spectrometer). *Medium* dispersion ($D = 2-10$) is employed when the analyte must mix and react with the carrier/reagent stream to form a product to be detected, while *large* dispersion ($D > 10$) is used only when the sample must be diluted to bring it within the dynamic measurement range of the detection device, which is imperative in a vast number of analyzers for determination of target species in cultivation media (7,11). *Reduced* dispersion ($D < 1$) implies that the concentration of the sample detected is higher than the concentration of the sample injected, that is, on-line preconcentration is effected (e.g. by means of liquid or by solid-phase extraction or by coprecipitation). The latter procedures have especially gained momentum for selective determination of ultralow levels of metals acting as potential inhibitors of enzyme reactions (see section below on SI-LOV).

70.3 SELECTED BIOANALYTICAL APPLICATIONS EXPLOITING FI

In the following will be mentioned some bioassays where the conditions of the FI system are manipulated so that the dispersion is optimal for the given purpose. As a good example of systems exploiting limited to small medium dispersion may serve the use of sensors (ion-selective electrodes (ISEs) or biosensors) (7,21). In potentiometry, it is observed that many ISEs operated in the dynamic mode facilitate fast and reproducible readout. ISEs are, however, generally characterized by fairly long response times to reach steady-state conditions, and therefore it can be difficult to ascertain exactly when to make the readout by manual operation. In FI, this decision is left entirely to the system, because the sample reaches the detector after a time governed exclusively by the manifold used. Besides, the well-known fact that many ISEs are more or less prone to interference from other ions can in many cases be eliminated, or considerably reduced, when making the measurement under FI conditions. Thus, by taking advantage of the short residence time and exposure time of the sample in the FI system, it is often possible, via kinetic discrimination between the ion under investigation and the interfering species (which frequently exhibit longer response times), to improve the selectivity and hence the detection limit of the sensor.

The same concept of manipulating the sample exposure time can be extended to more complex sensors such as enzyme sensors, in which a membrane containing one or more immobilized enzymes is placed in front of the active surface of a transducing element. The analyte is transported by diffusion into the membrane and here degraded enzymatically, forming a product which can then

be sensed by the transducer. Flow-injection biosensors for bioreactor monitoring usually combine oxidase or dehydrogenase-linked enzymic reactions with amperometric detection of molecular oxygen depleted or hydrogen peroxide generated (22–24). A common configuration for single parameter measurement involves a sandwich-type membrane configuration with the enzyme embedded in the intermediate layer in order to minimize enzyme leaching and microbial attack while preventing reducing or oxidizing interfering species from reaching the electrode surface (21). Sequential or simultaneous multiparametric detection can be accomplished by the use of either various enzymic sensors in a parallel or series configuration (23) or integrated electrode arrays (25–27), respectively.

A condition for obtaining a linear relationship between the concentration of analyte and analytical signal is, however, that pseudo-first-order reaction conditions are fulfilled, that is, the concentration of converted analyte reaching the detector surface must be much smaller than the Michaelis–Menten constant. Since this constant for most enzyme systems is of the order of 1 m*M*, and many sample matrices (e.g. substrates for culture broths) contain much higher analyte concentrations, the use of enzyme sensors in static (batch) systems often calls for complicated use of additional membrane layers aimed at restricting diffusion of analyte to the underlying enzyme layer, which in turn implies slow response, or, in case of electrochemical detectors, calls for chemically modified electrodes where the electron transfer is governed by appropriate mediators.

However, when operated in FI, the degree of conversion can be simply adjusted by the *time* the analyte is exposed to the enzyme layer, and therefore the amount of converted analyte can be regulated directly by adjusting the flow rate of the FI system (28). Thus in an FI system, used for the determinations of glucose by means of an amperometric sensor incorporating glucose oxidase, it was shown (Fig. 70.3), that by increasing the flow rate from 0.5 to 1.0 mL/min the linear measuring range could readily be expanded from 20 to 40 m*M* glucose (28). Of course there is a price to be paid for this convenience, and as seen in Fig. 70.3, it is that the sensitivity is slightly decreased. This approach has found much use in ensuing years. Thus, for instance Tsukatini and Matsumoto (29) have used it for the fluorometric determination of pyruvate, and in turn for the assay of acetate, citrate and L-lactate.

Additionally, the exposure time can be tuned for kinetic discrimination, taking advantage of differences in diffusion rates of analyte and interfering species within the membrane layer of the electrode. This was very elegantly demonstrated in the above-mentioned system (28), where temporal resolution of the signals due to glucose and paracetamol could be achieved, even when paracetamol was added at excessive levels. Besides, attention should be drawn to the fact that the operation of a (bio) sensor in the FI mode ensures a constant monitoring of the sensor itself, that is, while the recorded signal is a measure of the concentration measured, the baseline readout indicates directly the stability of the sensor.

In this context, it should be mentioned that considering the diversity of the chemical and physical events that can be involved in the function of a biosensor, in addition to satisfying individually dictated reaction parameters, it is not surprising that operational compromises frequently have to

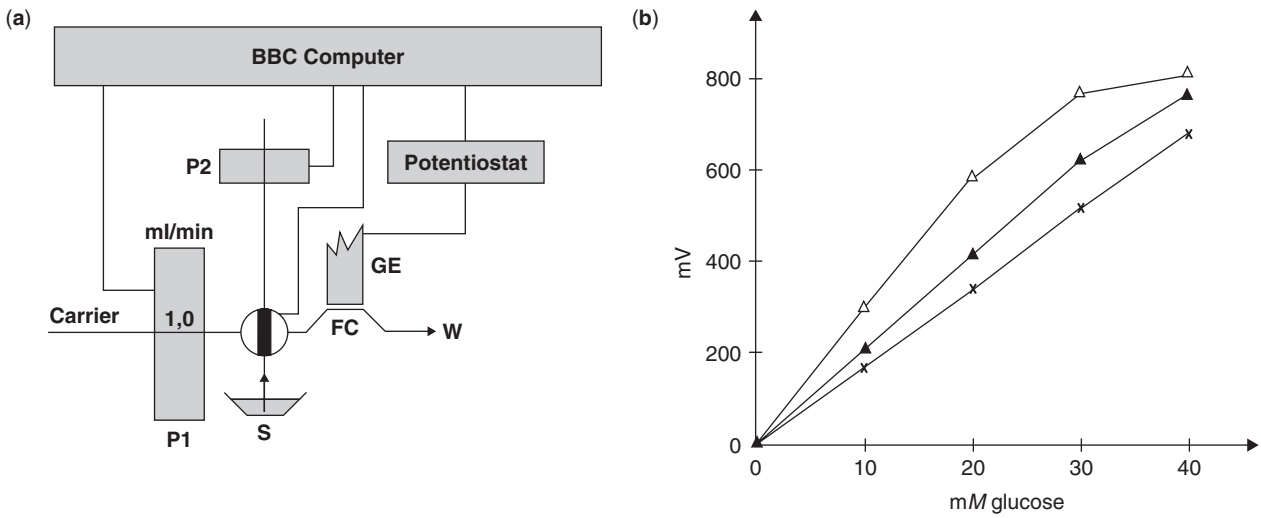

Figure 70.3. (a) FI manifold for the detection of glucose with an amperometric sensor to detect enzymatically generated hydrogen peroxide; (b) Calibration graphs for glucose in the concentration range 0–40 m*M* at three different flow rates: (Δ) 0.50, (▲) 0.75, and (x) 1 mL/min. (From Ref. 28, courtesy Taylor & Francis.)

be made for practical synchronization of all the processes required (30). Thus, the optimal pH used for the enzymatic degradation process might not (as is often the case) be identical to the preferential pH value for detection of the product generated. For example, if a gas sensor covered with a membrane of glutaminase is employed for determination of L-glutamine, the measurement of the ammonia evolved will require a pH value 2–3 units higher than that of the enzymic reaction. Furthermore, and in order to implement functions such as periodic calibration, conditioning and possible regeneration of the biosensor, and, very importantly, to yield the freedom to select the optimum detection means, it is advantageous to use these devices in the FI mode (31). Besides, utilization of biosensors in FI manifolds allows the sample to be modified/manipulated as required for execution of various unit operations such as separation, automatic dilution, or (bio) chemical derivatization prior to the final detection step. In fact, the ideal solution is to use an FI system where the enzymatic degradation of the sample and the detection step are separated and can be individually optimized, that is, the entire flow system is to be considered as a biosensor/biosensing device (32). For the very same reason, the emphasis on the development of biosensors has in recent years shifted from fabricating devices which can be used as probe sensors, similarly to the approach of ISEs in batch assays, to the development of flow-through sensor systems.

When applied in the FI mode, the use of immobilized enzymes offers not only the selectivity, economy and stability gained by immobilization, but also ensures that strict repetition, and hence a fixed degree of turnover from cycle to cycle, is maintained. Two types of reactors have been incorporated and evaluated in flow set-ups, namely, packed-bed reactors with the enzyme immobilized on controlled-pore glass (33–35), and wall-coated open tubular reactor with the enzyme attached to the inner surface of nylon tubing or silica-fused capillaries (36–38). The former features larger surface area and therefore larger enzyme load per unit volume, yet progressively tighter packing of the reactor might lead to increased backpressure with the consequent deterioration of the analytical performance of the analyzer. Thus, whenever several enzymic reactions are involved, co-immobilization strategies are preferred over coupling of various reactors in series. Several examples are found in the literature referring to biotechnological applications, mostly comprising the oxidase/peroxidase (35,39) or dehydrogenase/aminotransferase (34,40) pairs. Both optical and electrochemical detectors can be used to monitor the reaction(s). Thus, for dehydrogenases, involving NAD^+/NADH, spectrophotometry (34,40) or fluorometry (29) is directly applicable, while for oxidases, which give rise to the generation of hydrogen peroxide, amperometric measurements or spectrophotometric detection of a chromogenic redox reagent can also be employed (35,39).

In open reactors, the surface area per unit volume is orders of magnitude lower than that of the packed reactors and thus the enzyme load is much lower. Longer reactors are needed for attaining similar sensitivity, yet compromise should be taken to prevent undue sample/reaction product dispersion. The most relevant asset is the negligible flow impedance increase even after long operational protocols (41). Therefore, this alternative has found applications for monitoring high concentrations of dissolved substrate components, and also for products of bacteria or yeast cultivations when coupled to highly sensitive detection systems such as those involving luminol-based chemiluminescence reactions (35,36). Analyte detection via chemiluminescence is particularly fascinating and attractive, not merely because of the potentially high sensitivity achieved, but because of the wide dynamic range of luminescent procedures and fairly simple instrumentation needed. Furthermore, luminescence has an added advantage over most optical procedures, as light is produced and measured only when sample is present, there is generally no problem with blanking. However, the radiation in luminescence reactions is most often emitted as a flash which rapidly decreases, and for this reason, the conventional approach of quantification has been to integrate the intensity over a fixed period of time and relate this to the amount of analyte. It is obvious, however, that if the measurement of the intensity of light (dE/dt) can be made under precisely defined and reproducibly maintained conditions so that all samples are treated, physically and chemically, in exactly the same manner (i.e. the measurements can be taken repetitively at identical delay times t_i, Fig. 70.4), it is possible directly to relate any dE/dt value (and preferably the one corresponding to the maximum emission, Δt, Fig. 70.4) to the analyte concentration. This is feasible by means of FI, and therefore the combination of luminescence and FI has, in fact, revolutionized the application of bio- and chemiluminescence as analytical chemical detection procedures (42).

Numerous applications of enzyme assays in FI have been reported, advantage being taken of the fact that these components constitute the selective link in the analytical chain which therefore becomes selective overall (43). Some recent reviews contain extensive up-to-date FI enzymic assays and FI biosensing (7,21). Seen in this context, it is apparent that FI not only constitutes a complimentary facility to (bio) sensors, but in many cases offers itself as an attractive alternative.

70.4 THE ROLE OF FI FOR PROCESS ANALYSIS/MONITORING

In emphasizing the many analytical chemical possibilities that FI offers, it is of interest to end this section by drawing attention to an application of this concept that at an early

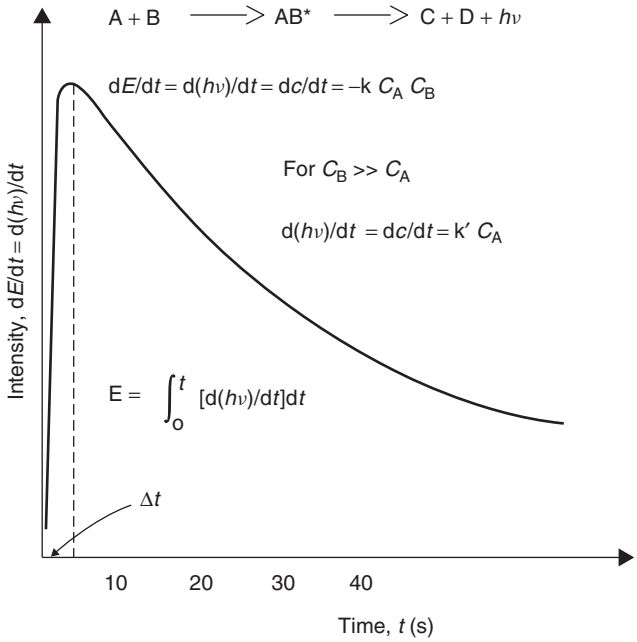

Figure 70.4. Typical course of light generation ($h\nu$) in a bio- or chemiluminescent reaction as a function of time. Quantification can be accomplished either by relating the amount of analyte to the energy released (i.e. integrating the area under the curve), or by using FI and determining the intensity (dE/dt) after a fixed period of time (Δt), which, if pseudo-first reaction conditions are fulfilled ($C_B \gg C_A$), is directly proportional to the concentration of the analyte (A).

stage promised to become very important, that is, its use for monitoring purposes notably in areas such as process control/development and optimizations. Traditionally, most industrial processes have been surveyed off-line in the laboratory after withdrawal of separate samples. However, for an efficient process monitoring and control, the time delay, the limited reliability, and the man power needed for analysis of a large number of samples are crucial parameters. Already in 1982, the first article on utilization of FI for process control appeared (44), and in their FI monograph, Ruzicka and Hansen (14) predicted that FI would turn out to play a major role in this area, because it potentially offered a number of advantages, the most significant ones being: (i) Because every FI readout inherently consists of a peak that goes from the baseline, through a maximum, and back to the baseline again, one cannot only monitor the analyte species via the reaction taking place in the manifold (i.e. via the peak maximum), but one can at the same time control the performance of the analytical system itself (i.e. by the baseline); (ii) FI allows occasional recalibrations or updates/checks of the calibration curve at will, that is, standards can be injected at any time desired, which is a necessity particularly if very complex samples are to be analyzed; (iii) FI is very economical in sample consumption—which not the least is important when used in pilot plant scale experiments—even if the procedure applied calls for the use of a reversed FIA assay (rFIA, i.e. where the reagent is injected into the sample); and (iv) FI permits appropriate pre-treatment of the sample prior to analyte detection, that is, subjecting the sample to dialysis, filtration, extraction or other separation procedures, thereby eliminating potentially interfering species.

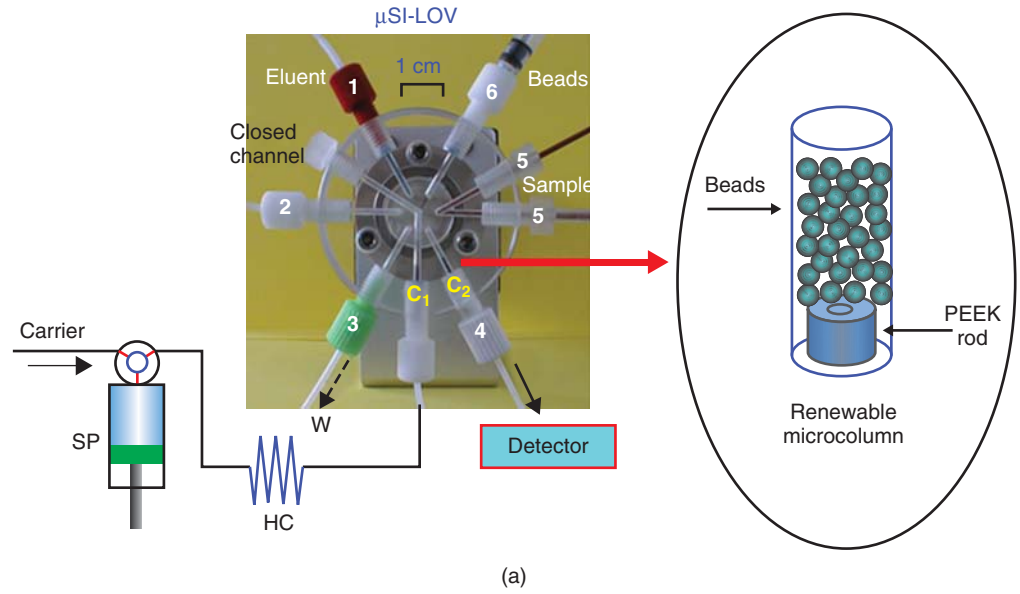
The ideal solution for process monitoring would be, of course, to implement an *in situ* totally selective (in fact, "specific") detection device (sensor). As this is virtually impossible (a pH electrode and a thermometer possibly constituting the only exceptions coming close to meet this criteria), and considering the remarks stated above, near real-time monitoring must necessarily be made in an *ex situ* set-up (7). Facilitating this has in the literature been called by several names, such as "on-line" or "in-line" (which in this context are obviously wrong). Since a sample must be in some manner withdrawn from the system (e.g. using microdialysis probes) and then analyzed, the proper tag would be either "off-line" or "at-line" detection. When using FI as the analysis system, the latter term is preferential, because it implies that the determination is made at the site and is as close as possible to real-time.

In 2001 and 2003 Workman *et al*. (45,46) presented comprehensive compilations of FI literature for process control applications. Although some additional articles have appeared in the literature since then (e.g. (35)), it is evident that FI has not played the role expected in this field. Seen in retrospect, the reason for this is simply that the commercial (and homemade) FI apparatus available often was designed for the laboratory environment, where continuous supervision of its function was a norm, and therefore was not sufficiently reliable for application in industrial settings (47). In fact, it took two decades and the development of SIA to resurrect the idea in earnest, that is, by replacing the peristaltic pumps with a single syringe pump, the injection valve with a multiposition valve, continuous flow with reagent saving programmable flow, and human supervision with computer control (4). Autonomous SI systems are now deployed in industry as well as in remote locations to provide 24/7 (24 h/7 days a week) monitoring of variety of analytes ranging from spectrophotometric determinations of dyes to fluorescence/enzymatic assays of *bacteria coli* (48).

70.5 FUNDAMENTALS OF SEQUENTIAL INJECTION ANALYSIS

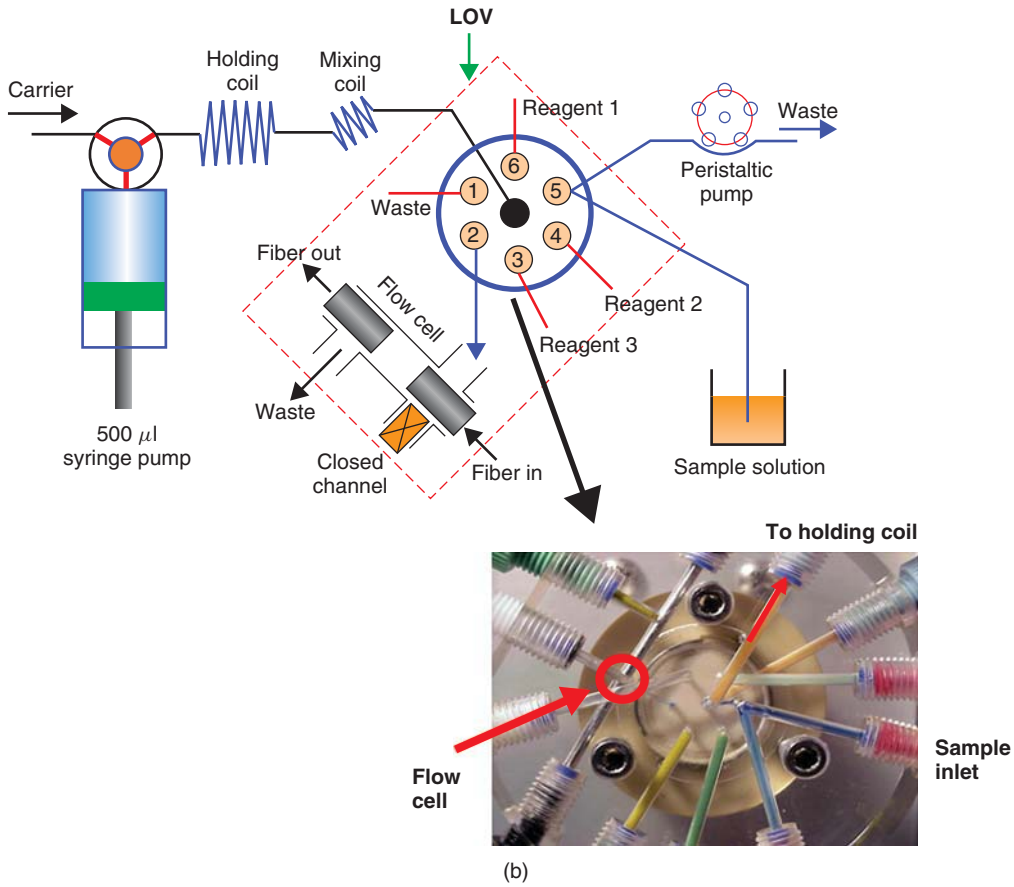
While most FI procedures employ continuous, unidirectional pumping of carrier and reagent streams irrespective of whether a sample is injected or not, which from the point of view of reagent consumption is a

drawback, sequential injection analysis (SIA or just SI) is based on using programmable, bidirectional discontinuous flow as precisely coordinated and controlled by a computer (3,4)). A sketch of a typical SI-manifold is reproduced in Fig. 70.1(b).



The core of the system is a multiposition selection valve (here shown as a six-port valve), furnished with a central rotary communication channel (CC) that can be made to address each of the peripheral ports (1–6), and a central communication line (CL) which, via a holding coil (HC), is connected to a syringe pump operating as the liquid driver. By directing the central communication channel to the individual ports, well-defined and precisely metered sample and reagent zones (typically 5–25 μL) are initially time-based aspirated sequentially into the HC where they are stacked one after the other. Afterwards, the selection valve is switched to the outlet port (here position 5), and the segments are propelled forward toward the detector, undergoing on their way dispersion and thereby partial mixing with each other, and hence promoting chemical reaction, the result of which is monitored by the detector. Notable advantages of SI as compared to FI are in particular that it allows the exact metering of even smaller volumetric volumes (of the order of a few microliters), which fostered the use of liquid enzymes (49,50) and costly cofactors as demanded in NAD-linked enzymic assays (40). Further, thanks to the use of a syringe pump, SI is much better suited for stopped-flow procedures where a very precisely selected delay time is necessary, and that it readily and reproducibly permits flow reversals, which, in fact, in addition as a mere means of transport, also might be used to promote mixing of sample and reagent(s) and to facilitate controlled sample dilution within the HC.

Besides, it is extremely economical as to the consumption of sample and reagents, and hence in waste generation, which nowadays is an important parameter since it is becoming increasingly expensive to dispose chemical wastes. And since all manipulations are computer-controlled, it is easy and simple to reprogram the system from one application to another, providing great versatility for monitoring multiple variables in fermentation broths (12,37) since all operating protocols such as sample injection, mixing, and separation are controlled precisely by the software without the need for physical reconfiguration of the system. However, it is generally difficult to accommodate (stack) more than two reagents along with the sample, although additional reagents might be added further downstream, that is, by making an FI/SI-hybrid. And due to the use of a syringe pump, SI has a somewhat limited operating capacity, although this in practice is rarely a constricting factor.



Allowing the communication to various peripheral ports at will, SI has proven itself especially useful for monitoring of fermentation processes as facilitated by automated recalibration of the system, injection of quality control standards, performing of standard addition methods, injection of samples from different sampling sites on a time basis and real-time calculation of actual concentrations of substrates and products as well (27,51). Besides, it has found notable use in pharmaceutical industries, allowing not only for analysis of drug formulations, but particularly facilitating monitoring of drug-dissolution profiles, *in vitro* drug-release testing and functional assays for screening of potential drugs (52–54).

70.6 MICROFLUIDIC DEVICES: LAB-ON-VALVE

In the LOV concept, (Fig. 70.1(c)) advantage is taken of using an integrated micromachined structure (5). The microconduit monolith (which has a diameter of about 5 cm, a thickness of about 10 mm; a photo of it is shown in Fig. 70.5(a)), made initially of Perspex, but more recently of hard polyvinylchloride, polyetheretherketone (PEEK) or polyetherimide (ULTEM) for improved chemical resistance to a wide range of organic solvents, is mounted atop of a 6- or 10-port selection valve. Allowing further downscaling of conventional SI systems, and designed to incorporate all necessary laboratory facilities for a variety of analytical chemical assays, hence the name *lab-on-a-valve*, it is made to contain mixing points for sample and reagents, working channels for sample dilution, overlapping of zones, sample and reagent(s) incubation and sample purification, and a multipurpose flow-through cell for real-time monitoring of the development of the chemical reactions (55). Thus, the LOV unit can readily be devised to incorporate optical detection facilities, that is, devices [namely, diode-array spectrophotometers, USB charged-coupled devices (CCDs), laser-induced spectrofluorimeters or luminometers] where the communications to the detector and/or the light source are made via optical fibers (Fig. 70.5(b)), and where the position of the fibers can be used to adjust the optical light path of the cell (5). Electrochemical detection has been recently proven feasible by use of the flow-through cell for housing a three-electrode voltammetric unit (16). The micro-fabricated channel system (typically 1.6 mm i.d.) is also amenable to admit conventional sized peripheral devices, thus facilitating the hyphenation with a plethora of optical detection techniques and modern analytical instruments (Fig. 70.5(a)), such as electrothermal atomic absorption spectrometry (56), inductively coupled plasma-atomic emission spectroscopy or mass spectrometry (57), cold-vapor atomic absorption spectrometry (58), electrospray ionization mass spectrometry (59,60), atomic fluorescence spectrometry (61), and, what is especially important for bioseparations and cell technology, to chromatographic/electrophoretic column separation systems coupled to UV–Vis or mass spectrometric detection for

(a)

(b)

Figure 70.5. (a) Close-up of LOV system for bead injection (BI) incorporating two microcolumn positions (C_1 and C_2), along with a diagram of a packed renewable microcolumn (from Ref. 55, courtesy Elsevier Science Publishers). (b) Schematic diagram and magnified close-up of an SI-LOV microsystem incorporating a multipurpose flow cell configured for measurement of absorbance. multiparametric assays (62–64). Thus, the role of the LOV is here to serve as a "front end" to execute appropriate sample pretreatments aimed at introducing the analyte optimally into the detection instrument.

A valuable asset of the microchannel structure is the microfluidic handling of not only metered volumes of solutions but also of solid suspensions as well for exploitation of heterogeneous chemical reactions (Fig. 70.5(b)). The LOV approach fosters the in-valve manipulation of sorbent materials carrying suitable surface moieties in order to generate packed column reactors for microscale solid-phase extraction (66,67), or micro-affinity chromatography (68), in a permanent or a renewable flow fashion, that is, the so-called bead injection (BI) scheme (69,70), depending on the particular chemical assay. In short, microcolumns are *in situ* generated by aspirating beads with particular surface characteristics and particle sizes, advantage being taken of the fact that the sorbent can be manipulated exactly as and when handling liquids. The solid entities can even be automatically transported between different column positions within the LOV, their retention within the columns, as reported elsewhere (66), being facilitated by fitting the column positions with appropriate stoppers (Fig. 70.5(a)), which will keep hold of the beads, yet allow solutions to flow freely. Following sample loading and clean-up protocols, appropriate eluents can be aspirated, and the eluate propelled to either the flow-through cell or an external detection device, as sandwiched by air or immiscible liquid segments in order to preserve its integrity (71,72).

To be operated in the BI-LOV fashion, there are some requirements to the bead materials, that is, they should be perfectly spherical (i.e. in the form of globe-shaped particles); they should be uniform in size distribution (falling within a range of 40–150 μm); and they should possess a density close to that of water. Nowadays, a wide array of bead particles (predominantly with a core of Sephadex type copolymers) with various surface characteristics are commercially available, and in the following section will be described the procedures for real-time monitoring of cellular activities via immobilized live cells (15,73), isolation and on-column fluorimetric detection of DNA (15), optimization of immobilization protocols for proteins (74), as well as investigation of biomolecular association and dissociation processes as exploited in enzyme-linked immunosorbent assays (75) and affinity chromatographic methods (59,60,76). Yet before that, it might be of interest to compare the LOV with the so-called micro total analysis systems (μTAS) (77), or as they lately have been termed Lab-on-a-Chips (LOC), which are frequently used in bionanotechnological applications (78,79).

The interest for μTAS/LOC microstructures was actually stimulated in the early 90s by electrical and mechanical engineers, who parallelly and intensively focused on miniaturization of flow devices (77). The channel network, which is made by various sophisticated procedures, such as micro-drilling, etching, photolithography, or laser erasing, is impressively exact and reproducible, allowing different channel profiles to be obtained. In many instances it can be made in inexpensive materials, namely silicon, glass, polymethyl methacrylate and polydimethylsiloxane, and mass-produced at low cost, in fact, at much lower expenditures than the LOV. However, the microfluidic devices are usually dedicated, that is, they have fixed architecture for predetermined chemistries. However, as opposed to what applies for LOC systems, LOV practitioners are not being dictated by a fixed architecture of their microfluidic devices in order to implement chemical assays, but are able to control the parameters at will in order to adapt the physical movements of the liquids to the chemistries to be implemented. This, very importantly, implies that they can intelligently exploit the interplay between thermodynamics and kinetics, which is of utmost relevance when dealing with chemistries that are not fast or instantaneous, or even require stepwise reaction sequences. In this context, it is interesting to note that the authors of microfluidic devices are customarily demonstrating the capacity of their LOCs for fast, single step bioassays (80,81), which leaves a multitude of very interesting and intriguing chemistries unexplored. Further, the small dimensions of the microchip channels pose a severe problem for sensitive and reliable absorbance measurements (82).

LOV practitioners possess the ability to manipulate the conditions in such a manner that the axial dispersion is minimized at the expense of the radial dispersion, thereby ensuring good mixing of sample and reagent within the individual microfluidic segments. This can readily be accomplished by destabilizing the laminar flow pattern via the geometry of the flow conduit, for example, the sample/reagent path is made to be nonlinear and/or nonuniform in diameter (5,83), and, as opposed to LOCs, by designing appropriate flow programming protocols which might comprise flow reversals, flow acceleration, stopped-flow and bursts of high flow velocity. These tools promote fast radial mixing, while axial mixing is controlled by choice of the injected volumes, and by the length travelled by the plug in forward and reverse direction. Since incubation times are promoted by stopping the flow (either in the HC or better yet in the LOV flow-through cell), the length of the conduit through which the sample will travel can be minimized. At the same time, by increasing the conventional narrow flow channels in LOCs from 10–100 μm up to 1.6 mm in LOV, the surface to volume ratio in LOV is reduced, thus minimizing adsorption of macromolecules on the walls of the microbore conduit. In addition, the low flow resistance of short and wide flow conduits allows precise flow manipulation, and the use of ultra-fast bursts of

flow that can wash out the channels rapidly and easily remove stray air bubbles or clogging particles. Readers are referred to a recently published comprehensive review article for a detailed and critical comparison of LOV and LOC micromachined units (84).

In the following are detailed a few practical examples of using the SI-LOV approach for biochemical assays and bioseparations.

70.7 SELECTED BIOANALYTICAL APPLICATIONS EXPLOITING SI-LOV

70.7.1 Exploiting the Stopped-Flow Approach

As mentioned earlier, the stopped-flow technique (Fig. 70.2) is a very powerful tool for determining analyte species participating in enzymatic or cellular assays (14). Relying on manipulating the concentrations of the constituents participating in the chemical reaction so that these can be considered constant during the measurement (for instance by recording absorbance as depicted in Fig. 70.2), that is, pseudo-zero reaction conditions are met ($dA/dt = k'C$, where C is the concentration of analyte), the slope of a plot of the analytical signal (*in casu* absorbance, A) against the time will be directly proportional to the concentration of analyte at least within a certain time frame, which is also why the procedure is termed *measurement of initial reaction rates*. In practice, the progression in the recorded detector signal (Δsignal) over a fixed period of time (Δt) is used. Furthermore, the plot will directly reveal within which range the reaction conditions are fulfilled (i.e. slope is constant), and which time interval is thus applicable for measurement. An added and unique advantage of this approach is that automatic blanking is obtained, because only the generated signal (Δsignal) within the time interval is utilized for quantification. When incorporated within the LOV format, where very minute consumptions of sample and reagents are required, and where one can take advantage of the extremely accurate operation of the incorporated syringe pump for aspiration and propelling of solutions, the approach presents itself as an ideal solution for process monitoring of both large and small scale bioreactors (5,85).

Several LOV applications of the stopped-flow approach have appeared in the literature. Thus, with an LOV system as depicted in Fig. 70.5(b) and using detection by spectrophotometry, Wu *et al*. (65) monitored ammonia, glycerol, glucose and free iron in a fermentor, while Chen and Ruzicka (18) determined glucose and ethanol. While the glucose assay was based on catalytic degradation of glucose oxidase leading to the generation of hydrogen peroxide, which was subsequently reacted with 4-aminoantipyrine to form a quinoneimine dye (18), ammonia was assayed via the Berthelot indophenol blue method with salicylate and hypochlorite as reagents. In Fig. 70.6 is shown the sequence of the aspirated sample and reagents, where NH_3 represents the sample, the reagent is salicylate, while the spacer is a plug of carrier solution (diluted aqueous solution of detergent) inserted for promoting sufficiently partial mixing of sample and reagents and allowing a suitable delay time before the stopped-flow measurements. As shown in the lower part of the Fig. 70.6, the stopped-flow readouts are very reproducible.

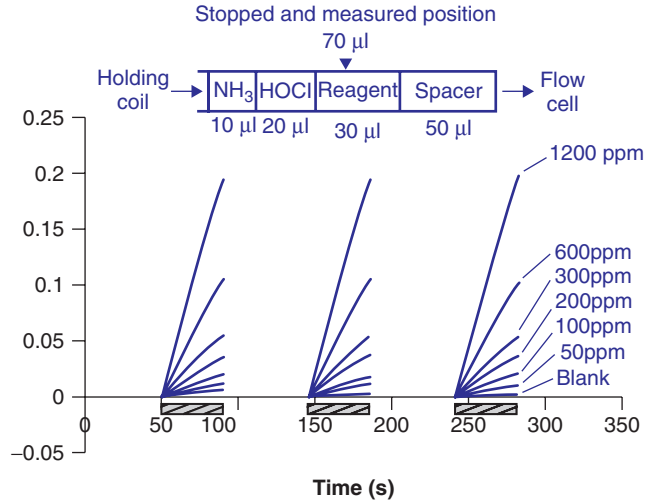

Figure 70.6. (Top) Sequence of the stacked zones of sample, reagents and spacer for the determination of ammonia. (Bottom) Stopped-flow readouts as shown in triplicate for different concentrations (0–1200 ppm) of ammonia, revealing the high reproducibility of measurements. The hatched rectangles indicate the stopped-flow measuring periods. (From Ref. 86, courtesy of the author.) (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

70.7.2 Bioseparations and Cellular Assays

Combining LOV and bead injection (BI), Ruzicka and coworkers have in particular focused on cellular analyses and immunoassays (15,68,74–76). The former are being used for screening of potential drugs by *in vitro* evaluation of biological responses. Cells are cultivated onto polysaccharide microbeads and thus a representative number of cells within the LOV is ensured using a minute volume of bead suspension. Cellular responses are evaluated by determination of different parameters, such as release of cytosolic calcium, intracellular or extracellular pH (15), metabolic oxygen consumption (16), lactate extrusion (73) or glucose consumption (65).

Immunoassays have been miniaturized within microfluidic devices for quantification of biomolecules by either monitoring them as they are captured on microbeads bearing antigen species as entrapped within the LOV flow cell

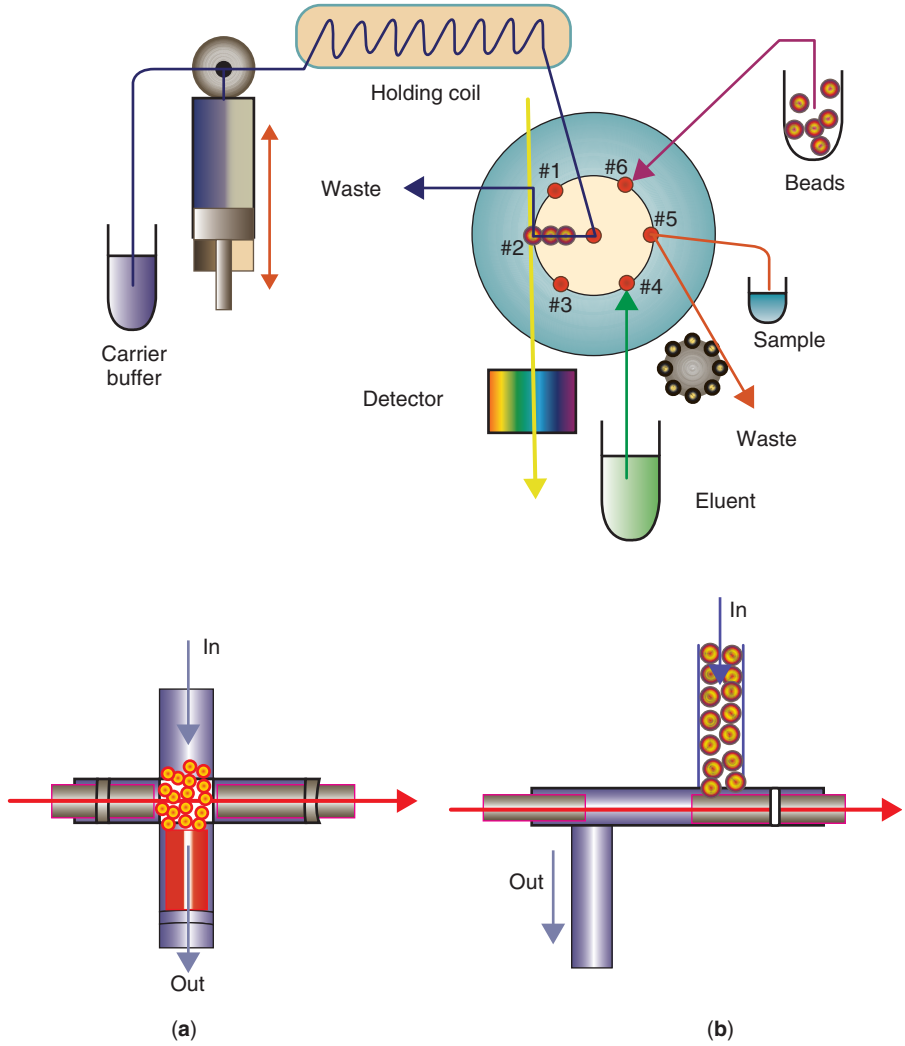

Figure 70.7. Experimental set-up for bead injection spectroscopy and micro-affinity chromatography. At the bottom is shown in (a) the configuration of the flow cell for capturing and monitoring of beads by UV–Vis spectrophotometry; and in (b) the configuration of the flow cell for micro-affinity chromatography. The beads are retained as a microcolumn by a sheath of optical fiber, designed to allow the mobile phase to pass freely into the flow cell (light path 10 mm). (From Ref. 86, courtesy of the author.) (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

via UV/VIS spectrophotometry or fluorometry (Fig. 70.7a) or by detecting them as they are eluted from the beads (Fig. 70.7b). While the first approach can be viewed as "on-column spectroscopy" (15,74,75), the latter one can be considered as miniaturized bioaffinity chromatography (59,60,68). Both methods employ in-valve bead injection analysis with renewable microcolumns and identical analytical instrumentation, whereby they can be exploited in a complementary fashion to get further knowledge on biomolecular association and dissociation reactions (76,87). The micro-affinity chromatography in the LOV format has been demonstrated for separation of immunoglobulins or nucleic acids, as based on molecular recognition between a site fixed on the stationary phase and the target species that is being captured, while unwanted matrix components, such as salts and proteins, are washed out by the mobile phase. In contrast to conventional immunoaffinity chromatography, it is readily feasible to control the operational pH, which is a very critical parameter, and compared to on-column spectroscopy, LOV-chromatography on a renewable bead column is more robust, since the volume of the beads captured within the microcolumn is far less critical, and also because the target analyte is eluted and monitored in solution and not on bead surfaces, thus precluding light scattering effects (68,76). Furthermore, by using a short pulse of eluant, the front elution contains almost all target

molecules, yielding excellent limits of detection. Yet, the most severe limitation of micro-affinity chromatography is that it cannot monitor antibodies when remaining immobilized irreversibly on the bioligand bearing beads. On the contrary, bead injection spectroscopy monitors the sorption process, whereby the elution of target species is not a must since beads can be automatically withdrawn following recording of the spectroscopic readout (74,76).

In this context it should also be mentioned that the SI-LOV system has been interfaced to capillary electrophoresis (CE) with UV detection for inorganic anion and protein separation (62,63). In this case, the multipurpose flow cell was reconfigured to act as a front end between the microfluidic device and the CE separation module. The microfluidic property of LOV did not merely provide an efficient sample delivery conduit for the CE system with various sample injection modes, including electrokinetic, hydrodynamic and head column field amplification sample stacking (62), but at the same time served as a versatile means of sample pre-treatment and chemical derivatization (e.g. protein labeling) (63) to facilitate the ensuing CE separation.

A detailed compilation of the work by Ruzicka and his coworkers can be found on the CD-ROM published by Ruzicka (86).

70.7.3 DNA Assays

A very active research group at Northeastern University in Shenyang, China, headed by Professor Jianhua Wang, has over the past few years published a series of articles focused on determination and/or purification of DNA exploiting the inherent features of LOV. In the first communication (88), using a LOV similar to the one shown in Fig. 70.8, they described a spectrophotometric procedure for DNA assay, where a small amount of crystal violet solution (10 μL) was de-coloured inside the flow cell of the LOV in the presence of 5 μL λ-DNA/*Hin*dIII within a certain pH range, the decrease in absorbance of the crystal violet solution being measured at 591 nm via optical fibers and employed as the basis of quantification. Obtaining a detection limit of 0.07 μg/mL, this work was supplemented by a procedure based on fluorescence measurement (89), where sub-nanoliter to a few microliters of DNA sample and ethidium bromide (EB) solutions were introduced into the LOV, resulting in the formation of a DNA–EB adduct, which afterwards was excited in the versatile flow cell of the LOV by a 473 nm laser beam, the emitted fluorescence being monitored *in situ* via optical fibers. By using this approach the detection limit was further decreased, that is, to 0.006 μg/mL by affixing the aspirated sample volume to 2.0 μL.

In a very recent publication (90), this research group has exploited the LOV for DNA separation/purification via solid-phase extraction with a silica microcolumn packed

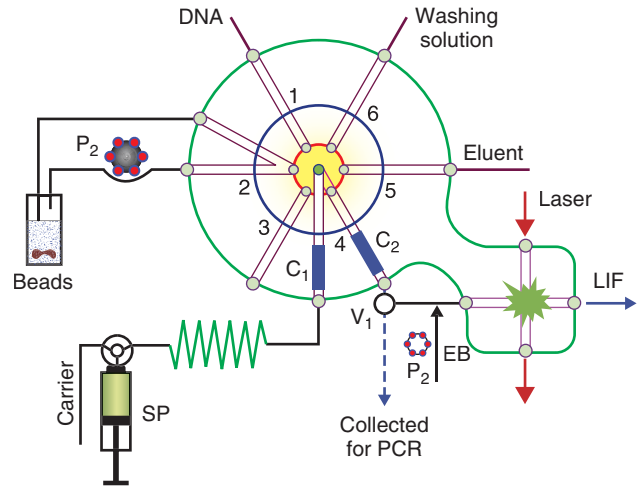

Figure 70.8. LOV system employed for DNA separation and purification from human blood, integrating a demountable fluorescence flow cell. EB, ethidium bromide; LIF, laser-induced fluorescence; P_1 and P_2, peristaltic pumps; SP, syringe pump; V_1, three-way valve; and C_1 and C_2, microcolumns. within an LOV microchannel. By proper selection of the sample loading and the elution media, the complex matrix components in human whole blood, including proteins, could be completely eliminated. The DNA purification process was monitored on-line by using LIF at 610 nm in a demountable side part of the LOV unit incorporating optical fibers (Fig. 70.8). The practical applicability of the entire system was demonstrated by separation/purification of λ-DNA in a simulated matrix and human blood genetic DNA by performing in-valve SPE, *in situ* monitoring of the purified products via fluorometric detection of DNA–EB, and postcolumn PCR amplification. It was demonstrated to offer significant advantages over chip-based separation/purification systems based on the same principle in terms of precision, sampling frequency as well as robustness. The employment of the bead injection technique facilitated automatic injection and withdrawal of the solid-phase material in the LOV-based purification system, as opposed to LOC microdevices where renewal of solid substrates is not feasible and thus the entire microchip should be discarded and replaced by a new one after short term operation.

The Chinese group (91) and the one headed by Professor Luque de Castro (92) in Spain have most recently compiled comprehensive reviews on bioanalytical applications of LOV, including cellular analysis, immunoassays, affinity chromatography, DNA separation/purification, and enzymatic assays. Readers are encouraged to consult these articles for further details.

70.8 CONCLUSION AND PERSPECTIVES

Being based on transient measurements and exact and reproducible timing, FIA and its sequels SIA and LOV have turned out to open an array of novel possibilities within bioanalytical sciences. A compilation of recently published automatic procedures for monitoring of fermentation broths are presented in Table 70.2. Although not exhaustive, it gives a rather good impression of the variability of the species determined and the techniques applied. In general it should be stressed that not only do the procedures consume very small amounts of sample and reagent solutions, and thus lead to generation of minute volumes of waste, but, more importantly, they allow entirely new and unique approaches to be implemented, which are not possible with conventional batch or continuous flow procedures.

The ultimate goal in modern (bio)chemical analysis is to identify individual analyte species in a given complex sample with sufficient selectivity and sensitivity which, in turn, often calls for appropriate sample pre-treatments or hyphenation of various selective detectors. Such schemes might entail physical/temporal separation of individual compounds via chromatographic or electrophoretic techniques or coupling of enzyme-based sensors in series, but might also involve the separation of the analytes from potentially interfering matrix constituents, or the execution of sample preconcentration protocols or, in fact, as most often encountered in practice, a combination of all strategies. Here, the SI-LOV approach presents itself as an ideal vehicle to act as the 'heart' of the system, because it is totally automated, miniaturized and fully computer-controlled. In SI-LOV, one has the advantage of being able to attach external units to facilitate individual operations, such as chromatographic columns for spatial separation of individual (bio) components, or the application of external energy sources such as UV light, or ultrasound radiation in order to effect desired reactions. But most importantly, a proper hyphenation will allow the implementation of intelligent chemistries, where advantage can be taken by the fact that the on-line systems operate under dynamic conditions so that one can exploit the interplay between thermodynamics and kinetics. Thus, what is needed in future applications is a realization of what this interplay implies, particularly in terms of facilitating the determination of (bio)chemical species in culture media or live cells, because this is exactly what differentiates the on-line LOV microanalysers from their batchwise counterparts—and, in fact, the LOCs. An eloquent alternative is to genetically engineer microbes to continuously report on their intracellular protein concentration with detection using FIA methods (93).

71.1 INTRODUCTION

Monitoring and control of bioprocesses is of main interest in bioprocess engineering especially in the pharmaceutical industry because bioprocess efficiency, productivity, and optimization are essential. In this regard, the U.S. Food and Drug Administration (FDA) defined regulatory affairs like the process analytical technology (PAT) initiative in 2004. The main purpose of PAT is the implementation of innovative measurement techniques in the manufacturing processes, in order to increase the knowledge of process interactions directly and thus, to realize better on-line process monitoring along with a better understanding of the process (1). Due to the complex nature of microbial growth and product formation in bioprocesses, powerful analytical techniques for monitoring and control result in an increased efficiency, productivity and reproducibility, reduced costs, and improved quality control. With the implementation of capable analytical tools, deviations from the expected process run should be detected as early as possible. Thus, significant variations from the main route of the production process can be avoided and the final product quality and quantity can be ensured by realization of optimal conditions for growth, biosynthesis, and/or downstream processing.

In all stages of the manufacturing bioprocess, physical and chemical parameters for example, temperature, pH, dissolved oxygen, and CO_2 are traditionally measured directly on-line without time delay. However, monitoring of important biological/biochemical parameters such as cell density, metabolic activity, substrate consumption as well as product concentration is rather difficult due to the complexity of the sample composition. Thus, the determination of these parameters is mostly performed by complex analytical off-line techniques.

Ideal technologies for bioprocess monitoring of chemical and physical as well as important biological process variables and metabolic interactions should operate *in situ*, be noninvasive, and generate on-line information simultaneously without any time delay.

In recent years, various bioanalytical systems have been developed and investigated for improved on-line bioprocess monitoring and control. The application of such

on-line sensor systems in pilot facilities and production plants can provide a better understanding of different types of bioprocesses including cultivation, biotransformation, degradation processes as well as downstreaming operations. Most of these sensor techniques are still invasive and can disturb the current process. To overcome these limitations, a lot of research groups are involved in the development of new analytical tools, which can be interfaced into the bioprocess without extra risk of contamination for noninvasive bioprocess monitoring and control.

In this regard, spectroscopic techniques became a powerful tool for application in bioprocess monitoring (2). They provide information directly related to the molecular nature of the process. Spectroscopic sensors offer the advantage of noninvasive, non-destructive, continuous, and simultaneous multianalyte monitoring without a risk of contamination and no consumption of the analyte. They can be easily interfaced to the bioprocess via glass fiber systems or liquid light conductors. Due to the short response time of this spectro-optical system, signals can be obtained instantaneously.

Among noninvasive optical techniques, fluorescence spectroscopy is an attractive option in the development of on-line methods for bioprocess monitoring because many cellular constituents and media components are biogenic fluorophors. Therefore, many applications of fluorescence spectroscopy have been investigated intensively over the last 25 years in many categories of biotechnology processes in order to analyze the suitability of this technique of bioprocess monitoring and control. Based on this fact, special fluorescence sensors have been developed and optimized in regard to an improved bioprocess monitoring.

71.2 PRINCIPLES OF ON-LINE FLUORESCENCE SENSORS FOR BIOPROCESS MONITORING

Fluorescence sensors are fiber optical measuring instruments which can be used for the determination of bioprocess key variables such as biomass, substrate and product concentration, for bioreactor characterization, and metabolic studies in general. The development of such sensor systems started with the application of simple single wavelength sensors in the early 1970s and was continuously improved to the point of multiwavelength sensor systems for industrial application in bioprocess monitoring and control.

71.2.1 Single Wavelength Fluorescence

The principle of single wavelength fluorescence sensors is based on the fluorescence studies of Duysens and Amesz (3). They demonstrated that the reduced forms of nicotinamid adenine dinucleotide (NADH and NADPH) exhibit fluorescence at a wavelength of 450 nm when excited with UV light at a wavelength of 360 nm. This coenzyme is involved in the main metabolic reactions. By measuring the emitted light via this optical technique, the monitoring of the NAD(P)H pool inside living microorganisms is possible. The intensity of the fluorescence signal is affected by the amount of viable biomass concentration, the metabolic state of the cells as well as abiotic factors such as air bubbles or other fluorescent components in the medium.

The first *in situ* fluorescence sensors were able to measure one single excitation/emission wavelength pair in particular for the determination of intracellular NAD(P)H. Harrison and Chance (4) were the first to design a spectrometer device for biotechnology application based on NAD(P)H fluorescence for *in situ* on-line monitoring of cultivation in glass bioreactors. The light source for excitation and the photomultiplier holder were placed at an angle of 60°. The excitation as well as the emission light was passed directly though the reactor wall. Since the excitation light must penetrate a few centimetres into the cultivation broth, measurements are mainly limited to low biomass concentrations. With this setup, changes from anaerobic to aerobic conditions of *Klebsiella aerogenes* can be observed. Zabriskie *et al*. (5) used the same setup for the estimation of biomass in cultivations of different microorganisms. In the following years, other applications were published by several research groups (6).

On the basis of these experiments, smaller miniaturized process fluorometers were built which can be interfaced with bioreactors via standard ports (7). These sensors are arranged as open-ended detectors to measure the emission in the backward direction. The excitation light of 360 nm as well as the 180 backward fluorescence signal passes the reactor through a quartz glass window (Fig. 71.1). The advantage of this setup is the elimination of the inner filter effect by measuring the surface fluorescence directly at the observation window.

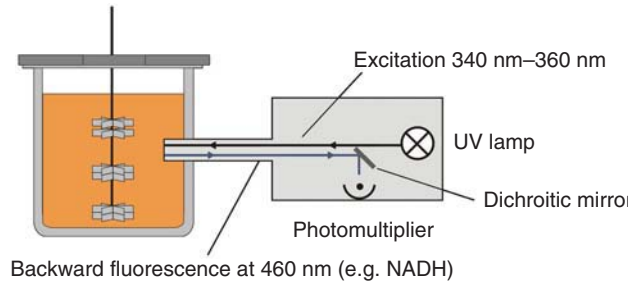

Figure 71.1. Principle setup of miniaturized single wavelength fluorescence spectrofluorometer for *in situ*, on-line measurements at a wavelength combination of ex350 nm/ em460 nm. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Commercially open-ended instruments were available by BioChem Technology, USA (FluoroMeasure) and Mettler Toledo, Switzerland (Fluorosensor). Both systems were restricted to the NAD(P)H fluorescence and culture fluorescence or fluorophors with the same fluorescence properties.

All these sensors have one disadvantage in common: they are restricted to one single wavelength pair and thus no verification of signals in regard to interfering fluorophors or disturbing factors (air bubbles, scattering particles) is possible.

One modification of these miniaturized fluorescence sensors was realized by Scheper and Schügerl in 1986 (8) for the simultaneous detection of two different emission wavelengths. The sensor was equipped with lenses, an optical filter system, and a special decoupled glass fiber optic for the emission light which is separated into two cables. Thus, a simultaneous detection of two different wavelengths is possible. The change of filters for excitation and emission wavelength offers the possibility of multiwavelength monitoring.

Single wavelength fluorescence sensors, developed for the determination of the NAD(P)H fluorescence, were tested for various applications regarding the bioprocess itself. Different cultivation processes including suspended or immobilized microorganisms were investigated mainly with regard to the determination of viable biomass or for on-line detection of metabolic changes during the cultivation process.

Several researchers correlated measured culture fluorescence to biomass concentration due to the fact that the fluorescence of the NAD(P)H pool inside the cells increases with an increase of cell concentration. Either a simple linear correlation is given or the fluorescence signal has to be linearized to biomass data in order to find a direct function between the coenzyme-dependent culture fluorescence and the biomass concentration. Under strictly defined conditions, on-line estimation of biomass is possible. Examples for biomass determination via single wavelength fluorescence for the growth in suspension are for example, *Saccharomyces cerevisiae*, a species of *Streptomyces*, *Zymomonas mobilis*, *Methylomonas mucosa* as well as *Pseudomonas putida*. Moreover, there are some applications for immobilized cell growth in regard to biomass estimation for example, *Clostridium acetobutylicum* and *S. cerevisiae*. A direct correlation with the culture fluorescence signal was not possible but an increase in fluorescence signal during cell growth has been observed.

However, as soon as limiting conditions occurred or the culture conditions were changed, deviations of the intracellular NAD(P)H pool were observed. Thus, not all attempts to correlate the biomass concentration with the fluorescence signal have been successful. An overview about the estimation of biomass via culture fluorescence in cultivations of different microorganism is given in (9). An updated summary concerning culture fluorescence is given in Table 71.1.

Monitoring of the NADH fluorescence inside the cells, the observation of the culture fluorescence can be used as indicator for environmental and metabolic changes during the cultivation process. Different applications are presented in the relevant literature (9,12).

Fluorescence and metabolic responses during aerobic and anaerobic transitions in the course of cultivation experiments of multiple microorganisms can be observed. The addition of substrates to starved cells or inhibitory reagents resulted in a metabolic change. The dynamic behavior of the initiated shift can be followed instantaneously. In chemostat cultures of *Escherichia coli* and *P. putida*, a change in dilution rate became obvious in the fluorescence signal, indicating that the intracellular redox state changes depending on the dilution rate. Based on the metabolic changes caused by external effects, Meyer and Beyeler (13) developed a system for the optimal control of the dilution rate for a continuous yeast cultivation process. Metabolic shifts during *Clostridium acetobutylium* growth, diauxic growth, or the glycolytic oscillations during the cell growth of *S. cerevisiae* can be measured as a function of the culture fluorescence.

The different applications of single wavelength fluorescence measurements are listed in Table 71.1. The broad applicability indicates that culture fluorescence provides much information on the metabolic state of the cells. Based on this information, further control strategies can be realized.

In conclusion, single wavelength fluorescence, measured at an excitation/emission wavelength pair of 360 nm/450 nm have been used as an indirect method to monitor biomass as well as metabolic changes along the bioprocess for different kinds of microorganisms over the last years. However, some application of these single wavelength measures showed that the interpretation of NAD(P)H fluorescence data is not always straightforward especially in regard to biomass estimation. The culture fluorescence is influenced by cellular metabolic changes. Furthermore, other medium components may fluoresce in the same region. Thus, interactions and overlapping effects with the fluorescence spectra of other fluorophors which are not detectable in a limited measuring range due to the very broad formation of the fluorescence peaks in general can occur. Especially in complex, turbid media which are common in biotechnological processes the interpretation of the data are difficult. Peak shifts and quenching effects due to other molecules as well as changes in chemical and physical parameters (like bubbles, pH, or dissolved oxygen) can influence the signal. Thus, broad applicability of the commercially available single wavelength fluorescence sensor in biotechnological processes is limited.

71.2.2 MultiWavelength Fluorescence

As bioprocesses are very complex systems, a detailed monitoring is required. Therefore, fluorescence measurements should be performed in a wide spectral range for both excitation and emission in order to get as much information as possible. More and more research groups developed and investigated measurement devices based on multiwavelength fluorescence in order to circumvent the restriction of single wavelength monitoring. Pioneering work was done by the research group of Humphrey (14) in 1991. They reported on the development of a multiple excitation fluorometric system with five different excitation light sources (289 nm, 313 nm, 334 nm, 365 nm, and 404 nm) in order to get a more detailed insight into the cultivation process of *Candida utilis*, *Pseudomonas putina*, and *S. cerevisiae*. Other important fluorophores besides NAD(P)H such as pyridoxine, riboflavin, and tryptophan were measured. These fluorophors are key vitamins and aromatic amino acids involved in cell growth and metabolism and in several cases their monitoring resulted in more reliable biomass estimation than the measurement of NAD(P)H. A major reason for this is the higher stability of these metabolites against diverse stresses such as oxygen limitations. Based on tryptophan monitoring, the amino acid concentration and protein expression can be followed. Measuring the fluorescence signal of tryptophan, a better correlation to cell mass concentration of *S. cerevisiae* was possible when compared to the determination based on NAD(P)H fluorescence. Further devices like the scanning fluorometer LS 5B (PerkinElmer/USA) were applied to a bioreactor via optical fibers (15). With these devices the scanning of a whole fluorescence spectrum can be realized by varying both excitation and emission wavelength independently in a wide spectral range. Problems of signal interpretation still remain, but in comparison to common single wavelength fluorescence sensors more reliable information on cell metabolic state and different processes variables can be gained.

The measuring of multiwavelength fluorescence generates a high density of information. In this case, the fluorescence is described by three parameters: the excitation wavelength, the emission wavelength, and the resulting fluorescence intensity. A full description requires an excitation-emission data matrix containing the data in numerical values. To visualize the fluorescence, a two dimensional (2D) spectrum can be generated based on the prepared matrix which represents the fluorescence intensity of the emission spectra at different excitation wavelengths. In this spectrum of excitation versus emission, different compounds can be identified by their position. Furthermore, an area free of fluorescence can be identifed in the spectrum. In the area where emission equals excitation wavelength, the scattered light is represented. Two illustrations of 2D spectrums are common. The contour plot shown in Fig. 71.2(a) is the most common projection in which fluorescence peaks are visualized by bright shadings. The isometric plot shown in Fig. 71.2(b) is more illustrative because the intensity of the fluorescence peaks is directly visual.

71.2.3 Biogenic Fluorophors

It is well known that many media components and cellular substances such as important vitamins like riboflavin and pyridoxine, aromatic amino acids like tryptophan, tyrosine and phenylalanine, enzymes and coenzymes like NAD(P)H as well as some proteins such as the green fluorescent protein (GFP) are biogenic fluorophors. A classification of these fluorophors can be done due to their intrinsic fluorescence in a characteristic spectral range (Fig. 71.3). By application of 2D fluorescence spectroscopy, it is possible to monitor all these fluorophors, which occur outside and inside the cell, simultaneously. A detailed insight into the metabolic state can be given based on these data and a better correlation to important process variables like biomass, substrate, or product concentration should be accessible.

In this context, the GFP is of great interest. The natural protein can be excited at wavelengths of 395 nm and 475 nm and has its maximum fluorescence emission intensity at a wavelength of 509 nm. GFP can be utilized as a reporter of gene expression and protein localization or folding. For this purpose it is used in bacteria, mammalian cells, plant cells, and yeasts. Due to its intrinsic fluorescence, it offers the possibility for on-line monitoring of product formation in recombinant protein production processes (16).

71.2.4 Chemometrics for the Evaluation of 2D Spectra

If 2D spectra from a process are considered, many intensity values representing different excitation and emission wavelength combinations of the spectrum are collinear, that is, the values are highly related and carrying the same information but with different sensitivity and specificity. However, the goal of the on-line measurement of such spectra is frequently the prediction of important process variables, which cannot be measured directly or just with extraordinary effort. To calculate a calibration model, off-line measurements of these process variables have to be carried out. However, a usual multilinear regression with all the data of the spectra and the off-line measurements is not recommendable to obtain a robust calibration model, because of the highly related data in a spectrum. Consequently, a special evaluation technique is required that allows obtaining independent variables out of the spectra, and results in a robust calibration model. The most prominent evaluation methods for this purpose are principal component regression (PCR) and partial least squares regression (PLSR).

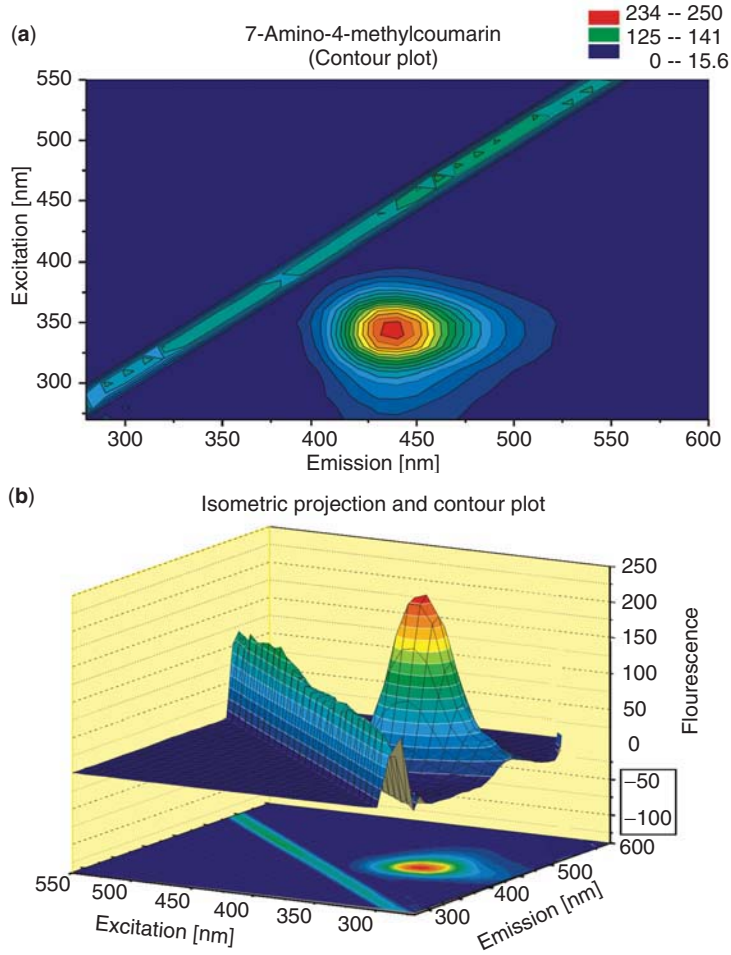

Figure 71.2. Contour plot (a) and the corresponding isomeric projection (b) of a fluorescence spectrum of 7-amino-4-methylcoumarin. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

PCR is performed in a two step process. During the first step which is called principal component analysis (PCA) the mean centered data of the spectra are processed by using a successive variance maximizing rotational transformation of the coordinate system. During this transformation, the so-called principal components are calculated one after the other. To calculate the first component, which is the first determined axis of the new coordinate system, an axis is rotated around the origin of the mean centered data until it carries as much of the variance of the spectra data as possible. Then, the second axis is calculated in a way that it is perpendicular to the first axis and carries as much of the remaining variance of the data as possible. The third axis has to be perpendicular to the already calculated axis and represents as much of the remaining variance as possible. This procedure is repeated, until only noise is left in the residual data set. As a consequence, a new coordinate system is obtained, whose axis have decreasing variance. The number of the new axes is usually much less than the number of different excitation-emission wavelength combinations in a spectrum. Using the data represented in the new coordinate system by the principal components, a multilinear regression model can be calculated in the second step of the evaluation. The calibration model obtained by this method will robustly relate the spectra to values of important process variables.

Using PLSR the transformation, which is now performed with respect to the covariance of the spectra data and the off-line measurement data, and the regression are performed in a single step. PLSR gives for some applications better calibration models than PCR. The PLSR models can be calculated in two different ways. Using PLS1 to calculate a model to predict process variables, the transformation and regression is done for each process variable independently. As a result, one has to perform the calculation several times, whereas for a PLS2 model this calculation is performed together to get a single vector model. Here, the covariances

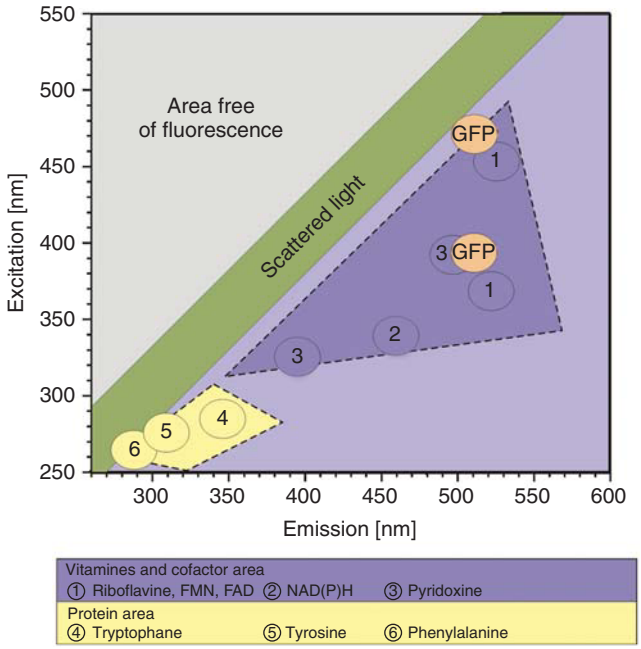

Figure 71.3. Biogenic fluorophors in a 2D fluorescence spectrum (17). Green flourescent protein (GFP), flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

of the spectra data and all of the off-line data are used altogether simultaneously to calculate the calibration model.

For some applications it is advantageous not to use the full spectra for the above evaluation but just a few combinations of excitation and emission wavelengths intensity values. The reason for this is that some intensity values might not carry any information about the process but only noise. However, this has to be analyzed by calculating many calibration models and choosing the best validated one.

If the relation between the spectra data and the process variables are nonlinear, PCA and PLSR have to be modified. A simple approach is to use the original data set of the spectrum as well as the squared intensity values. Alternatively, the transformed data of PCA can also be used as input variables of a neural network, which will estimate the process variables (18).

Due to the fact that all the above mentioned modeling techniques are data driven, many calibration measurements are usually necessary to calculate the corresponding chemometric calibration model. This is a big drawback in almost all process spectrometers and not just the ones based on fluorescence measurements. However, a possible solution of this problem might be presented by Oliveira *et al*. (19), who used a theoretical process model to calculate the calibration model of a biotransformation process. The parameter values of the theoretical process model will be estimated inherently during the calibration procedure and are not required to be known beforehand.

A detailed discussion of the latest developments in multivariate statistical process control and its application to industrial processes as well as a critical review of the methodology and a description of how it is transferred to the industrial environment is given by Kourti (20).

71.2.5 Laboratory 2D Spectrofluorometer and Industrial Process Systems

For the measurement of 2D fluorescence several commercially available spectrofluorometers can be used. Different kinds of spectrofluorometers are available, commonly used in laboratories. These spectrofluorometer can be used either for off-line applications or, equipped with optical fiber for remote scanning, if on-line monitoring is preferred. Two commercially available examples are the ones produced by PerkinElmer, USA (Model LS 50B) and the one produced by Hitachi, Japan (Model F4500).

The fluorescence spectrophotometer Model F4500 is a very sensitive measurement device especially for laboratory application. Spectra can be generated in a range of 250 nm to 550 nm for excitation (10 nm step size) and 260 nm to 600 nm for emission (20 nm step size). The spectrometer allows a very fast scanning speed of 30,000 nm s^{-1}. An entire 2D spectrum can be measured within 1 min. For the selection of excitation and emission wavelengths, reflection grating monochromators are used on both excitation and emission sides. Excitation and emissions slits are selectable manually from a range of 2.5 nm, 5 nm, 10 nm, or 20 nm. A Xenon lamp is used for excitation. A reference photomultiplier is installed in order to compensate variations in the intensity of the excitation light source. A second photomultiplier (700 V) is used for the detection of the emission fluorescence signals. The configuration of the measuring setup is shown in Fig. 71.4.

After the sterilization of the reactor, the measuring chamber (place of cuvette holder in Fig. 71.4) of the spectrofluorometer can be connected with a bifurcated liquid light conductor (Lumatec, Germany) in an open-end-arrangement to a quartz window utilizing a 25 mm port of the bioreactor. For fluorescence measurement, the excitation light is guided via the fiber optic into the reactor and the emission light is guided via the second fiber optic to the detector. A computer with appropriate software is used for the configuration and control of the spectrofluorometer, data acquisition, and storing. With this setup, the sensor is not in contact with the medium and therefore a noninvasive, *in situ*, on-line measurement without the risk of contamination is possible.

A fluorescence sensor especially developed for fully automated industrial measurements and applications in bioprocess engineering is the BioView® sensor (DELTA, Denmark). The BioView® sensor is a very robust

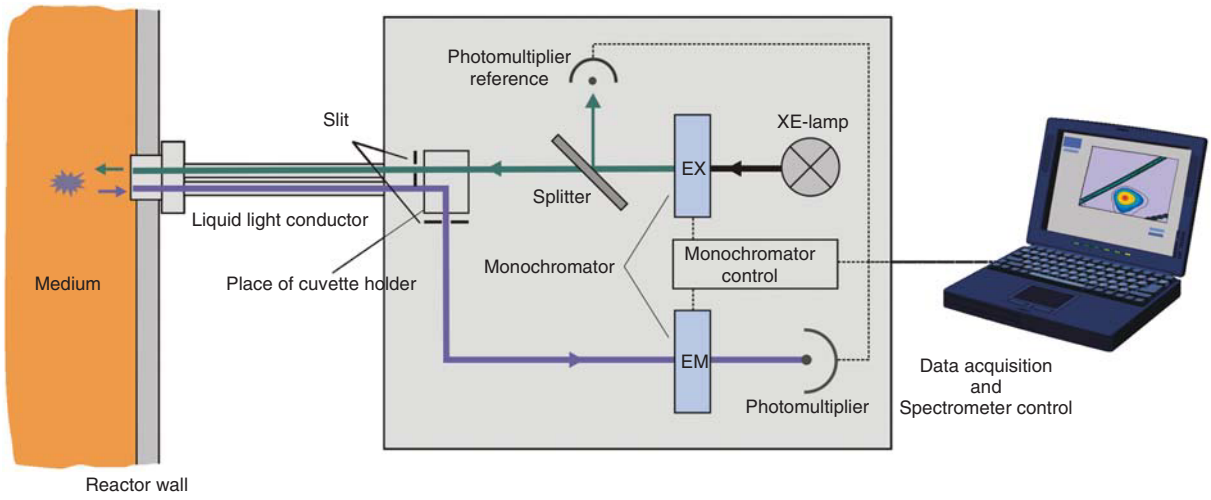

Figure 71.4. Measuring setup of a laboratory 2D fluorescence spectrometer (Hitachi F4500). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

device that is encapsulated in a high-grade steel box for protection against harsh industrial environments such as high temperature, moisture as well as electromagnetic interference. In industrial facilities, long distance has often to be overcome for data transfer between the computer and the spectrometer. Therefore, a single-fiber asynchronous modem is used, which overcomes a distance of up to several hundred meters.

The sensor is solely designed for *in situ* on-line measurements. Therefore, the sensor is connected by a 2 m bifurcated liquid light conductor to a 25 mm standard port of the bioreactor. The port contains an adapter with a quartz glass window to ensure the noninvasive monitoring and thus, to eliminate the risk of contamination.

The optical part of the sensor is also optimized for the use in biotechnology processes. Instead of a grating monochromator, the sensor is equipped with two independently rotating filter wheels, one for excitation and one for emission, with 16 interference filters (DELTA, Denmark) for excitation (270–550 nm) and emission (310–590 nm). These filters can be chosen individually to meet the requirements of each individual process. The recording of a whole spectrum takes 90 s with a resolution of 20 nm. The measuring setup of the BioView® sensor is presented in Fig. 71.5. A Xenon flash lamp is used for excitation. The excitation filter wheel is set to the first filter position and the excitation light passes the first filter. The restricted light is guided via the liquid light conductor into the reactor. The emission signals of all excited fluorophores are guided backwards via the second light conductor and are monitored separately after passing each of the rotating emission filters. Afterwards, the excitation filter switches to the next position and the next data set is obtained. If the excitation wheel performed a complete cycle, the measurement of a whole spectrum is finished. This high measurement frequency enables the collection of information with no significant time delay and thus permits an estimation of different bioprocess variables simultaneously. In order to cover most of the information potential, properties and steps of filters can be adjust individually. Furthermore, the time of measurement can be minimized by reducing the number of filters used in a spectrum, for example, depending on the available or suitable fluorophores.

71.3 APPLICATION OF ON-LINE 2D FLUORESCENCE SPECTROSCOPY

2D fluorescence spectroscopy offers the possibility of simultaneous analysis of several fluorphores. Thus, the disadvantages of single wavelength spectroscopy can be overcome and important information based on multiwavelength fluorescence measurement can be obtained.

With 2D fluorescence spectroscopy, a closer insight into the bioprocess can be realized and a more detailed study of metabolic phenomenon is possible.

For monitoring of bioprocesses especially in the pharmaceutical industry, it is of great interest to get as much information as possible in order to guarantee optimal cultivation conditions for best bioprocess performance. Besides the on-line estimation of metabolic processes (e.g. aerobic-anaerobic transition, effect of metabolic uncoupler, diauxic growth, and the effect of pulse addition of substrate) a noninvasive simultaneous analysis of important bioprocess variables like cell density, substrate consumption as well as product concentration is essential. The application of fluorescence spectroscopy restricted

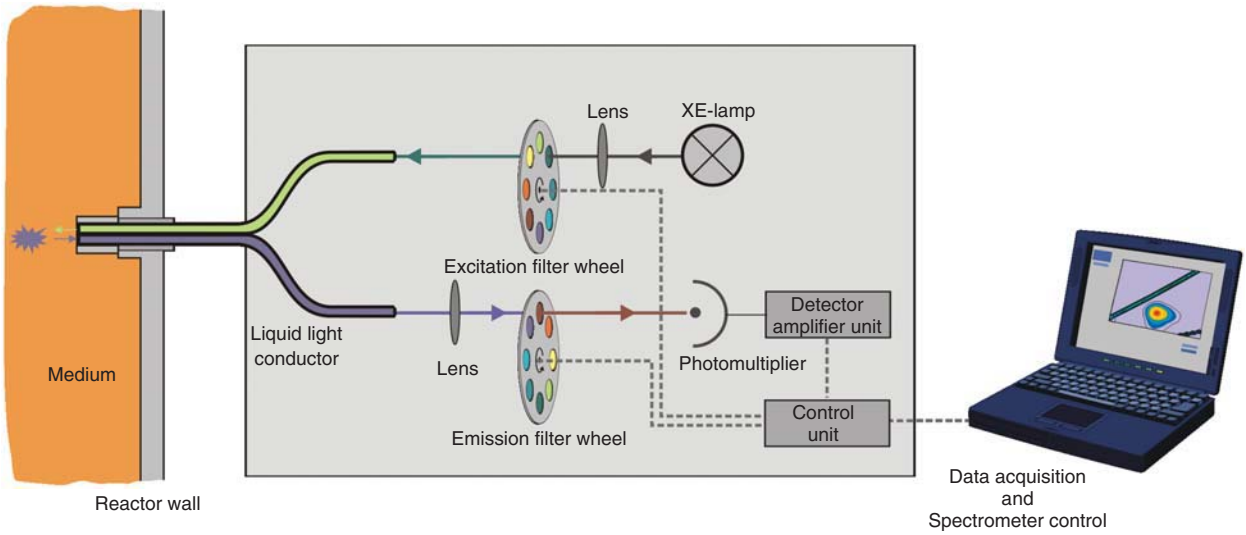

Figure 71.5. Measuring setup of industrial 2D fluorescence spectrometer (BioView® sensor). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

to a single wavelength offers the possibility of biomass estimation in some cases under strictly defined conditions. For example, the NAD(P)H or tryptophan fluorescence showed a good correlation to the determined biomass concentration. However, multiwavelength fluorescence offers the possibility of determining various factors important for bioprocess monitoring and control.

Large-scale culture processes in combination with recombinant DNA technology have enabled the biotechnological production of proteins for pharmaceutical applications in a number of different hosts. Therefore, the potential of the application of 2D fluorescence spectroscopy for optimal process monitoring and control has been investigated for various organisms. Besides prokaryotic and eukaryotic systems like fungi, yeasts, and plant cells, the potential of the application of 2D fluorescence for process monitoring and control was also investigated for mammalian cells due to its increased application in the recombinant protein production processes. It is shown that this technique offers a good possibility for the monitoring of cultivation process of various organisms.

Table 71.1 gives a detailed overview of noninvasive on-line applications used in the last 25 years, for single and in particular, multiwavelength fluorescence spectroscopy with regard to metabolic studies and analysis of bioprocess relevant variables classified in prokaryotic and eukaryotic systems. It has been shown that the prediction of many process variables is possible utilizing multiwavelength fluorescence spectroscopy either due to direct correlation of the fluorescence signal of a single wavelength with the predictable relevant process variable, or by means of chemometric modeling as described in the previous section of this chapter. Moreover, determination of nonfluorescence process variables such as the glucose concentration is also possible. In high cell density cultivations (HCDC) in particular, 2D fluorescence seems to be a useful tool for on-line control and modeling of bioprocesses (9).

In a 2D fluorescence spectrum, various excitation-emission regions can be correlated to biomass concentration for several organisms as summarized in Table 71.1. Correlations to off-line cell mass concentrations during *S. cerevisiae* cultivations with the culture fluorescence in different regions of protein, cofactor, and vitamin area were performed. Information about cell growth and metabolism were obtained by correlations to fluorescent products and substrates (17).

Mycelia growth complicates common methods for biomass estimation. But even for the filamenteous fungi *Claviceps pupurea*, the on-line estimation of the biomass by 2D fluorescence spectroscopy is possible (17). Utilizing 2D fluorescence spectroscopy in combination with chemometric analysis, the estimation of ergotalkaloids which have a variety of pharmaceutical applications was achieved with only a minor error margin of 3%–4% (21). In contrast to common methods of alkaloid determination which are very time-consuming, 2D fluorescence spectroscopy enables on-line monitoring of ergotalkaloid concentration.

Accurate determination of viable cell density and glycoprotein concentration in batch and fed-batch cultivations of baby hamster kidney cells (BHK) confirm that multiwavelength spectroscopy seems to be a reliable method for on-line monitoring of bioprocesses (10). In fed-batch processes, the control of the substrate concentration at a low level is often required in order to prevent the production of overflow metabolites and to optimize the biomass

yield. In this context, Hantelmann *et al*. have developed a glucose feeding strategy for *S. cerevisiae* fed-batch cultivations based on the prediction of the metabolic state directly from fluorescence intensity. This approach avoids ethanol production while increasing the biomass yield (22).

Besides the determination of relevant process variables other studies based on metabolic changes were performed. For instance, strain stability of recombinant organisms is essential for consistent production in industrial applications. Johannson *et al*. demonstrated that on-line 2D fluorescence measurements provide information about metabolic changes useful for studying strain stability of plasmid containing *E coli*. This technique gave quicker and more extensive information in comparison to traditional time-consuming methods without influencing the cultivation process (23).

Investigation of *Aspergillus niger* cultivations demonstrated the potential of 2D fluorescence spectroscopy to detect the onset of spore germination, which represents a critical time-point in fungal bioprocesses. Furthermore, the quantitative formation of a mutant GFP in fed-batch cultivation as well as metabolic activity was determined (24).

During the last years, other applications of this noninvasive technique were investigated. Using fluorescent tracers, on-line characterization of bioreactors (e.g. mixing time experiments) can be performed under bioprocess relevant conditions in all types of bioreactors.

On-line monitoring of an industrial chromatographic desugarization process of molasses was realized by using 2D fluorescence technique. A noninvasive monitoring and prediction of different molasses compounds for a better process control were established (25).

Furthermore *in situ* fluorometry is a promising tool for monitoring anaerobic digestion processes in waste water treatments because waste water contains large amounts of proteins, amino acids, and other fluorescent compounds. Also, for various cultivations of microbial degradation processes of pollutants like chlorinated organic compounds 2D spectroscopy was used.

Since biocatalysis is of great interest for the production of industrial products, novel enzymes which show the ability to discriminate among many potential substrates are investigated. In this case, 2D fluorescence offers the possibility for a fast and effective on-line estimation of enantioselectivity of enzyme catalyzed reactions in aqueous and organic systems. Furthermore, the application of this technique for monitoring these reactions in supercritical carbon dioxide ($SSCO_2$) has been demonstrated (26).

71.4 CONCLUSION

2D fluorescence spectroscopy offers interesting applications in various fields of biotechnology. A noninvasive on-line monitoring and control of different process relevant variables as well as metabolic changes in bioprocesses can be performed simultaneously by using this optical analysis technique. In combination with chemometric modeling, a highly sophisticated process monitoring and control can be achieved, resulting in an improved economical process management. Thus, the implementation of 2D fluorescence spectroscopy in standard bioprocesses is a particularly useful tool for further bioprocess optimization and control in a wide range of applications.

OFF-LINE ANALYSIS IN ANIMAL CELL CULTURE

HEINO BÜNTEMEYER
Institute of Cell Culture Technology, University of Bielefeld, Bielefeld, Germany

72.1 INTRODUCTION

The cultivation of mammalian cells *in vitro* requires special environmental conditions. Except primary cells taken directly from an organ, cultured cells usually derive from immortal or immortalized cell lines. The cells may be genetically engineered or manipulated by transfection or fusion techniques. The behavior of this new cell depends very much on the origin of the basal cell line.

While some requirements are general for every cell, others can be very special for one cell line. All cells need isotonic conditions of about 300 mosmol/kg. Usually the cells need oxygen and also a carbon source (mostly glucose). As the cells cannot synthesize the essential amino acids and vitamins, they have to be supplied. Some additional components may basically not be needed for surveillance, but they can support the cells to optimize cell growth and productivity. This knowledge leads to complex media formulations that seldom contain less than 40 different components. During optimization of culture conditions and process strategies a detailed analysis of the nutrient requirements has to be performed. Many different analysis methods have to be established in a laboratory to comply with this extensive task.

In this chapter methods for almost all media compounds are described. All methodsthat are described in detail in this chapter, were developed, adapted, or checked in the laboratory for suitability of analysis of cell culture media and supernatants. They should be easily transferable to similar laboratory conditions. In this chapter, the methods for the analysis of proteins are only very briefly described. For each protein, special conditions and methods may apply. In general, the characterization of proteins includes a variety of steps. Methods for the analysis of amino acid sequence, glycosylation, molecular weight, heterogeneity, and activity have to be employed. A description of all these procedures would be beyond the scope of this chapter. For this reason, protein separation methods such as electrophoresis and protein and peptide chromatography are not included here.

For almost all suppliers of special equipment or chemicals cited in this chapter, a listing of the home pages (World Wide Web) can be found at the end of this chapter. All other products may be delivered by local suppliers. When a method is described in detail, an equivalent apparatus of any supplier may also be suitable.

72.1.1 Composition of Cell Culture Media

Cell culture media contain a multitude of components. In most cases a complete medium consists of a chemically well-defined basal medium with additions of more or less defined additives. The basal medium contains low molecular weight substances, such as inorganic ions, amino acids, vitamins, and some other components (e.g. glucose, pyruvate, etc.). In Table 72.1 the formulations of the three main basal media are listed. All three media contain roughly the same substances. Differences can be found in the individual concentrations. Often some low molecular weight compounds like ethanolamine, diaminobutane, selene dioxide,

glutathione, taurine, ascorbic acid, fatty acids, cholesterol, and so on are added to support the cells for distinct biochemical pathways. Particularly for continuous and high density processes, the concentrations of the main nutrients (glucose and amino acids) are elevated and animal- or plant-derived peptones are often added. High molecular weight supplements, in particular proteins, are sometimes added to fulfill the requirements of certain cell lines. Besides proteins, these supplements may also contain peptides, lipoproteins, phospholipids, or lipids. Sometimes it is necessary to use serum or serum substitutes as an additive to the basal medium, especially during development and establishment of new cell lines when the behavior and the requirements of the new cells are not known. The function of some of the proteins is known. Insulin stimulates the glucose metabolism, transferrin acts as the carrier for iron ions and possibly other trace elements, and albumin actsas an adsorbent for free lipids and toxic pollutions. Lipoproteins supply the cells with cholesterol and fatty acids. All in all, mammalian cells *in vitro* require a complex medium that consists of many chemically different components.

72.2 ANALYSIS OF CELL DENSITY

The determination of cell numbers is the main task during the monitoring of cultivation progress. Besides total cell number, the ratio of viable and dead cells is also of particular interest. Methods using cell staining and optical means are faced methods measuring particle size or volume.

72.2.1 Cell Density Determination by Cell Staining

The most common method of cell staining is the trypan blue exclusion method. A cell suspension is mixed with a 0.4% trypan blue solution (isotonic, 0.81% sodium chloride, 0.06% potassium dihydrogen phosphate) and placed in a calibrated hemocytometer chamber (Neubauer chamber). Anchorage-dependent cells have to be removed from the surface prior to the staining procedure. For this removal the cells are incubated with a trypsin solution for some minutes. The cells are manually counted by using a phase contrast microscope at a magnification of 100–400 times. The dye cannot pass the intact cell membrane. Therefore, viable cells are not stained. Dead cells are dyed blue. From cell count and calibrated chamber size the cell density and viability can be calculated.

In some special cases a direct cell counting is impossible. When the cells grow in aggregates (spheroids) or inside of macroporous carriers, a representative aliquot cannot be taken to ensure correct counting. In those cases it may be useful to lyse the cells and stain the nucleus. For this purpose a cell pellet is resuspended in a crystal violet solution (0.08% crystal violet in 0.1 M citrate) and incubated at 37°C for at least 3 h. Subsequently the nuclei can be counted microscopically using a hemocytometer chamber.

72.2.2 Automated Cell Density Examination Systems (Innovates, Beckman Coulter)

An improvement of the cell staining method has been made in regard to automation procedures. The Cedex and Cedex HiRes systems (both innovates AG, Germany) and the Vi-CELL series systems (Beckman Coulter, IN) use the trypan blue exclusion method in a fully automated liquid handling system with flow-through chamber combined with video microscopy and image processing. The algorithms of the image recognition technology are able to classify the mapped objects, discriminate living cells from dead ones, and detect cells aggregates, debris, and other objects. The necessary sample sizes are between 0.3 and 1 mL and the analysis time including automated image examination is below 5 min. The instruments differ furthermore in their hardware setup. While the Cedex instrument uses a microscope stative with a 4 × magnification lens, in the Cedex HiRes instrument the principle of a dynamic microscope (8.75 × magnification) is realized. This enables the Cedex HiRes to analyze objects from 1 to 90 μm and the Cedex from 4 to 40 μm, respectively. The Vi-CELL series systems are able to analyze objects from 2 to 70 μm. Some further cell parameterssuch as diameter spectrum, eccentricity histogram, and tendency of aggregation are available from the data on user request. In addition to the cell densities and viability, these parameters are helpful to assess the condition of the culture. The automation of the trypan blue method leads to a much higher precision and accuracy compared to the manual hemacytometer results. While deviation up to 35% are possible in the results of manual counts, the automated systems reduce this to 5%.

72.2.3 Coulter Particle Counter (Beckman Coulter)

The Coulter method of sizing and counting particles is based on measurable changes in electrical resistance produced by nonconductive particles suspended in an electrolyte. A small opening (aperture) between anode and cathode is the sensing zone through which suspended particles pass. In the sensing zone, each particle displaces its own volume of electrolyte. The volume displaced is measured as a voltage pulse. The height of each pulse is proportional to the volume of the particle, independent of shape, color, and density of the particle. The quantity of suspension drawn through the aperture is controlled to allow exact counting and sizing of particles for a reproducible volume. A differentiation between viable and dead cells can only be performed by examination of the particle (cell) size.

72.2.4 CASY Particle Counter (Innovates, Formerly Schärfe System)

This system combines the established resistance measuring principle with the pulse area signal processing method. This allows a very high dynamic range, high resolution, and excellent reproducibility for the volume determination. The cells are suspended in a weak electrolyte and driven through a capillary of predefined geometry at a constant stream velocity. Electricity is supplied to the capillary across two platinum electrodes. While passing through the capillary, the cell displaces an amount of electrolyte equal to its own volume. This change in resistance level becomes an indication of cell volume. The measuring signal is scanned by the system at a frequency of 1 MHz. The amplitude and width of the pulse are captured and the integral is determined (pulse area analysis). These integrals are stored for each particle. A size distribution over all particles is computed in a resolution of 1024 channels from the stored pulse area values (integrals) (1). Viable and dead cells can only be differentiated by their cell volume and/or size. The size ranges for viable and dead cells may vary from cell line to cell line. An adjustment has to be made by the analyst to compare the data.

72.3 ANALYSIS OF MEDIUM COMPONENTS

72.3.1 Analysis of Nutrients

72.3.1.1 Glucose. Glucose is the main nutrient for almost all mammalian cells. Therefore, the quantitative determination of the glucose concentration is very important. A multitude of established chemical and biochemical methods are there, but not all of them can be employed for a direct quantification in a complex mixture such as cell culture medium. Only a specific method that is insensitive to interference with other compounds can be used. All common methods use enzymes as specific agents. Two of the most often employed determination methods are described in this chapter.

72.3.1.1.1 Photometric Glucose Assay (e.g. R-Biopharm, formerly Boehringer Mannheim). D-glucose is converted in the presence of adenosine triphosphate (ATP) by the enzyme hexokinase to D-glucose-6-phosphate. This product is then converted by the second enzyme glucose-6-phosphate-dehydrogenase in the presence of $NADP^+$ to D-gluconate-6-phosphate. During this last reaction NADPH is formed. The concentration of NADPH can be easily monitored at a wavelength of 340 nm. The concentrations of produced NADPH and assayed glucose are proportional (2).

Reactions:

$$\text{D-GLUCOSE} + \text{ATP} \xrightarrow{\text{Hexokinase}} \text{D-GLUCOSE-6} + \text{ADP}$$

$$\text{D-GLUCOSE-6-P} + \text{NADP}^+ \xrightarrow{\text{Glucose-6-phosphate-dehydrogenase}} \text{D-GLUCONATE-6-P} + \text{NADPH} + \text{H}^+$$

This assay test kit is desired to be used in a cuvette UV spectrophotometer and needs no further laboratory equipment. The method can be recommended when only few or sporadic measurements are necessary. Otherwise, the analysis is too time consuming and expensive in labor. In that case, the acquisition of an automatic analyzer should be considered.

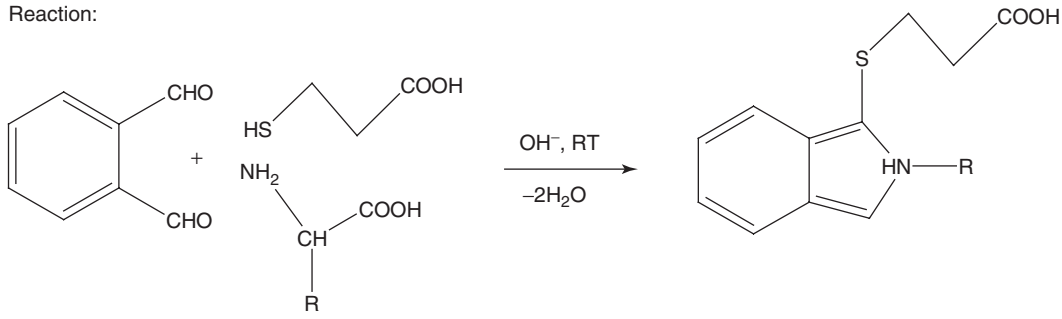
72.3.1.1.2 Enzyme electrode-based biosensor (e.g. Model YSI 2700, Yellow Springs Instruments; BioProfile Analyzer Series, Nova Biomedical). In both analyzers enzyme electrodes are used as glucose-specific parts. The following description explains the situation for the YSI 2700 analyzer. The enzyme electrode consists of an amperometric hydrogen peroxide sensitive electrode combined with immobilized glucose oxidase trapped between synthetic membranes. The electrode itself consists of a platinum anode and a Ag/AgCl cathode. The platinum anode is polarized at +700 mV relative to the cathode. At the electrodes, a current results from decomposition of hydrogen peroxide to water and oxygen. The membrane covering the electrodes consists of three layers. The outer layer, made of polycarbonate, is in direct contact with the sample. The next layer is the immobilized glucose oxidase enzyme followed by a cellulose acetate membrane, which readily passes H_2O_2 but excludes chemical compounds with a molecular weight above approximately 200 Da. This last cellulose acetate film also protects the electrode from fouling caused by proteins, detergents, lipids and other substances (3). After applying a sample that contains glucose, a dynamic equilibrium is achieved very rapidly, when the rate of peroxide production and peroxide diffusion to the electrode is equivalent, indicated by a steady state current response from the electrode. The current is proportional to the hydrogen peroxide conversion and the glucose oxidation (reactions).

Reactions:

$$\text{D-GLUCOSE} + \text{O}_2\ \text{ATP} \xrightarrow{\text{Glucoseoxidase}} \text{Glucono-}\delta\text{-lactone} + \text{H}_2\text{O}_2$$

$$\text{H}_2\text{O}_2 \xrightarrow{\text{Pt anode}} 2\text{H}^+ + \text{O}_2 + 2\text{e}^-$$

The enzyme electrode is placed in a small chamber in the automatic system. Calibration and maintenance procedures are performed routinely by a liquid handling system. The sample volume needed is typically 25 μL (5–65 μL, adjustable) and the minimal sample glucose concentration is 0.05–0.1 g/L. The analysis of one sample lasts about 1 min. The sample can be applied without any prior preparation. Nevertheless, a removal of cells (e.g. by centrifugation) is strongly recommended in order to prolong the stability of the enzyme membrane. The membrane, once placed on the electrode, normally runs stable for some weeks. All in all, this method (and the apparatus) is a reliable glucose quantification method that can be recommended when a variable number of samples have to be analyzed daily. Further automation can be set up by installing autoinjectors or connecting the instruments to online sampling probes.



72.3.1.2 Amino Acids. Besides glucose, other sugars, or peptides, amino acids are the major group of medium compounds from which cells generate energy and carbon. The amino acids can be divided into two groups, essential and nonessential amino acids. This classification comes from a gradation made for animals and human beings. This might not be completely valid for mammalian cells cultured *in vitro*. Depending on donor and organ origin of each cell line, one or more amino acids, formerly classified as nonessential, might also be essential. Therefore, almost all amino acids are present in the defined basal medium formulations (Table 72.1), some in high and some in low concentrations. The amino acid with the highest medium concentration is glutamine, classified as a nonessential amino acid. But for all cell lines that do not express the glutamine synthetase gene, glutamine is essential. The cells can convert glutamine to α-ketoglutarate, which is introduced directly into the tricarboxylic acid (TCA) cycle.

From a chemical point of view, the amino acids are a very heterogeneous group of chemicals. Aliphatic, aromatic, polar, nonpolar, acidic, basic, and cyclic amino acids are present. Common for all acids is the carboxy and the primary (except proline and hydroxyproline) amino groups at the α-carbon. Except the three aromatic amino acids phenylalanine, tyrosine, and tryptophan, all other amino acids cannot be reasonably detected by spectrophotometrical means. An analysis method capable of quantification of all amino acids usually includes a separation procedure and a derivatization procedure to introduce a detectable group to the amino acid molecule. A multitude of methods have been developed using different derivatization reagents and chromatographic separation techniques. Two principles have been established: the pre-column and the post-column derivatization technique. In a pre-column method the amino acids are chemically modified first to introduce a chromophore or a fluorophore. The derivatization products are then separated on a chromatographic column and detected by an optical detector (spectrophotometer and fluorimeter). Usually an aromatic group is introduced to the amino acid molecule. The derivatives can be separated on a reversed phase column and monitored with an UV or fluorescence detector. In a post-column method the amino acids are separated first on an ion-exchange column and then modified just before detection. Almost every derivatization procedure modifies the amino acid in the amino group, which is much more reactive in an aqueous solution, especially at alkaline pH. In this chapter only the most important and commonly used methods are described in more detail.

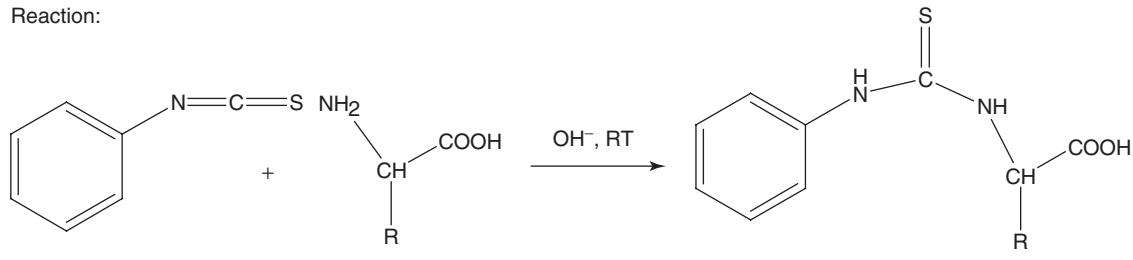
72.3.1.2.1 Ninhydrin Method. This method is the only commonly used post-column derivatization method (4,5). The amino acids are separated on specially developed cation exchange columns (heated to temperatures of 40–70°C) by eluting stepwise with five different acidic lithium citrate buffers (containing also methanol and phenol) at pH of 2.5–5.0. At the end of the column the elution stream is merged with the ninhydrin reagent (20 g ninhydrin, 1.7 g hydrindantin in 65% dimethyl sulfoxide, and 35% 4 M lithium acetate buffer), passed through a reaction coil (T = 90–120°C) and applied to a VIS detector. Chromatograms are taken at wavelengths of 570 and 440 nm. Ninhydrin reacts under these conditions with all primary amino groups to form a dye which can be detected best at 570 nm. During this reaction only the amino group stays as part of the dye molecule (Ruhemann's purple). Secondary amino groups (proline, hydroxyproline) form other derivatives (yellow chromophores) than primary amino groups. These derivatives are detectable best at 440 nm. Although almost all biogenic amines and amino acids can be detected with this method it is replaced more and more by pre-column derivatization methods because of its very long analyzing time of more than 2 h, the unstable ninhydrin reagent, and the toxic and corrosive elution buffers.

72.3.1.2.2 o-Phthaldialdehyde Method. Primary amino groups react at alkaline pH in the presence of selected thiol compounds with *o*-phthaldialdehyde (OPA) to form unstable isoindoles. These isoindoles can be immediately separated on C_{18} (ODS)-reversed phase columns and detected with a fluorescence detector (6,7).

Dependent on the thiol used, the resulting derivative is more or less hydrophobic. Therefore, different elution buffers and profiles have to be used. The more hydrophilic the thiol is, the less hydrophobic the elution buffers can be. The following thiols were tested: 2-mercaptoethanol, mercaptoacetic acid, 2-mercaptopropionic acid and 3-mercaptopropionic acid. Good fluorescence yields can only be achieved when using 2-mercaptoethanol or 3-mercaptopropionic acid.

Only primary amino groups of amino acids and amines can react with OPA. Secondary amino groups will not be modified. Therefore, proline and hydroxyproline cannot be analyzed. But it is possible to employ a second derivatization with NBD chloride (7-chloro-4-nitrobenzofurazan) after OPA derivatization to form other fluorescent active products. Owing to the fluorescence quenching effect of sulfur, cysteine and cystine give only very poor fluorescent derivatives that are not quantitatively detectable. To overcome this problem it is possible to oxidise cysteine and cystine with an oxidant such as performic acid prior to OPA derivatization and quantify both together as cysteic acid. The OPA derivative of cysteic acid is very well detectable. The reagent OPA itself is not fluorescent and produces no interfering signals.

Procedure: The complete analysis of amino acid in samples from cell cultures can be performed with an automated high performance liquid chromatography (HPLC) system. A programmable autoinjector first mixes the prepared sample with the reagent mixture (OPA reagent) and then injects an aliquot onto a C_{18}-reversed phase HPLC column after a reaction time of 1.5 min. The OPA derivatives are eluted in a binary gradient in less than 30 min and passed through a fluorescence detector. Data recording, evaluation, calculation, and device control are done with a chromatography software (e.g. Galaxie CDS, Varian). A detailed description of this method follows.



Sample Preparation: Cell-free supernatant is mixed 1:1 with 10% $HClO_4$ containing 300 μM of norvaline as an internal standard. The mixture is centrifuged for 5 min to remove the precipitated proteins. An aliquot is mixed with two aliquots of 0.4 M potassium borate buffer pH 10.4 to alkalize and dilute the sample.

Derivatization: 20 μL of the prepared sample is filled into a sampler vial. The sampler mixes with 70 μL of reagent (50 mg OPA, 1 mL methanol, 100 μL 3-mercaptopropionic acid, and 9 mL 0.6 M sodium borate buffer pH 10.4) and injects 20 μL onto the column after 1.5 min reaction time.

Elution: The mixture is separated on a C_{18}-reversed phase column (Kromasil C18, 5μ, 4.6 × 150 mm, Eka Nobel) with a multistep binary gradient in less than 30 min. The column temperature is set to 30°C. Buffer A consists of 89% 0.085 M sodium acetate pH 7.5 and 10% methanol and1% tetrahydrofurane. Buffer B is a mixture of 85% methanol and 15% 0.085 M sodium acetate pH 5.2. Total flow is set to 1.2 mL/min. The gradient is set as follows: 3% B at time 0, linear increase to 10% B in 8.2 min, linear increase to 34% B in 1 min, linear increase to 37% B in 9.5 min, linear increase to 77% B in 7.5 min, hold 77% B for 1 min, linear increase to 0% B in 1 min, and hold for 2 min.

Detection: The OPA derivatives are detected with a fluorescence detector set to excitation and emission wavelengths of 350 nm and 450 nm, respectively.

Figure 72.1 shows an example chromatogram obtained for a standard mixture. All amino acids are baseline separated and can be quantified by peak area integration.

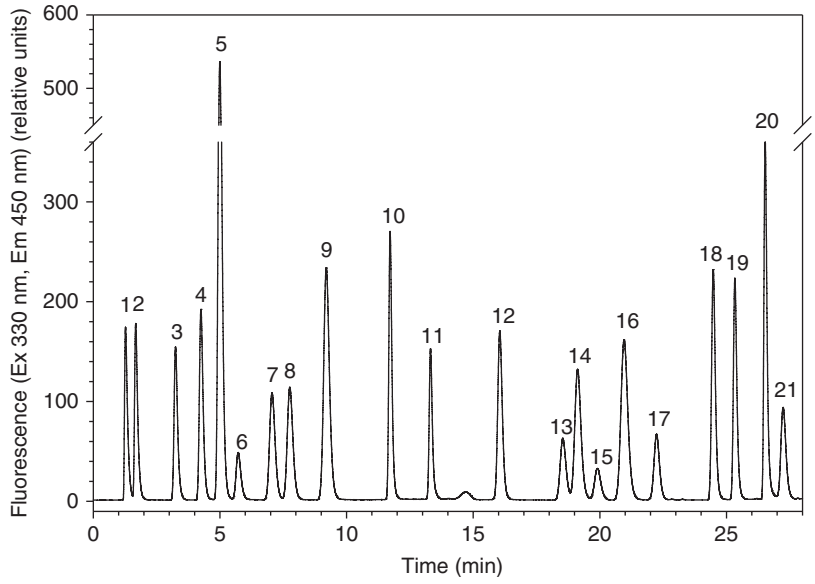


Figure 72.1. Standard chromatogram of amino acids processing the OPA method. Separation conditions apply as described in the text. List of amino acids: (1) aspartic acid, (2) glutamic acid, (3) asparagine, (4) serine, (5) glutamine, (6) histidine, (7) glycine, (8) threonine, (9) arginine, (10) alanine, (11) tyrosine, (12) ethanolamine, (13) methionine, (14) valine, (15) tryptophan, (16) norvaline (internal standard), (17) phenylalanine, (18) isoleucine, (19) leucine, (20) lysine, (21) by-product.

72.3.1.2.3 Phenylisothiocyanate Method. Phenylisothiocyanate (PITC) reacts under alkaline conditions with both primary and secondary amino groups (Edman reaction). The derivatives can be separated on C_{18} (ODS)-reversed phase columns and detected with a UV detector at 254 nm (8).

The method of sample preparation and derivatization follows a stringent procedure that involves many labour-intensive steps and cannot be completely automated. An improvement was made by introducing the PicoTaq system (Waters), a semi-automatic apparatus to perform the drying and derivatization of the sample (9,10). However, the resulting phenylthiocarbamyl derivatives are very stable and easy to handle.

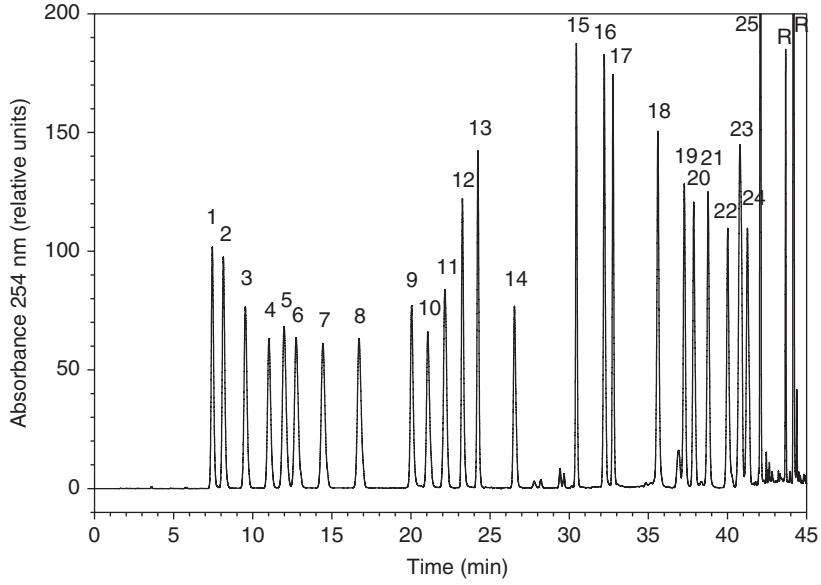
Procedure: The analysis of samples from cell cultures is done with an automated HPLC system. An autosampler injects an aliquot of the prepared sample onto a C_{18}-reversed phase HPLC column. The PITC derivatives are eluted in a binary gradient in less than 50 min and passed through a UV detector. Data recording, evaluation, calculation and device control are done with a chromatography software. A detailed description of this method follows.

Sample preparation:Cell-free supernatant is mixed 1:1 with an internal standard solution of 300 μM norleucine. An aliquot of 100 μL is lyophilized with a vacuum concentrator.

Derivatization: 20 μL of mixture 1 (2:1:1 methanol: water:triethylamine) is added to the lyophilizate, vortexed and dried again. For derivatization, 20 μL of mixture 2 (7:1:1:1 methanol:water:triethylamine:PITC) is added and mixed during a reaction time of 20 min at room temperature (22°C). The mixture is lyophilized again to remove excess of PITC. The lyophilizate is dissolved in 100 μL elution buffer A and 40 μL are injected onto the column.

Elution: The mixture is separated on a C_{18}-reversed phase column (ODS Hypersil, 5μ, 4.6 × 250 mm, Hypersil) with a multistep binary gradient in less than 50 min. The temperature of the column is set to 39.5°C using a water bath. Buffer A consists of 98% 0.085 M sodium acetate pH 5.2, 2% acetonitrile. Buffer B is a mixture of 70% acetonitrile and 30% 0.085 M sodium acetate pH 5.2. The total flow is set to 1.4 mL/min. The gradient is set as follows: 2% B at time 0, hold 2% for 9 min, linear increase to 4% B in 1 min, linear increase to 10% B in 10 min, linear increase to 25% B in 9 min, linear increase to 31% B in 8 min, linear increase to 90% B in 3 min, and hold 90% B for 4 min.

Detection: The PITC derivatives are detected with a UV detector set to a wavelength of 254 nm. Figure 72.2 shows an example chromatogram obtained for a standard mixture. All amino acids are baseline separated and can be quantified by peak area integration.



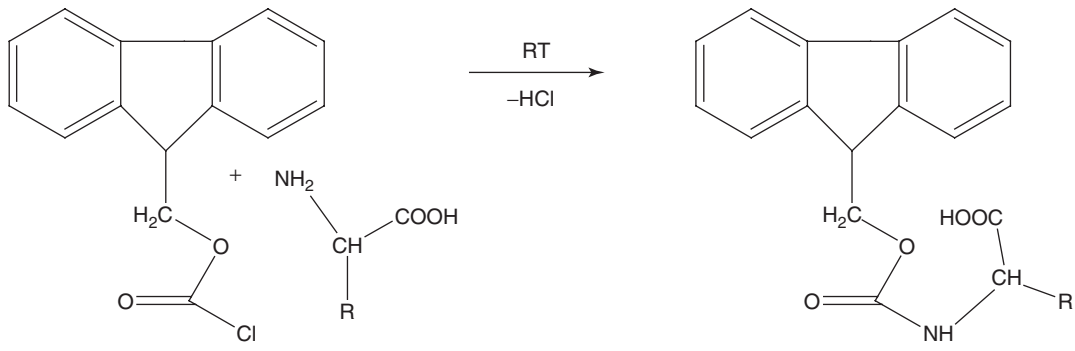


Figure 72.2. Separation of standard mixture amino acids using the PITC method. Amino acids identified as follows: (1) aspartic acid, (2) hydroxyproline, (3) glutamic acid, (4) serine, (5) asparagine, (6) glycine, (7) glutamine, (8) taurine, (9) histidine, (10) threonine, (11) alanine, (12) arginine, (13) proline, (14) ethanolamine, (15) tyrosine, (16) valine, (17) methionine, (18) cystine, (19) isoleucine, (20) leucine, (21) norleucine (internal standard), (22) phenylalanine, (23) ornithine, (24) tryptophan, (25) lysine, R reagent.

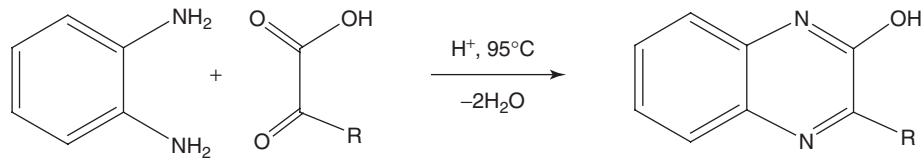
72.3.2 FMOC Method

9-Fluorenylmethoxycarbonyl chloride (FMOC) reacts with both primary and secondary amino groups. Owing to the introduction of the large hydrophobic fluorenylmethyl group, the derivatives can already be separated on a C_8-reversed phase column. Detection is done with a fluorescence detector at excitation and emission wavelengths of 260 nm and 310 nm, respectively.

FMOC offers a sensitivity comparable to the OPA method when used with fluorescence detection. But, FMOC and its hydrolysis products have similar fluorescence spectra to the FMOC amino acids. Excess FMOC remaining after derivatization reacts with water to form FMOC-OH (9-fluorenylmethyl alcohol), which elutes as a large broad peak. Removal of FMOC-OH can be achieved by liquid–liquid extraction into pentane. A more elegant method of preventing interference of FMOC-OH is to reactivate excess FMOC with a very hydrophobic amine (e.g. aminoadamantane) to form a derivative that elutes after all amino acids.



Reaction:

72.3.3 Analysis of Other Ingredients

72.3.3.1 Pyruvate. Pyruvate is the end product of aerobic glycolysis. At this point it can undergo several reactions, especially oxidative decarboxylation to produce acetyl-CoA or reduction to lactate (the end product of anaerobic metabolism). It was shown that free pyruvate is consumed by some mammalian cells rapidly, probably to bypass glycolysis. Other cell lines were observed to produce pyruvate to a certain extent. Nevertheless, no significant effect on cell growth and productivity was reported yet. Some basal medium formulations (e.g. F12) contain pyruvate in a concentration of 1 or 2 m*M*.

Reaction:

The determination of pyruvate cannot be performed without any molecule modification since no chromophore is present, except when employing an enzyme assay (using lactate dehydrogenase). On the other hand, pyruvate possesses an α-keto group which is reactive enough to react with primary amines under aqueous conditions. With *o*-phenylenediamine (OPD) (11) or 1,2-diamino-4,5-dimethoxybenzene (DMB) (12) fluorescent products (2-quinoxalinol derivatives) are formed, which can be separated on reversed phase columns and detected in a fluorescence detector.

Procedure: The analysis of pyruvate in samples from cell cultures can be performed with an automated HPLC system. The OPD derivatives are eluted in a binary gradient in less than 20 min and passed through a fluorescence detector.

Sample preparation: Cell-free supernatant is mixed 1:1 with 3% $HClO_4$ containing α-ketoglutarate as an internal standard. The mixture is centrifuged for 5 min to remove the precipitated proteins.

Derivatization: 50 μL of prepared sample is mixed with 500 μL of the OPD reagent (0.1 g OPD and 250 μL 2-mercaptoethanol in 100 m*M* 2 N hydrochloric acid) and derivatized for 2 h at 95°C. After cooling, 100 μL of the solution is mixed with 100 μL of 0.4 M sodium borate buffer pH 9.5 and 20 μL is injected onto the column.

Elution: The mixture is separated on a C_{18}-reversed phase column (Ultrasphere ODS, 5μ, 4.6 × 150 mm, Beckman Coulter Inc.) with a binary gradient in less than 20 min. The column temperature is set to 27°C. Buffer A consists of 0.085 M sodium acetate pH 7.5 and 1% tetrahydrofurane. Buffer B is a mixture of 70% methanol and 30% 0.085 M sodium acetate pH 5.2. Total flow is set to 1.0 mL/min. The gradient is set as follows: 20% B at time 0, linear increase to 100% B in 9 min, and hold 100% B for 4 min.

Detection: The OPD derivatives are detected with a fluorescence detector set to excitation and emission wavelengths of 340 nm and 412 nm, respectively (Fig. 72.3).

72.3.3.2 Inorganic Salts. Cell culture media contain inorganic cations and anions. The predominant salt in the medium is sodium chloride in a concentration of 6–7.5 g/L. This high concentration is necessary to maintain an osmotic pressure of about 300 mosmol/kg to ensure isotonic conditions for the cells. Besides sodium, only potassium, magnesium, and calcium cations are present in considerable concentrations. Sulfate, phosphate, and nitrate are the anions along with chloride. Some trace

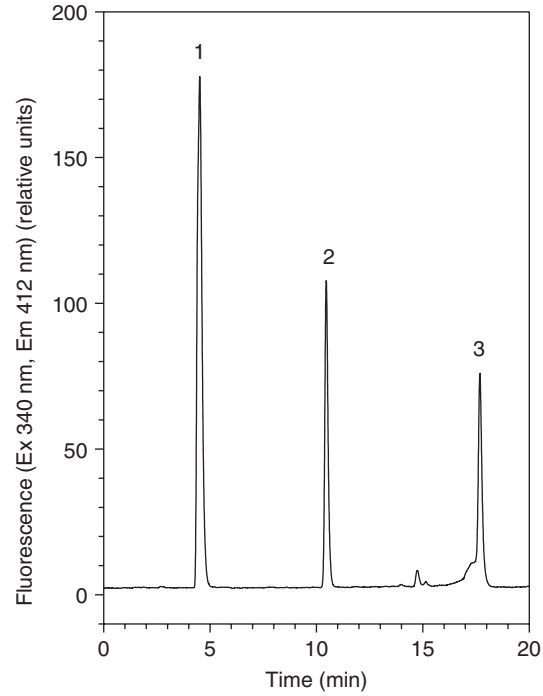


Figure 72.3. Separation of pyruvate (2) and ascorbic acid (3) standard solution on RP18 column after o-phenylendiamine derivatization (using α-ketoglutarate (1) as internal standard, concentration of each substance 1 m*M*).

elements like iron, zinc, copper, and selenium, each in very low concentration, may also be present. Sodium bicarbonate/carbon dioxide is usually the main pH buffer of the medium.

Ionic substances including inorganic cations and anions can be well separated by ion-exchange chromatography. The separated ions can easily be detected by using a conductivity detector, if the ion concentration is high enough to compensate the poor sensitivity. Conductivity detection is not suitable for the detection of trace elements. In that case methods like mass spectrometry (ICP-MS) or atomic absorption spectroscopy may apply.

Procedure: The ion separation can be performed with an ion chromatograph (e.g. Dionex, Metrohm) or any HPLC system equipped with a conductivity detector. The temperature of the column and of the flow cell of the detector has to be controlled very constantly since conductivity is extremely temperature sensitive.

Sample preparation: Cell-free supernatant is mixed with an internal standard (e.g. cesium bromide) and filtered (0.45 μm). The mixture has to be diluted with ion-free water to meet the detection range (e.g. 1:100).

72.3.3.2.1 Cation Separation. Inorganic cations can be separated on a cation exchange column [IC Cation SuperSep (silica, polybutadiene—malic acid), 125 mm × 4,0 mm, Metrohm] and eluted isocratically with a buffer consisting of 4 m*M* tartaric acid and 0.7 m*M* pyridine-2,6-dicarboxylic acid in less than 20 min. The column temperature is set to 30°C and total flow is set to 1.0 mL/min. A chromatogram obtained under these conditions is shown in Figure 72.4.

72.3.3.2.2 Anion Separation. The anions are separated on an anion exchange column (Anion/R (polystyrene, $-N(CH_3)^{3+}$), 10μ, 0,19 meq/g, 250 mm × 4.1 mm,

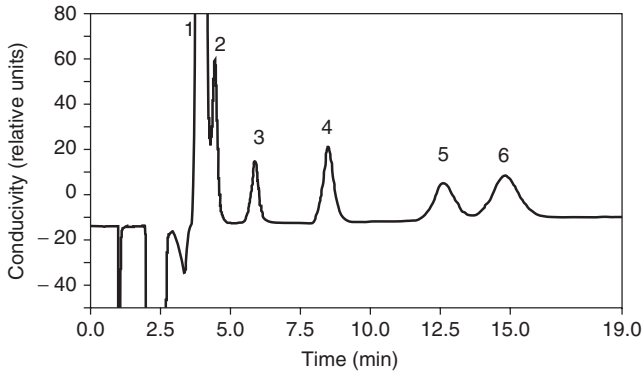

Figure 72.4. Separation of cations on a cation exchange column. Cell culture basal medium was diluted 1:100 prior injection. Identified cations are (1) sodium, (2) ammonium, (3) potassium, (4) cesium (internal standard), (5) calcium, (6) magnesium.

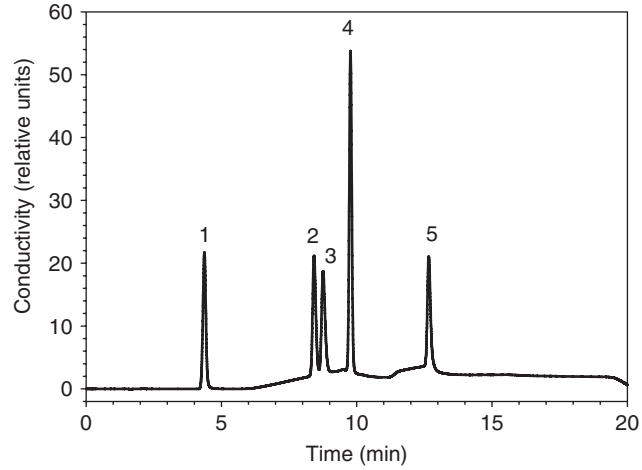

Figure 72.5. Anion separation by anion exchange chromatography. Separated anions of 1 m*M* standard calibrator are identified as follows: (1) chloride, (2) bromide, (3) nitrate, (4) sulphate, (5) phosphate.

Alltech) and eluted with 5 m*M* *p*-hydroxy benzoic acid, pH 8.5 (adjusted with LiOH) in 30 min. The column temperature and total flow are set to 30°C and 2.5 mL/min, respectively. Good results can also be obtained by using a Dionex ion chromatograph with suppressor technology equipped with an anion exchange column AS11 and a gradient elution with 10 and 100 m*M* sodium hydroxide solutions. Figure 72.5 shows an example of a standard chromatogram.

72.3.3.3 Vitamins. Cell culture basal media contain about 10 different vitamins and precursors (Table 72.1). Sometimes, special media recipes contain additional vitamins or provitamins such as Vitamin C (ascorbic acid), retinoic acid (Vitamin A acid), or E (α-tocopherol). From a chemical point of view, the group of vitamins is an extremely heterogeneous collection of substances with different chemical properties. Most of the vitamins are water soluble, but some are only fat soluble. Hence, a uniform analysis method cannot be achieved. A second problem for the determination derives from the very low concentrations, generally far below 10 mg/L. Nevertheless, the knowledge of vitamin requirements during cell cultivation (especially long term and high density cultures) may improve cell growth and productivity.

The analysis of vitamins is often performed in the food industry for quality control of multivitamin preparations, juices, engineered food, and other materials. In general, the vitamin concentrations in these matrices are much higher than in culture medium. However, some progress has been made in adapting methods for the analysis of certain vitamins to cell culture conditions. In the following

text, determination methods for some vitamins, which have been recently developed in our laboratory, are described.

72.3.3.3.1 Ascorbic acid. Ascorbic acid (Vitamin C) is often used in media as antioxidant and is known to be important for the cultivation of primary (embryonic) cells. It can be present to a concentration of 0.5–1 m*M*, sometimes much less. Vitamin C can be analyzed using the method and reagent described for pyruvate. It elutes considerably after ketoglutarate and pyruvate (Fig. 72.3).

72.3.3.3.2 Pantothenate. Pantothenate, a member of the vitamin B_2 group, is a dipeptide formed from 2,4-dihydroxy-3,3-dimethyl butyric acid and β-alanine. In conjunction with cysteamine, adenosine, and diphosphate, pantothenate forms the coenzyme A. The pantothenate molecule contains no chromophore or fluorophore. An analysis method was developed using a refractometer as detector (13). The low concentration in medium in a range of 0.4–4 mg/L and many other medium ingredients make the use of such a detection method impossible. Direct analysis of pantothenate from cell culture medium may be performed using liquid chromatography coupled to a mass spectrometer with electrospray ionization (ESI-MS) or by gas chromatography with mass spectrometry (GC-MS) detection after sialylation. If such equipment is not available, a promising alternative can be an acidic hydrolysis with later analysis of the released β-alanine. The β-amino acid β-alanine can be derivatized with one of the reagents described in the amino acid section. The second product of the hydrolysis is pantolactone. Pantolactone may be analyzed by gas chromatography after liquid–liquid extraction from the hydrolysis mixture using dichloromethane as organic solvent.

Procedure: The quantification of β-alanine after hydrolysis of pantothenate can be carried out with an HPLC system.

Sample preparation: 100 μL of sample and 200 μL concentrated hydrochloric acid is boiled for 15 min in a water bath. The mixture is lyophilized in a vacuum concentrator and resolved in 100 μL of 0.4 M sodium borate buffer pH 9.5.

Derivatization: 40 μL of the prepared sample is filled into a sampler vial. The sampler mixes with 70 μL of reagent (50 mg OPA, 1 mL methanol, 100 μL 2-mercaptoethanol, 9 mL 0.6 M sodium borate buffer pH 10.4) and injects 60 μL onto the column after 1.5-min reaction time.

Elution: The mixture is separated on a C_{18}-reversed phase column (e.g. Ultrasphere ODS, 5μ, 4.6 × 150 mm, Beckman Coulter Inc.) with a multistep binary gradient in less than 20 min. The column temperature is set to 39.5°C. Buffer A consists of 0.1 M sodium acetate pH 7.5, 1% tetrahydrofurane. Buffer B is a mixture of 70% methanol and 30% 0.1 M sodium acetate pH 5.2. Total flow is set to 1.8 mL/min. The gradient is set as follows: 25% B at time 0, linear increase to 50% B in 3 min, hold 50% B for 10 min, linear increase to 80% B in 1 min, and hold 80% B for 4 min. This gradient has to be chosen to separate the β-alanine derivative from all other amino acid derivatives present in the sample at much higher concentrations.

Detection: The OPA derivatives are detected with a fluorescence detector set to excitation and emission wavelengths of 330 nm and 450 nm, respectively.

72.3.3.3.3 Riboflavin. Riboflavin (7,8-dimethyl-10-ribityl-isoalloxazine), a member of the Vitamin B_2 group, is contained in prosthetic groups (FMN, FAD) of flavoprotein. Aerobic and anaerobic dehydrogenases often belong to the group of flavoproteins. Such enzymes are involved especially in the respiratory chain. The isoalloxazine structure in riboflavin acts in this context as a reversible redox system.

Riboflavin itself is fluorescent without any modification and an analysis is easy when the concentration is high enough (14–16). Usually the riboflavin concentration in cell culture media is in the range of 0.04 to 0.4 mg/L, which is too low for direct measurement. But a 10-fold concentration is sufficient for quantitative determination.

Procedure: The quantification of riboflavin can be performed with an HPLC system. Riboflavin is separated from disturbing substances on a C_{18} column and detected with a fluorescence detector.

Sample preparation: 1 mL of sample is lyophilized in a vacuum concentrator and resolved in 100 μL buffer.

Elution. The concentrated sample is injected onto a C_{18}-reversed phase column (e.g. Ultrasphere ODS, 5μ, 4.6 × 150 mm, Beckman Coulter Inc.) and eluted with a buffer consisting of 99% 0.01 M sodium acetate pH 7.4 and 1% tetrahydrofurane. Total flow is set to 1 mL/min.

Detection. Riboflavin is detected in a fluorescence detector set to excitation and emission wavelengths of 436 nm and 535 nm, respectively. At these wavelengths only a low interference was observed.

72.3.3.3.4 Thiamine. Thiamine, the Vitamin B_1, is in form of its diphosphate, the prosthetic group of the enzyme decarboxylase-dehydrogenase, one of the three units of a multienzyme complex performing the oxidative decarboxylation.

The thiamine concentration in cell culture media is in the range of 0.3–4 mg/L which is sufficient for quantitative determination, if a sensitive detection method is used. Although thiamine contains a pyrimidine and thiazole ring in the molecule a much more sensitive detection can be achieved when the thiazole ring is oxidised. The resulting thiochrome is fluorescent (17–19).

Procedure: The quantification of thiamine can be carried out with an HPLC system. Thiamine is oxidized by potassium hexacyanoferrate in alkaline solution to thiochrome. Thiochrome can be separated on a C_{18} column and detected with a fluorescence detector.

Sample preparation: 0.5 mL of sample is mixed with 0.5 mL of 1% $K_3Fe(CN)_6$ in 15% NaOH. After 45 s the reaction is stopped by adding 75 μL phosphoric acid.

Elution: The reaction mixture is injected immediately onto a C_{18}-reversed phase column (Ultrasphere ODS, 5μ, 4.6 × 150 mm, Beckman Coulter Inc.) and eluted with a buffer consisting of 99% 0.01 M sodium acetate pH 7.4 and 1% tetrahydrofurane. Total flow is set to 1 mL/min.

Detection: Thiochrome is detected in a fluorescence detector set to excitation and emission wavelengths of 364 nm and 436 nm, respectively.

72.3.3.4 Lipids. The cell membrane of mammalian cells consists basically of a lipid bilayer of phospholipids. The phospholipids (e.g. phosphatidyl choline, phosphatidyl ethanolamine, and phosphatidyl-serine) themselves are diesters of phosphoric acid with glycerin on one side and choline, ethanolamine, or serine on the other side. Glycerin is esterified at its two other hydroxyl groups with fatty acids. The fatty acids (saturated and unsaturated) can be synthesized by an enzyme complex (fatty acid synthetase complex) located in the cytosol starting from acetyl-CoA. Another main component of the cell membrane is the steroid cholesterol. It has a rigid structure and can strengthen the cell membrane if it is incorporated into the lipid bilayer. Cholesterol can also be synthesized from acetyl-CoA by another pathway.

Although the cells can prepare their lipids need, special additives to basal cell culture media can contain fatty acids, cholesterol and phospholipids to support the cell status. In medium additives like serum, lipoprotein mixtures, and protein/fatty acid mixtures these components may be included.

72.3.3.4.1 Fatty acids. Fatty acids may be analyzed either by liquid or by gas chromatography. Generally present in low concentrations, a concentration step is necessary. This concentration can be carried out by liquid–liquid extraction with a lipophilic solvent and subsequent lyophilization.

Procedure: The lyophilized fatty acids can either be dissolved and applied directly to a gas chromatograph equipped with a special column or have to be derivatized prior to HPLC analysis (13). In each case the same sample preparation procedure may be used.

Sample preparation: 0.4 mL of sample, 10 μL internal standard solution (5 m*M* heptadecanoic acid) and 1 mL of extracting agent (Dole mixture; isopropanol/*n*-heptane/2 M phosphoric acid 40:10:1) are vortexed for 10 min. 0.4 mL *n*-heptane and 0.6 mL pure water are added and mixed again. 0.4 mL of the upper (organic) phase are taken and lyophilized.

GC analysis: The lyophilized fatty acids are dissolved in *n*-heptane, dried with sodium sulphate and applied to the gas chromatograph. The gas chromatograph may be equipped with a split injector, an FID (flame ionization detector), and a polar capillary column (e.g. FFAP-CB, 25 m, Chrompack). The temperatures of injector and detector are both set to 300°C. The fatty acids elute at temperatures of 200 to 270°C.

HPLC analysis: Before injection the fatty acids have to be derivatized to add a chromophore. The lyophilized fatty acids are dissolved in 200 μL acetonitrile. 12 μL of reagent (50 m*M* p-bromophenacyl bromide, 5 m*M* 18-crowne-6) and 1 mg $KHCO_3$ are added and held for 45 min at 85°C. The fatty acid derivatives can be separated on a C_8-reversed phase column (Kromasil Octyl, 5μ, 125 × 4.6 mm, Eka Nobel) by binary gradient elution in less than 30 min. Solvent A consists of 50% acetonitrile, 50% water and solvent B of 99% acetonitrile, 1% water. The total flow is set to 1.3 mL/min. The gradient is set as follows: 0% B at time 0, linear increase to 100% B in 30 min, and hold 100% B for 2 min. Detection is carried out by UV absorption at 254 nm. Figure 72.6 shows an example chromatogram.

72.3.3.4.2 Cholesterol and Cholesteryl Esters. Cholesterol may be analyzed by gas chromatography. After liquid–liquid extraction from the aqueous sample with an organic solvent and subsequent lyophilization it can be acetylated and chromatographed on a nonpolar column. Cholesteryl esters can be hydrolyzed prior to acetylation.

The analysis of cholesterol acetate may be carried out with a normal gas chromatograph equipped with a split injector, an FID (flame ionization detector), and a nonpolar capillary column (e.g. CP-5-Sil CB, 10 m, Chrompack).

Sample preparation: 2 mL of sample is added to 2 mL of extracting agent (75% diisoproylether, 25% *n*-butanole) and mixed for 3 h in an end-over-end mixer. The nonaqueous phase is taken and lyophilized. The cholesteryl esters can now be hydrolyzed with ethanolic KOH (0.6 mL 33% KOH, 9.4 mL ethanol) for 1 h at 60°C. After neutralization (HCl) and extraction (hexane, three times) cholesterol can be derivatized.

Derivatization: The solvent (hexane) is removed and acetic anhydride is added. After 1 h at 100°C the reaction is stopped by adding ice water. Cholesterol acetate is extracted into hexane (three times). The joined organic phases are washed with pure water and lyophilized afterwards.

Chromatography: The dried extract is dissolved in hexane and an aliquot is applied to the gas chromatograph. The temperatures of injector and detector should be set to 270°C and 300°C, respectively. Cholesterol acetate elutes

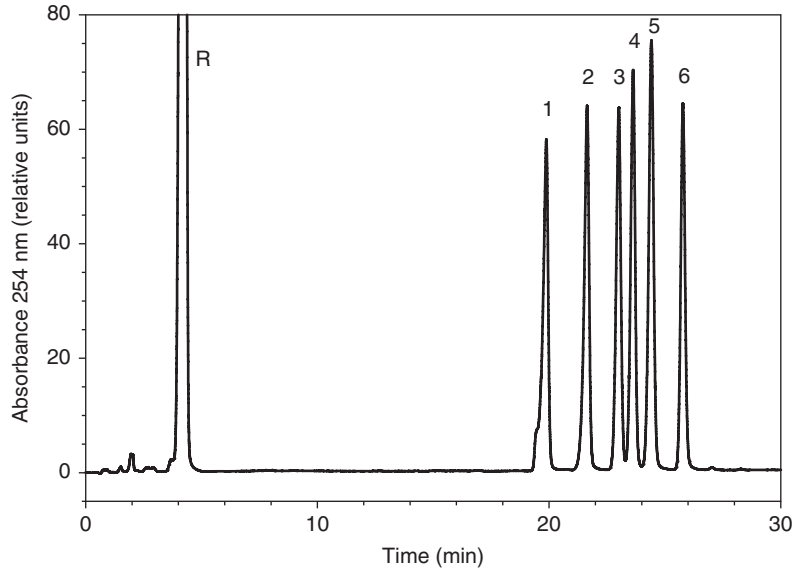

Figure 72.6. HPLC separation of standard mixture of predominant fatty acids. All conditions as described in the text. Identified fatty acids: (1) linolenic acid (18:3), (2) linoleic acid (18:2), (3) palmitic acid (16:0), oleic acid (18:1), heptadecanoic acid (17:0) (internal standard), (6) stearic acid (18:0), R reagent.

at a temperature of 240–270°C. For improved reproducibility an internal standard (e.g. stigmasterol acetate) may be added early during sample preparation.

72.4 ANALYSIS OF METABOLIC END PRODUCTS

During metabolization of glucose, amino acids, and other compounds, the cells also produce substances that are released into the surrounding medium. The main end products of metabolism are lactic acid (lactate) and ammonia. Both substances are known to affect cell viability and product formation. Therefore, it is necessary to monitor the concentrations in the culture supernatant to be able to maintain low concentrations through special means or process procedures.

72.4.1 Lactate

Lactate is the end product of anaerobic metabolism of glucose. Almost all cells *in vitro* produce lactate also under aerobic conditions. Lactate is formed from pyruvate by the enzyme lactate dehydrogenase. A maximum of two moles of lactate can be produced from 1 mole of glucose under completely anaerobic conditions. Additionally, lactate may also be synthesized by other pathways, especially amino acid metabolism. The two most common methods of lactate analysis are described below.

72.4.1.1 Photometric Lactate Assay (e.g. R-Biopharm, formerly Boehringer Mannheim). Lactate is converted in the presence of NAD^+ BY THE ENZYME L-lactate dehydrogenase to pyruvate. During this reaction NADH is formed, which can be monitored at a wavelength of 340 nm. The reaction is reversible and the equilibrium is more on the lactate side than on the pyruvate side. Therefore pyruvate has to be removed. This can be achieved by adding the second enzyme glutamate-pyruvate-transaminase, which converts pyruvate in the presence of glutamate to alanine and 2-oxoglutarate. The assay is desired to be used in a cuvette UV spectrophotometer and needs no further laboratory equipment (20,21).

Reactions:

$$\text{L-Lactate} + \text{NAD}^+ \xrightarrow{\text{L-Lactate dehydrogenase}} \text{Pyruvate} + \text{NADH} + \text{H}^+$$

$$\text{Pyruvate} + \text{L-Glutamate} \xrightarrow{\text{Glutamate-pyruvate-transaminase}} \text{L-Alanine} + \text{2-Oxoglutarate}$$

Enzyme electrode-based biosensor (e.g. Model YSI 2700, Yellow Springs Instruments, BioProfile Analyzer Series, Nova Biomedical): The principle of these systems is already described in detail in the section titled Glucose. In case of lactate determination the immobilized enzyme

is lactate oxidase, which oxidizes lactate and generates hydrogen peroxide.

Reactions:

$$\text{L-Lactate} + O_2 \xrightarrow{\text{Lactate oxidase}} \text{Pyruvate} + H_2O_2$$

$$H_2O_2 \xrightarrow{\text{Pt anode}} 2H^+ + O_2 + 2e^-$$

The YSI 2700 analyzer is capable of holding and maintaining two enzyme electrodes in its chamber. Therefore, from the same sample volume (25 μL) two determinations (e.g. glucose and lactate) can be made at the same time.

72.4.2 Ammonia

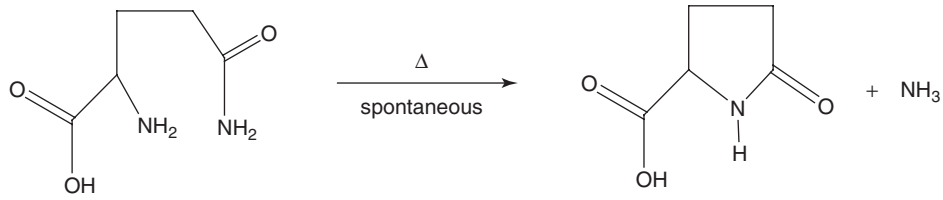
In animal cell culture, other than in mammals, ammonia is the main end product of nitrogen metabolism. Besides ammonia, alanine is also produced in a remarkable amount while only little urea is secreted by the cells. Especially, when high glutamine and other amino acid concentrations have to be used to supply the cells, an ammonia concentration of several millimolars can be found. High ammonia concentrations can affect cell growth, productivity, and product integrity very drastically. Several analytical methods have been used for the quantification of ammonia including enzyme assay systems (e.g. R-Biopharm, formerly Boehringer Mannheim) (22,23), gas sensitive electrodes (e.g. Mettler–Toledo), ion chromatography (e.g. Metrohm, Dionex), and derivatization. The methods are discussed in the following text. Each of these methods has its advantages and disadvantages.

72.4.2.1 Enzyme Assay. Owing to the use of a special enzymatic reaction (glutamate dehydrogenase), the enzyme assay is highly specific for ammonia. The concentration of NADH can be easily monitored at a wavelength of 340 nm. The concentrations of reacted NADH and assayed ammonium are inversely proportional. The necessity of the coenzyme NADH and the consumption of enzyme make this method a cost-intensive analysis procedure.

Reaction:

$$\text{2-Oxoglutarate} + \text{NADH} + NH_4^+ \xrightarrow{\text{Glutamate- dehydrogenase}} \text{L-Glutamate} + NAD^+ + H_2O$$

This assay test kit is desired to be used in a cuvette UV spectrophotometer and needs no further laboratory equipment. The method can be recommended when only few or sporadic measurements are necessary.



72.4.2.2 Gas-Sensitive Ammonia Electrode. An ammonia electrode works by the principle that under alkaline conditions ammonia degasses from aqueous solutions, passes through a hydrophobic membrane [polytetrafluoroethylene (PTFE)], and dissolves in an acidic solution where the resulting pH shift can be measured and quantitatively evaluated. In most cases this is also a specific detection method. The main disadvantages are the size of the electrode and the fragile membrane adapter. Depending on the ammonia concentration in the sample and a predilution possibility, a sample volume of up to 10–20 mL may be necessary for analysis.

Procedure: 2 mL of cell-free sample are diluted with water to a volume of 20 mL. The ammonia electrode is placed into the solution. After obtaining a stable value, 0.5 mL of 10 M NaOH is added and the highest value is registered.

72.4.2.3 Ion Chromatography. The ion chromatography analysis of ammonia is based on cation exchange chromatography (24) and conductivity detection. Owing to the chemical similarity of ammonium and potassium cations and the high sodium concentration, a good resolution may be difficult to obtain. A small sample volume requirement and an automatic analysis procedure are advantages of this method, whereas the high equipment requirement (chromatography system) is the main disadvantage.

72.4.2.4 Derivatization with Fluorescence Detection. OPA reacts with primary amines including ammonia in the presence of mercaptoacetic acid (thioglycolic acid) at basic conditions to unstable, fluorescent isoindole derivatives. The reaction product is analogous to the products formed with 3-mercaptopropionic acid and amino acids, but its fluorescent property is quite different. Whereas the fluorescence intensity at excitation and emission wavelengths of 330 nm and 450 nm (amino acids), respectively, is very poor, the fluorescence yield can be increased very much by shifting to wavelengths of 415 nm and 485 nm, respectively. On the other hand, the fluorescence intensity of the amino acid derivatives is negligible at those wavelengths. Therefore, this method has good selectivity for ammonium quantification.

Procedure: The reagent is prepared by dissolving 1.85 mmol OPA and 4 mmol mercaptoacetic acid (thioglycolic acid) in 2 mL methanol and adding 100 mL 0.4 M sodium borate buffer pH 10.4. The mixture can be stored at 4°C in 10 mL aliquots. Before measurement one aliquot was allowed to reach room temperature (20°C). The reaction is directly carried out in half micro quartz cuvettes by adding 1–1.3 mL reagent to 20 μL of cell-free sample. After a brief mixing the cuvette is immediately placed in a spectrofluorimeter (RF551, Shimadzu) set to excitation and emission wavelengths of 415 nm and 485 nm, respectively.

72.4.3 Urea

Urea is the end product of nitrogen metabolism in mammals. Normally it is produced in the liver and secreted by the kidney into the urine. Cells *in vitro* are usually not able to synthesize urea. Therefore, the predicted urea concentration in the supernatant may be very low. On the other hand, a considerable amount of urea may be found in medium additives like serum or plasma.

Urea may be quantified by using a two-step enzyme assay (25,26). The reaction may be monitored by following the NADH conversion at 340 nm. The reaction is specific for urea, but the method is not very sensitive.

Reaction:

$$\text{Urea} + H_2O \xrightarrow{\text{Urease}} 2NH_3 + CO_2$$

$$\text{2-Oxoglutarate} + \text{NADH} + NH_4^+ \xrightarrow{\text{Glutamate- dehydrogenase}} \text{L-Glutamate} + NAD^+ + H_2O$$

72.5 ANALYSIS OF OTHER SUBSTANCES AND PARAMETERS

72.5.1 Pyroglutamic Acid

Pyroglutamic acid (5-oxo-2-pyrollidone carboxylic acid) is a molecule, which is formed from glutamine in a spontaneous thermal intramolecular cyclization reaction.

Under cultivation conditions glutamine has a half-life of about 6–8 days (27). Therefore, when high glutamine concentrations are used and maintained under such conditions (e.g. high density batch and perfusion cultivations) a considerable amount of pyroglutamate is produced.

In principle, pyroglutamate can be analyzed by using the same derivatization procedure as described for HPLC analysis of fatty acids. But sample preparation and elution conditions distinguish clearly because the formed derivative is much more hydrophilic and cannot be separated on a C_8-reversed phase column.

Procedure: The analysis may be carried out using a binary gradient HPLC system with UV detection.

Sample preparation: The cell-free sample is adjusted to pH 3.50 μL thereof are lyophilized and resolved in 180 μL acetonitrile.

Derivatization: 20 μL reagent (50 m*M* p-bromophenacyl bromide, 5 m*M* 18-crowne-6) and 1 mg $KHCO_3$ are added to the solution and heated for 90 min to 85°C. The reaction mixture is rapidly cooled with ice water and 15–30 μL is injected.

Elution: The pyroglutamate derivative can be separated on a C_{18}-reversed phase column (Ultrasphere ODS, 5μ, 4.6 × 150 mm, Beckman Coulter Inc.) by binary gradient elution in less than 30 min. Solvent A consists of 20% acetonitrile, 80% water; and solvent B of 90% acetonitrile, 10% water.

The total flow is set to 1.3 mL/min. The gradient is set as follows: 0% B at time 0, linear increase to 100% B in 30 min, and hold 100% B for 2 min. Detection is carried out by UV absorption at 254 nm. Besides pyroglutamate, lactate can also be analyzed quantitatively with this method. Figure 72.7 shows an example chromatogram.

72.5.2 Enzyme Activities

Several enzymes are released from necrotic and apoptotic cells and cell membranes into the cell culture medium during cultivation. These enzymes may also be active in medium influencing cell behavior or product quality. Monitoring these enzyme activities may be necessary to assess culture status or product quality.

72.5.2.1 Lactate Dehydrogenase Activity. Lactate dehydrogenase is a cytosolic enzyme. The detection of lactate dehydrogenase activity in the cell culture supernatant indicates cell damage by defective membranes or cell lysis. This enzyme is often used as marker enzyme for cell death. As described in the section Lactate, lactate dehydrogenase converts pyruvate in the presence of NADH into lactate (or *vice versa*). The enzyme activity can be monitored by following the NADH conversion in a temperature-controlled spectrophotometer at a wavelength of 340 nm. A standardized procedure can be performed as follows. 100 μL cell-free supernatant is mixed with 700 μL of 30 m*M* sodium phosphate buffer pH 7.4, 100 μL of 10 m*M* sodium pyruvate solution (in phosphate buffer), and 100 μL 2.7 m*M* NADH solution (in phosphate buffer) in a quartz half micro cuvette. The cuvette is placed in a temperature-controlled (37°C) photometer. The linear extinction decrease at 340 nm is monitored for 1 min. The enzyme activity can be calculated

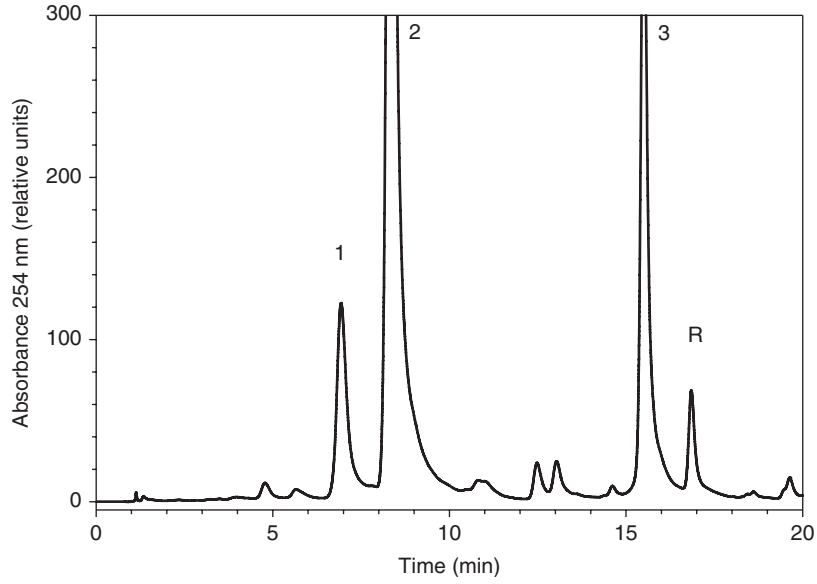


Figure 72.7. Chromatogram obtained by following the pyroglutamate derivatization procedure. Derivatization and separation conditions apply as described in the text. Identified substances are (1) pyroglutamate, (2) lactate, (3) unresolved amino acids (mainly glutamine), R reagent.

from the slope in comparison to the autolytic decomposition of NADH in a reference experiment.

72.5.2.2 Neuraminidase Activity and Sialic Acids. Many of the therapeutical proteins produced by cell culture are glycosylated. Variability in the oligosaccharide pattern can affect their behavior after application to a patient (half-time, biodistribution, and biological activity). Terminally linked sialic acids are particularly involved in various biological events. Sialic acids are easily cleaved off the oligosaccharide by neuraminidases. Neuraminidase activity has been localized on the subcellular level in the plasma membrane, the Golgi apparatus, the lysosomes and the cytosol. Moreover, neuraminidase activity has also been detected in cell culture fluids (28).

72.5.2.3 Determination of Neuraminidase Activity. The neuraminidase activity is determined fluorometrically with 4-methylumbelliferyl-α-D-N-acetylneuraminic acid substrate (MUF-NeuAc5) (29). A standardized assay can be performed as follows (30). After centrifugation (15,000 $\times$ g, 15 min), 250 μL of supernatant, 25 μL of 4 m*M* MUF-NeuAc5 solution, and 25 μL of 1 M phosphate buffer pH 7.0 are mixed and heated for 1 h at 37°C. The reaction is stopped by adding 700 μL 0.375 glycine/KOH buffer pH 10.4. The mixture is centrifuged again (15000 $\times$ g, 5 min), and the fluorescence is determined at excitation and emission wavelengths of 362 nm and 448 nm, respectively.

72.5.2.4 Determination of Sialic Acids. Free sialic acids can be derivatized with 1,2-diamino-4,5-methylenedioxy benzene (DMB) into fluorescent derivatives which can be separated on a C_{18}-reversed phase column (31,32). 20 μL of cell-free supernatant is mixed with 40 μL ice-cold acetone to precipitate soluble proteins. After centrifugation (15,000*g*, 5 min) 15 μL of the mixture is lyophilized in a vacuum concentrator. The lyophilizate is dissolved in 200 μL of 25 m*M* H_2SO_4. 200 μL of DMB reagent (7 m*M* DMB, 18 m*M* disodium dithionite, 1 M 2-mercaptoethanol in water) are added and heated for 2.5 h at 60°C. The reaction is stopped by cooling to 0°C (ice water). After centrifugation (15,000*g*, 5 min) 20 μL of the mixture is injected onto the column (Kromasil C18, 5μ, 4.6 $\times$ 150 mm, Eka Nobel). The sialic acid derivatives are eluted isocratically (1.2 mL/min) with a solvent consisting of 5% acetonitrile, 7% methanol, and 88% water and quantitatively detected with a fluorescence detector at excitation and emission wavelengths of 373 nm and 448 nm, respectively.

72.5.3 Osmolality

The cytosol interacts with the medium through the water permeable cell membrane. Depending on the concentration ratio of all substances on both sides of the cell membrane, the cell is exposed to an osmotic pressure. The osmotic pressure of a solution is given by its osmolality. The osmolality of the medium should be in the range of approximately 300 mosmol/kg $\pm$ 50 mosmol/L to provide isotonic conditions. For the determination of the osmolality, the

molar lowering of the freezing point (Raoult's law) by a dissolved substance can be measured. The osmolality is independent of the kind of the dissolved substance, but cumulative for all dissolved substances. The measurement can be performed with a freezing point osmometer (e.g. semi-automatic half micro osmometer, Knauer). 150 μL of cell-free supernatant is needed for the process.

72.6 ANALYSIS OF PROTEINS

There are several proteins present in cell culture fluids. Some are added to the medium to support cell growth and product formation. The others are produced by the cells, among which the desired product can be found. For this reason an overall, unspecific protein assay can usually not be used to determine product quantity. For each product a special assay, regarding the properties of that protein, has to be established; if not only quantity but also activity has to be analyzed. Nevertheless, the total protein content in the medium is often a useful parameter.

72.6.1 Unspecific Protein Assays

A number of methods have been developed to determine total protein concentration. Besides direct UV absorbance and fluorescence, dye staining and reaction with a copper containing reagent are the most common methods. The main problem of all those methods is that the response for different proteins may vary widely. With a complex mixture of unknown proteins this may lead to completely wrong results. Much care must be taken when choosing a method for a special purpose. The most common methods are discussed briefly in the following overview. A very detailed description of all methods including working instruction can be found in Dunn (33).

UV absorbance at 280 nm. Determination of absorbance of aromatic amino acids in the protein (phenylalanine, tyrosine, and tryptophan).

UV Absorbance at 205 nm. Determination of absorbance of peptide bonds.

Fluorescence (excitation 280 nm and emission 340 nm). Determination of tryptophan fluorescence in the protein.

Dye staining. The dye coomassie blue G 250 binds in strong acidic solution to positively charged protein molecules forming a blue product that can be determined at 595 nm (34).

Biuret reaction. Copper (II)—ions in alkaline solution form a purple complex with proteins (peptide bonds). Detection at 540 nm (35).

Lowry method. The method is based on the Biuret reaction and the Folin-Ciocalteau phosphormolybdicphosphotungstic acid reduction to heteropolymolybdeum blue by the copper-catalysed oxidation of aromatic amino acids (36). Detection at 750 nm.

BCA reagent. An alternative detection reagent, bicinchoninic acid (available from Pierce), has been developed for use with the Lowry method. Detection at 562 nm (37).

Protein Assay ESL. The method is an improvement of the Biuret method. Spare copper(II) ions are reduced to copper(I) ions by ascorbic acid. These copper(I) ions form a complex with bathocuproin which can be detected at 485 nm (38). Since spare copper ions are measured the extinction is inversely proportional to the protein concentration. An assay kit is commercially available (Roche Diagnostics).

72.6.2 Enzme Linked Immunoassays

For highly specific determinations the antibody–antigen binding is very useful. Whenever an antibody against a substance (protein) is available or can be produced, an immunoassay is the method of choice. An immunoassay may be performed in a multi-well micro titer plate as an enzyme-linked immunosorbent assay (ELISA), as a radio immunoassay (RIA), as an affinity chromatographic analysis or even otherwise (39).

A standard sandwich ELISA procedure usually provides sufficient selectivity and sensitivity. Sensitivity may be improved by use of the (strep)avidin biotin amplification method. The sandwich ELISA is performed in four steps. First, the multi-well micro titer plate is coated with a primary antibody. Remaining binding sites on the plate are saturated with inert protein (albumin, casein). Secondly, the samples and standards containing the desired protein are applied. After incubation and removal of supernatant, an enzyme-labeled antibody (secondary antibody, conjugate), is added at the third step. The fourth step is carried out by adding a substrate of the enzyme. The conversion of the substrate by time is monitored photometrically. By comparison to standard concentrations a quantitative determination can be obtained. Commonly labeled enzymes are horse radish peroxidase and alkaline phosphatase. The most appropriate substrates for the peroxidase may be OPD or ABTS (2,2′-azino-di-[3-ethylbenzthiazoline sulfonate(6)] diammonium salt). For the phosphatase *p*-nitrophenylphosphate is a useful substrate.

72.7 ANALYSIS WITH CLINICAL ANALYZERS

Fully automated analyzers are widely used in central hospital laboratories. These systems often have a sample

throughput of up to several hundred measurements per hour. A wide variety of parameters of clinical interest can be analyzed. These parameters can be categorized in groups of basal substrates, enzymes, electrolytes, or immunochemicals. In the group of basal substrates the following substances and parameters are compiled: albumin, bilirubin, cholesterol, creatinine, glucose, urea, uric acid, triglycerides, and total protein. Among others, the activity of the following important enzymes can be quantified: alkaline phosphatase (ALP), amylase (AMYL), cholinesterase (CHE), creatin kinase (CK), glutamate dehydrogenase (GLDH), aspartate aminotransferase (AST/GOT), alanine aminotransferase (ALT/GPT), γ-glutamyl transferase (GGT), lactate dehydrogenase (LDH), lipase (LIP). Additionally, analytical methods for electrolytes such as sodium, potassium, calcium, magnesium, chloride, iron, and inorganic phosphate are integrated in the clinical autoanalyzer systems. Some of these analyzers are also able to perform immunological quantifications for immunoglobolins (A, G, M), lipoproteins (APO), transferrin etc. All of these methods are based either on reactions followed by photometrical detection or on measurements with ion-selective electrodes.

An alternative to these methods based on liquid chemistry are systems using strip technology. All chemicals needed for one special detection are placed and fixed on a prepared area on the strip. The strip is dipped into the sample or wetted with a sample drop. With ongoing reaction a color or change in color is produced. Depending on the special strip used, this color can be evaluated either by comparison with a color table or by using a strip photometer. Fully automated analyzers based on this strip technology have also been developed for use in a clinical laboratory.

To explain each method in detail in this chapter would lead too far, but a complete description of each detection and quantification method can be obtained from the manufacturers of the clinical analyzers. These clinical systems are offered from companies such as Roche Diagnostics/Hitachi Instruments, Siemens Medical Solutions (formerly Bayer Diagnostics), Beckman Coulter, Randox, or Olympus Diagnostica.

All methods used in the clinical analyzer systems, as described above in this chapter, are optimized and established to meet the requirements of clinical samples such as whole blood, serum, plasma, urine or other body liquids. If these conditions are also satisfying a cell culture technologist to analyze his samples from culture supernatants or cell extracts has to be exactly and independently proven for each single method. Special attention has to be drawn to detection limit, sensitivity, reproducibility and presence of disturbing substances. When all these parameters are satisfactory, the use of a clinical analyzer may be a substantial help for routine analysis. Some methods used in the autoanalyzers are also offered as complete analyzing kits optimized for manual operation (Roche Diagnostics). Randox has adapted some of the parameter on their RX daytona analysis system to meet the requirement in cell culture.

Acknowledgments

The excellent technical assistance of Mrs Angela Ehrlich, Mrs Ute Bürstenbinder, Mrs Gesche Rottmann, Mrs Anja Ehrlich and Mrs Jana Schäfer and the help of Mrs Ulrike Baillie during the preparation of this manuscript are gratefully acknowledged. Furthermore, I thank all other current and former members of the institute who contributed to the development of certain methods.

PROCESS ANALYTICAL TECHNOLOGY: STRATEGIES FOR BIOPHARMACEUTICALS

Anurag S. Rathore and Gautam Kapoor
Department of Chemical Engineering, Indian Institute of Technology, Hauz Khas, New Delhi, India

73.1 INTRODUCTION

The topic of process analytical technology (PAT) with respect to applications in the pharmaceutical sector was first discussed at the Federal Drug Administration (FDA)'s Advisory Committee for Pharmaceutical Science (ACPS) meeting in 2001. A subcommittee on PAT consisting of experts from industry and academia was formed with the objective(s) of identifying potential technologies and strategies for implementation of PAT in pharmaceutical development and manufacturing (1). Both general principles and case studies were discussed at this meeting (2). On the basis of the recommendations of the ACPS PAT subcommittee, the FDA released the Guidance for Industry PAT—A Framework for Innovative Pharmaceutical Development, Manufacturing and Quality Assurance (3) in September 2004. This was a result of collaborative work between several divisions, including the Center for Drug Evaluation and Research (CDER), Center of Veterinary Medicine (CVM), and Office of Regulatory Affairs (ORA).

The guideline defines PAT as "a system for designing, analyzing, and controlling manufacturing through timely measurements (i.e. during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality" (3). It should be mentioned that the term *analytical* in the PAT context was viewed broadly to include chemical, physical, microbiological, mathematical, and risk analysis that are conducted in an integrated manner. The purpose of the guidance was to "1. Improve the scientific basis for establishing regulatory specifications, 2. Promote continuous improvement and 3. Improve manufacturing while maintaining or improving the current level of product quality" (3). The PAT initiative has also been adopted by several organizations to support its implementation, with the most prominent being the International Conference on Harmonization (ICH) and the American Society for Testing and Materials (ASTM) International Committee E55 (4).

The concept of PAT is in alignment with those of another important regulatory initiative, namely, quality by design (QbD). The latter was introduced later for pharmaceutical manufacturing in 2004 in the "Pharmaceutical Current Good Manufacturing Practices of the 21st Century—A Risk Based Approach" (5) initiative by the US FDA and has received a lot of attention lately. The general approach involves defining the target product profile (TPP), identification of the critical quality attributes (CQAs) that are of significant importance to product's safety and/or efficacy, definition of product design space via drug substance and drug product specifications, establishment of process design space for producing product that meets the expectations of quality, creation of control strategy that ensures consistent process performance, validation and filing of the process to demonstrate the effectiveness of these elements and their documentation, and finally, monitoring to ensure robust process performance over life cycle of the product (1,6). The concepts of risk assessment and management, raw material management, and use of statistical approaches provide a foundation to these activities. Table 73.1 shows the key enablers essential for successful implementation of PAT in the QbD paradigm.

TABLE 73.1. Enablers of PAT Implementation (3)

Enabler	Objective
Multivariate tools for design, data acquisition, and analysis	1. To identify and study the effects of and interactions among various product and process variables 2. To identify potential failure modes
Process analyzers	1. To make univariate process measurements such as pH, temperature, and pressure 2. To measure product quality attributes
Process control tools	1. To monitor the state of the process
Continuous improvement and knowledge management tools	1. To perform data collection and analysis over the life cycle of the product 2. To understand relevant multifactorial relationships

73.1.1 Definition and Objectives

As mentioned earlier, PAT has been defined as "a system for designing, analyzing and controlling manufacturing through timely measurements (i.e. during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality" (3).

The objectives of introducing such a scheme in pharmaceutical manufacturing could be several and include (1,3)

1. Better process understanding
2. Improved yield due to prevention of scrap, rejects, and reprocessing
3. Reduction in the production cycle time
4. Decrease in energy consumption and improved efficiency from conversion of batch process into a continuous process
5. Cost reduction due to reduced waste and energy consumption
6. Real-time release of batches
7. Improved operator safety and reduced human errors due to more automation.

73.1.2 Implementation of PAT

Implementation of PAT involves a thorough understanding of the process and the CQAs of the product. Figure 73.1 outlines the steps in the implementation of PAT and how it contributes to overall product and process understanding (7,8).

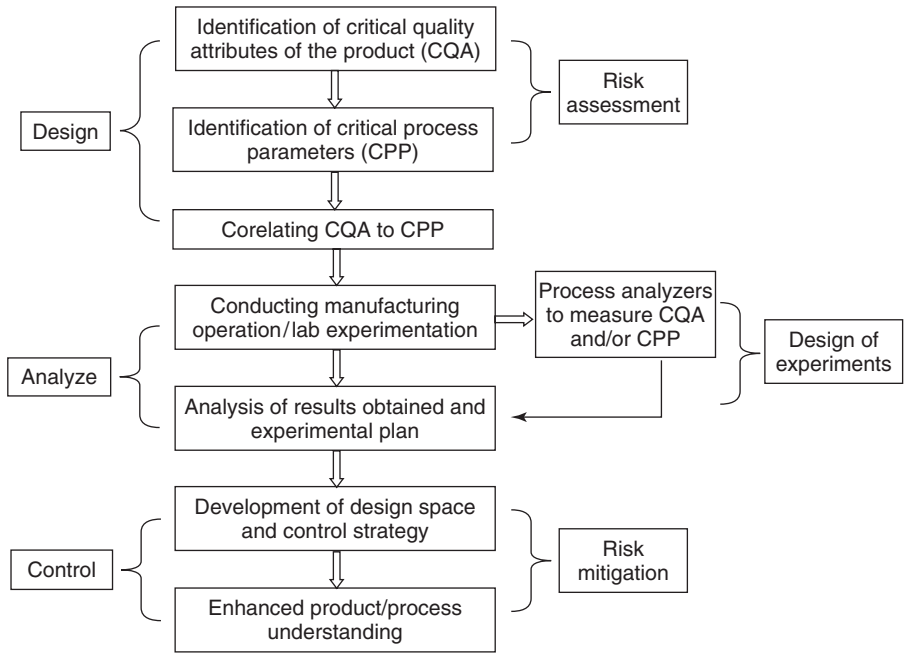

Figure 73.1. Overall scheme of PAT implementation: The three key phases of "design," "analyze," and "control" are shown along with the various steps that are required for making the implementation successful

A process is considered well understood when all critical sources of variability are identified and explained, variability is managed by the process, and product quality attributes can be accurately and reliably predicted over the design space established for materials used, process conditions, manufacturing, and environmental and other conditions (1).

On the other hand, a CQA is defined in the ICH guideline as (9) "physical, chemical, biological or microbiological property or characteristic that should be maintained within an appropriate limit, range or distribution to ensure the desired product quality." Implementation of PAT involves the following steps (7,8):

1. *Design:* The first activity in this step is identification of the CQAs of the product using the risk assessment tools, mentioned in the ICH Q9 guideline, based on information gathered from literature review and clinical and nonclinical studies with the molecule (10,11). Next, the manufacturing process is examined to understand which of the CQAs are affected by each unit operation of the process. Finally, CPPs are identified for each unit operation, which are found to affect the CQAs and a process model is created relating the CQAs to the CPPs.
2. *Analyze:* This step involves identification and development of analytical method for performing (7):
   (a) Real-time direct measurement of a product (or raw material) CQAs
   (b) Real-time measurement of CPPs
   (c) Real-time measurement of any other parameters that confirm that a unit operation/piece of equipment continues to be fit for purpose (e.g. filter back pressure, column integrity).

   Table 73.2 lists the process analyzers commonly used in a PAT-based scheme. Furthermore, these measurements can be online (sample is diverted from the manufacturing process and may be returned to the process stream), at-line (sample is removed, isolated from, and analyzed in close proximity to the process stream), in-line (sample is not removed from the process stream and the analyzer can be invasive or noninvasive), or off-line (sample is removed, isolated, and analyzed far from the process stream) (3).
3. *Control:* The data acquired in the analyze step is processed by various data analysis techniques to extract useful information. Techniques such as principal component analysis (PCA), partial least squares (PLS), and parallel factor analysis (PARAFAC) are used to decipher multivariate data sets, reduce redundancy, and eliminate noise (10,12,13). Empirical relationship between the CQAs and the CPPs can thus be formed and these can be used to establish the design space (acceptable operating range) for process parameters (14). A dynamic process control strategy can be established, where the process parameters can be suitably altered within the design space to nullify the variability caused by process inputs, thus resulting in consistent

TABLE 73.2. Process Analyzers Commonly Used in PAT (15)

Type of Analyzer	Subtypes	Typical Use
Sampling units	Membrane based (dialysis and ultra-/microfiltration)	To withdraw cell-free samples from the process equipment
	Flow injection analysis (FIA)	To inject into carrier stream that transports the sample to the analyzer
	Sequential injection analysis (SIA)	Advanced form of FIA, where reagent and sample quantity required is less. Used in association with flow cytometry
	Lab on valve (LOV)	Integrated microconduit that can conduct all unit operations of a given assay (immunoassays/enzymatic assays)
Spectroscopy	NIR spectroscopy	To monitor fermentation process and measure concentration of organic species in complex media
	Infrared and Raman spectroscopy	To monitor fermentation process and measure concentration of organic species in complex media
	FTIR	To monitor fermentation process (water-based samples)
	Photoacoustic spectroscopy	To measure gas concentration
	2D fluorescence spectroscopy	To detect trace compounds and determine biomass concentration
	Dielectric spectroscopy	To estimate biomass and viable cell count
Biosensors	Electrochemical Thermal Optical	To detect analyte using a bioanalytical method
Mass spectrometry	—	To monitor simple organic compounds
Machine vision and real-time imaging	—	To estimate cell density, cell size, and cell aggregation
Soft sensors	—	For state estimation and prediction

product quality. Most modern manufacturing equipments are capable of maintaining the process variables close to desired set-point values. Thus, it is feasible to design a process control scheme that can determine the appropriate control action to be taken to achieve the desired product quality.

4. *Optimize and monitor:* Multivariate statistical process control (MSPC) techniques are used to monitor process performance and report deviations from ideal performance. Data are collected throughout the life cycle of the product, stored using knowledge management tools, and analyzed by sophisticated statistical approaches to optimize the process.

Furthermore, Fig. 73.2 depicts the different configurations of bioprocess analyzers.

73.1.3 PAT Challenges in Biopharmaceutical Production

Biopharmaceutical production processes involve a series of unit operations. The upstream stage involves growing the cells in large production tanks in a defined media. The cells may be engineered to produce the protein either internally or secrete it into the culture media. The protein is then harvested. Downstream processing involves multiple purification steps to capture the target protein and remove endogenous and adventitious contaminants. The protein is then formulated with appropriate excipients to make it fit for use.

Biotech processes and products present unique challenges with respect to PAT implementation (7,8,11):

1. Biopharmaceuticals are produced in complicated cell-based systems that are sensitive to external factors such as temperature and pH.
2. In-process intermediates are often complex mixtures that contain impurities and other host cell-derived proteins along with the protein of interest. They may also contain adventitious contaminants such as viruses, which may not be detectable by process analyzers.
3. Raw materials are complex and variable and in many cases known to affect the final product quality.

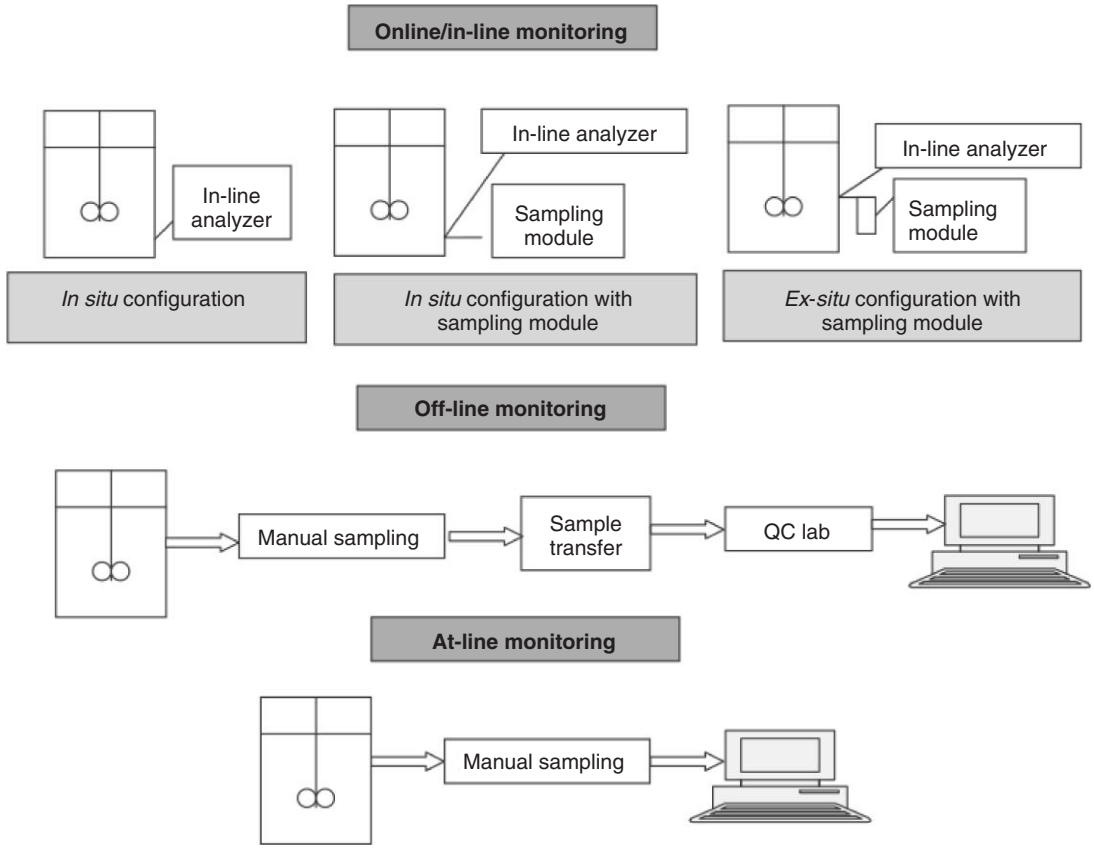

Figure 73.2. Different configurations of bioprocess analyzers: The time delay between sampling and analysis ranges from fast timescales of 1 s for in-line analysis to as long as 1 day for off-line methods. The data generated from the analyzers are sent to a data acquisition and control system

4. Minor excursions in the manufacturing process may drastically affect the final product quality.
5. Production process is complicated in terms of the number of process steps, in-process controls, and supporting documentation.
6. The understanding of the link between presence and level of product variants and other impurities and the product's clinical safety and efficacy is generally limited (1).

Table 73.3 summarizes the major unit operations in a biopharmaceutical manufacturing process along with the process and analysis times for each. The decision to transition from one unit operation to the next in a production process is made at definite decision points. The decision is taken based on real-time information that is provided. For each operation, ratio of the time taken to take the decision to the time needed for analysis is taken. This ratio serves as an indicator for the ease of PAT implementation for a given unit operation. Operations where the time for taking decision is more with respect to the time needed for analysis, the ease of PAT implementation is high (1). Figure 73.3 illustrates a plot of the ratio of the decision time and the analysis time for different process steps.

73.2 PAT APPLICATIONS FOR UPSTREAM OPERATIONS

Upstream operations of microbial and mammalian cell culture comprise media preparation, seed cell culture, and production cell culture.

In general, medium development for a fed-batch process involves batch medium and feed concentrate development, as well as optimization of the feeding strategy. The latter is often regarded as cell line dependent and is, therefore, based on the metabolism and nutrient consumption of a specific cell line (16). Several approaches can be used systematically for medium optimization, such as single component titration, spent medium analysis, and medium blending. During medium preparation, pH and/or temperature may require adjustment to ensure complete dissolution. The optimal feeding strategy involves giving consideration to nutrient consumption, by-product accumulation, and the balance between growth and production (16). Statistical design of experiments (DOEs) integrated with a high throughput platform are generally used to develop suitable media for the process.

A typical cell culture process starts with thawing a frozen vial of a working cell bank (WCB), which contains mammalian or microbial cells, followed by expanding the cell population through a series of seed trains in different culture vessels. Biomass concentration and specific biomass growth rate greatly affect the final product yield and quality during the seed production stage (16). The culture is then transferred to a production bioreactor where the cells continue to grow and the expressed product accumulates in the culture broth. To achieve a high product titer, high cell mass and cell viability need to be maintained in the production bioreactor. Two of the most popular process modes are fed-batch (feeding concentrated nutrient solutions to a batch production bioreactor) and perfusion (maintaining and recycling the cells to a bioreactor while continuously replacing spent media with a fresh supply). The fed-batch process is

TABLE 73.3. Listing of Typical Process Times, Decision Time, Quality/Process Attribute, Analytical Method, Analysis Time and Ratio of the Decision Time to Analysis Time, for the Various Process Segments, Namely Upstream, Harvest, Downstream, and Drug Product Processing [a]

Process Segment	Major Process Steps	Typical Process Time, t_p (h)	Typical Decision Time, t_d (h)	Quality Attribute (QA) or Process Attribute (PA)	Analytical Method	Typical Analysis Time, t_a (h)	Ratio (t_d/t_a)
Upstream	Microbial fermentation (production)	24	2	Misincorporation	HPLC	1	2
	Mammalian cell culture (production)	240	10	Glycosylation	Oligosaccharide profile	1	10
Harvest	Centrifugation	8	1	Recovery	HPLC	1	1
Downstream	Refolding	20	2	Misfolds	HPLC	0.5	4
	Chromatography	8	0.5	Aggregation	HPLC	1	0.5
Drug product processing	Formulation	6	0.5	Protein concentration	A280	0.1	5
	Lyophilization	24	1	Moisture	NIR	0.1	10
	Filling	12	2	Foreign particles	Visible particles	0.5	4

[a] aIt is seen that downstream unit operations offer the biggest challenges in PAT implementation, while upstream and drug product processing offer the least in most cases. Reprinted with permission from Ref. 1.

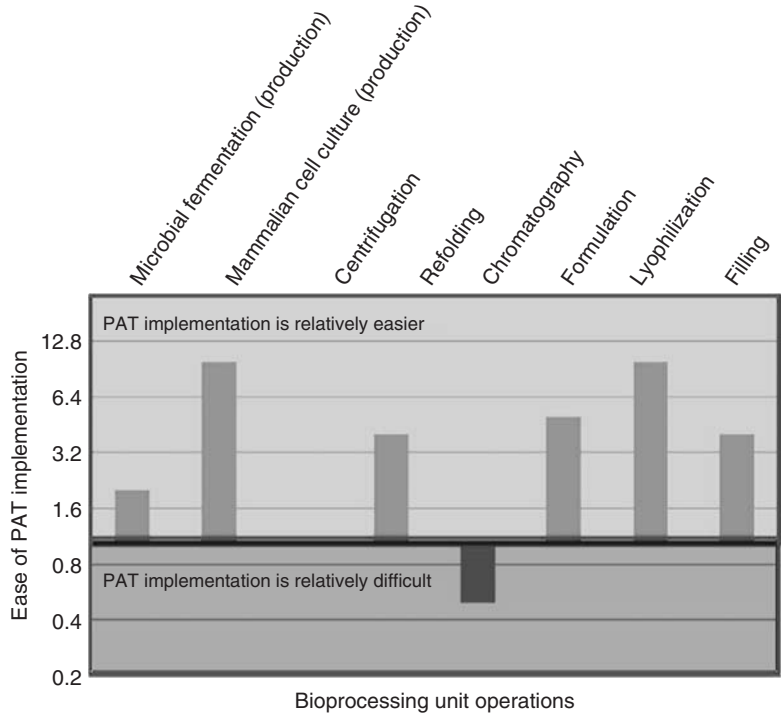

Figure 73.3. Ease of PAT implementation for some of the commonly used unit operations in biotech processes (Reprinted with permission from Ref. (1)): When the ratio is <1, PAT implementation is difficult. It is evident that most unit operations are amenable for PAT applications

often used due to its scalability, ease of operation, and high volumetric productivity.

Culture conditions need to be optimized within the bioreactor by balancing cell growth with product formation. A preferred cell growth condition may not be the optimal condition for product expression and vice versa. Although a bioreactor's physical environmental parameters such as pH, dissolved oxygen (DO), and temperature can be monitored online and controlled, monitoring of chemical and biological parameters is limited due to the lack of reliable online sensors. The measurement of cell density, metabolites, and protein concentrations usually occurs through daily bioreactor sampling and subsequent analysis by off-line methods. It is extremely important to monitor and control this stage of the production process as this is where the product and product-related impurities are produced (1). Posttranslational modifications such as glycosylation and deamidation generate product-related variants that have equivalent potency and safety profile, whereas aggregates and truncated forms generate variants that do not have an equivalent potency and safety. Thus, it is important to control the process parameters to obtain a product with the desired quality attributes.

Several examples illustrate the application of PAT in microbial and mammalian cell culture unit operations.

1. *Measurement of cell metabolites:* Monitoring of metabolic activity of mammalian cells and thus estimation of specific growth rate has been made possible by use of techniques such as nuclear magnetic resonance (NMR), mass spectroscopy, and radioactive tracers (17). High density perfusion cultures of Chinese Hamster ovary (CHO) cells employ C-glucose and two-dimensional (2D) NMR spectroscopy to control metabolic activity and predict the flux (18). Several strategies have been adopted to control specific growth rate and product quality in mammalian cell culture. These include utilization of multiwavelength fluorescence (MVF), software sensors, and multivariate data analysis (MVDA) to estimate glucose and biomass concentrations (19) and near infrared (NIR) spectroscopy to estimate biomass, glucose, and acetate concentrations (20). Ion chromatography with piezoelectric quartz crystal has been used for online monitoring of lactic acid for control of production rate (21).
2. *Estimation of biomass: In situ* microscopy has been used for estimation of hybridoma cell concentration in mammalian cell cultures (22). Amperometric sensors have been used online for measurement of viable cells and control of their metabolic activity (17). Conductance- and capacitance-based biomass

probes have been utilized to monitor specific growth rate and product formation to determine onset of stationary phase and cell lysis (23).

3. *Process control:* NIR spectroscopy has also been used for at-line control and fault analysis in fermentation processes (24). Flow injection systems have been extensively used in recent times in conjunction with online sensors to monitor ammonia and control feed addition rate in fed-batch penicillin fermentation (25). Similar system has been used for measurement of glucose concentration and control of cell growth when coupled with biosensors (26). Ion chromatography has emerged as an analytical tool of choice for measuring concentration of cations (Na^+, K^+, Ca^{2+}, NH_4^+) for control of cell growth in an in-line mode in association with double chamber acoustic wave detector (27).
4. *Media screening:* A combination of NIR spectroscopy and MVDA has been successfully used for screening many basal medium powders used in a mammalian cell culture process (28).

A summary of the process analyzers for microbial and mammalian cell culture is provided in Table 73.4.

As is seen from Table 73.4 , several sensors have been developed to monitor the upstream processing in microbial and mammalian processes and thus facilitate PAT. The upstream stage is arguably the most crucial with respect to impact on product quality and it also allows sufficient time for decision making to the next stage (Table 73.3). This makes implementation of PAT relatively simpler and of high impact. However, the biggest challenge is our limited ability in performing real-time testing of product titer or quality due to the significant quantity, as well as diversity of impurities that are present in the typical cell culture broth. Another challenge is the complexity of this step. Even if one is able to detect an underperformance with respect to product quality while a cell culture is being performed, it is not very straightforward to identify the root cause and the corrective measure that can be taken. As a result, most of the applications so far have focused on using pseudomarkers for product titer and quality and these have their own limitations. The upstream stage holds the greatest promise for development of PAT tools in the future. There is significant scope of improvement in our understanding of this step and then utilizing this understanding in designing robust PAT applications.

73.3 PAT APPLICATIONS IN HARVEST OPERATIONS

The harvest stage is an intermediate stage that marks the end of the upstream operations and beginning of the downstream operations. The decision to commence the harvest operations is typically based on measurement of biomass concentration and/or product titer. The harvest stage involves isolation of the target protein by clarification, often achieved by centrifugation, tangential flow filtration, or expanded bed adsorption. The clarified supernatant then undergoes primary purification by depth filtration to remove unwanted residual impurities. Flocculation, precipitation, and extraction methods have also been used to isolate the product of interest from the broth containing a plethora of impurities. PAT applications have been developed for real-time monitoring of these unit operations and are described later.

73.3.1 Centrifugation

Centrifugation involves clarification of particulate matter (cellular debris, protein, nucleic acids, etc.) suspended in a liquid medium based on sedimentation rates using centrifugal force. It is a versatile technique capable of performing applications varying significantly in their need of resolution of separation and throughput. On one hand, it is commonly used as a first step to separate whole cells from the supernatant. On the other, it can also separate protein aggregates from the supernatant after a precipitation step. NIR spectroscopy has been utilized to estimate sedimentation velocity during centrifugation (50). NIR transmission data from horizontally inserted samples has been used for measurement of separation/sedimentation kinetics of bentham/xantham gum mixtures during centrifugation. This information enabled optimization of concentration of excipients to be added in the final formulation (51).

73.3.2 Flocculation

Addition of flocculating agents such as chitosan, polyethyleneimine, and other polyelectrolytes assists in agglutination of cell debris and other fine particles, thus reducing turbidity. PAT has been applied to monitor and control the concentration of flocculating agents such as chitosan for achieving higher clarification throughput of the product of interest. Absorbance at 600 nm, estimation of flocculant strength, and filter resistance have been used as tools to control the addition of the flocculant (51).

73.3.3 Precipitation

Precipitation aids in removal of the product of interest from the broth containing other contaminants. Spectroscopic methods such as infrared (IR) and Raman spectroscopy have been applied to control the precipitation process by real-time measurement of solid–liquid suspensions (51). A microcentrifuge designed for autosampling and washing out of solids from the bowl has been proposed to monitor

TABLE 73.4. PAT Enabling Sensors for Cell Culture Unit Operations

Sensor	Application	Examples				References
		Tool	Status	Application	Type of Cell Culture	
Surface plasmon resonance	Assess product concentration and affinity	Same as sensor	Automated	Detection of antigen antibody complexes	Mammalian	(29)

precipitation. Kinetics of precipitation has been estimated by sensors such as attenuated total reflection-Fourier transform infrared (ATR-FTIR) associated with proportional integral derivative (PID) controllers for controlling the feed rate of the precipitant (51).

73.3.4 Extraction

Extraction involves separation of the components on the basis of their relative solubility in two different immiscible liquids (aqueous and organic phase). NMR and IR spectroscopy have been used to monitor and thus optimize the proportion of organic solvent mixtures (51). A scheme to monitor the harvest process of a monoclonal antibody using hollow fiber membrane has been presented where the permeate was analyzed using chromatography and the results obtained were used to monitor the harvest process (52).

In summary, typical harvest unit operations have shorter process times when compared with upstream unit operations and this offers challenges with respect to creating successful PAT applications (Table 73.3). The issues associated to complexity of the sample matrix when analyzing for titer or product quality apply here as well. Furthermore, as, typically, the product quality is not affected to a great extent at this stage, creation of PAT applications may not be as impactful as for upstream or downstream stage. However, for cases where the product is known to degrade if held in harvest for too long due to presence of proteases or other reasons, developing PAT applications for these unit operations may be of significant value.

73.4 PAT APPLICATIONS IN DOWNSTREAM OPERATIONS

As most of the therapeutic proteins are parenteral, they require high purity and must be free of viruses, other proteins, nucleic acids, and pyrogens. Downstream operations must ensure that the product of interest is recovered in sufficient quantity with an acceptable impurity profile. The purification process should be capable of removing process-related (host cell proteins, DNA, etc.) and product-related (aggregates, fragments, etc.) impurities. Each unit operation in the downstream process serves a unique purpose and is capable of removing particular impurity/impurities.

73.4.1 Filtration

Filtration is an integral part of the purification process. It may be operated as normal flow filtration (depth filtration, nanofiltration, and sterile filtration) or as tangential flow filtration [ultrafiltration–diafiltration (UF-DF) and microfiltration]. Common applications include desalting, concentration, and buffer exchange of proteins. Typically, the operating conditions to be controlled include flow rate and pressure. High values of flow rate and transmembrane pressure (TMP) across the filter membrane may lead to denaturation/loss of the product on the filter surface. Sensors for real-time monitoring of these parameters include pressure gauge and flow meters installed with the filtration setup, which ensure smooth operation of the process with optimal yield.

Applications include

1. *Measurement of CQA:* Absorbance of the filtrate at 410 nm has also been used as a tool to monitor the depth filtration of host cell proteins (53).
2. *Monitoring of membrane fouling:* A series of techniques have been used to monitor cake formation and membrane fouling (which cause blockage of the membrane) during filtration. Formation of the deposition layer on the membrane has been tracked by image analyzers (54) and laser triangulometry (55). These techniques, however, are unable to measure cake porosity and can only track monolayer formation. However, this has been overcome by optic laser sensors, which can measure a cake layer of thickness of up to 30μm (56). Ultrasonic time domain reflectometry has been used to measure membrane fouling, though it is not specific to porous structure or membrane skin layer (57). Light deflection techniques such as shadowgraphy (58) and refractography (59) have been used to measure the concentration profile within medium and concentration gradient, respectively. This helps in monitoring concentration polarization. Magnetic resonance imaging has been used to measure the concentration polarization in colloidal suspensions (60) and electron diode array microscopy has been used in case of ultrafiltration and microfiltration (61). Adoption of the techniques mentioned earlier can help avoid blockage of the filter membrane by providing information to predict the timing of back-flushing the membrane, thus ensuring constant flux and greater retention.
3. *Monitoring process parameters in lieu of CQAs:* UF-DF offers unique challenges toward implementation of PAT. Diafiltration is currently carried out using fixed volumes. There are cases when there is a need to restrict the excessive consumption of costly diafiltration buffer and also to reduce the process time for maintaining product stability. PAT has been applied to signal the end of a diafiltration process by monitoring different species collected in the permeate after each diafiltration volume (62). A control species was identified and a correlation between its concentration and pH was established and verified at multiple concentrations.

73.4.2 Refolding

The expression of proteins in certain microbial systems (e.g. *Escherichia coli*) results in the formation of inclusion bodies that contain the product in an inactive and insoluble form. These inclusion bodies need to be solubilized using chaotropic/reducing agents to disrupt noncovalent interactions and break interchain disulfide bonds. Subsequently, in the refolding step, the concentration of the solubilizing agents is decreased, resulting in protein refolding (63). This can be achieved by buffer exchange via batch dilution or liquid chromatography. In such a process, the time required for refolding is critical and the process should be stopped when refolding is complete to ensure consistent product quality. The time of refolding is dependent on the refolding rate, which in turn is dependent on the characteristics of the feed material and the operating conditions. A PAT-based control scheme utilizing high performance liquid chromatography (HPLC) has been proposed (62), wherein the purity of the product as well as the levels of different product-related variants and impurities were monitored as a function of time, allowing effective decision making on when to stop the process. Such a scheme is practical to implement for cases when exceeding the refold time will lead to an increase in the level of one or more impurities. A different PAT approach has been applied to monitor the refolding of recombinant human vascular endothelial growth factor (rhVEGF) (64). As refolding process is dependent on oxygen, the DO profile was used as a tool to understand the oxygen needs of the reaction and its impact on product quality. An in-line DO probe was used to monitor the oxygen levels in the reaction vessel and reverse-phase high performance liquid chromatography (RP-HPLC) was used to assess product quality and a correlation was established between them (64). The aeration parameters were scaled up to manufacturing tanks of capacity 2000 and 15,000 L, and the DO profiles showed similar trends across scales; hence, this method was successfully used to control process performance at commercial manufacturing scale.

73.4.3 Chromatography

Process chromatography, commonly used in batch-wise mode, involves separation of a mixture of species based on differential interactions between the sample components and the resin particles (stationary phase) packed in the column in the presence of the mobile phase. Chromatography encompasses a wide range of separation modes that can be categorized as nonadsorptive (e.g. size-exclusion) or adsorptive (e.g. ion-exchange). The adsorptive modes of chromatography include but are not limited to ion-exchange, hydrophobic interaction, reversed-phase, affinity, and immunoaffinity (16).

Conventionally, pooling of chromatography columns is performed on the basis of absorbance at 280 nm. However, ultraviolet absorbance is unable to differentiate between product- and other protein-based impurities as both of them have similar absorbance profiles (7). Use of online RP-HPLC for separating recombinant human insulin-like growth factor-I (IGF) and IGF aggregates to facilitate real-time pooling based on product quality has been successfully demonstrated (65). A similar application using chromatographic separation with protein A-immobilized media has been shown to reliably control antibody loading on a protein A column in a CHO-derived recombinant antibody purification process (66). Stopped flow analysis has been used as an at-line tool to provide a visual description of product levels and real-time representation of yield during the production of alcohol dehydrogenase via hydrophobic interaction chromatography (HIC) in *Saccharomyces cerevisiae* (67). Implementation of PAT in a chromatographic step is most difficult in comparison with other unit operations due to the short window of decision that it normally offers (Table 73.3). The analysis time has to be reduced considerably to make an informed decision of proceeding further in the process. Very recently, the feasibility of utilizing online HPLC (68), online ultra-performance liquid chromatography (UPLC) (69) and at-line tryptophan fluorescence (70) has been assessed to facilitate real-time analysis and decision making in process chromatography. A case study pertaining to the use of online HPLC with process chromatography is presented later in the chapter.

73.4.4 In-Line Mixing

In-line mixing systems are often used to blend large volumes of premixed buffer solutions. A programmable logic controller (PLC) can be used as a PAT tool to monitor the composition of the blend during mixing and prevent release of the blend to the process until its composition accurately matches the set point (8). A similar technology has been implemented in Technikrom's patented in-line buffer dilution technology (71), where water for injection (WFI) and buffer concentrate are pumped into a mixing loop, where the buffer concentrate is diluted down The molarity of the buffer has a specific conductivity that can be monitored and controlled by an in-line process analyzer (conductivity sensor) that interfaces with a process control feedback loop. The sensor continually monitors conductivity of the buffer blend in the mixing loop and sends an output signal to the process control feedback loop. That loop then references the current process value to a user-defined conductivity target set point for the diluted buffer. It sends a signal to adjust the pump speeds accordingly so that the dynamic ratio of WFI to salt buffer in the mixing loop is continually adjusted toward the set point. When conductivity is sufficiently close

to the set point (within specification), buffer is released to a product collection vessel. When the buffer is not within specification, it is diverted to waste until the conductivity process value comes back into specification. In this manner, process conditions are always known and out-of-spec buffer cannot reach the product. For a process chromatography unit operation, a small decrease in variability of the mobile phase prepared in a PAT-controlled in-line mixing system or tank blending system can greatly improve separation efficiency, thus affecting product quality.

73.4.5 PEGylation of Proteins

PEGylation reaction involves association of PEG onto one or more accessible lysine residues or the N-terminal amino groups of the protein to stabilize the protein and increase its solubility. A PAT-based control strategy consisting of an online analytical HPLC system has been used to monitor and control the reaction so as to produce homogenous/active product (7).

73.4.6 Viral Filtration

Viral filtration is carried out to reduce the virus load in the process stream. For certain filter types such as the Viresolve NFP, the instantaneous clearance capacity has been shown to be tightly associated with the flux. Thus, the extent of fouling or alternatively the flux decay (which is easy to measure) has been considered as the critical process parameter and used to ensure effective and consistent viral clearance (7). Table 73.5 summarizes the process monitoring tools for downstream operations.

In summary, the downstream operations in most cases directly and significantly affect quality of the final product. While the process chromatography is the primary work horse of purification, it is challenging to design PAT applications due to the short decision time it offers (Table 73.3). The situation is marginally better with other unit operations, especially refolding. Along with the upstream operations, it is evident that PAT could have a very significant impact in ensuring that the final product is of acceptable quality and that the quality is consistently achieved lot after lot.

73.5 PAT APPLICATIONS IN DRUG PRODUCT OPERATIONS

Drug product unit operations are needed to turn a purified drug substance into the final dosage form, the finished product. The formulation step involves taking the purified protein at the desired concentration and dispensing it with the correct excipients that can ensure product quality and integrity during the subsequent fill/finish steps that may include filtration, filling, lyophilization, inspection, packaging, storage, transport, and delivery.

73.5.1 Bulk Freeze-Thaw

Bulk freeze-thaw is commonly employed during biopharmaceutical manufacturing to gain operational flexibility while maintaining product quality. A frozen drug substance provides several advantages over liquid storage, including increased product stability, reduced microbial growth, and reduced foaming during transportation. However, in such cases, the frozen bulk needs to be thawed before it can be formulated and processed. Thawing can cause further stress and damage to the protein. Excessive freezing and thawing rates can lead to shear-induced and surface-mediated protein denaturation. Temperature–time profiles can be obtained experimentally by freezing the bulk (or placebo because the actual product may not be available for such studies) in the selected container and freezer, and positioning temperature recorders at different places in the solution and control on the freezing/thawing rate may be achieved circulating a heat transfer fluid that allows rapid heating and cooling of vessel contents (72).

73.5.2 Formulation

The first step after thawing the bulk is to formulate it with the pertinent buffer and to the target concentration. The formulation step involves adding the desired excipients at target concentration and adjusting pH, conductivity, and protein concentration. Mixing speeds and times are critical during the mixing of the purified protein bulk and the formulation buffer. Inadequate mixing can leave the solution heterogeneous, while excessive mixing can result in the protein undergoing shear-related stress. The speed needs to be, therefore, continuously monitored and adjusted.

73.5.3 Sterile Filtration

After formulation, the active product is sterile filtered (using 0.22-μm pore size membrane) to ensure that the product is free of bioburden. Critical parameters that require careful consideration include allowable pressure drop across the filter, the duration over which filtered formulated product can be held to maintain protein integrity and product sterility, temperature of operation, and the mode of liquid transfer during filtration. These parameters can be conveniently measured by pressure gauges and flow meters.

73.5.4 Filling

Once the drug substance has been formulated and sterile filtered, it is filled into the primary drug product containers, which are usually vials, or syringes for prefilled injectables. Excessive fill speeds can result in foaming and subsequently in protein denaturation. Over extended periods of filling, it is possible that proteins/excipients interact with the

TABLE 73.5. Process Monitoring Tools for Downstream Operations (8)

Unit Operation	Sensor	Objective	Measurement Principle
Ultrafiltration/diafiltration	pH, conductivity probes, and OD probes	To timely terminate the process	Measure product concentration of the desired species directly using OD probes or alternatively establish a correlation between the pH and conductivity of the species (obtained in the permeate) and its concentration
	Pressure gauge to calculate transmembrane pressure, flux feed/permeate/retentate	To ensure the membrane integrity	Damage to the membrane will reduce the transmembrane pressure across the membrane
Chromatography	In-line analytical methods, online detectors, as UV, RI	For pooling	Product of interest will absorb light in the UV range and give a distinct peak in the chromatogram
	System control	For performing gradient elution	Controller within the chromatographic system automatically proportions the mobile phase constituents
	pH, concentration (System control)	For performing column equilibration	Chromatographic system automatically adjusts the pH and concentration to the desired set point
	Mock eluate	For performing column cleaning and regeneration	To collect the eluate, analyze it, and make sure it is free from impurities
	Height equivalent of theoretical plate (HETP)	For deciding when to repack	Analyze by test method using acetone and manual computation
In-line mixing	System control	For monitoring flow rate	In-built flow meter
	pH, concentration, conductivity	For deciding when blending is done	Programmable logic controller can be used to monitor the composition of the blend during mixing
Refolding steps	Addition control	For measuring concentration of reagents	Controlling the addition manually
Conjugation reactions	Product quality, reaction time	For indicating end of reaction	Monitor the reaction using online analytical HPLC

tubing/pumping surfaces. Therefore, it is necessary to characterize and prevent such interactions. Most manufacturing facilities use automatic fill machines with multiple needles. Automatic fill machines typically have the capabilities to periodically test fill-weights online. Fill parameters, including the filler speed and nozzle design, are controlled to avoid other issues such as dripping and liquid spurting (72,73).

73.5.5 Lyophilization

Most biopharmaceuticals show limited stability toward physicochemical degradation. To achieve acceptable shelf life, protein drug products are often lyophilized. Lyophilization is the process by which the moisture content of the product is reduced by freezing followed by sublimation under vacuum. The lyophilization process primarily consists of three stages. The first stage involves freezing the product and creating a frozen matrix suitable for drying. The second stage is that of primary drying and involves removal of ice by sublimation caused by reduction in pressure (to typically around 50–500 mm Hg) while maintaining the product temperature at a low, desirable level. The third stage in the process is called *secondary drying* where the bound water is removed until the residual moisture content reaches below the target level. The critical process parameters to be monitored during freeze drying include degree of undercooling, product temperature, sublimation rate, and primary drying endpoint determination (51). A series of tools have been developed to monitor the lyophilization process that include single-vial and batch monitoring tools. The preferred attributes of these tools include (51)

1. Provide absolute measurements representative of a batch, and not of a single vial
2. Capability of monitoring the slowest drying vials in the batch
3. Compatible with process procedures and flow (loading and unloading of vials/trays)
4. Compatible with cleaning and steam sterilization
5. No impact on lyophilizer stability and vacuum
6. Scalable for use and integration with laboratory through a production-scale freeze drying equipment.

Table 73.6 provides the monitoring tools for the lyophilization process. Two different approaches have been proposed to monitor the freeze drying process. The first involves a soft-sensor that allows for monitoring a single vial using a temperature measurement. It measures the temperature of the product (or of the vial) and uses a mathematical model of the process to provide a real-time estimation of some parameters or state variables such as the temperature profile in the product and the mass and heat transfer coefficients.

The second tool is called as the *dynamic parameters estimation* (DPE) algorithm and it allows for monitoring the whole batch by measuring the pressure rise that occurs when the valve placed between the drying chamber and the condenser is closed for a short time interval [pressure rise test (PRT)] (74). The DPE algorithm is a nonintrusive method useful for estimating the average state of the whole batch. It uses an unsteady mathematical model to interpret the pressure rise curve experimentally acquired and it supplies a full-state estimation of the system, that is, the moving front temperature and position, the temperature profile in the product, and the mass and heat transfer coefficients. *LyoDriver* is a control system that uses DPE, process variables, and an unsteady-state mathematical model for the time when the product temperature is varying and predicts potentially damaging temperature overshoots and anticipates the control actions accordingly (74).

A widespread technique for monitoring primary drying is the PRT. Several model-based methods were investigated using the PRT to monitor the primary drying of a lyophilization process. These included manometric temperature measurement (MTM), pressure rise analysis (PRA), and DPE and an optimization algorithm was used to estimate the product temperature and the residual water content looking for the best fit between the pressure measurement and the values obtained by mathematical simulation. Other parameters such as the heat transfer coefficient between the shelf and the vials and the resistance of the dried product to vapor flow can also be estimated from the PRT but require modern control tools to deliver process optimization and desirable product quality (75).

73.5.6 Inspection

Filled vials are inspected to ensure the absence of foreign contaminants. Automated inspection can be used at this stage to inspect the filled vials or syringes for presence of visible particles (73).

In summary, process analyzers for monitoring drug product operations are able to provide results well within the decision period required for forward processing. Hence, the current level of technology is well equipped to facilitate a PAT-based control scheme for drug product unit operations. This is also an area where PAT implementation is furthest ahead at present.

73.6 PAT AND RAPID MICROBIOLOGICAL METHODS

Traditional culture-based in-process microbiological analysis techniques have very limited value in PAT due to the

TABLE 73.6. Process Monitoring Tools for Lyophilization (51)

Tool	Method	Comments	Commercial Viability	Product Temperature	Sublimation Rate	Primary Drying Endpoint Indicator
TEMPRIS	Single vial	Sterilizable wireless battery-free temperature sensors that can be used in both laboratory and manufacturing scale	Yes	Yes	No	Yes
Thermocouples	Single vial	Positioned bottom-center in the vial. Used mainly in laboratory scale	Yes	Yes	No	Yes
RTD	Single vial	Reliable, easy to sterilize. Accurate positioning is difficult, limited validity due to measurement of temperature. Used in manufacturing scale	Yes	Yes	No	Yes
Microbalance	Single vial	Determines the loss of weight of a sample vial during freeze drying by intermittent or continuous weighing information about sublimation rate and process step endpoints	No	No	Yes	Yes
Pirani	Batch	Dependent on type of gas, calibrated for a specific gas (usually N_2)	Yes	No	No	Yes
MTM	Batch	Pressure rise tests are performed periodically by rapid closing (<0.1 s) of the isolation valve between chamber and condenser (laboratory scale)	Yes	Yes	Yes	Yes
Dewpoint	Batch	Determination of concentration of water vapor in a gas	Yes	No	No	Yes
Lyotrack (plasma emission spectroscopy)	Batch	Spectroscopic measurement of water concentration in the chamber atmosphere using a cold plasma source connected to the chamber	Yes	No	No	Yes
Residual gas analyzer (mass spectroscopy)	Batch	Measures water vapor, N_2, and also any additional residual solvents and volatiles	Yes, but cannot be steam sterilized	No	No	Yes s
Tunable diode laser absorption spectroscopy (TDLAS)	Batch	NIR-spectroscopic method for the determination of trace concentrations of a gas. No contact to the product. Used in sterile processes (manufacturing) and in all scales of freeze dryers	Yes	Yes	Yes	Yes
Infrared Spectroscopy	Single vial	NIR: for residual moisture measurements in vials through continuous measurements during secondary drying. Raman: for determination of physical product characteristics	No	No	No	Yes

TABLE 73.7. Common Rapid Microbiology Methods Used in Bioprocessing

Objective	Tools	Principle
Growth-based detection of biochemical or physiological growth indicators		
	ATP bioluminescence	Breakdown of ATP from microbial cells to produce light
	Colorimetric detection	Color change in growth medium due to microbial metabolism
	Autofluorescence detection	Fluorescence emission by microbial colonies growing on solid surface
	Headspace pressure measurement	Positive/negative pressure changes in headspace detected by electronic transducers
	Impedance	Change in electrical conductivity of growth media when AC is passed across two electrodes
	Turbidimetry	Difference in opacity at specified wavelength
Viability-based cell labeling techniques to detect and quantify viable microorganisms		
	Flow cytometry	Detection of a fluorescently labeled viable cell
	Microcalorimetry	Measurement of heat resulting from microbial catabolism
	Solid-phase cytometry	Filtration of potential microbial contaminants before detection of a fluorescently labeled viable cell
Molecular methods	Polymerase chain reaction (PCR)	Amplification of specific sections of microbial nucleic acids
Endotoxin testing limulus amebocyte lysate (LAL) assay		
Cell component-based technology	Biochemical assays, antigen–antibody interaction by enzyme-linked immunosorbent assay (ELISA), fatty acid profiling, gram staining, mass spectrometry, and immunological and spectroscopic techniques	To establish identity of microorganism

lengthy analysis time (2–28 days). Rapid microbiological methods (RMMs) are capable of producing results in real time, and thus are far more useful, because timely microbiological data are often critical not only for product release but also for continuous process monitoring and control. The most visible application for RMM in pharmaceutical manufacturing is in the release of finished products, where the shorter "time to result" may generate considerable cost savings. But RMM can also play a key role in other routine tests, including raw material testing, in-process testing, microbial limit testing, bioburden assessment, process water testing, environmental monitoring, and sterility testing. These applications have the potential to contribute to PAT, and in the near future, it is very likely that continuous real-time monitoring of microbiologicals in the manufacturing process will be feasible, resulting in very significant savings in both time and production costs. One may have to compromise on sensitivity over speed of the method chosen as the level of sensitivity required for the RMM is dependent on the level of sterility essential at that step in the process (8). Table 73.7 outlines some of the RMM that are commonly used in manufacturing facilities.

73.7 APPLICATIONS OF CHEMOMETRICS IN PAT

Chemometrics can be defined as the use of statistical tools toward analysis of complex data sets for uncovering information about the product or the process. Such information may be useful for process monitoring, control, and endpoint determination. Chemometrics encompasses many important fields of chemical data analysis, notably statistical analysis, optimization, signal processing, multivariate curve resolution, multivariate calibration, regression, pattern recognition, parameter estimation, structure–property relationships, cluster analysis, discrimination analysis, multiway analysis, factor analysis, library search, informatics, and artificial intelligence (4). These numerical techniques serve different roles in their diverse applications. In process development and scale-up, their primary goal is for process understanding, which is achieved by elucidating process-related physicochemical correlations and information such as kinetics, thermodynamics, product/process stability, and safety. In manufacturing scenarios, the computational methods may be used for MSPC, fault diagnosis, and continuous process knowledge management. Use

of statistical tools to analyze data from biopharmaceutical manufacturing is gaining popularity as the data obtained is very complex and subjecting the data sets from manufacturing to univariate or bivariate analysis can often be inefficient and result in misleading conclusions (76,77). Moreover, qualitative data analysis using chemometrics has been shown to aid in identification of patterns in data via trend analysis and to help in eliminating outliers, whereas quantitative data analysis using regression methods is useful for predicting relationships between independent and dependent variables (1).

Several applications involving the use of chemometric tools in biotech production have been published recently (Table 73.8). MVDA has been evaluated for scale-up, process comparability, process characterization, and fault diagnosis of a cell culture process. Several input parameters (pCO_2, pO_2, glucose, pH, lactate, and ammonium ions) and output parameters [purity, viable cell density (VCD), viability, and osmolality] for cell culture unit operation were evaluated in this analysis (78). MVDA has been used as a tool to identify process parameters that affect cell culture performance and their interactions. A PLS model has been shown to predict the concentration of glucose and ethanol during yeast fermentation by utilizing spectral data from mid-infrared (MIR) spectroscopy (79). Such models have been used to monitor and control fed-batch fermentation processes and are capable of detecting fault conditions and inferencing quality variables that are otherwise hard to estimate (80). Artificial neural network (ANN) has been employed to improve the fermentation process of docosahexaenoic acid production by predicting optimal conditions for fermentation using gas chromatography data as input (81). A flexible process monitoring method for fault detection and diagnosis was developed for an industrial cell culture pilot plant (82). Faults that were identified included differences in equipment, operational issues, and imminent batch failure. The study demonstrated that data from even a small number of batches (approximately 20) can still be used to monitor for a wide range of process faults and develop a control strategy to avoid them. NMR-PLS has been used to analyze spectral data for prediction of cell culture titer for a given peptone lot to optimize efficiency and consistency of protein production (83). Chemometrics analysis has also been used for optimizing and predicting protein–ligand binding conditions in affinity capillary electrophoresis (84,85).

Response surface methodology (Box–Behnken design) has been used to model the effect of injection time, voltage, and ligand concentration on protein–neutral ligand binding. The model was subsequently validated by a series of experimental runs (82). Combination of PLS and NIR has been used for monitoring a process that involves selectively removing contaminants such as cell debris, host cell proteins, and nucleic acids by flocculation of yeast cell homogenate. The approach was very cost effective and yielded a 90% correlation between the predicted and the actual data (99). Data pertaining to chromatographic behavior of conjugates of benzoic acid measured using high performance size-exclusion chromatography was analyzed by PCA. Analysis was performed on the data matrix of 18 conjugates described by 19 variables and the 6 principal components. The resulting model could explain 85.7% of the total variance in the data and was able to describe the structural behavior of each conjugate compound (100).

73.8 CASE STUDIES ON IMPLEMENTATION OF PAT

There are numerous case studies that demonstrate the successful application of PAT in biotech unit operations (56). Two of them are highlighted below:

73.8.1 Case Study 1: Real-Time Monitoring of Multiple Parameters in Mammalian Cell Culture Bioreactors Using an In-Line Raman Spectroscopy Probe

Raman spectroscopy is a highly specific method for establishing molecular identity (101). It measures the amount of light scattered inelastically at different frequencies by molecular vibrations. This case study demonstrates the feasibility of using a Raman probe for continuous acquisition of real-time data for process monitoring at large-scale mammalian cell culture (500-L bioreactor). For this purpose, a total of four bioreactors were operated in the fed-batch mode. Multiple Raman immersion probes were coupled to a Raman spectrometer for in-line collection of spectra, while at-line sampling was carried out daily in parallel for measurement of glucose, glutamine, glutamate, lactate, ammonium, VCD, and total cell density (TCD). The Raman spectra were correlated with at-line measurements using PLS modeling. Of the four bioreactor runs that were conducted, data from the first three were used in the calibration data set and data from the last lot were used to validate the models. The predictions from the model based on Raman spectra matched the measured and calculated values for glutamine, glutamate, glucose, lactate, and ammonium throughout the course of the run and also the increases in nutrient levels and decreases in metabolite levels after feeding. Similarly, VCD and TCD predictions also matched at-line measurements with slight deviations. Hence, in-line Raman spectroscopy was capable of successfully monitoring process conditions in a large-scale mammalian cell culture and has the potential to develop into a major PAT tool due to its favorable characteristics such as

TABLE 73.8. Chemometrics Applications in Biotech Production

Application	Process Analyzer	Chemometric Application	Observations	References
Scanning unprocessed culture fluid samples from a complex antibiotic production process	NIR	PCA	Process diagnosis and rapid assessment of process performance	(86)
Quality prediction and fault diagnosis for simulated fed-batch fermentation of penicillin	—	Multivariate statistical process monitoring	Enabled prediction of the end-of-batch quality during progress of the batch; this was useful for anticipating effects of excursions on final quality	(87)
To predict in advance the final quality of fermentation of antibiotic from *Streptomycetes*	FT-NIR reflectance spectroscopy	PCA (Kohonen network)	Kohonen network did predict successfully approximately 70% of the examples	(88)
Monitoring, detection, and diagnosis of small and embedded impurity peaks appearing in analytical chromatography	UV absorbance	MSPC based on PCA modeling	Applying this procedure for the detection of new peaks makes a fully automatic monitoring of complex chromatograms	(89)
Detection and diagnosis of abnormal process conditions in an industrial fed-batch cell culture process	NIR	PCA	The model was successfully able to detect abnormal process conditions, which resulted from three known fault types, namely, irregular thermal heating, elevated dissolved oxygen values, and large variation in agitation	(82)
Measurement of glucose, lactate, glutamine, and ammonia in undiluted serum-based cell culture media	NIR	PCA	Robust, analyte-specific models were generated	(90)
Monitoring the concentration of viable cells and the concentration of recombinant proteins in mammalian cell culture	2D fluorometry	PCA and PLS	Both viable cell density and glycoprotein concentration were accurately estimated	(91)
Monitoring concentrations of key analytes in a *Streptomyces clavuligerus* bioprocess for the synthesis of clavulanic acid	ATR-MIR	PLS	Quantitative, at-line models having low prediction error were developed and validated	(92)
Monitoring of fractionation of a whey protein isolate (WPI) during dead-end membrane filtration	Fluorescence spectroscopy	PLS models	Good agreement was obtained between predicted and measured values	(93)
Extract useful information from the manufacturing data for potential use in process optimization and enhancement of efficiency and robustness	—	PLS	Specific activity could be predicted reasonably well from the process data	(94)
Measurement of multiple analytes in undiluted serum-based cell culture media	NIR spectroscopy	PLS	Robust, analyte-specific models were generated with low prediction errors	(90)

Online batch fermentation process monitoring	NIR	PCA, PLS, MSPC charts	Easy and efficient identification of abnormal fermentation runs at an early stage of the fermentation	(95)
Yeast fermentations	MIR spectroscopy	PLS	Prediction of concentrations of glucose and ethanol	(79)
Use of online HPLC for making real-time decisions for pooling of process-scale chromatography columns based on product quality attributes to get consistent product quality	HPLC	Linear regression	Scalability demonstrated using online anion exchange HPLC for operations at pilot scale and eventually at manufacturing scale for pooling of a hydrophobic HIC column	(96)
	UPLC	Linear regression	UPLC offered significantly faster separations (7 min) while retaining the separation efficiency	(69)
	HPLC	Linear regression	Feasibility of using a commercially available online HPLC system for real-time pooling of process chromatography column	(68)
Real-time control of antibody loading during protein A affinity chromatography	Online HPLC, off-line ELISA	Linear regression	Accurate control of antibody loading on a protein A column in a CHO-derived recombinant antibody purification process and assessment of chromatography column performance	(97)
Thin layer chromatography for analysis of amino acids	NIR spectroscopy	PCA	Fast and easy method for classification of L-form amino acids either in dissolved or solid condition in blood samples	(98)

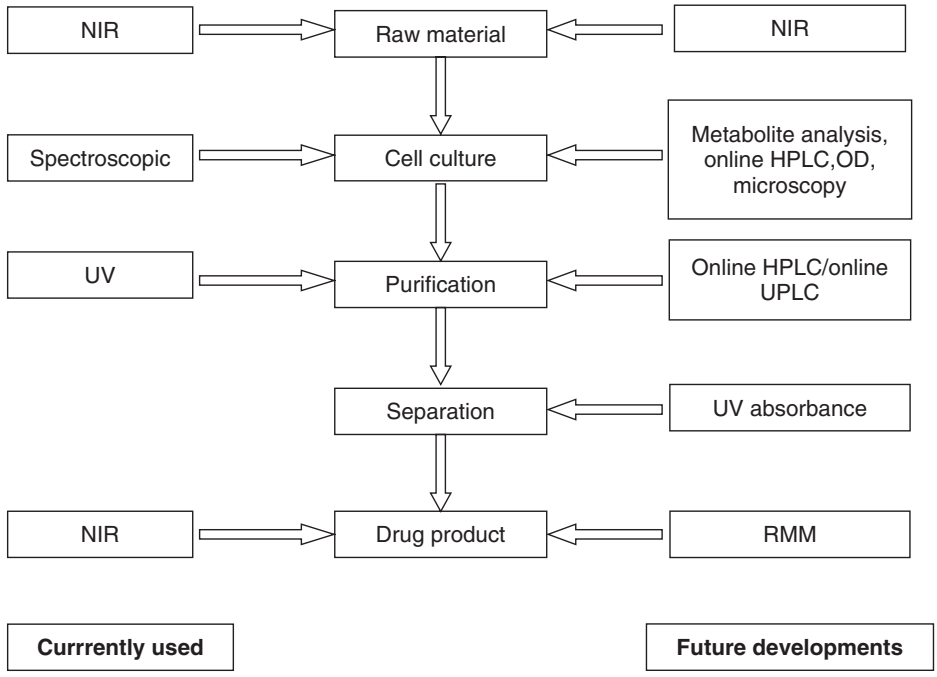

Figure 73.4. Status of PAT implementation in biopharmaceutical manufacturing: The left part shows tools that are currently used, primarily for monitoring. The right part shows tools that will possibly be used in the future to create true PAT applications

ease of sampling and potential to measure multiple analytes simultaneously.

73.8.2 Case Study 2: Use of Online HPLC for Making Real-Time Pooling Decisions for Process Chromatography

In this case study, a hydroxyapatite column was used for the separation of monomeric form of the product from higher molecular weight impurities (68). Product quality was determined using size-exclusion high performance liquid chromatography (SE-HPLC). The sample was collected directly from the hydroxyapatite column and its real-time analysis was performed. To achieve real-time decision making for pooling, it was necessary to not only decrease the elution flow rate for the Hydroxyapatite column but also to reduce the analysis time of the online SE-HPLC assay. As a result, implementation of this PAT application requires the ability to model the purity data in such a way that we can use the data from purity analysis of a fraction (x) to predict the pool purity if pooling was terminated at the next fraction ($x + 1$).The application can be extended to other modes of process chromatography and/or HPLC analysis. However, achieving this on the manufacturing floor would require a higher level of process understanding for designing such an approach and increased operational complexity.

73.9 CONCLUSION AND FUTURE PERSPECTIVE

PAT aims at improved monitoring and control for biopharmaceutical manufacturing processes. Figure 73.4 summarizes the current status of PAT for biopharmaceutical manufacturing. The focus in PAT implementation is on the principles of building quality into the product and process as well as continuous process improvement. This involves the use of multivariate tools, process analyzers, process control tools, and continuous improvement and knowledge management tools for manufacturing of the biopharmaceuticals. Control of the process by making real-time decisions based on measurement of product quality attributes would result in a more consistent product quality and a more efficient use of manufacturing capacity. However, this requires thorough understanding of the process and more specifically of the unit operation. While the emphasis has been on analysis and monitoring of the CQAs of the product or the critical process parameters, a greater degree of understanding is required of how process control (e.g. feedback and/or feedforward) can be achieved to ensure consistent process outputs. The recent development of chemometric tools has aided in deciphering useful information from data generated by process analyzers. Hence, the implementation of PAT is likely to result in a significant decrease in variability of product quality in the industry.

VENT GAS ANALYSIS

David Pollard and Jens Christensen
Merck & Co. Inc., Rahway, New Jersey

74.1 INTRODUCTION

Most biological processes involve the exchange or consumption of gases and volatile compounds, which makes the monitoring of exhaust gas an invaluable tool for the research or monitoring of fermentation processes. The monitoring of gas concentrations, such as CO_2 and O_2, in the inlet and outlet gas streams, and incorporating them into liquid and gas balances, makes it possible to quantify rates of gas utilization and respiratory quotient (RQ). The use of this data in conjunction with the fast response of the analyzers, provides an invaluable tool for on-line, real-time monitoring of the physiological state of the fermentation including growth kinetics, substrate consumption, and product formation (1,2). The aqueous concentration of organic volatile compounds, such as ethanol, butanol, and methanol, can also be determined from vent gas analysis and have been used to optimize productivity in industrial processes (3,4).

74.2 METHODS OF VENT GAS ANALYSIS

There are a variety of methods available for monitoring gases, however, only the methods most applicable for bioprocesses are described. These include thermal conductivity, flame ionization, gas chromatography (GC), electrochemical sensors, infrared absorption, and paramagnetism but by far, the most versatile and widely used is mass spectrometry which is why a considerable portion of this chapter is devoted to this widely used technology.

74.2.1 Gas Chromatography with Detection by Flame Ionization or Thermal Conductivity

GC combined with thermal conductivity or flame ionization detectors, has been used to determine H_2, CO_2, O_2, N_2, and organic volatiles. An analysis time of around 5–30 min is typical for each sample. This is much longer than other simpler, faster, and less expensive methods. GC is the phase separation of gas components by adsorption equilibrium differences between the stationary and mobile phases (5). The stationary phase is coated on small, solid particles (typically silica or polystyrene) packed or coated onto the walls of highly efficient fused silica columns (several meters in length). The particles have an affinity for the chosen gas analysis to achieve separation of gas components based on equilibrium differences. The system requires a carrier gas to transport the gas sample through the stationary phase (typically oxygen-free dry helium), a sample injection system, column temperature controller, and detector.

Thermal conductivity provides a resistance temperature detector whereby gas is passed over a heated filament and the magnitude of cooling is measured by the change of resistance of the filament as measured by a Wheatstone bridge (6). Typical units contain a bypass with two flows; one path houses the sensor with two heated coils. The heated gas is transported from upstream to downstream coils, changing their resistance. The bridge circuit with constant current input gives an output voltage in direct proportion to the difference in resistance, with heat input and specific heat assumed constant. For detectors used in GC, the heat transfer of the sample gas is compared with the

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.
© 2013 John Wiley & Sons, Inc. Published 2013 by John Wiley & Sons, Inc.

transfer of the carrier gas. The rate of transfer depends on the thermal conductivity of the gas which is proportional to the square root of molecular weight. The Wheatstone bridge balances the current through the sample element to restore its temperature to that of the reference. Instruments are calibrated for the gas to be used and can have a fast response time of 1 s, detection threshold of 30 ppm and accuracy of 2%. Carbon dioxide is often measured with this technique as the thermal conductivity of CO_2 is around two-thirds that of oxygen and nitrogen. The bypass units where the bulk of the flow bypasses the sensor are less sensitive to gas flow rate fluctuations but have larger response times, 20 s compared to 1 s. Although this technology has been used for many years it does not provide accuracy or long-term reproducibility. It is sensitive to gas flow rate, temperature, and mechanical vibration. Contamination of the sample cell can lead to drift and frequent calibration of these inexpensive devices is required. Sample pretreatment is often required to remove contaminants by condensation and drying.

An alternative is flame ionization, which is limited to the analysis of ethanol and organic volatiles because O_2, N_2, H_2, CO_2, Ar, H_2O, and NH_3 have no response. The sample gas is burned in a hydrogen- or air-induced flame and an electrical voltage is applied across two electrodes to remove the resulting ions from the flame. The current created across the two electrodes is a measure of the ion concentration (6). The detector has high linearity and sensitivity (ppb) with a short response time. This makes the method universal for organic analysis by GC, especially as contaminants, water, air, and ammonia, are not detected.

74.2.2 Electrochemical Sensors

Amperometric gas sensors can be used to measure oxygen concentration in vent gas. The sensor, 10–30 mm in length, measures the current across a working and counter-electrode as a function of analyte concentration in an electrochemical cell. The gold or platinum electrode hase a porous coating to allow the analyte gas to diffuse to the electrode surface which acts as a catalyst for electrochemical redox reactions. The oxygen diffusion results in a temperature-sensitive process and sensors are prone to drift from membrane fouling (7–9).

The electronic nose, an array of semiselective chemical gas sensors coupled with a pattern recognition algorithm, have been employed to analyze the volatile organic compounds (VOCs) and gases of fermentation vent gas (9,10). Typically, the arrays include 10–20 metal oxide sensors (MOS) operated at 300–500°C and 20–30 metal oxide semiconductor field effect transistors (MOSFETs) at 140–170°C. The MOS are ceramic cylinders <10 mm in length, containing a heating coil mounted onto a holder. The outside of the pellet is coated with metal oxide, usually SnO_2 doped with a small amount of Pd or Pt (Fig. 74.1). VOCs take part in redox reactions on the surface of the MOS while gases act as oxidizing agents at MOS operating temperatures. This results in a change in resistance of the sensor upon exposure to the VOC or gas. Selectivity of the sensor is fixed by changing the catalyst type or the operating temperature, which typically requires careful control to achieve sensitivities of 5–500 ppm. The MOSFETs typically use SiO_2 as the insulator and the common transistor configuration operates with three contacts: the source, drain, and gate (Fig. 74.1) (9). Applying a potential at the metal gate (typically platinum, palladium or iridium) determines the current. An inversion at the semiconductor–insulator boundary creates a channel that allows electrical current to flow from the source to the drain. This current of the transistor is controlled by the surface potential of the semiconductor. This in turn, determines the size of the depletion region as well as the concentration of charge carriers at the surface. Any gas reaction that causes a change in the metal gate or insulator properties will result in a change in the MOSFET sensor's electrical properties and a change in the drain current. The sensor response is measured by the change in gate voltage required to keep the drain current constant. Changing the temperature, gate metal type, thickness, and porosity of the metal gate will change the operation and selectivity. Sensor size is typically <1.5 mm and it operates around 150°C. Combinations of sensors allow good sensitivity but have slow response times, typically in the 5–10 min range. The data profiles are analyzed by principle component analysis and data sets require extensive validation of up to 10 repeated batches (10). The generated batch profiles can provide a real-time method of recognizing deviations from normal cultivation behavior (11). This can lead to methods for early contamination detection, providing a potentially powerful method to ensure product and process quality (12–14).

74.2.3 Infrared Absorption

The fundamental frequencies of vibration and rotation of a particular compound exposed to radiation, can be used to identify it from a mixture. IR (infrared) analyzers can only be used to monitor CO_2 and organic volatiles such as ethanol (15) since oxygen and nitrogen contain only one element. They are also sensitive to interference from other components of the gas, such as water. Most commonly used analyzers are nondispersive; they exclude most wavelengths apart from a few narrow bands of radiation. They are less selective than dispersive analyzers but more sensitive, simple, and reliable (16). Sources of radiation include quartz iodide lamps, tungsten filaments, and nichrome wires (6). A specific interference filter assembly, a monochromator, is chosen to filter out all wavelengths except for a desired wavelength band. The resulting radiation is a narrow band based around the mean of the desired wavelength

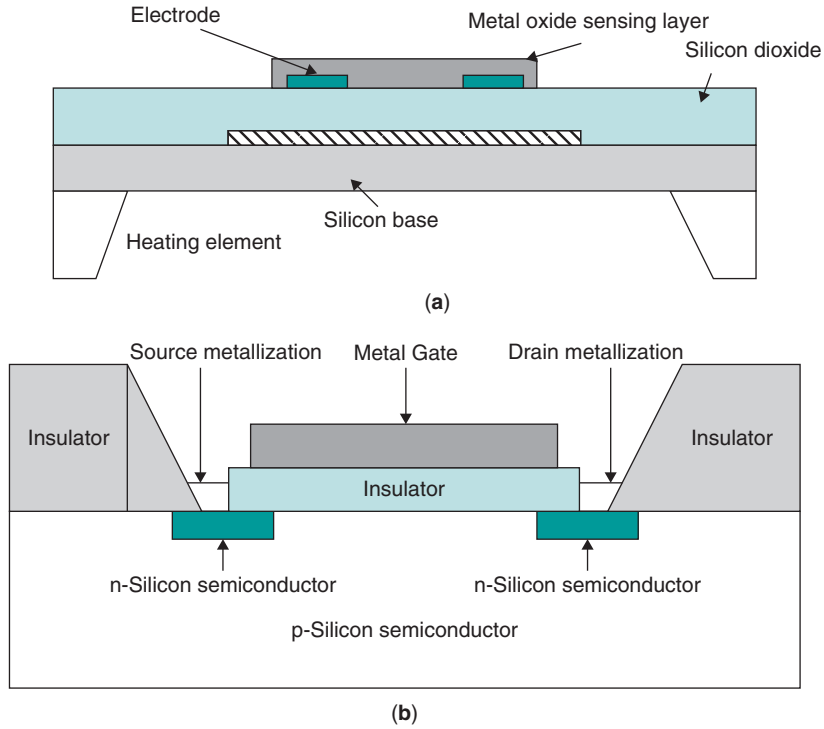

Figure 74.1. Schematic of (a) the metal oxide semiconductor (MOS) gas sensor and (b) the metal oxide semiconductor field effect transistor (MOSFET). [Adapted from 9]. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

(4200–4400 nm for CO_2). Alternatively, a cell containing the gas of interest is used to isolate the desired wavelength source.

In a typical optical arrangement, such as the Luft analyzer, an optical beam splitter is used to split the single radiation source into two beams which pass into two separate chambers (Fig. 74.2). One chamber houses the sample cell and the other the reference cell. Both chambers contain a gas that absorbs at the desired wavelength and the detector gas is usually the same as the desired gas for analysis. Differences in IR absorption occur between the two chambers, reference and sample, which generates pressure imbalances. This distorts a diaphragm which separates the two chambers in the detector and forms part of a condenser microphone. A chopper wheel, that is a perforated or segmented disc, is used to block the radiation from one chamber and allow radiation to reach the detector through the other chamber. The alternate blocking of the reference and sample chambers allows each radiation to be sampled at their appropriate side of the detector. The alternating flow of radiation produces an oscillating effect on the diaphragm. The amplitude of the oscillations is measured by the capacitance of the condenser microphone which is correlated to the concentration of absorbed gas. The accuracy of IR analyzers is reasonable for fermentation processes, typically around 1% of range, but are prone to drift (up to 1% full-scale per day for both the zero and span). The calibration curve is typically nonlinear which gives added difficulty to the frequent recalibration required to counteract drift. However, the 0–90% response time of 0.5–5 secs is reasonably fast compared to other technologies already discussed.

A number of low-cost systems have become available in the last few years, which combine the IR absorption sensor with an amperometric electrochemical gas sensor or paramagnetic sensor for dual analysis of CO_2 and O_2 for a single fermenter. Magellan Instruments provide a unit with IR sensor and electrochemical sensor (17) while other similar technologies exist from Bluesens, Servomex, and Dasgip. While these units may provide a low-cost solution for a single fermentor they don't necessarily provide cost effectiveness for a large research or manufacturing facility. The units are prone to daily drift and sensors usually have to be replaced at least once a year.

74.2.4 Paramagnetism

When a magnetic field is applied to a gas, the atoms orientate themselves in the direction of the field. The thermomagnetic analyzer uses the principle that the magnetic susceptibility is proportional to the difference between sample temperature and the Curie point of 80°C for oxygen (6). A typical instrument is the Quincke-type analyzer which

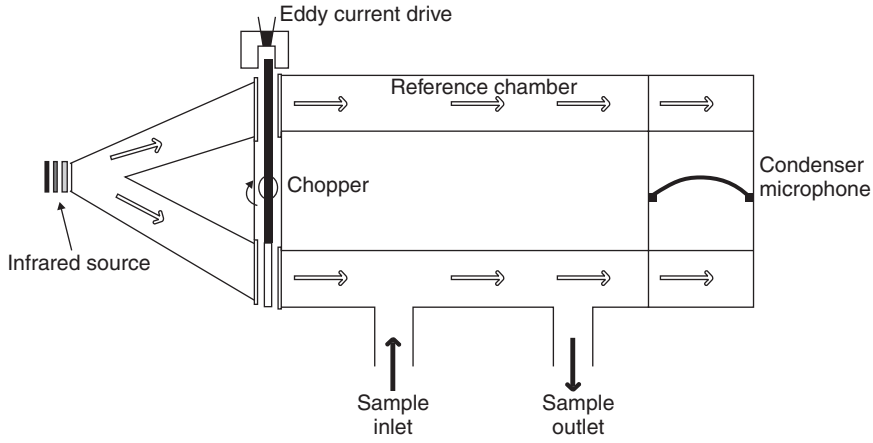

Figure 74.2. The Luft nondispersive IR analyzer with microphone sensor.

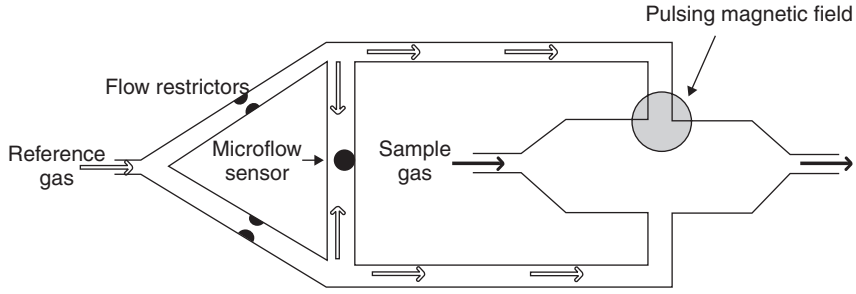

Figure 74.3. Quincke-type oxygen analyzer with capacitance sensor.

measures the pressure difference when two gases with different oxygen concentrations come together in the magnetic field. The reference gas (N_2, O_2, air) flows through two restrictions, so the gas entering either side of the sample chamber has equal flows (Fig. 74.3). One section of the reference gas is subjected to a pulsating magnetic field and if oxygen is present then a pressure difference is created between the two reference flows. The Luft capacitance sensor has been used as a detector. Alternatively, Siemans AG developed an analyzer with a microflow detector in a connecting channel which detects the pulsing flow, producing a current proportional to the oxygen concentration (Fig. 74.3). The separation of the sample from the detector reduces the possibilities of drift and instrument failure from contamination or corrosion of parts.

These paramagnetic analyzers have been found to be susceptible to vibration, pressure, and sample conditions with respect to moisture content and flow rate, resulting in frequent calibration to compensate for drift (2). Nevertheless, Quincke-type analyzers have been found to be more robust and have been widely used, including in the Merck & Co. Inc. production facilities. However, they are used only for single component analysis and are susceptible to moisture and high sample flow requirement. They have poor accuracy (1–2% of range) with slow response times (5–100 s) (18). The units require calibration from drift, the frequency of which depends upon care upon calibration, maintenance of the machine, and sample treatment (19). The use of microfluidics has renewed interest in paramagnetism, for the miniaturization of the oxygen sensor. A multilayer ceramic technology has been proposed with the integration of the magnetic coil into the fluidic system (20). This may provide a future source of inexpensive sensors.

74.2.5 Mass Spectrometry

This technology allows simultaneous measurement of both, air gases (e.g. Ar, O_2, N_2, CO_2) and volatile substances (including ethanol, acetone, and acetic acid (21,22) present in the fermenter headspace. A mass spectrometer with multipoint analysis and fast response times (in seconds) allows many fermentors and different processes to be monitored using the same instrument. This makes a cost-effective device for multifermenter sampling despite the high purchase cost of an individual unit. The analysis involves admitting a gas stream to an ion source and then ionizing the molecules by electron bombardment under a high vacuum. The ions produced are subsequently

separated according to their mass-to-charge ratio, by either a magnetic sector or a quadrupole mass filter, and detected sequentially. A typical magnetic sector mass spectrometer instrument has excellent repeatability of ±0.1% of range at calibration, zero and gain drift less than 1% of range/month and a response time of 1 sec (1,19,23). The limiting step of the response time becomes the passage through the sampling system, rather than the mass spectrometer itself. Maintenance is usually associated with contamination of the inlet device and filament and ion pump replacement. This is offset by the rapid analysis for polar organic species, excellent long-term accuracy, and precision plus flexibility of analysis. These features make mass spectrometry the most flexible and versatile instrument for vent gas analysis.

74.2.5.1 Vacuum System. A high vacuum (between 10^{-6} and 10^{-8} mmHg) is required to minimize collisions between particles in the analyzer chamber. At this pressure, the mean free path of particles will be long enough, 50 m as opposed to <0.01 m at atmospheric pressure, and the number of collisions small enough for good analysis (6). Particle collision reduces instrument resolution and sensitivity by increasing kinetic energy distribution of the ions, inducing fragmentation or preventing ions from reaching the detector (24). The vacuum is created in two stages: a roughing pump, which drives the vacuum down to 10^{-3} mmHg then a diffusion or turbomolecular pump is used to obtain pressure as low as 10^{-9} mmHg. The roughing pump is usually a reciprocating mechanical pump lubricated with low vapor pressure oil to prevent contamination of the mass spectrometer (6). The diffusion pump uses an oil, often polyphenol ether, to force molecules out of the vacuum chamber. The oil is heated at the bottom of the pump causing it to vaporize, and water-cooled coils at the top of pump then allow the oil to cool and condense. Large oil molecules force the smaller molecules down into the pump via momentum exchange and smaller gaseous molecules exit through the mechanical pump, around 200 L/sec. The disadvantage is that diffusion pumps are selective as noble gases are pumped at reduced rates (25). Turbomolecular pumping is mechanical where molecules are forced into the fins of the turbomolecular pump by momentum exchange. Fins revolve at around 10,000 rpm and produce an effective pumping capacity of about 400 L/sec. Turbomolecular pumps are often preferred to diffusion types as they give a very low contamination by hydrocarbons and high vacuum is obtained very fast on start-up. However, turbomolecular pumps are noisy (this can be muffled to some degree) and highly mechanical, requiring regular servicing.

74.2.5.2 Sample Inlet. The most popular design is the capillary inlet where a small representative sample flows from the main sample gas stream which is continually venting, and "leaked" into the instrument, typically at 20 mL/min (26,27). The constant flow of gas stream from sample line to vent and to the leak of the analyzer means that line-flushing can be ignored. The capillary is heated at 80–120°C to preserve the vapor state of the sample. The rotary pump draws the sample by creating a pressure drop through the capillary. At the outlet, before the ionization chamber, the molecules cross a fritted glass or metal filter to further reduce pressure (16). The response times of such an inlet system can be around 0.5 s, achieved by low dead volumes and maintaining the whole system at 80°C (22). Volatile components in the gas stream can contaminate the stainless steel capillary by adsorption and desorption, causing larger response times and memory effects from long transition times through the capillary (18,27). These factors can be reduced by using a capillary (diameter 3 mm and length 1–3 cm) lined with borosilicate glass which is heated resistively through a stainless steel outer sheath to 150°C.

74.2.5.3 Ionization. Electron impact ionization is the most common technique where the gas passes into an electron beam, resulting in electron ejection and a degree of fragmentation (2). Electrons ejected from a heated tungsten filament are accelerated through an electric field at 70 V to form an electron beam. The vacuum system draws molecules through the sample leak into the ionization chamber. Neutral molecules pass freely through the negatively charged ion-repeller in front of the leak and are thermally desorbed into the electron beam, transferring kinetic energy to the sample molecule (M). The ionization (electron ejection) results in parent ions with the same mass-to-charge, to molecular weight (MW) with 6 eV of excess energy (Fig. 74.4). The excess energy in the molecule leads to some degree of fragmentation of molecular ions, fragment ions, and neutral fragments. A negative ionization step (electron capture) also occurs but is 100 times less efficient than electron ejection. Electron bombardment is most stable and reliable but is complicated by the excessive fragmentation. Hence, other soft ionization techniques have been developed which produce only a few fragments: fast atom or ion bombardment, matrix-assisted laser desorption or ionization, and electrospray ionization. These methods give greater sensitivity and mass range but have primarily been developed for analysis of large molecules and solids (24).

74.2.5.4 Ion Separation. Separation of the ions of mass m from the ions of m' is most commonly done by the magnetic analyzer or the quadrupole filter as they are compact and easy to operate (28). The magnetic analyzer uses a magnetic field to separate the different ions. A moving charge passing through a magnetic field will experience a force, and travel in a circular direction with the radius of

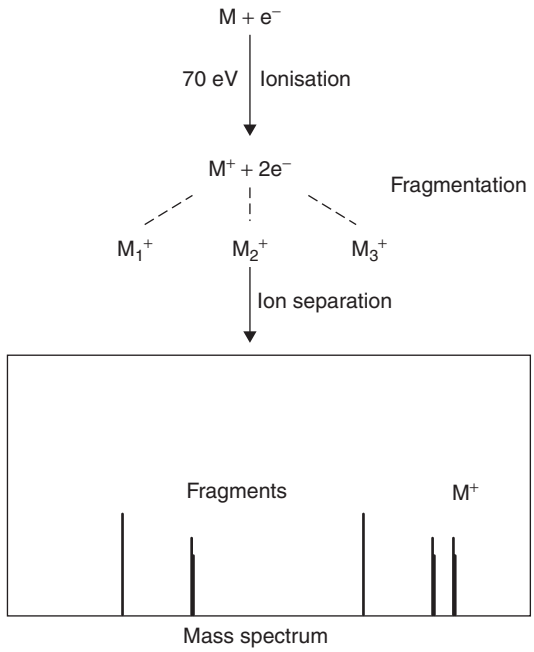

Figure 74.4. Ionization of molecules (M) producing fragment ions (M_1^+, M_2^+, and M_3^+).

curvature depending upon the mass charge ratio *m/z* of the ion. A magnetic analyzer separates ions according to their radii of curvature and therefore, only ions of given *m/z* will be able to reach a point detector in any given magnetic field (Fig. 74.5) (28). In a single detector system, an electromagnet is used to adjust the magnetic field to detect any *m/z* peak of interest (2). Alternatively, a multicollector system is set up, whereby each ion fragment is measured by a small number of Faraday bucket collector assemblies located along the focal plane according to which particular signals are of interest. Single detector systems are more common as they allow the combined use of the secondary electron multiplier (SEM) that is too large to be used in conjunction with multiple detector systems.

An alternative is the quadrupole filter that is a set of four cylindrical rods, typically 125–300 mm long and 6–16 mm in diameter, held in a square array to which an RF and DC potential are applied (25,29). Two rods are connected, and two are kept 180° out of phase (Fig. 74.6). This forms crossed, oscillating electric fields, perpendicular to the line of travel of the ions between the source and the detector. If the oscillating motion of the ion is out of resonance, the ions strike the walls and are not detected. Application a certain voltage and RF can control the trajectory of a known mass-to-charge ratio to selectively strike the detector (28). Scanning RF and DC voltages from zero, allows ions to be transmitted through the quad-filter sequentially, in order of their *m/z* values with constant resolution allowing multiple ion analysis. Resolution attained is determined by the accuracy of control of the parameters U (amplifier output amplitude), f (output frequency), V (amplifier voltage output) and α radius within the quad-rods (28).

Quadrupole systems are known to be faster, less expensive, and smaller than magnetic sector instruments. Yet, the resolution is lower, easily contaminated, and less stable over time, making the magnetic sector a superior choice for industrial on-line monitoring (18,28). The response times of both systems are comparable as the magnetic hysteresis associated with magnetic sectors has been eliminated using laminated magnets. The precision from magnetic sectors comes from the flat-topped peak profiles of ion current versus the magnetic field strength that they exhibit (Fig. 74.5). Thus peak center and peak height can be precisely determined. Any minor drifting that may occur due to temperature fluctuations has no effect. This results in high stability, accurate peak jumping, and long periods between recalibration (up to several weeks for fermentation applications). Absolute accuracy is <0.05% for O_2, <0.1% for N_2. Quadrupole filters exhibit a Gaussian-type peak profile and are more susceptible to drift (Fig. 74.6) and temperature variation; reduced accuracy and precision results in more frequent calibration. Insufficient resolution leads to an 'abundance sensitivity' problem whereby at low concentrations, peak discrimination is difficult with adjacent peaks. Comparisons between the quadrupoles and magnetic sectors have shown the improved accuracy and drift by a factor of 2 for magnetic sectors over the quadrupole systems (27,30). Although a considerable amount of useful applications for fermentation vent gas analysis have been demonstrated using quadrupole systems (31,32), the experience at Merck & Co. Inc. over the last three decades, favors magnetic sectors as opposed to quadrupoles. Suitable magnetic sector instruments for process monitoring are manufactured by Thermo Fisher Scientific (Prima δb) and by Applied Instruments (Hamilton Sundstrand, MGA series).

74.2.5.5 Detectors. The Faraday cup is a common detector used for mass spectrometry, where the ions pass the beam-defining slit of the cup and strike a metal dynode plate of a secondary emitting material such as BeO, GaP or CsSb. This induces several secondary electrons to be ejected and temporarily displaced. This temporary emission of electrons induces a current in the cup and provides for a small amplification of signal when an ion strikes the cup (24). The signal is measured by an electrometer and is directly proportional to the ion concentration. For the single collector system, with single amplifier and auto-gain switching, high precision can be maintained over the widest range. In this arrangement, any such drift is equal for all components and can therefore be compensated for by using any internal standard (2).

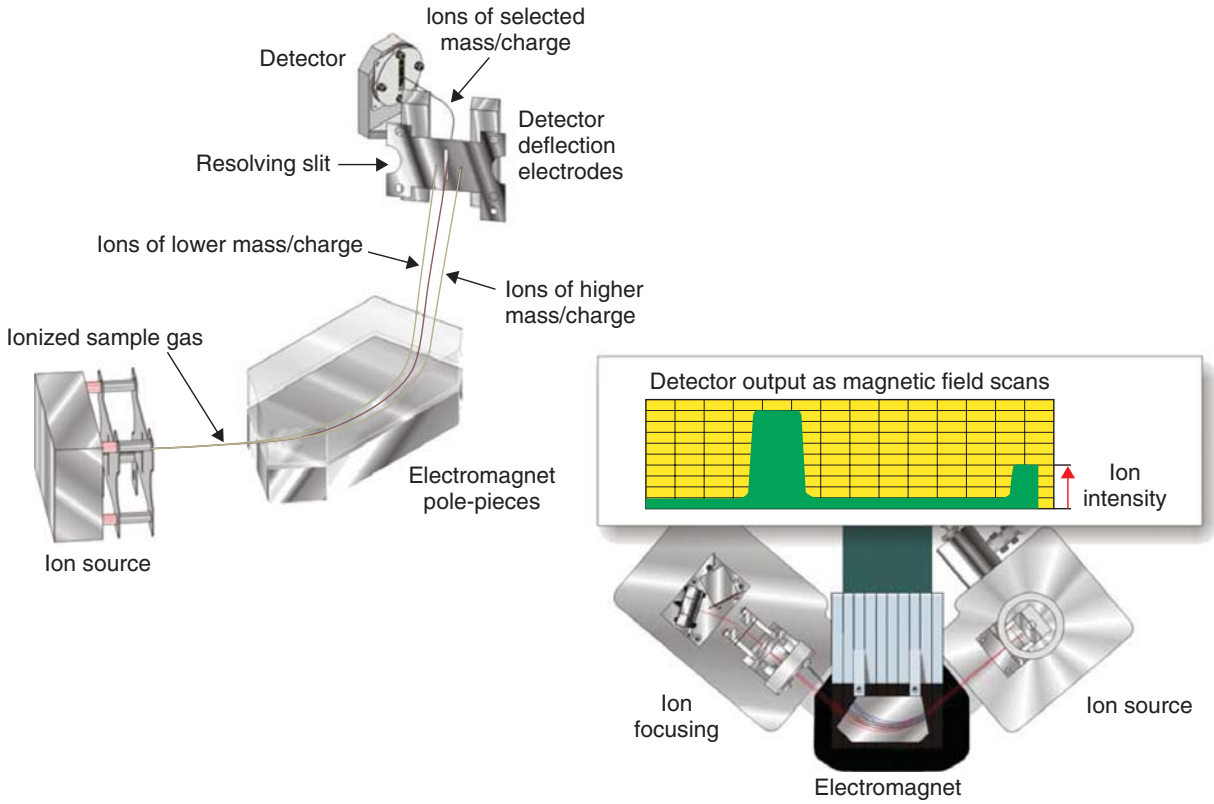

Figure 74.5. Magnetic sector mass spectrometer showing ion trajectory through magnetic field and the flat-top type of profile of the ion current versus magnetic field strength. [Thermo Fisher Scientific.]. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

A second detector is the SEM, which is a series of dynodes (around 10) maintained at ever-increasing potentials. Ions strike the dynode surface, resulting in emission of secondary electrons which are attracted to the next dynode where again, secondary electrons are generated. This produces a cascade of electrons transferring from plate to plate, in a cycloidal flow path between two glass plates. The signal amplification or current gain of an electron multiplier is 10^6 with a lifetime of 1 to 2 yr. This is limited due to surface contamination from incident ions or poor vacuum (18). The Faraday cup is considered rugged, reliable, and is typically capable of measurements down to 1–10 ppm concentration levels (23). However, the SEM detector offers greater sensitivity (sub-ppm) with a faster response but has poorer long-term stability and is generally less accurate (2). SEM can be sensitive to repeated air exposure, background noise increases when the gain decreases, and is far less rugged than the Faraday cup (16). In a single collector arrangement with either a magnetic sector or quad, it is common to have remotely switchable Faraday cup and SEM assemblies. The appropriate detector is selected by the software, allowing all species to be monitored from 100% to ppm (25). For example, a Faraday cup is used for air components and a secondary system for volatiles such as ethanol, acetone or butanediol (22).

74.2.5.6 Spectral Analysis. To calculate the individual component concentrations c_1, c_2 ... c_n of a mixture of ion-fragment intensities with n components, requires a series of linear equations to be solved. The ion current signal, S_1, for each mass/charge is considered to be the sum of the contributions of all components, which are proportional to the concentration of each component:

$$s_1 = c_1 m_{11} + c_2 m_{12} + \cdots + c_q m_{1q}$$

$$\cdots$$

$$\cdots$$

$$\cdots$$

$$s_p = c_1 m_{p1} + c_2 m_{p2} + \ldots + c_q m_{pq}$$

or

$$\vec{s} = \mathbf{M}\,\vec{c}$$

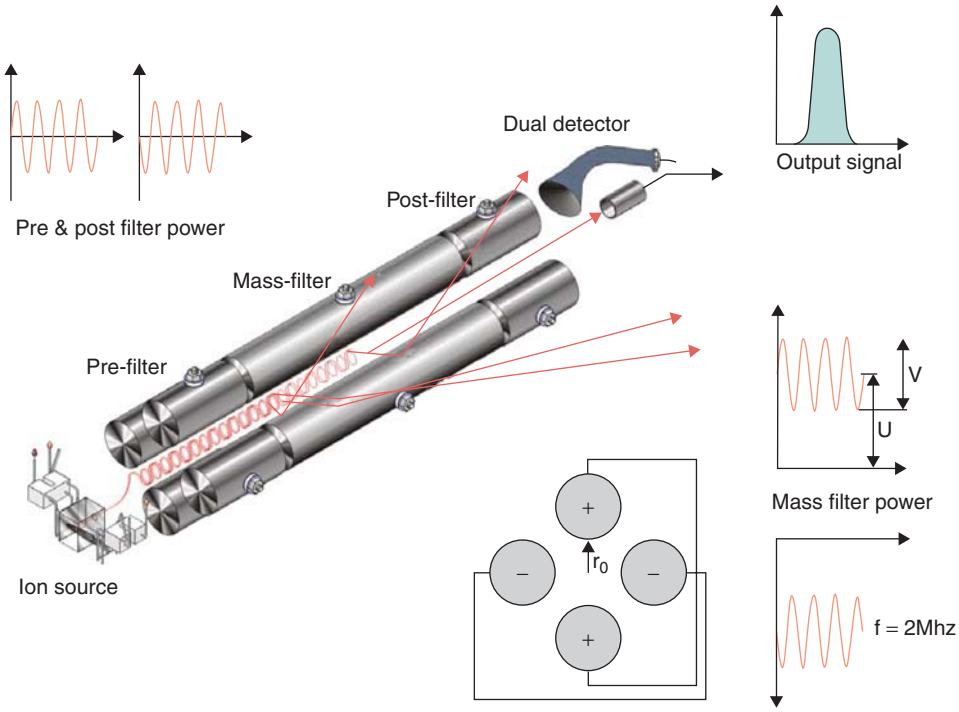

Figure 74.6. Magnetic sector mass spectrometer showing ion trajectory through magnetic field and the flat-top type of profile of the ion current versus magnetic field strength. [Thermo Fisher Scientific.]. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

where s is the signal, **M** is the fragmentation pattern or sensitivity factor matrix determined by calibration with individual pure components, and c is the desired concentration (23).

Most species produce several peaks due to fragmentation or double ionization. For instance, nitrogen has peaks at nominal m/z values 28, 14, 29, and 15. So a set of linear equations is over-determined and solved using an iterative route of multidimensional least squares technique (33). The best fit is then made between the observed spectrum and that which can be synthesized following small adjustments of the species concentration. These adjustments use the known fragmentation patterns of various species. Therefore, all of the mass spectral information is made available by the single detector instrument which is most effectively used in achieving the concentration analysis.

74.3 INSTALLATION AND OPERATION

The design of a sampling system for vent gas analysis requires careful consideration and usually involves the multiplexing of one analyzer to a variety of fermenters. A sample handling system incorporates gas transport from the fermenter, followed by pretreatment, before passing through the multipoint sampling manifold into the analyzer. The design of such a system must minimize the response time of sample analysis. Most applications require removal of moisture and contaminating species from the vent gas which involves steps such as filtering and heating, before the analyzer. The materials of construction for transport lines, line purging, sample flow rate, and minimizing tubing lengths must all be considered.

74.3.1 Fermenter Sampling Location

If fermenter overpressure is to be used for gas transport to the mass spectrometer, then it is pertinent to have the sample port between the head plate and the back pressure control valve. The vent line of fermenters often contain a condenser, double piped steam heater or vent filters which are steam-dried from a jacket. These techniques can remove volatile compounds from the exhaust gas, so the sampling point should be upstream of these devices if organic volatile analysis is desired. Moisture must be removed before the analyzer, so sampling after the condenser may be advantageous. Foaming and liquid entrainment can occur into the vent line. Entrainment into the sampling system can be prevented to some extent by facing the sample port downstream of the gas flow (33). Gas has to make a 180° turn to the sample port while tending to exclude liquid, as its inertia prevents it from turning. Foam detection systems can

also prevent sample-line contamination. The foam sensor using capacitance or conductivity between two elements, usually probe and tank wall or two elements in the probe, can be mounted on the fermenter headplate. This can be part of an automatic defoamer addition system upon foam detection. A second probe can be mounted in the vent gas line to close off the gas sample valve upon foam detection.

74.3.2 Sample Delivery and Pretreatment

The fermenter headplate, over pressure, is often used to transport gas to the analyzer. However for laboratory-scale vessels, a gas membrane or piston pump may be required. A 0.1 bar pressure is sufficient for a 100-m length of standard 6-mm nylon tubing (or 1/4-inch tubing) (23). The tube can be stainless steel, nylon or preferably, polytetrafluoroethylene (PTFE) for volatile samples. The tubing is heated to between 60 to 160 °C to ensure compounds remain in the vapor phase, which avoids their removal via condensation. This can be done electrically, by steam or by jacketed hot water (29). For volatile analysis, the tube is heated to around 150°C and the use of Teflon is essential for fast response times (34). Adsorption or desorption effects of volatile components with the stainless steel tubing walls can hinder response times (>5 min) and cause memory effects.

The vent gas is often passed through a (0.2 μm) hydrophobic filter (PTFE) as a final particulate protector before the analyzer. For unheated lines, moisture removal occurs by condensation. Knockout pots are used in combination with a coalescing filter whereby large drops form and settle by gravity (33). A graded porosity hydrophilic matrix is used with a drain layer to direct coalescing liquids into a sump at the base of the housing. Automatic draining of the pot is ideal via solenoid actuation, periodically or upon liquid detection. If further moisture removal is required, various technologies are available including small concentric tube or coil in shell-heat exchangers with refrigerated coolant. Other systems include the Peltier effect cylindrical gas cooler with a sealed tube containing a pure fluid. A wick lines the inner walls, which ensures the fluid return by capillary action. One end of the tube is heated, liquid evaporates and the gas flow displaces the steam toward the end of the tube. The steam expands and condenses back to the heated end (16). Desiccants such as anhydrous calcium chloride, alumina or silica gel can be used for further sample drying but this is rarely necessary.

74.3.3 Sample Handling Manifolds

A single mass spectrometer for vent gas analysis is usually applied to an array of fermenters (>10). This requires a fast, cross-contamination and leak-free manifold system to automatically switch between fermenter samples and calibration gases. A typical system has the sampling streams from all tanks under permanent flow in order to guarantee instant sampling availability and avoiding line purging (Fig. 74.7). Three-way valves can eliminate dead legs and two valves per sample stream allow gas to flow to the drain, rather than contaminate other streams if both valves fail. Solenoid valves are often used as they are inexpensive and

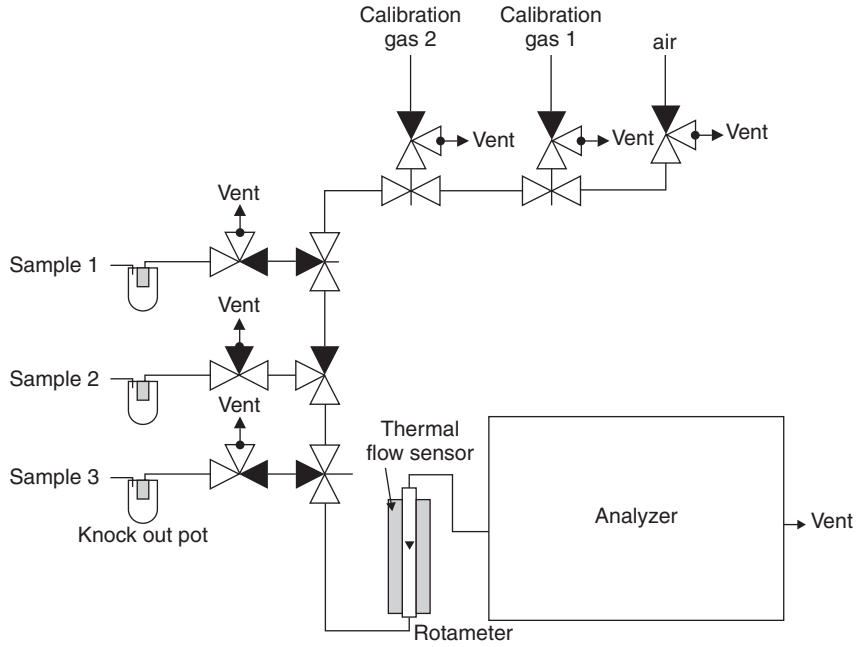

Figure 74.7. Multistream sample switching system. (Solid segments indicate valve's closed position).

compact compared to air-actuated ball valves. Rotameters can be used to verify flow at the vent side of the three-way valve. The manifold is mounted in a cabinet with heat control, to a temperature above the process temperature or to the 110°C required for organic volatiles. Multistream rotary valves have been designed using an actuated electric stepper motor for cross-contamination sampling (23,27). The RMS (rapid multistream sampler) unit designed by Thermo Fisher Scientific, can be configured for 32 or 64 sample streams connected to the periphery of a circular, flat, distribution plate which vents into a cylindrical housing with a common exhaust (Fig. 74.8 and 74.9). The electric stepper motor drives the rotary arm to position at a sample stream and the sample flows directly into the sample transfer tube. Cross-contamination of other gases is inhibited by a spring-loaded face-sealing sleeve (2). A single analyzer can hold two RMS units to enable analysis of a total of 127 streams. The response time of the manifold system can be reduced by minimizing tubing lengths. The time required to flush the lines should be 4 times the gas residence time (2). This is estimated using plug flow, but experimental measurements are preferred because of back-mixing through valves and regulators.

74.3.4 Sample Flow Control and System Monitoring

Sample pressure will directly influence vent gas analysis as the signal from a gas analyzer is proportional to volumetric concentration of the component of interest. This can be remedied by measuring internal standards (typically N_2, or Ar), then the concentration for all other components, followed by completion of a mole fraction. Alternatively, the pressure can be measured and the data corrected using the ideal gas law or by controlling the pressure at the fixed value (33). Pressure control can be overcome by simply venting the instrument outlet to the atmosphere. An upstream needle valve can be used to reduce the pressure and control sample flow rate through the instrument. Locating the valve as far upstream as possible reduces the lag time, as the gas velocity is increased after the pressure reduction. However, this leaves a 2–3% variation due to atmospheric pressure. If this is unacceptable error, then an absolute back-pressure regulator must be employed on the outlet (33). Temperature is controlled within the analyzer but it is useful to control temperature of the manifold cabinet by an electric heater. A temperature greater than 60°C will prevent condensation unless moisture has been removed, and minimize adsorption of compounds. Water can be detected in a manifold system by a U-shaped liquid trap with a sensor to detect water in the sample lines. The low electrical conductivity of water in the sample means that the sensor must monitor either the dielectric constant or the refractive index of the stream, or even the thermal dissipation from a self-heated thermistor or electric coil. The sample flow rate (greater than 1 mL/s) can be controlled by a simple needle valve and rotameter. The thermal sensor and autocontrol valve will ensure sample flow rate is adequate and stable. Leak testing is done by pressuring the system from instrument air and closing the valves.

Figure 74.9. Magnetic sector mass spectrometer unit from Thermo Fischer Scientific fitted with the rotary motor sample device. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

Alternatively, the pressure can be monitored while the sample system is evacuated if this step is part of the sampling sequence. Diagnostic packages are supplied with most analyzers, which will sound an alarm for problems associated with the capillary, filament, vacuum, and power supply.

74.3.5 Process Measurements Required for Variable Calculation and Data Acquisition

To calculate useful fermentation variables such as oxygen uptake rate (OUR), carbon evolution rate (CER), and RQ measurements of pressure, volume, airflow, and dissolved oxygen are required. Broth volume can be determined by load cell or differential pressure transducers. Airflow rate can be measured by a mass flow meter and dissolved oxygen concentration by polarographic probe whose response should be checked systematically by varying the headspace pressure or degassing with N_2. Strain gauge, piezoresistive, capacitance or resonant wire transducers can be used for pressure measurements. For a number of fermenters connected to a multistream manifold, such as an RMS, fast turnover of samples is required although accurate measurements must be made. Therefore data acquisition must occur after a suitable line purge time. Multiple measurements can subsequently be made and filtered or smoothed to reduce noise (2). A typical approach is to use an algorithm to produce a stable reading (33). A linear exponential filter is used where each successive measured value c_t is used to update a smoothed estimate as $\hat{c}_t = \kappa c_t + (1-\kappa)\hat{c}_{t-1}$ where k is a filtering parameter. The trend in the smoothed data is estimated as $\hat{S}_t = \lambda(\hat{c}_t - \hat{c}_{t-1}) + (1-\lambda)\hat{S}_{t-1}$, where λ is another parameter. A typical algorithm acquires at least $1/\kappa$ values and continues until the absolute value of the trend $\hat{S}_t$ is less than a target tolerance δ, indicating that a stable result has been obtained. The values of κ, λ, and δ depend on the rate of data acquisition and on instrument performance (33). Vent gas analysis processes gases on a dry gas basis, whereas the actual gases from the fermenter are saturated with water vapor. Standard handbooks can be used to correct this data (35). Most vent gas analysis is expressed as a mole fraction. If this is not the case, then data should be adjusted using the ideal gas law, to standard conditions of temperature and pressure, to allow mass balances to be performed. Good precision is achieved if signals are noise-free with no drift. However, the combination of vent gas data with on-line data such as airflow rate and dissolved oxygen for mass balancing introduces noise. These errors of measurement can dramatically enlarge errors in the data. Low pass filters can be used to smooth the data and many acquisition systems have built-in analog filters used for this purpose.

74.4 PARAMETER CALCULATION

The microbial physiology of a fermentation can be characterized using the consumption rates and metabolic factors which require equation balances for the gas and liquid phases. The following balance equations (Eqs 74.1 and 74.2) for species 'i' in the gas and liquid phases, are written assuming well-mixed phases in the fermenter. This assumes that concentrations are uniform throughout the liquid phase, and that mole fractions are uniform throughout the gas phase. The assumption is accepted for small-scale stirred reactors but is less valid at large scales >100 L. Axial volumetric concentration gradients of species in the gas phase, as a consequence of the hydrostatic pressure gradient, have been observed at a large scale. This leads to alternatives for large-scale vessels; these are discussed in the next section. For low pressure and dilute concentrations of interest, the ideal gas law and the simplest form of Henry's law (relating equilibrium gas- and liquid-phase concentrations through a simple proportionality constant) can be used. The equations have been given by Heinzle and Dunn (1991) (2), and modified by Salmon and Buckland (33). It is assumed that the

fermenter is isothermal and has a uniform cross-sectional area.

$$\frac{dV_G C_{G_{e,i}}}{dt} = G_o C_{G_{o,i}} - G_e C_{G_{e,i}} - k_{L_i} a V_L (C^*_{L_{e,i}} - C_{L_{e,i}}) \quad (74.1)$$

$$\frac{dV_L C_{L_{e,i}}}{dt} = L_o C_{L_{o,i}} - L_e C_{L_{e,i}} + k_{L_i} a\ V_L (C^*_{L_{e,i}} - C_{L_{e,i}}) - V_L \sum r_i \quad (74.2)$$

where $C_{G_{o,i}}$, $C_{G_{e,i}}$, $C_{L_{o,i}}$, and $C_{L_{e,i}}$ are the gas and liquid phase concentrations, subscripts o and e refer to the influent and effluent, and subscripts G and L refer to the gas and liquid phases. V_G and V_L are the gas- and liquid-phase volumes, G_o, G_e, L_o, and L_e are the influent and effluent gas and liquid flow rates, $k_{L_i}a$ is a mass-transfer coefficient, $C^*_{L_{e,i}}$ is the liquid-phase concentration that would be in equilibrium with $C_{G_{e,i}}$, and $\sum r_i$ is the total consumption rate of species i in the liquid phase. Standard conditions of pressure and temperature (typically $P_{ref} = 1$ atmosphere, $T_{ref} = 25^\circ C$) have been used for gas-phase concentrations, volumes, and flow rates.

An expression can be written for $C^*_{L_{e,i}}$, liquid-phase concentration, using Henry's law and integrating over the fermentation broth volume (33):

$$C^*_{L_{e,i}} = (RT_{ref}/H_i P_{ref})(P_h + V_L \rho_L g/2A) C_{G_{e,i}} \quad (74.3)$$

where H_i is the Henry coefficient, P_h is the headspace pressure, ρ_L is the liquid-phase density, and A is the cross-sectional area of the fermenter. It is usual to assume that the liquid-phase supply, removal, and accumulation terms in Equation 74.1 are negligible for gases such as oxygen which have low aqueous solubility. The gas-phase accumulation term in Equation 74.1 is also ignored as gas holdup is small and changes in oxygen utilization occur slowly. However, this simplification may not be valid for rapidly growing cultures (36) or when sudden metabolic changes occur (36), in which case the calculated results will lag behind actual events in the fermenter. Using the discussed assumptions, Equations 74.1 and 2 can be added and rearranged to obtain an expression for $OUR = r_{O_2}$, the net oxygen utilization rate:

$$OUR = G_o \left(C_{G_{o,O_2}} - G_e/G_o C_{G_{e,O_2}} \right) / V_L \quad (74.4)$$

An expression for the mass-transfer coefficient, in a dimensionless form, can also be derived from Equation 74.1.

$$\alpha_{O_2} = \frac{k_{L_{O_2}} a V_L}{G_o} = \frac{C_{G_{o,O_2}} - G_e/G_o\ C_{G_{e,O_2}}}{\beta_{O_2}(1+\gamma/2) C_{G_{e,O_2}} - C_{L_{e,O_2}}} \quad (74.5)$$

where $\beta_{O_2} = RT_{ref} P_h / H_{O_2} P_{ref}$, and $\gamma = V_L \rho_L g / A P_h$. Values of the Henry coefficient, H_{O_2}, can be obtained from the literature (37). The aqueous oxygen concentration $C_{L_{e,O_2}}$, found in Equation 74.5, can be measured on-line using a polarographic probe calibrated to read $\beta_{O_2}(1+\gamma/2) C_{G_{o,O_2}}$ before inoculation. The constant, 1, assumes that the difference of oxygen solubility in the fermentation medium is negligible when compared to water. This assumption is reasonable as the constant can be estimated for most fermentation broths (37,38) and a value of 0.945 is achieved for a typical broth containing, salts, yeast extract, and glucose.

Inert gas species (such as Ar or N_2) are monitored to compensate for gas-flow changes due to the presence of moisture and volatiles in the exhaust gas. The net utilization for the inert gas is zero and consequently $G_e/G_o = C_{G_{o,inert}}/C_{G_{e,inert}}$ by using the simplifications for oxygen.

For carbon dioxide, the situation is more complex as its high solubility (H_{CO_2} of 34 L bar/mol compared to H_{O_2} of 856.9 L bar/mol) means that the liquid-phase accumulation cannot be ignored. Also carbon dioxide reacts with water to give to biocarbonate at pH >6.5.

$$CO_2 + H_2O \underset{k_b}{\overset{k_f}{\rightleftarrows}} H_2CO_3 \overset{K_a}{\longleftrightarrow} H^+ + HCO_3^- \longleftrightarrow 2H^+ + CO_3^{2-} \quad (74.6)$$

The hydration of CO_2 to $H_2CO_3^-$ has a slow rate constant, however its concentration is low (<0.3% of CO_2 present) (39) as it is almost instantaneously dissociated to HCO_3^-. At the pH range of 4–8 for fermentation processes, the concentration of carbonate ions is negligible; complexing of CO_2 with amine groups can be ignored and the reaction of dissolved CO_2 with OH^- is negligible (40). Bicarbonate accumulations increase with pH and at pH 6.3, the concentration can be equal to the dissolved CO_2. Thus the basic liquid phase Equation 74.2 must be modified to include accumulation of bicarbonate:

$$\frac{dV_L C_{L_{e,CO_2}}}{dt} = L_o C_{L_{o,CO_2}} - L_e C_{L_{e,CO_2}} + k_{L_{CO_2}} a V_L (C^*_{L_{e,CO_2}} - C_{L_{e,CO_2}}) + V_L \left(CER - r_{HCO_3^-} \right) \quad (74.7)$$

$$\frac{dV_L C_{L_{e,HCO_3^-}}}{dt} = L_o C_{L_{o,HCO_3^-}} - L_e C_{L_{e,HCO_3^-}} + V_L r_{HCO_3^-} \quad (74.8)$$

where $CER = -r_{CO_2}$ is the net carbon dioxide evolution rate from the biomass, and $r_{HCO_3^-}$ is the net rate of bicarbonate formation given by:

$$r_{HCO_3^-} = k_f C_{L_{e,CO_2}} - k_b / K_a C_{L_{e,H^+}} C_{L_{e,HCO_3^-}}. \quad (74.9)$$

Values for the constants k_f, k_b, and K_a can be obtained from the literature (41). Rearrangement of Equation74.1, gas-phase balance, and neglecting accumulation terms as before, can produce this balance:

$$k_{L_{CO_2}} a V_L (C^*_{L_{e,CO_2}} - C_{L_{e,CO_2}}) = G_o C_{G_{o,CO_2}} - G_e C_{G_{e,CO_2}}. \quad (74.10)$$

and solved for the liquid-phase CO_2 concentration,

$$C_{L_{e,CO_2}} = \left\{ \frac{1}{\alpha_{CO_2}} \frac{G_e}{G_o} + \beta_{CO_2}(1 + \gamma/2) \right\} C_{G_{e,CO_2}} - \frac{1}{\alpha_{CO_2}} C_{G_{o,CO_2}} \quad (74.11)$$

where $\alpha_{CO_2} = k_{L_{CO_2}} a V_L / G_o$, and $\beta_{CO_2} = RT_{ref} P_h / H_{CO_2} P_{ref}$. Henry coefficient H_{CO_2} estimates are found from the literature (38). Combining Equations 74.7, 74.8, and 74.10, rearrangement gives:

$$CER = \frac{1}{V_L} \left\{ \begin{array}{c} \dfrac{dV_L \left(C_{L_{e,CO_2}} + C_{L_{e,HCO_3^-}} \right)}{dt} \\ - L_o \left(C_{L_{o,CO_2}} + C_{L_{o,HCO_3^-}} \right) + L_e \left(C_{L_{e,CO_2}} + C_{L_{e,HCO_3^-}} \right) \\ -G_o \left(C_{G_{o,CO_2}} - G_e / G_o C_{G_{e,CO_2}} \right) \end{array} \right\}. \quad (74.12)$$

The evaluation of $C_{L_{e,HCO_3^-}}$ can be considered in three algorithms of complexity (32). Equations 74.8 and 74.12 can be solved progressively as the fermentation proceeds, using current and past data. This enables monitoring of CO_2 evolution under dynamic conditions, as long as the rate of data acquisition by the analyzer is sufficiently rapid. This may be a problem when acid is introduced intermittently for pH control because after each addition, the CO_2 concentration in the vent gas will increase for a short period (42). A second approach can be applied if the time constant for process changes is greater than 5 min. In this case, the hydration reaction can be assumed to be at equilibrium, yielding $C_{L_{e,HCO_3^-}} \approx (k_f/k_b) K_a 10^{pH} C_{L_{e,CO_2}}$. Substituting this expression into Equation 74.12 allows the value of *CER* to be calculated directly if the rate of change of the dissolved CO_2 concentration is estimated using current and past data (32). Lastly, it is common practice to ignore the transient terms as long as changes of pH and CER are slow. Heinzle *et al*. (1990) demonstrated that including dynamic changes of CO_2 and HCO_3^- into a simulation only produced relative errors of $<2\%$ in the CER.

74.4.1 Large-Scale Mixing Models

Upon scale-up to manufacturing (100 to 10,000 L), axial gradients and large mixing time are observed and so previous equations for oxygen transfer rate, OTR and OUR based on the well-mixed system may not be valid. Hydrostatic pressure gradients in tall fermenters will cause large differences in oxygen solubility C_L from liquid surface to tank bottom. The dissolved oxygen concentration in a stirred tank can vary linearly from 5.4 mg/L at surface to 12.1 mg/L at a depth of 10 m. At the bottom of the tank, the oxygen solubility for a given gas composition is twice, as a consequence of the doubled hydrostatic pressure as shown by Henry's law. This will double the maximum OTR and hence, dissolved oxygen concentrations, oxygen solubilities, gas holdup, and transfer parameters may vary with depth in tall reactors. There is limited experimental data available for concentration heterogeneity within large fermenters, but radial and axial gradients of pH, conductivity and dissolved oxygen have been observed (43–45). Residence-time distribution data using liquid and gas transfers have characterized the mixing to produce a variety of models (46–51). Various models have been determined for large-scale mixing where axial back-mixing has been described by dispersion theory or a tank in series with recirculation based on the measurement of residence time distribution. Other research groups compartmentalize the reactor into distinct zones, such as a well mixed zone at the impeller and a second zone for the remainder of the reactor. The pumping power of the impellers (43,50) dictates the transport between the two compartments. The model behavior is described through simulations of the coupled material balance equations for OTR, mixing, and kinetics. The importance of back-mixing and hydrostatic pressure upon scale-up was demonstrated by using a three-phase multimixed compartment model (48). The flow conditions of these models fall between extremes of well-mixed and plug flow. Simplification for large-scale reactors involves assuming that the liquid phase is well-mixed but that the gas-phase moves in plug flow (no back-mixing) from inlet to outlet (52). The gas-phase concentration of species '*i*' was described by Salmon and Buckland (33) using the equation given below:

$$\frac{dC_{G_i}}{dx} - \alpha_i \left\{ \beta_i \left[1 + \gamma(1 - x) \right] C_{G_i} - C_{L_{e,i}} \right\} = 0 \quad (74.13)$$

where α_i, β_i, and γ are defined in the previous section. For the gas-phase concentration of species i: a closed-form solution to this equation was used to calculate $C_{G_{e,i}} = C_{G_i}(1)$ from the inlet condition of $C_{G_i}(0) = C_{G_{o,i}}$. Salmon and Buckland (33) used this solution to produce a comparison between the estimates of equilibrium between liquid and gas phases at two scales, 0.15 and 60 m^3 (where differences are solely due to hydrostatic pressure), and between

the two models of well-mixed phases and a gas phase with plug flow. For a given mass transfer coefficient, the predicted liquid-phase concentrations were closer to equilibrium with the effluent gas for the plug-flow model than with the well-mixed system. This difference was accentuated with the large-scale tank (where hydrostatic pressure is significant). This seems reasonable as the mass-transfer coefficient required to achieve a desired liquid-phase concentration is lower for a production vessel than for a small, laboratory fermenter. So for a given mass-transfer coefficient, the gas-phase and liquid-phase concentrations in a large vessel will be closer to equilibrium than those in a small vessel. This agrees with the observation that the dissolved carbon dioxide in a large tank can be calculated by presuming equilibrium with the vent gas, whereas this assumption is not appropriate for small fermenters.

74.4.2 Aqueous Concentration Estimation for Volatile Organic Compounds

Assuming a well-mixed system, then the liquid-phase concentration for an organic species can be calculated as for $C_{L_{e,CO_2}}$(Eq. 74.11) (35):

$$C_{L_{e,i}} = \beta_i \left\{ \frac{1}{\alpha_i \beta_i} \frac{G_e}{G_o} + (1 + \gamma/2) \right\} C_{G_{e,i}}. \qquad (74.14)$$

As $\alpha_i \beta_i \rightarrow 8$, the liquid-phase concentration approaches $\beta_i(1 + \gamma/2)\ C_{G_{e,i}}$, which is the concentration in equilibrium with the gas phase at the average fermenter pressure. Equilibrium constants can be attained for any volatile compound under most conditions (22), as most compounds have a high affinity for the liquid phase and a low Henry's coefficient (ethanol 10^{-2} bar/L/mol) compared to gas. Camelbeeck *et al*. (30) have experimentally confirmed this conclusion by demonstrating that changes in the rates of agitation and aeration have no influence on the vent gas measurements. The ability to monitor a specific organic compound depends on concentration, volatility, and analyzer sensitivity. Oeggerli and Heinzle (22) compared partial pressures above an aqueous solution at a concentration of 0.1 g/L at 30°C. Compounds were considered analyzable if the partial pressure was above 1 μbar hence, ethanol at 22.24 μbar and acetone at 181 μbar could be monitored (oxygen was $> 10^6$ μbar). However 2,3-mesobutanediol was considered undetectable as the partial pressure was 0.0174 μbar, and its limit of detection was found to be 5 g/L with a quadrupole mass spectrometer. Calibration is usually by adding a known amount of compound to the fermenter before inoculation, and measuring concentrations off-line from liquid samples by HPLC (high performance liquid chromatography) or GC. Most volatiles require an SEM for accurate detection as volatiles are in the ppm level in the headspace (22,27).

74.4.3 Growth Kinetics

The yield of biomass from oxygen consumed Y_{x/O_2}, from carbon dioxide evolution, Y_{x/CO_2} and the specific growth rate (51,52) can be simply determined using vent gas analysis:

$$Y_{x/O_2} = \frac{d(TOC)/dt}{dx/dt} \qquad (74.15)$$

$$X = Y_{x/O_2}(TOC) \qquad (74.16)$$

where *TOC* is the total oxygen consumed estimated from the summation of the *OUR* versus time, *X* the biomass concentration from oxygen. Linear regression from a curve of biomass concentration (determined off-line) versus *TOC* and total carbon dioxide evolution (TCE) can then lead to the respective yield factors for biomass from oxygen and carbon dioxide. The specific growth rate can be determined by:

$$\mu = \frac{d(TOC)/dt}{TOC} = \frac{OUR}{TOC} \qquad (74.17)$$

where the Y_{x/O_2} is assumed to be constant. Good agreement can be made between specific growth rates as calculated on line using *TOC* data and off line data from experimental dry cell weight (53). This provides a useful on-line tool for analyzing growth rate during process and development. The control of specific growth is important for the synthesis of secondary metabolites such as avermectin by *Streptomyces avermitilis* (53) (Fig. 74.10). The impact of a decrease of temperature by a few degrees at 12 h into the fermentation clearly showed a dramatic decrease in specific growth rate when compared to the control, as measured by the on-line method.

74.4.4 Mass Balancing and RQ

Vent gas analysis can be used to describe the substrate utilization and production kinetics of a fermentation via mass balancing (2,33). A typical fermentation could involve:

$$CH_{h_S}N_{n_S}O_{o_S} + aNH_3 + bO_2 \rightarrow Y_{X/S}CH_{h_X}N_{n_X}O_{o_X} + Y_{P/S}CH_{h_P}N_{n_P}O_{o_P} + cCO_2 + dH_2O$$

where biomass $CH_{h_X}N_{n_X}O_{o_X}$ and product $CH_{h_P}N_{n_P}O_{o_P}$ are formed from substrate $CH_{h_S}N_{n_S}O_{o_S}$. The coefficients a, b, c, and d can be solved from elemental balances for carbon, hydrogen, nitrogen, and oxygen. Coefficients for oxygen and carbon dioxide are $b = (\gamma_s' - Y_{X/S}\,\gamma_x' - Y_{P/S}\,\gamma_p')/4$ and $c = 1 - Y_{X/S} - Y_{P/S}$, where $\gamma_i' = 4 + h_i - 3n_i - 2o_i$ is the so-called generalized degree of reduction for compound $CH_{h_i}N_{n_i}O_{o_i}$. The value of γ for biomass is consistently about 4.2, and the values for some common

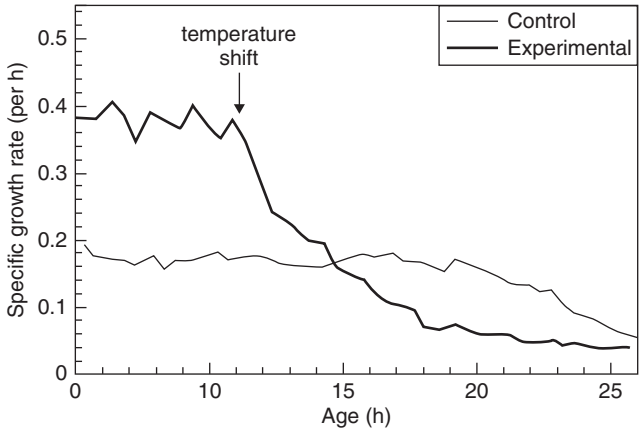

Figure 74.10. Impact of temperature shift on estimated specific growth rate (on-line) of *Streptomyces avermitilis* at 800 L (52).

substrates and products can be found in the literature (8). An expression can then derived for the RQ, the ratio between the rates of CO_2 evolution and oxygen utilization, as $\mathrm{RQ} = 4(1 - Y_{X/S} - Y_{P/S})/(\gamma'_s - Y_{X/S}\,\gamma'_x - Y_{P/S}\,\gamma'_p)$. Thus for a given fermentation the RQ, defined from vent gas analysis, CER/OUR, can be used along with off-line analysis of biomass, carbon, nitrogen, and production concentrations to define the yield coefficients for substrate and product (31). It is recommended that elemental balancing use high precision gas analysis with 0.01% accuracy, because a 1% error relative offset calibration error for oxygen can result in an error for product estimation of >50% (2).

Vent gas analysis is a valuable tool for studying process kinetics and metabolism. For recombinant protein expression it is common to limit feed rates to control the growth, preventing formation of overflow metabolites such as acetate, which are often inhibitory to growth and protein expression. During a yeast fermentation the OUR, CER and RQ can be seen responding to adjustments of the nutrient feed rate (Fig. 74.11). The rapid growth rate on the initial nutrient charge (batch phase) is seen on the off gas profiles. When the initial charge is depleted and after a transition phase, a nutrient feed is started. The rapid response to the feed rate adjustments is easily observed by the vent gas profile. The change in RQ indicates the switch to a different carbon source. After the adjustments, the second feed rate is increased exponentially and finally, kept at a constant rate to control the growth of the culture.

The scale-up of fermentations requires a good understanding of the impact of the chemical and physical environment on cell physiology. This is often hindered when little is known about the new organisms. For instance, the production of pneumocandin B_0 from the filamentous fungus *Glarea lozoyensis* was impacted by a range of unwanted pneumocandin analogs (54). Dissolved oxygen was suspected to affect the levels of these unwanted analogs but it is historically difficult to separate this from the effects of operating conditions such as agitation, or a changing microbial morphology. Gas blending experiments were designed to separate the effects of dissolved oxygen from agitation (55). Vent gas analysis was a key element of this experimental gas-blending design. In separate reactors, ranges of dissolved oxygen levels were controlled

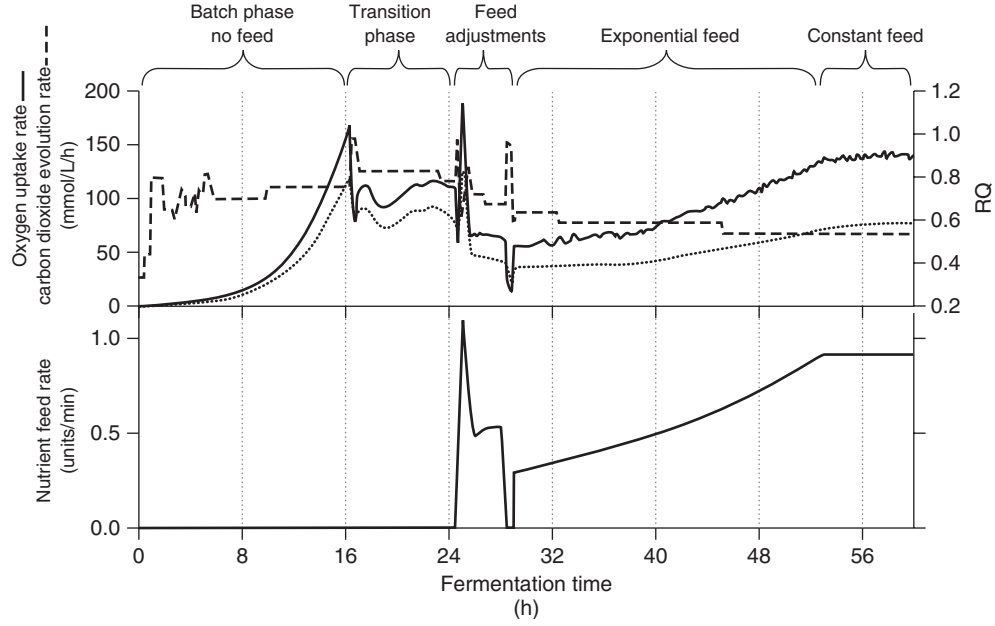

Figure 74.11. Comparison of vent gas analysis to off-line substrate data for a fungal fermentation at 1600 L.

at single setup points for the duration of the fermentation, using a combination of nitrogen and oxygen sparges into the fermentation inlet air. The control of the inlet gas composition was done from a combination of dissolved oxygen (DO) and the vent gas analysis. The experiment determined a relationship of pneumocandin analog formation with DO, and defined an operating range of DO to maintain the unwanted analogs at acceptable levels (54,55). Another example is from whole cell biocatalysis for the bioreduction of a pharmaceutically important unsaturated ketone (56). Yeast cells were exposed to the substrate in the presence of excess nutrients. During the rapid reaction there was a dramatic reduction in the OUR. This indicated a possible toxic effect of the substrate which was later confirmed with viable cell studies. This information led to process designs to minimize the effect of the toxic substrate, maximize conditions to maintain the OUR, and extend the duration of viable cells.

It is not possible to outline examples for all the applications of vent gas analysis. However, it is clear that the technology has provided tremendous value to all areas of fermentation including continuous culture (57), high cell density fermentation (58), the formation of metabolic models for metabolic and pathway engineering (59), systems biology models (60,61), and to even cell culture (62).

ANTIBODY MANUFACTURE, DISPOSABLE SYSTEMS

Regine Eibl and Dieter Eibl
Zurich University of Applied Sciences, School of Life Sciences and Facility Management, Institute of Biotechnology, Wädenswil, Switzerland

75.1 INTRODUCTION

Monoclonal antibodies (MAbs) are considered to be a mainstream class of biopharmaceuticals and the most rapidly growing segment among modern life science products (1). The market launch of such potent products (for example, MabThera, Avastin, Herceptin, Erbitux, Remicade, and Synagis) has greatly revolutionized therapies for several types of cancer and immune disorders. Whereas hybridomas and murine lymphoid cells were the biocatalysts of choice in the early days of biotechnological MAb productions, more robust production vehicles [e.g. transfected Chinese hamster ovary (CHO) cells and human embryonic retinal (PERC.6) cells] have become established and widely used over the last 10 years (2). By increasing the availability of high-productivity cell lines and optimal culture media that are serum-free, protein-free or even chemically defined, cell productivity has moved from tens of milligrams per liter to a double-digit gram level (3–6).

This success has contributed to a rise in antibody therapeutics, which is predicted to continue. Total sales of MAbs are projected to reach $30 billion by 2010 (2). In order to respond to the needs of international markets, developers, biopharmaceutical manufacturers, and contract manufacturing organizations (CMOs) have striven for faster design, construction, and commissioning, and more efficient operation of MAb production facilities while improving process economy. Hybrid facilities in which disposable components are implemented have been identified as a sound way of achieving these aims. Devices that are typically accepted in disposable format are flexible tubing, connectors, sterile liquid containment bags, mixing systems, bioprocess containers for solution preparation and storage, single-use filters, chromatography equipment, sampling and transfer systems, pumps, centrifuges, and bioreactors (sensors included).

As the term *disposable* or *single-use* implies, the components used are nonreusable. They are mainly composed of Food and Drug Administration-approved plastics such as polyethylene, polystyrene, polytetrafluorethylene, polypropylene, or ethyl vinyl acetate (7). In contrast to their counterparts made of stainless steel, which always need to be steam sterilized (autoclaving or sterilization in place, SIP) by the applier prior to use, the majority of disposable components are gamma irradiated (dose levels between 25 and 50 kGy) by the manufacturer and can therefore be quickly put into operation (8,9). After process operations have finished, the disposables are decontaminated and discarded. Thus, time-consuming, expensive cleaning procedures are reduced and sterilization procedures are no longer required. Higher flexibility (easier process and product change) as well as reduced microbial and cross-contaminations are further benefits of disposables, along with additional time and cost savings (e.g. development time, setup time, time to market, production turnaround time, costs related to capital investment, and cost of goods) (10–12).

Limitations arise from short-term experience of using them, their material strength (chemical and physical compatibility, breakage), and their scalability. However, the most frequently discussed aspect of disposables is

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

the way they react and leach undesirable substances (leachables and extractables), which can interact with the product (13–16). Another critical factor which should be considered is the continual renewal of the disposable component, which increases the cost of solid waste disposal and consumables, and ultimately, running costs. In addition, high-level automation solutions are precluded. A further limiting issue is the restricted availability of disposable sensors (17) and some peripheral elements such as valves, connectors, and fittings. Finally, extra training for staff is required as the capacity of a manufacturing facility increases.

Starting with a general overview of single-use devices in antibody production processes, this chapter focuses on disposable bioreactors dominating the market. In MAb upstream processing, disposable bioreactors have become well established at the preclinical, clinical, and production scales during recent years (18). Interestingly, of all the disposable devices available, disposable bioreactors achieved the highest growth rate in 2008 (19). We present frequently used disposable bioreactor types, their characteristics and obtainable results, and suggest general trends for disposables in antibody manufacture.

75.2 SINGLE-USE DEVICES IN ANTIBODY PRODUCTION PROCESSES: AN OVERVIEW

An antibody production process has three main process stages: upstreaming, downstreaming, and the final formulation and filling. In the upstream stage, the culture medium is prepared (mixing, sterilization, storage), and the seed and inoculum train of the cells is produced. Cells and medium are introduced to a production bioreactor or fermentor in which the target molecule is generated. It is contained in the culture broth, separated from cells and clarified using centrifugation, depth filtration (lenticular filtration), and/or cross-flow filtration (microfiltration) (20). In the following downstream procedures, the isolated target molecule is subjected to a series of further separation, purification, and concentration steps in order to produce a purified antibody with high quality and quantity (21–24). These steps include chromatography processes (e.g. ion exchange membrane chromatography, gel filtration chromatography, affinity chromatography, hydrophobic interaction chromatography, and immobilized metal affinity chromatography) and cross-flow filtrations (ultrafiltration, UF or diafiltration, DF). In addition, intermediate liquid storage and buffer preparation are performed during downstream processing. Finally, the purified antibody is formulated by adding stabilizers to the liquid solution, then sterilized by filtration and/or aseptically poured into sterile containers.

All of the previously delineated main processing steps for MAb production have to date, become partly disposable. However, an MAb facility operating exclusively with disposables is not realistic in the near future. While in media preparation and its storage, cell cultivation steps, product hold, transfer and product storage, disposables are fully established up to commercial biomanufacturing at middle-volume scales; the application of disposables is less common in polishing, filtration, and mixing steps (24,25). Moreover, protein A affinity steps (frequently employed as a capture step to meet the purity, yield, and throughput requirements for antibody purification) are reusable (5,25), a fact which is not expected to change soon. As depicted in Fig. 75.1, the disposable systems available can be divided into three categories, namely expendable laboratory items (protective clothing, syringes, pipettes, vent and liquid filters, etc.); simple peripheral elements (stand-alone components) for single-use; and disposable multicomponent systems for unit operations (26,27).

Flexible tubing, fittings, valves, tri-clamps, protective caps, and aseptic transfer systems are typical disposable products in the category of peripheral elements. In addition, numerous types of disposable connectors (which differ in quality) are sold by various suppliers (e.g. Sartorius Stedim Biotech, Millipore, GE Healthcare, Colder, Pall). The customer can choose from laminar flow connectors (connection under laminar flow conditions), steam-in-place connectors (*in situ* sterilized), and aseptic connectors (connection in an unclassified environment). Instead of sterile coupling with a connector type listed above, fully automated heat weld tubing devices can be used without laminar flow. For thermal production of permanent and consistent leak-free seals on thermoplastic tubing, transportable disconnection devices are applicable. Dispensing and sampling bag manifold systems are further important peripheral elements with disposable design. Their main advantage is the significant reduction in the number of manipulations in the process. For example, dispensing manifolds allow a volume of liquid made up for a given batch to be dispensed into several bags of smaller volume. These bags are then stored and used according to process needs. Sampling manifolds permit multiple sampling for quality control purposes over a defined period of time. Simple liquid containment bags have also been considered as peripheral elements. To date, the volume of the bags ranges from a few millilitres up to 3000 L (7). However, when powdered culture medium is to be transferred, special bags should be used.

A basic requirement for a fully disposable design of unit operations and main process stages was the engineering of further disposable equipment for transport, storage, and heating as well as cooling, mixing, downstreaming, cell production, and protein expression. For this reason, bioprocess container systems (BPCS) have been in use

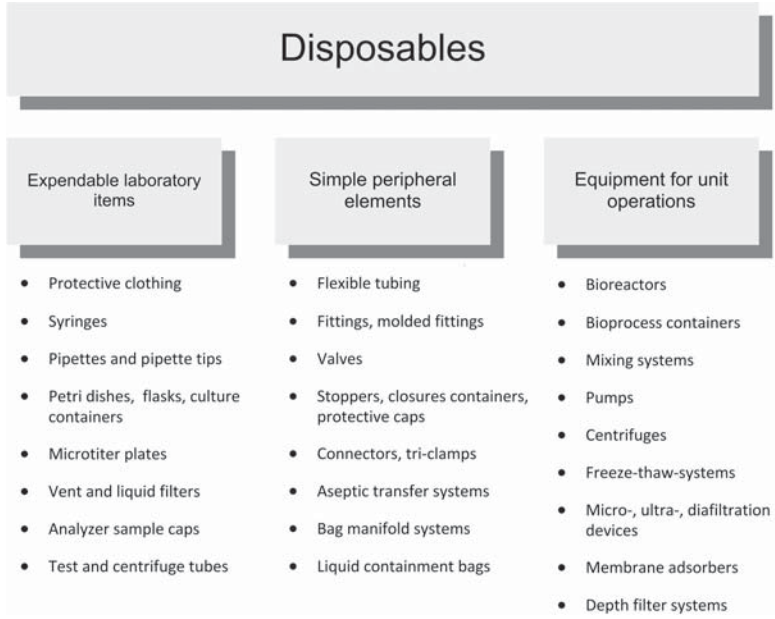

Figure 75.1. Categorization and overview of main disposables used in antibody manufacture.

for more than 10 years (5,7). Nowadays they consist of a flexible two- or three- dimensional bag and a pallet tank, and may also be equipped with cooling and mixing devices. The user can choose between more than 10 disposable mixing systems (27). The majority operate with a rotating or tumbling stirrer integrated into the bag, exceptions being the Wave Mixer (GE Healthcare), the BayShake (Bayer Technologies), the FlexMixer (GE Healthcare), and the VibroMixer (Meissner). Mixing in the Wave Mixer (Fig. 75.2a) is achieved by horizontal oscillation of the bag and in the BayShake (Fig. 75.2b) by the bag's vertical oscillation. In contrast, mixing in the FlexMixer (Fig. 75.2c) is accomplished by up and down movement of an integral perforated diaphragm in the bellow-like bag. In the VibroMixer (Fig. 75.2d), the movement of a conically perforated disk (which is fixed on a vertically oscillating hollow shaft) induces mixing. It is generally assumed that disposable mixing systems will become increasingly accepted and scaled up to 10,000 L.

New to the disposable equipment portfolio are disposable pumps and freeze–thaw systems with a maximum volume of around 16 L and maximum freezing temperatures of -60°C (5,28). This also applies to disposable centrifuges and UF or DF devices. However, disposable membrane absorbers (which remove high molecular weight contaminants such as DNA and viruses by flow-through anion exchange chromatography) and disposable depth filter systems are better known and commonly used up to the production scale (5,24,25). Finally, disposable bioreactors with a flexible or rigid plastic cultivation container have become increasingly influential in MAb productions during the last 10 years (26), even though non- or less-instrumented, small-scale membrane bioreactor systems were already described in the 1980s (29).

75.3 DISPOSABLE BIOREACTORS IN MAb PRODUCTION PROCESSES

75.3.1 Membrane Bioreactors

The introduction of hollow fiber technology by Knazek and his team (30) resulted in the development of hydraulically driven hollow fiber bioreactor systems (HFBS), as shown in Fig. 75.3a. In the 1980s and 1990s, they were favored for continuous *in vitro* productions of hybridoma-derived MAbs at low volume scale (29–31). This is explained by the high cell density levels provided (10^7–10^9 cells/mL) and high concentrations of MAbs (100 mg to several grams), which both arise from the perfusion mode in HFBSs.

Thousands of semipermeable hollow fibers that have been embedded in the cylindrical production cartridge allow adherent or suspension cells to grow on their outside. This is known as the *extracapillary space* and is where high molecular weight secreted proteins (such as antibodies) are also retained. At the fiber's molecular weight cutoff (MWCO), which is considerably less than the molecular weight of the target molecule, the passage of macromolecules through the fiber wall is affected as the oxygen-enriched culture medium flows through the fibers

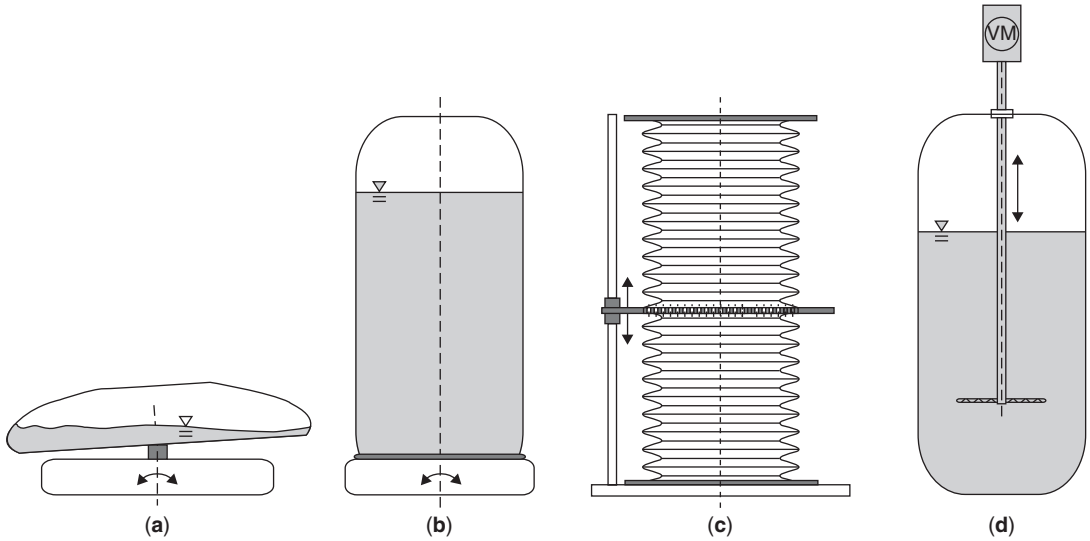

Figure 75.2. Working principles of nonstirred disposable mixing systems: (a) Wave Mixer, (b) BayShake, (c) FlexMixer, and (d) VibroMixer.

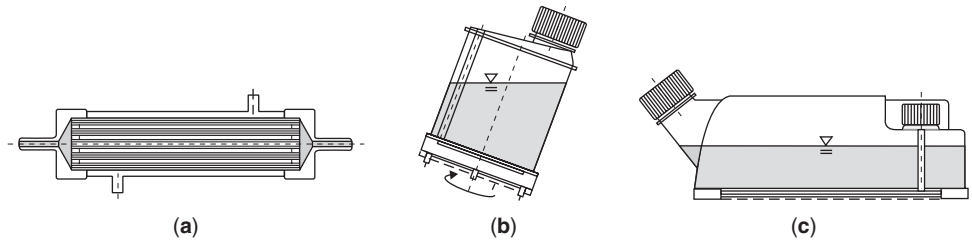

Figure 75.3. Schematic diagrams of different types of membrane bioreactors: (a) HFBS, (b) rotating two-compartment dialysis bioreactor, (c) T-flask-based two-compartment dialysis bioreactor.

(intracapillary space). However, due to restrictions (32) pertaining to the homogeneity of the culture environment and scale-up (one production module is limited to 110 mL with a maximum of 20 multiple modules), HFBSs play a subordinate role among disposable bioreactors in MAb production processes today. Nevertheless, they are still in use in R&D and the manufacturing of diagnostic antibodies (e.g. ProstaScint) required in small amounts of between 1 and 2 kg per year (33–35).

In the late 1990s, a rotating and a static two-compartment dialysis membrane bioreactor entered the cell culture labs: the roller bottle-like MiniPerm (Fig. 75.3b) and the T-flask-based CELLine (Fig. 75.3c). As in the case of HFBSs, a semipermeable membrane separates the cells from the medium and permits quasi-perfusion mode. Unlike HFBSs, they should be kept in a CO_2 incubator in order to ensure an optimum growth and production environment. A silicone membrane on the outside of both the CeLLine and the MiniPerm guarantees efficient gas transfer for culture volumes ranging from 5 to 35 mL and supports high cell density growth ($>1 \times 10^7$ cells/mL) as well as antibody production, generally in double-digit milligram range (36–39). As handling of the MiniPerm is more laborious, CeLLine systems are more popular in preclinical and clinical sample productions of MAbs at the milliliter scale (39–41). It therefore comes as no surprise that current efforts are aimed at further development of CeLLine systems with, for example, the installation of disposable sensors.

75.3.2 Wave-Mixed Bag Bioreactors

In 1998, the first version of a disposable wave-mixed bag bioreactor, the Wave Bioreactor System 20, was launched. By rocking its platform, a wave is induced in the fixed bag which contains culture medium and cells. In this way, mixing is enabled and bubble-free surface aeration takes place. Mass and energy transfer, which both have an influence on cell growth and product formation in this bioreactor system, are highly

dependent on wave development and propagation (42). These features can be adjusted via rocking angle, rocking rate, and filling level. Initially, many cell culture specialists were skeptical about this new mixing method, that is, the wave-induced motion (WIM), and the suitability of the originally less-instrumented plastic bag for cell and protein productions. However, promising results from early engineering and biological studies have demonstrated the potential of the Wave Bioreactor System 20 in animal and human cell-based processes as well as further possible uses (42,43). In comparison to reusable stirred bioreactors (the gold standard in cell cultivation processes), similar or higher cell densities and product titers have been achieved, which has lead to the scaling-up of the Wave Bioreactor System 20. In 2000 the first Good Manufacturing Practice (GMP) version of a wave-mixed bag bioreactor (100 L maximum culture volume) came onto the market. An improved system (resonance operation) with 500 L culture volume was patented in 2004 (44). This patent resulted in the Wave Bioreactor System 500/1000 from GE Healthcare which has till date, the largest bag size (500 L maximum culture volume) per rocker platform among wave-mixed bag bioreactors.

The first generation of wave-mixed bag bioreactors was mainly used for MAb productions with stably transfected and transient mammalian cell lines cultivated in batch, fed-batch, and perfusion modes (45–49). Internal perfusion up to 100 L culture volume can now be provided by perfusion bags with a floating or bottom-side fixed membrane in combination with a weight-based or volume flow rate–perfusion controller which balances culture medium renewal with the harvest rate. However, for culture volumes exceeding 100 L, external cell separation devices (e.g. cross-flow filtration units using hollow fiber modules, spin filters, gravity settlers, centrifuges, and hydrocyclones) should be used (50).

There is no doubt that the development of further wave-mixed bag bioreactor types such as Applikon's AppliFlex Bioreactor (51), CatchMab's Tsunami Bioreactor (52), Sartorius Stedim's BIOSTAT CultiBag RM series, and Cellution's CELL-tainer (18) can be ascribed to the triumphant success of the BioWave and Wave Bioreactor. They differ from each other in their control units, number of platforms and movement, as well as in culture bag design (material, scale, dimension, kind of sensor probes). Currently, it is possible to fit their bags with standard or disposable noninvasive sensors for dissolved oxygen (DO) and for on-line measurement and control of pH (17,53). It is also worth mentioning that, in only one decade, disposable wave-mixed bag bioreactors have secured a solid position in mammalian cell-based process developments and in small and middle scale manufacture of recombinant proteins and antibodies.

75.3.3 Stirred Bioreactors

In 2006, Hyclone and Xcellerec produced the first stirred bag bioreactors, which have a customized steel support container in order to assure the bag's cylindrical shape. A sparger, an excentrically mounted axial flow impeller, gas filters, and ports for the integration of sensor probes and line sets are included in the temperature-controlled cultivation bag. Currently, SUBs (single-use bioreactors) from ThermoFisher Scientific (which have been developed for antibody production processes at Baxter in cooperation with Hyclone) hold market-leading positions among stirred disposable systems. The 50, 100, 250, and 1000 L versions of the SUB are top-driven and have mechanical seals. Similarities in their engineering parameters, product quantities (middle to high cell densities, antibody titers in *g*-range) and product quality with stirred cell culture bioreactors made of stainless steel have been reported for CHO and PERC.6 cultivations (18). Cell growth and protein titers comparable to those in reusable cell culture bioreactors have also been found in disposable stirred tank bioreactor (XDR) SUBs from Xcellerex (54). XDR systems have bottom-driven magnetic impellers and can be operated with the largest culture bags available until now (2000 L).

A cubical bag shape and a tumbling impeller (based on the Pad-Drive Mixing System) are features of ATMI Life Science's Nucleo Bioreactors (Fig. 75.4a), which can be obtained up to 1000 L scale. Results of fed-batch and continuous cultivations with different kinds of mammalian cells were acceptable and reproducible (55). The BIOSTAT Cultibag STR series (Sartorius Stedim), available as 50, 200 (Fig. 75.4b), and 1000 L systems, comes as close as possible to the classical configuration of a reusable stirred cell culture bioreactor (56,57). Here a height/diameter ratio of 2:1 (typical for animal cell performances) can be realized. For aeration, it is possible to implement microspargers and ring spargers, the most frequently applied aeration devices for mammalian cells. Aeration and mixing is provided by centrically positioned three-blade segment impellers as well as by six-blade disk impellers.

All these stirred bag bioreactors have mainly been implemented in the labs and production facilities of process developers and CMOs, whose products are MAbs in the first instance. They have been primarily equipped with standard sensors for the measurement of temperature, DO, and pH. Meanwhile, single-use sensors have also come onto the market. At the same time as stirred bag bioreactors were gaining a foothold, noninstrumented disposable spinner flasks from different suppliers as well as Sartorius Stedim's SuperSpinner D 1000 became more and more popular for cell expansions. The SuperSpinner enables higher cell densities due to membrane aeration (58,59).

Figure 75.4. Product pictures of different types of fully controlled stirred bioreactors with disposable cultivation unit: (a) Nucleo-1000, (b) BIOSTAT CultiBag STR 200, (c) Mobius CellReady 3 L Bioreactor (with kind permission of ATMI Life Sciences, Sartorius Stedim, and Millipore).

The gap in the lower L-range for fully instrumented disposable stirred bioreactors was bridged with the introduction of the 3 L Mobius CellReady Bioreactor (Fig. 75.4c) in summer 2009 (60). This disposable bioreactor, developed by Millipore and Applikon, has a rigid plastic cultivation vessel. Measurement and control of key process parameters are feasible with standard sensors.

75.3.4 Orbitally Shaken and Pneumatically Driven Bioreactors

The finding that mammalian cells are not as sensitive to shear stress as originally presumed has resulted in increasing usage of surface aerated, orbitally shaken containers for process developments. Shaken multiwell plates and classical "Erlenmeyer" flasks have become the workhorses for high-throughput screening experiments at microliter- and milliliter scales (61). Fortunately, advanced adaptations (e.g. μ24 Microbioreactor from Applikon, the BioLector from mp2-labs, and Sartorius Stedim's Sensolux) have recently become available. These downscale systems are stand-alone versions enabling on-line measurement of pH and DO with disposable sensors during cultivation (62).

Following the discovery of Wurm and his team that mammalian cells are non-oxygen limited when grown in noninstrumented 50 mL centrifuge tubes with ventilated caps (the TubeSpin cultivation vessels), a new wave in orbital shaking began. These tubes (commercially available under the trade name CultiFlask 50 disposable bioreactors, distributor Sartorius Stedim) have to be vertically mounted on the platform of a shaker incubator. At agitation speeds between 180 and 220 rpm (25 mm displacement radius) and culture volumes between 20 and 40 mL, their volumetric oxygen mass transfer coefficients range between 5 and 30 h^{-1} (63). Consequently, the comparability of the high cell densities achieved ($>10^7$ cells/mL) for transfected CHO cells (64,65) and further cell lines (66) to the values of nondisposable stirred and disposable wave-mixed bioreactors comes as no surprise to experienced cell culture technologists. Owing to the ample oxygen supply and low mechanical stress, the feasibility of scaling-up orbital shaking technology (OrbShake technology) for mammalian cells up to 1000 L culture volume was demonstrated by Zhang *et al*. (63). This culminated in the design of the recently presented SB200-X Disposable Shaken Bioreactor System (see also http://www.shakingtechnology.com), which was developed in cooperation with ExcellGene, Adolf Kühner, and Sartorius Stedim (67). AmProtein's Current Bioreactor line (ranging from 20 mL to 300 L) is based on a similar approach (68,69).

Promising results have also been reported on cultivations in a novel, pneumatically driven bag bioreactor and in a hybrid system, both of which have special bag shapes deviating from the common cylindrical and cubical bags. In the pneumatic bioreactor system (PBS) there is an air-wheel design and a dual sparger system to facilitate mixing and aeration. At 2, 10, 50, and 250 L scales, high cell density growth (comparable to that in conventional stirred cell culture bioreactors) is guaranteed for a CHO cell line (Brian Lee, PBS, personal communication). In the case of the hybrid CellMaker Plus (18,70), mixing and aeration is achieved by using the air flow from a sparger tube and two magnetic impellers. The aeration is realized in the slim part of the bag, which is the lower area. As the air bubbles rise, "riser" flow is generated

and intensified by the impellers. The result is a transverse liquid movement which provides satisfactory mixing of aerated medium and cells. To minimize or even eliminate excessive foam formation (which is a well-known problem in pneumatically driven bubble columns), pressure to the headspace may be applied. Again, these bioreactors allow appropriate sensors to be implemented.

75.4 CONCLUSIONS AND APPARENT TRENDS

This chapter shows the wide variety of disposables that are employed in all process stages in the development and manufacture of MAbs. In addition to BPCs for buffers, media and bulk products, filtration and chromatography equipment, and mixing systems, disposable bioreactors are being increasingly used. They are implemented as both seed and production bioreactors, and are mainly stirred or wave-mixed. Driven by the successful scale-up of orbital shaking and the availability of the first suitable single-use shaking bioreactors, it is expected that this technology will have greater influence in the future. Provided that desired cell densities, product titers, and qualities are achieved while guaranteeing high process safety and cost savings, radical new concepts for disposable bioreactors are conceivable. Owing to strong international competition in the field of biotherapeutics and worldwide cost pressure in the healthcare sector, developers and manufacturers are increasingly willing to deviate from the "gold standard," that is, the stirring.

The development stage of disposable technology achieved, together with its connectivity, means that hybrid solutions are available for production facilities. Because of greater antibody titers, realization of fully disposable upstream processing is occasionally or even generally possible, as in the case of the manufacture of personalized and diagnostic antibodies (where only amounts in one-digit *g*-range are required). However, limitations such as the lack of technically mature in-process-control (IPC) with single-use sensors should not be overlooked. Nevertheless, pH and DO sensor technologies have proven favorable and additional sensor variations, which could potentially be utilized on obtainable controllers, are in the pipeline. At the time of writing, the lack of fully disposable facilities for MAb manufacturing at large scales can be attributed to the affinity purification step in downstream processing. Currently, there is no alternative to stainless steel (60).

Ongoing research by manufacturers of disposables focuses on the characterization of disposables and the elimination of present limitations. A promising tool for generating data on local and temporary components, temperature and velocity distributions, mixing times, shear and dissipation rates in the disposable systems investigated is computational fluid dynamics (CFD) (71–74). Successfully verified CFD data will allow the scale-up as well as comparison of different systems and support optimized bioprocessing in the long term. Further activities are aimed to make disposable systems the end user in a modular design available. By integration of gamma-sterilizable radio frequency identification (RFID) tags, rapid paperless identification of system parameters (e.g. part number, lot number, description, manufacture, and expiration dates) can be made. Furthermore, their combination with single-use sensors controlling critical process parameters appears to be feasible in the future. In conclusion, RFID-based connections may facilitate rapid setup and running of hybrid facilities as well as the realization of complete single-use manufacturing processes (5,75).

BIOREACTOR OPERATIONS

David R. Gray
Chiron Corporation, Emeryville, California

76.1 PREPARATION

Bioreactor operations may be segregated into two different areas that constitute the overall production cycle. The first area includes operations involved with the preparation of the bioreactor system before the production phase. The second area deals with the operation and control of the bioreactor when cells are present, the production phase. This section describes operations in the first of these categories, the activities of harvesting, cleaning, sterilization and instrumenting of the reactor before inoculation. These operations encompass the physical and chemical processes that govern the cleaning, sanitization of the process contacting surfaces, sterilization of equipment and media, instrumentation, aseptic addition of sterile media components, calibration of measurement devices, preinoculation preparation, system checks for sterile operation (contamination control), and some aspects of fundamental maintenance. The sequences of events that must occur in starting up a bioreactor system are shown in Figure 76.1. Following cleaning to remove residual cell product and media components from the system, the equipment is sterilized using pressurized, saturated, clean steam at temperatures that inactivate any residual live bacteria. Media components, which may be degraded by exposure to high temperature, must be sterilized by filtration followed by aseptic transfer to the reactor. All sensors and probes used in monitoring or controlling the production phase must be installed, sterilized, and calibrated.

The precise methods used in bioreactor operations are a function of the scale of the reactor and the objectives of the process. The process may be required for manufacturing, development, proof of concept, or research. The scale of operation of a bioreactor is a function of the product demand (kg/yr.), process productivity (kg/m^3), and the facility occupancy (fractional yr.). In process development, the scale of operation may be 1–10% of the putative manufacturing scale and may feature a flexible, highly instrumented reactor. Cell culture bioreactors range from 10 L for simple development scale operation, 100–500 L for pilot- scale operation, and may be as large as 10,000 L for manufacturing (1). Plant-cell culture reactors of 20,000 L and greater are used in tobacco cell suspension culture (2,3). Process economics strongly affects the choice of scale in commercial manufacturing and can dictate the use of high volume bioreactors for the industrial production of low-value market products.

Bioreactors and process vessels up to 500 L in volume can be mobile and autoclavable and are amenable to manual cleaning procedures (referred to as cleaning out of place or COP). Tanks of 1000 L and greater are normally fixed-in-place, immobile, with hard-piped systems to supply nutrients, gases, and utilities to the bioreactor skid. (Note: A skid refers to the integrated bioreactor system including the associated piping, instrumentation, and point of use utility connections). Associated process recovery equipment and utility equipment would be also fixed-in-place. Fixed piping facilities are operated without long lengths of hoses on the floor, and spills and leakage from connections are minimized or avoided. A fixed piping layout requires installation of a large number of valves and components to direct the flow of fluids. These systems require a large initial capital expense. Cleaning-in-place (CIP) procedures are required to ensure that all process components are effectively cleaned.

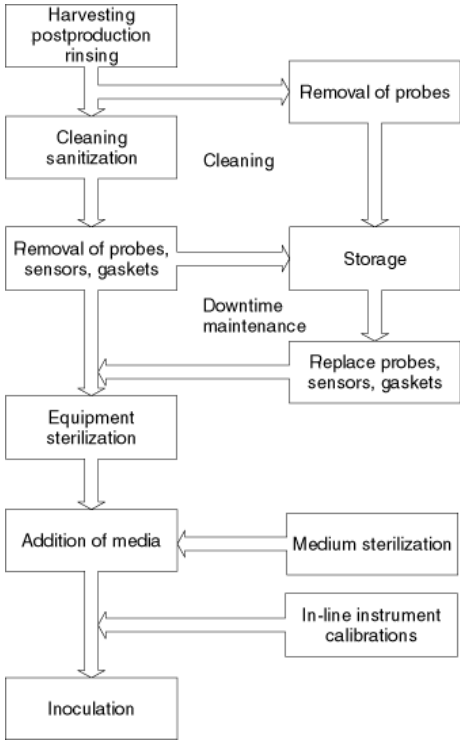

Figure 76.1. Bioreactor operations. Preparation of the bioreactor and associated skid components following the production phase through to inoculation. The sequence of activities are shown with reference to their location section numbers in this discussion of bioreactor operations.

Consistent optimal performance in bioreactor processes requires operation within narrow ranges of environmental parameters. In this respect, bioreactors are often equipped for automatic process control. Feedback control systems require output signals from the bioreactor sensors to provide information for determining controller outputs to actuate valves, pumps, and other devices remotely. Consequently, instrumentation of the bioreactor, calibration of probes, maintenance, and procedures for testing important sensors are important set-up operations. Sterilization of the equipment to provide asepsis is a key requirement. This is achieved by using pressurized (15 psig) steam at 121°C. The sterilization procedure is usually designed as an automatic process that uses sequentially programmed actuation of valves. For small and simple bioreactors, sterilization can be a manual or a semiautomatic process. Heat-sensitive media components are sterilized by submicron filtration. Sterilization of heat-sensitive plant tissue may be accomplished by chemical sterilization. Maintenance of asepsis requires careful control procedures following the SIP process, for example, good sterile (aseptic) technique, avoidance of low internal pressure relative to the environment, and the use of aseptic connections.

76.1.1 Cleaning

Cleaning is an important unit operation in the process industry. In the chemical process industries, the term cleaning refers to the removal of deposits in the form of scale or sediment following the prolonged use of such equipment. This is considered part of a scheduled maintenance program. These cleaning procedures are important in preserving and maintaining process surfaces, but may be equally important in many cases to prevent corrosion or scale buildup, which could decrease the efficiency of operation. Such cleaning may not be obligatory after every process batch and may be driven by economic factors. In the food processing industry, cleaning is absolutely required for producing clean and sterile equipment surfaces to avoid product spoilage. In the biotechnology industry, cleaning is a mandatory process which must achieve high standards of cleaning, sanitization, and reproducibility. Large-scale systems require cleaning in place (CIP) methods.

A simple cleaning procedure, after termination of a development bioreactor process, may be used when strict cleaning is not demanded. The basic procedure first involves disabling the controller alarms and information-gathering processors, such as chart recorders. Addition pumps are set to manual and output set to zero, or else switched to the off mode. The pH control is set to manual or off, and the sparger airflow rate lowered to a minimum flow to prevent debris from entering the sparger holes. The agitator should be set for general mixing during harvesting of the broth and during the rinsing and cleaning procedure. After the evacuation of the cells and product from the reactor, the inside surfaces are rinsed with DI water. After rinsing, the pH and DOT probes are removed from the vessel ports and replaced with blind plugs. The vessel is filled to operational volume with DI water, and concentrated sodium hydroxide is added to a final concentration of 0.5 N. The reactor is sanitized by using caustic for 1–4 hours at 40–60°C. During caustic cleaning, the agitator is operated at maximum rpm, and the spargers should be operated at a low airflow rate.

For small-scale vessels, the agitator motor and external disposable tubing connections would be removed. The top dish is opened and the internal surfaces rinsed with DI water. All O-rings are removed and discarded. Probes are removed and replaced with blind plugs. pH probes are placed in buffer. The empty vessel is rinsed with DI water several times through the top ports. The equipment can be washed with 7X detergent and finally rinsed with DI water. Spargers and small bore SS tubing are cleaned by circulating of 0.5 N NaOH for 30–60 minutes. After final DI water rinsing, the vessels and components are dried by using air.

Large-scale bioreactor systems are cleaned in place (CIP). In a CIP process all product-contacting surfaces are cleaned by circulating cleaning agents within the process equipment. Some of the equipment components may be

removed and cleaned out of place. This may be required for hard to clean equipment where adequate flow of CIP cleaning reagents is not possible, (e.g., internal settlers, spargers, and threaded components).

In clinical product manufacturing processes, the cleaning procedures must be validated to demonstrate their ability to remove cellular components, products, and solutes from the equipment surfaces. This becomes increasingly stringent for biotechnological manufacturing process equipment in which multiple products are produced. Absence of batch-to-batch and product-to-product carryover must be demonstrated in clinical product production. Thus CIP is also concerned with minimizing the risk of batch carryover.

The principles and standards used for cleaning and sanitization in the biotechnology and pharmaceutical industry originated in the dairy industry (4). The fundamental principles of CIP unit operation are based on the 3-A dairy standards (5). The important keys to successful CIP are given here:

- Construct equipment with cleanable smooth surfaces. In biotechnology, 316L stainless steel (SS316L) has become the standard. Seamless tubing is preferred.
- Design piping and other ancillary process equipment to ensure direct contact with the cleaning reagents. This requires excluding hard to clean valves, dead legs, and instruments from the bioreactor skid design.
- Select cleaning reagents capable of dissolving organic residues (proteins, lipids, carbohydrates).

Figure 76.2 provides a view of the important elements in CIP processes.

Typical CIP cleaning agents (shown in Table 76.1) are caustic soda (organic dissolving power and bactericidal power), sodium carbonate (limited organic dissolving power but compatible with brass), sodium metasilicate (dispersing and rinsing), trisodium phosphate (dispersing power), nonionic detergents (wetting agents, dispersing and rinsing, organic dissolving power), sodium tripolyphosphate (sequestering power), and EDTA and sodium gluconate (sequestering power and calcium dissolving power). A discussion of CIP reagents is given in Ref. 6 for the difficult cleaning challenges experienced in the brewing industry. The choice of reagent depends on the nature of the process residue and soil. In biotechnology applications, circulation of sodium hydroxide (0.1 N) at 50°C is normally suitable for cleaning and may be coupled in series with a detergent (1% Triton X100 or 1% SDBS) to enhance the organic dissolving power.

76.1.1.1 CIP. CIP methods are commonplace in the food, brewing, and pharmaceutical industries. In the food industry and in particular the dairy sector, a number of guidelines were established many years ago. The foremost of these is the document entitled "3-A Accepted Practices for Permanently Installed Sanitary Products, Pipelines, and Cleaning Systems (5)," which provides a basic guide for designing process systems and cleaning procedures used to clean such equipment. Discussions of CIP relating to bioreactor skid systems have described the importance of selecting effective cleaning chemistry (7), materials of construction (8,9), and sanitary valves and components (10,11).

CIP is a process for cleaning process equipment without dismantling it. CIP is the procedure by which flushing, washing, rinsing, and sanitizing solutions are brought into immediate contact with all soiled surfaces and continuously replenished. The cleaning process is essentially chemical, and in large-scale generally requires recirculating cleaning reagents to minimize water and chemical costs. CIP is the expedient choice for large-scale processing equipment because it is a reproducible, labor-saving process that provides consistency with minimal equipment damage. CIP is achieved by contacting all process surfaces with the cleaning solution at a correct flow rate. For piping, adequate flow rate and exposure to the cleaning agent is needed. If piping of several different diameters is present in the system, the larger tubing will be the path of least resistance, and special design considerations may be required.

In designing a CIP process for cleaning cell-culture equipment, some basic guidelines can be followed. The equipment and piping should be arranged to physically circulate the liquid across product contacting surfaces at velocities that promote liquid turbulence in piping and sufficient flow across all of the internal surfaces of vessels. Suitable cleaning reagents should be chosen for effectiveness in solubilizing the components of the cell membranes and product and in eliminating any potential process solutes that may reside in equipment.

The general process equipment design requirements for efficient cleaning are as follows:

- Use 316L stainless steel for all process contacting equipment surfaces (see Table 76.2).
- The equipment should confine the cleaning solutions.
- Use seamless SS316L tubing.
- Pitch the bottoms of flat vessels not less than 1/4″ per ft from rear to front and 1/2″ per ft from side to center to provide reasonable flow for moving of suspended solids.
- Pitch flat top surfaces approximately 1/2″ per ft from center to sidewalls to encourage the continual flow of water sprayed on the surfaces toward the sidewalls.
- A minimum radius of 1″ is desirable at all tank corners, whether vertical or horizontal.
- Equip the vessel with an adequate permanent vent to protect against all changes in pressure or vacuum resulting from the heating and cooling associated with the cleaning process or design it with appropriate vacuum and pressure ratings.

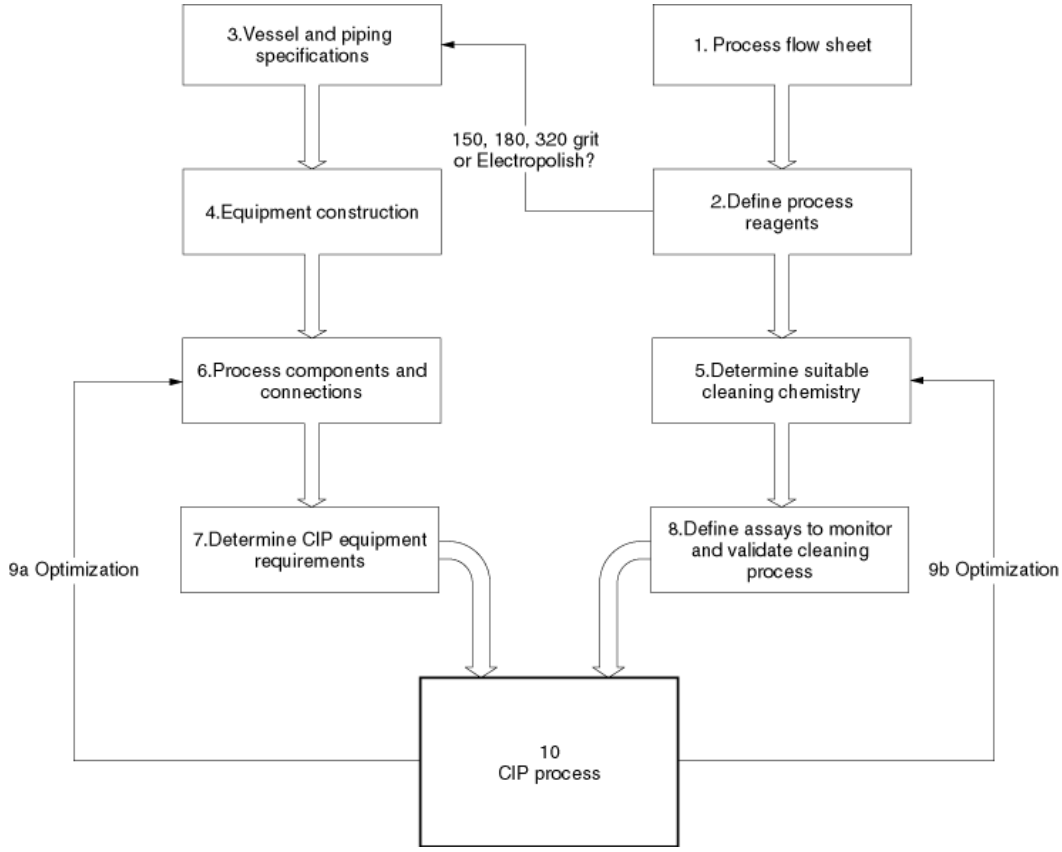

Figure 76.2. Fundamental elements for developing a CIP process for effective cleaning of bioreactor systems. The process flow sheet provides information for specifying of the process equipment and cleaning chemistry for the likely process residuals. Specification of electropolished surfaces may be based on the potential difficulty of cleaning the process, equipment. Numbers reflect the time sequence of the activities.

TABLE 76.1. Composition of CIP Reagents Used in Large-Scale Cell Culture Equipment Cleaning

Category	Compound	Comments
Prerinsing	Sodium phosphate buffer (50–100 m*M*, pH 6–8) DI water	Removal of loose protein and cellular material before cleaning
Caustic	0.1–1 N Sodium hydroxide 30–60°C	Strong organic dissolving power
Caustic detergents	0.1–1 N Sodium hydroxide+0.04% Sodium dodecyl benzene sulfonate (SDBS)	SDBS helps solubilize oil/lipid material and is easier to remove than SDS
Alkaline detergents	Trisodium phosphate and sodium hydroxide	Improved dispersion of soils; not used often in fermenters
Chlorinated caustic and alkaline detergents	Sodium hypochlorite (50–100 ppm Cl_2) with) trisodium phosphate and sodium hydroxide	Inceased cleaning and sanitization; has been used in filration membrane cleaning; requires extensive flushing with DI water to remove chlorine (can destroy oxide layer and lead to pitting)
Neutral detergents	0.1–1% Triton X-100, 0.1% Tween 80	Occasionally used as a orthogonal choice to caustic for hard to clean protein precipitates
Acids	Phosphoric acid	Used in neutralization step

TABLE 76.2. Composition of Common AISI Grades of Austenitic Stainless Steels

Grade	% Carbon by weight	% Chromium by weight	% Nickel by weight	% Titanium by weight	% Molybdenum by weight
304	0.08	18–20	8–11		
304L	0.03	18–20	8–12		
321	0.08	17–19	9–12	≥5 × Carbon	
316	0.08	16–18	10–14		2–3
316L	0.03	16–18	10–14		2–3

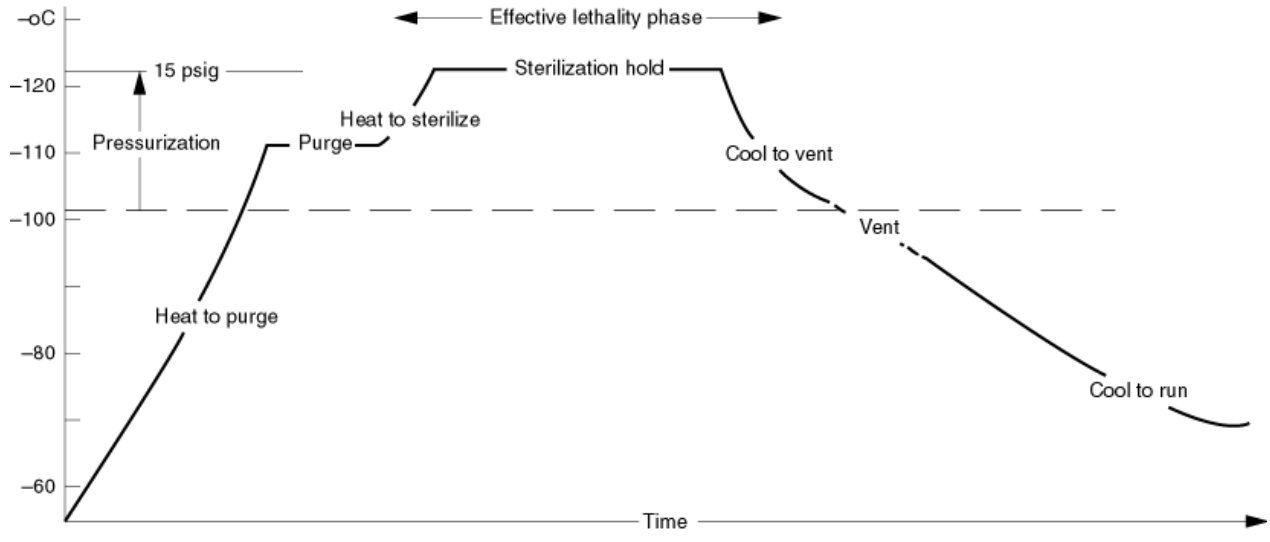

Figure 76.3. Typical sterilization temperature–time profile.

- Inert-gas fusion-welded joints are the most suitable for all permanent connections in transfer systems constructed of 316L stainless steel.
- Clamp-type joints of CIP design are acceptable for semipermanent connections. Such joints should maintain the alignment of the interconnecting fittings, have gaskets which remain flush with interior surfaces, and be designed to ensure that pressure exists on each side of the gasket to avoid product buildup that might occur in joints that are otherwise watertight.
- Pitch piping at 1/16″ to 1/8″ per ft sloping to the drain ports. The pitch must be continuous.
- Avoid dead-ends and branches in piping. Locate any required branches or tees in a horizontal position and limit them to not more than three pipe diameters long. Vertical dead-ends are undesirable because trapped air prevents cleaning solution from reaching the upper portion of the fitting.
- Use valves of diaphragm, pinch, or metal bellows sealed stem designs (12,13). Other designs such as ball valves are prone to accumulate particles and debris in the vicinity of the gasket (14).
- Construct equipment of components and materials which meet 3-A standards. Use appropriate materials such as EPDM, Teflon EPDM-backed silicone, and Teflon for gaskets.
- Polish contact surfaces to a #4 finish (RMS surface roughness factor of Ra 30–35 μinch) or better finish. This may also be specified as 150 grit (See Table 76.3) and for a Ra of 15–30 μinch 180 grit. Electropolishing, although not mandatory, may be a good choice to facilitate easy cleaning. Electropolishing involves polishing to at least a 180-grit finish followed by anodic electrochemical dissolution of vessel surface irregularities. The electropolishing process produces a smoother surface finish, reducing the surface roughness (Ra) to 0.18–0.22 μm (<10 μinch), and improves cleanability by removing pockets, that might retain solutes and microbes (15). Electropolishing passivates the stainless steel surfaces by forming a stable oxide layer that renders the surface resistant to corrosion. Chemical repassivation is necessary periodically using nitric acid or chelating solutions (16).
- For large-scale systems (>1000-L bioreactor) the CIP unit should operate reliably with minimal quantities of solutions in the total system to reduce water, chemical, and steam requirements and the cost of treating aqueous waste.

TABLE 76.3. Specified Stainless Steel Surface Finishes

Finish/Polish	Grit	Ra[a] (μinch)	AppearanceProcess Uses	Relative Cost		
No. 1 finish	80–120	40–50	Rough, dull, Imperfections	Hot rolled, annealed, and descaled	Not used in biotechnology	
No. 2D finish			Dull	Cold rolled, annealed, and descaled		
No. 2B finish			Bright gray	Cold rolled, annealed, descaled, and rolled through polish roll	A preliminary step to higher quality finishes; nonproduct contacting areas; media preparation tanks	1.00
No. 3 polish			Semipolished			1.04
No. 4 polish	150–180	15–30	Bright finish with grain marks; no surface imperfections		Standard 3-A polish Common dairy finish; bioreactors	1.05
No. 6 polish	240	10–15	Dull satin	Brushed in a medium of abrasives and oil	ms	1.07
No. 7 polish	320	<10	Highly reflective but some grit lines	Buffed, finely ground surfaces; a high-quality SS	Tissue cultures and QWFI system	1.08
No. 8 polish	320	<10	Mirror finish	Successive stage polishing with finer abrasives; extensive buffing with rouges to remove grit lines; high-quality SS	Bioreactors	
Electropolished	320	<10	Smooth, bright finish	Removal of a thin layer 0.01″ to 0.0001″ deep	WFI process equipment; bioreactors	1.10

[a]The average Ra is derived from readings taken at four cross sections approximately 90° apart. Ra readings taken across grain

The process of CIP may also be assigned some basic operational guidelines to ensure success. These are as follows:

- During CIP, the equipment remains assembled.
- Piping systems can be effectively cleaned via recirculation of flush, wash, and rinse solutions at flow rates that produce a velocity of ≥ 5 ft.s^{-1} in the largest diameter piping in a CIP circuit. A minimum Reynolds number of 10,000 leads to good radial mixing of solutes and soil, efficient heat transfer, effective mass transfer for removal of solutes, and a level of momentum that scours the equipment surfaces.
- Tanks can be effectively cleaned by distributing flush, wash and rinse solutions on the upper surfaces at pumping rates equivalent to 2.0–2.5 gpm/ft^2 of circumference for vertical vessels or at 0.2–0.3 gpm ft^2 of internal surface for horizontal and rectangular tanks.
- Use of one or more spray balls inside vessels, to distribute the cleaning fluids evenly across all the inside surfaces of the vessel and to avoid producing a "bathtub ring" that results from simply filling and draining a vessel.
- Use multiple spray balls in tanks that contain baffles and other internals that may interfere with the CIP fluid flow.

The essential cleaning problem is typical for all vessels. Vertical sight glasses, side ports for pH, dO_2 and temperature probes are present in the vessel sidewalls and present horizontal ledges. Inlet ports exist above the liquid level for acid, alkali, and antifoam addition, that may be vulnerable to aerosol deposition and drying. Spargers for efficient oxygenation and CO_2 and ammonia addition must be CIP cleanable. Agitators are top or bottom entry designs

requiring seals at the point of vessel entry. Magnetic drive agitators with simple internal ceramic seals can be used for mixing in small-scale suspension bioreactors. These mixers should be removed periodically to check and renew worn seal surfaces. Additional bearings within the vessel zone are needed for large-scale reactors with long agitator shafts. Foam at the liquid surface as a result of bubble aeration may lead to a dry biomass ring on the vessel surface. Pressure vessels are designed to operate at a maximum of 40–45 psig (150–180°C) and are equipped with pressure rupture disks. These disks may be in a remote location inside a nozzle outlet and require periodic maintenance and cleaning if foaming occurs. The vessel top-dish may also contain entry ports for sensors such as foam probes and pressure sensors, which will be fouled by foam and aerosol-entrained debris. Such problems may require spray-ball installations to access such locations with CIP reagents.

The degree of difficulty of cleaning is a function of the quality of the equipment surfaces, sanitary design, and the type of organism or biological material that causes the soiling. A mycelial polysaccharide-type soil will be harder to clean than a yeast or bacterial soil. Caustic, detergent, and water (Reverse Osmosis (RO water), Water For Injection (WFI)) rinses are generally suitable reagents for cleaning in cell culture reactors. Occasional nitric acid rinses for repassivation are performed. Rinsing of hydroxide can be monitored by pH, and rinsing of detergent can be monitored by a shake/foam test. From the standpoint of water usage, it is more efficient to use repeated low-volume rinses versus a few large-volume rinses.

Sanitary design of equipment is a fundamental requirement. The surface texture of equipment should be 180 grit or higher for vessels and 150 grit or higher for piping. In constructing the bioreactor, the surface quality should be preserved. Following mechanical polishing, the surfaces are washed and dried, oxides are removed by passivation, and surfaces maybe electropolished. Avoidance of dead legs in piping, use of high-quality welding to avoid hard to clean pits in cracks, and the use of diaphragm valves, and regular maintenance are fundamental to CIP. With electropolished vessels, CIP prevents damage to the surface that may be inflicted during COP operations. In addition to the aforementioned principle related to process equipment and CIP flow parameters, it is necessary to consider the design of the CIP recirculation equipment. The CIP systems consist of a centrifugal recirculation pump, heat exchanger, piping, and valves and tanks for storing CIP reagents. A waste collection vessel may be present for spent cleaning reagents enabling pH adjustment prior to evacuation to a sewer. In CIP systems, the multiple tank approach involves using a single tank per CIP solution. A single tank for each reagent utilizes more floor space but enables faster cleaning of many pieces of equipment. The single-tank approach, where one tank is used for all solutions, takes up less space, provides more flexibility, and will cost less but is less economical in the use of cleaning solutions (17). In medium-scale systems, it is usual to use the bioprocess tanks as CIP storage tanks. In this mode of operation, the bioreactor is rinsed and cleaned first and is then used as the CIP storage vessel for the external system cleaning. A vessel that is used for storing CIP reagent should possess a suitably sized drain port to allow an adequate flow rate from the supply tank to the inlet of the CIP pump. An NPSH calculation indicates the maximum frictional losses tolerable.

$$\mathrm{NPSH} = P_a + P_z + P_{vp} + P_f$$

where NPSH is the net positive suction head

P_a is the atmospheric pressure
P_z is the difference in vertical elevation between the supply tank liquid level and the pump inlet
P_{vp} is the vapor pressure of the liquid
P_f is the pressure drop due to frictional losses

Minimizing frictional losses by oversizing the supply tank outlet and adequately elevating of the supply tank are important. Tanks should be fitted with a vortex breaker above the tank outlet to avoid air entrainment and pump cavitation. Avoidance of cavitation and vortex formation will enable effective tank drainage and emptying. This is most important in the final water rinsing steps.

Validation of the CIP process is required in clinical product manufacturing processes but is a useful exercise in most situations. IQ and OQ Validation involves inspecting the installation of the valves and equipment to eliminate dead legs in the assemblies and to ensure that the cleaning fluid circulates at appropriate velocity of through the system. The PQ involves measuring the process residuals after cleaning. A minimum volume of sequestering solution is circulated through the equipment to contact and solubilize any residuals. The detection of residual is by a Lowry Petersen protein assay (18), which can detect ≥ 2 μg/mL protein. A total organic carbon (TOC) assay measures low quantities (0.5 ppm) of organic carbon containing residuals and has been applied in measuring residuals following CIP (19). Direct surface swabbing, in conjunction with TOC, can be used to investigate specific harder to clean surfaces such as gaskets. Acceptance criteria for process residuals depend on the potential level likely to associate with the flow of product through the process. Typically CIP should reduce the residual protein level to <100 ppm.

76.1.1.2 SIP. The steam-in-place (SIP) process has developed from the requirement to sterilize equipment that is too bulky or heavy to be moved into autoclaves or ovens. Although sterilization may be accomplished by wet heat, dry heat or chemicals, SIP has become synonymous with "sterilize-in-place." The biotechnology industry

has adopted saturated steam as the effective sterilizing agent for fixed-in-place equipment and autoclaving bioreactors and other tanks involved in parenteral filling operations (20).

Feed lines, inlet gas, exhaust lines, sensors, liquid feed filters, gas filters and vessels must be SIP compatible. A typical SIP cycle for a vessel involves several stages:

- Heat to purge (raising the temperature from ambient to ~105°C)
- Purge (eliminate air by steam at ~105°C). Air purging in SIP must be achieved by displacing the air with steam. In the air purge and initial heating stage, steam is introduced into the top of the vessel ports and the top port of the vessel heating/cooling jacket. In the example of a simple skid in Figure 76.4, the vessel drain port BRHV-1 on the base of the vessel, the steam solenoid valves SV-1 through SV-4, diaphragm valves D8, D10, D12 and D14, and exhaust line pressure regulating valve NV-1 are opened. The steam line to the vessel jacket, SV6, and the steam trap solenoid valve SV-7 are open and external steam/steam condensate heats the vessel walls and minimizes condensate buildup on the interior walls. The steam displaces the air from the vessel through the harvest drain line for several minutes, and the harvest line diaphragm valve D17 is closed to direct the steam condensate to the steam trap through the open diaphragm valve 18. If the air is not effectively removed by the air purge, the vessel will develop an air barrier, which increases the heat transfer resistance from the jacket. If this occurs, the mixture of air and steam will lower the saturation pressure of the steam resulting in a sterilization temperature below the targeted value of 121°C for a 15-psig sterilization pressure.
- Heat to sterilize (elevate temperature from 105°C to 121°C). In the heating period, the pressure in the system is allowed to approach the supply steam pressure (15 psig) by closing exit valves D14. Condensation is produced during the heating phase and is removed from the system through steam traps placed in drains, vents or the harvest line at the base of the vessel. Removal of condensate is very important because it may have the opportunity to supercool on the walls of the equipment.
- As the temperature increases, the steam flow through the system is reduced to the amount consumed by the traps and orifices plus the amount needed for heating. A manual steam pressure reduction valve (PRV-S) regulates steam pressure (18–25 psig).
- Sterilization (hold at 121°C for a designated duration of between 15 and 60 minutes). When the sterilization temperature is reached, the time and temperature are monitored. When the sterilization hold period is completed, steam valves SV1-SV-4 are closed, shutting off the steam. Vent valve NV-1 is used to reduce the system pressure after opening valve D14.
- Cool to vent (reduce temperature from 121°C to 100–105°C). After shutting off the steam supply, the pressure in the system decreases as a result of steam condensation and flow through the vessel vent filter.
- Vent sterile air (open D15) is used to displace the condensing steam vapor to avoid vacuum formation and to maintain a slight internal positive pressure to prevent possible ingress of gaskets, probe components, and nonsterile air. Allow the temperature to reach <100°C. The vessel drain valve BRHV-1 is closed, and the steam trace is initiated through solenoid valve SV-5. Residual heat in the vessel evaporates the cooling condensate as the pressure is reduced.
- Cool to run (reduce temperature to run temperature of 20–37°C, and maintain positive pressure inside the vessel).

Dead legs are most likely to be present somewhere in hard-piped systems. They may be present in tee connections for instrument housings, valves, or short pipe lengths before isolation valves. Unlike conditions in a straight pipe or a tank, air cannot be displaced by convection or a washout process. In the worst-case analysis, we assume that the air would be eliminated by diffusion from the dead leg into the main path. Orientation of the dead leg should allow condensate to drain into the sloped main path.

Autoclaves purge air through a slow vacuum cycle prior to the heating phase. Use of vacuum purging of air for large-scale process equipment is limited by the expense required to install a plant-wide vacuum system and the vacuum pressure rating of the process vessels and equipment. Bioreactors are typically built as pressure vessels rated for 3-bar internal pressure and for full internal vacuum at 150°C. In SIP, the relative positive pressure in the vessel is always maintained. In autoclaving, it is necessary to ensure that non-pressure-rated vessels are fitted with large enough vent filters to accommodate the rate of pressure change during vacuum/steam cycling and slow vent cool down.

Very few detailed engineering descriptions of the SIP process are provided in the literature. However, a singular detailed analysis has been provided by Noble (21). The following discussion of steam-sterilization design is taken from Noble's topical paper.

76.1.1.2.1 Air purging. During the purge phase, air is mixed with steam by convection and is removed as an air/steam mixture. The mixing process is poorly defined because forced circulation is not present. In practice, the

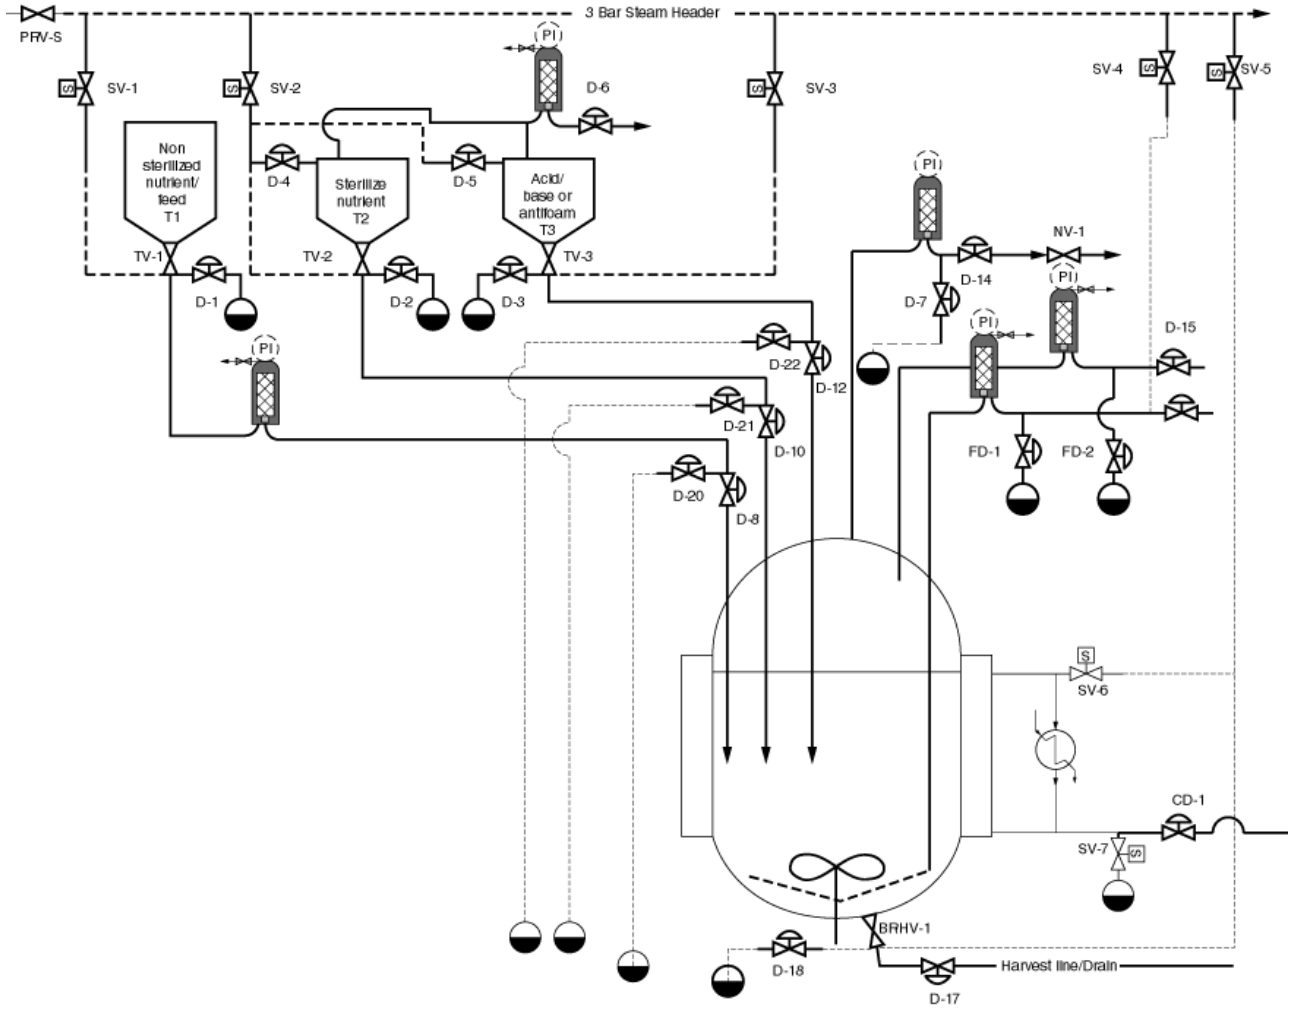

Figure 76.4. Bioreactor-skid pipe and valve arrangements. Representation of a fixed-in-place bioreactor showing interconnections with nutrient supply, inlet gases, and exhaust gas supplies. T1 piping is an example of filter sterilization of a nutrient to be fed to the bioreactor. T2 and T3 piping layouts are typical examples of direct addition of sterile components. TV-1, TV-2, and TV-3 are flush-mounted, steam-sterilizable, piston-design, tank harvest valves.

momentum of the in-flowing steam provides the mixing energy. The fastest removal of air can be anticipated when the agitation and flow approximate to an ideal Continuous Stirred Tank Reactor (CSTR). For this to occur, the mixing time (t_H) must be much less than the space-time (τ). For design purposes assume that

$$t_H = 0.1\tau \tag{76.1}$$

For a turbulent steam jet (Re_N range of 10,000–90,000), t_H can be estimated from an experimental correlation given by Henzler (22):

$$t_H = \frac{C_H d_i}{v_i} \tag{76.2}$$

where the subscript (i) refers to the diameter d and velocity v of the inflowing jet. The dimensionless mixing number C_H is (in the turbulent range) a function only of the geometry:

$$C_H = 1.1\left(\frac{D}{d_i}\right)^{2.75} \tag{76.3}$$

for $L = D$. For this geometry, the space-time is defined by

$$\tau = \frac{D^3}{(v_i)d_i^2} \tag{76.4}$$

In this case it is assumed that the steam is not condensing. In actual reality, the value is then larger because condensation

reduces the flow. Substituting these relations equation 76.6, there is no ratio of d_I/D that also ensures turbulent jet flow. The relationship in equation 76.1 is not feasible and this infers that, in practice, good mixing, provided by steam inflow, cannot be created in tanks unless special nozzle developments can improve jet-mixing performance. In reality, the mixing time is less than the space-time so that some mixing is to be expected. From a design perspective, d_i should be minimized and v_i should be maximized to reduce processing time and create a turbulent steam jet.

At maximum steam flow, the operation can be characterized by

$$\tau = \frac{4V}{\pi d_i^2(v_i)} = 0.0364\frac{V}{d_i^2} \tag{76.5}$$

and

$$w_s = \frac{\rho V}{\tau} \tag{76.6}$$

For a 1-inch steam inlet supplying a 1000 L bioreactor

$$\tau = 56.4 \text{ S}$$

and the steam flow is given as

$$w_s = 0.1213 \text{ kg} \cdot \text{s}^{-1} = 76.6 \text{ kg} \cdot \text{hr}^{-1}$$

for saturated steam at 1-bar gauge pressure.

It is recommended in practice that the air-purge step should be allowed a factor of 4 times τ.

Air is transported down to the harvest valve at the base of the vessel air and radially to the vessel wall where it may form a boundary layer. Cold air is denser than steam (ρ air is 1.225 kg m^{-3} at STP, steam 0.013 kg m^{-3} at 121°C). Trapped air may be found predominantly in the base of the vessel. This raises the importance of bottom vent purging.

In the equation of motion, the driving force for forced convection was described in Bird (23) as ∇P. The corresponding driving force for free convection is $\Delta\rho g$, which is related to the Grashof number. For the extreme combination of air at 25°C and steam at 121°C,

$$\Delta\rho g \approx 12 \text{ Nm}^3$$

whereas the average pressure gradient, assuming a 2-atm steam supply and a drain at 1 atm is

$$\nabla P \approx \frac{\Delta P}{L} \approx \frac{10^5}{5} = 2 \cdot 10^4 \text{ Nm}^3$$

Providing that the steam flow is not largely throttled during the air purge, free convection should be of minor importance, and an intact air body should not remain in the vessel. When the steam and air become mixed, a gravity-induced polarization will not be a measurable phenomenon. Gradients will be insignificant, as predicted using the relationship from Bird *et al*. (23, p. 576) employed for a similar situation.

$$\left(\frac{X_s}{X_{s0}}\right)^{\overline{V_a}}\left(\frac{X_{a0}}{X_a}\right)^{\overline{V_s}} = \exp\left[(\overline{V}_s M_a - \overline{V}_a M_s)\frac{gL}{RT}\right] \tag{76.7}$$

After mixing, the air purging will occur when steam mixes with the air and exits through both the drain and vent lines.

76.1.1.2.2 Heating. Heating the vessel space by displacing colder gas and by sending heat through the vessel wall will increase the temperature of the internal surfaces of the equipment. In this situation, heat transfer resistance becomes relevant. Insulation of vessels and pipe will reduce condensate load.

Thermal response time is estimated from

$$t_T = \frac{\Delta x^2}{2\alpha} \tag{76.8}$$

where α is the thermal diffusivity and the thermal resistance is calculated from

$$R_S = \frac{\Delta x}{k} \tag{76.9}$$

The temperature changes are very rapid in the wall and condensate film compared to the insulation. The condensate film plays a critical role, and a change in its thickness can have a large impact on the response of the system. This is a result of its relatively low thermal diffusivity.

76.1.1.2.3 Sterilization Hold. In this stage, a pseudosteady state can be assumed. Temperature is constant, and concentrations do not change significantly. Because temperature nonuniformities are minimal, normal convection will be unimportant. Transport of heat and mass will depend on diffusive driving forces.

Under these conditions the heat transport can be estimated. In a pipe it is required that the pipe wall temperature be at 121°C. For a well-insulated pipe, the heat flux becomes

$$\left(\frac{Q}{A}\right)_{INS} = \frac{(121-25)2k_{INS}}{D\ln(D + 2\Delta x_{INS}/D)} \tag{76.10}$$

Ignoring curvature, equation 76.15 gives

$$\left(\frac{Q}{A}\right)_{INS} = 344 \text{ W} \cdot \text{m}^{-2}$$

which is calculated when $\Delta x = D$ and $D = 2.54$ cm, $K_{INS} = 0.05$ W·m^{-1}·°C^{-1}, $\Delta x_{INS} = 0.0254$ m.

A correlation is available from Perry and Green (24) for convective and radiative heat transfer coefficient for noninsulated and insulated steel pipe in a room at 80°F. The result for a 1-inch diameter pipe is 16.1 W · m^{-2}·°C^{-1} which can be used to calculate Q/A below

$$\left(\frac{Q}{A}\right)_{\text{bare}} = h\delta T = 16.1(121 - 25) = 1550 \text{ W} \cdot \text{m}^{-2} \tag{76.11}$$

The fluxes correspond to the required minimum steam flow from which the expected condensate flow can be estimated. The minimum flow w_s is the entering steam flow and exiting condensate flow:

$$w_s = \left(\frac{Q}{A}\right) \cdot \frac{\pi DL}{H} \tag{76.12}$$

Laminar flow will prevail at the pipe exit. At the entrance of the pipe, turbulent flow will arise if the pipe exceeds a critical length, corresponding to a value of Re = 2000 at the entrance:

$$L_{\text{crit}} = \frac{500\mu_s H}{(Q/A)} \tag{76.13}$$

L_{crit} is in the range of 10–50 m for the heat flux determined in equation 76.10. Assuming a worst case of laminar steam flow and horizontal stratified flow of condensate, the depth of liquid (Δx_c) condensate in a round pipe is hard to calculate. Rectangular channel models have been described (25) and may provide a relevant solution, considering the low depth of condensate likely in SIP where curvature effects are not so important:

$$w_s = \frac{4a\Delta x_c^3 N}{K} \tag{76.14}$$

where a is the channel width, K is a geometric constant,

$$N = \frac{\rho^2 g(\sin\beta)}{\mu c} \tag{76.15}$$

and β is the angle between the pipe and the horizontal. For pipes with a diameter of 1 inch, a good approximation is $a = 10\Delta x_c$, and substituting equation 76.12 gives

$$\Delta x_c \propto \left[\frac{(Q/A)DL}{\sin\beta}\right]^{1/4} \tag{76.16}$$

76.1.1.2.4 Steady-State Models and Analysis. A one-dimensional model is depicted in Figure 76.5 for a region at a horizontal wall. During the sterilization hold period, the largest nonuniformities in properties would be expected in this region.

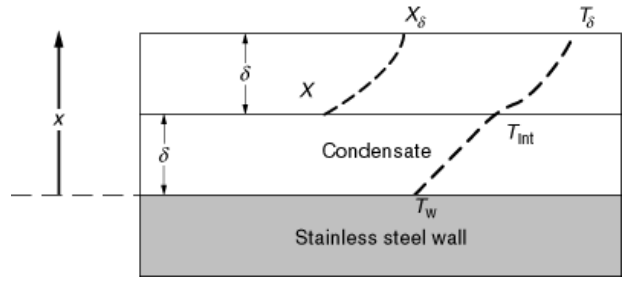

Figure 76.5. One-dimensional model of temperature profile for condensate layer at pipe wall. Adapted from Ref. 21.

Heat transfer in the condensate layer occurs only by conduction. This is described by

$$\left(\frac{Q}{A}\right) = k_c \frac{(T_{INT} - T_W)}{\delta_C} \tag{76.17}$$

Assuming that the maximum allowable temperature difference is limited to 0.5°C, a maximum condensate layer may be derived using the heat fluxes defined earlier.

$$(\delta_{C,max})_{INS} = 1.0 \cdot 10^{-3} \text{ m}$$

$$(\delta_{C,max})_{bare} = 2.2 \cdot 10^{-4} \text{ m}$$

Relating equation 76.17 to equation 76.16, a design aid for placing steam traps or orifices can be determined as

$$\Delta L = \frac{(9.28 \cdot 10^{16})k_c \sin\beta}{(Q/A)^5 D\Delta T^4} \tag{76.18}$$

Using a 1″ pipe sloped to 1/8″/ft as an example, the length at which the buildup of condensate creates a 0.5°C drop is given below:

$$(\Delta L_{max})_{INS} = 110 \text{ m}$$

and

$$(\Delta L_{max})_{bare} = 0.057 \text{ m}$$

Clearly, the result shows the importance of insulating piping. A similar result is obtained by using flow relationships for round channels instead of equation 76.12. Because liquid flow in this model is laminar, it will not thermally mix. A temperature probe in the drain will measure the mixed condensate stream. From this average temperature measurement, it will be difficult to measure the extent of subcooling. This average temperature can be computed from

$$\langle T \rangle = \frac{\int_0^{\delta_c} T v_z dx}{\int_0^{\delta_c} v_z dx} \tag{76.19}$$

In a rectangular flow model, the velocity profile is well known and is given as

$$\langle T \rangle = T_{\mathrm{INT}} - (T_{\mathrm{INT}} - T_{\mathrm{w}})/6 \tag{76.20}$$

Where the cold spot is associated with T_{w}, the equation indicates that the temperature deviations are damped severely in the resultant T.

76.1.1.2.5 Gas Phase. A model for one-dimensional condensation of vapor in the presence of a noncondensable gas is well-known and used in psychrometric calculations (see Ref. 23, example 18.5-1). The basic equations to be solved are heat transport, mass transport, air properties, (assuming ideal gas), and steam properties (obtained from curve fits to the steam tables). The sum of mole fractions is limited to one, and the pressure is constrained to be constant over the boundary layer. The heat transport equation is then given by

$$-\left(\frac{Q}{A}\right) = -k\frac{dT}{dx} + N_{\mathrm{s}}M_{\mathrm{s}}[C_{\mathrm{p}}(T - T_{\mathrm{INT}}) + H] \tag{76.21}$$

where the constant N_{s} is the molar flux of steam to the wall. The molar flux is constant in this model and is the solution for diffusion through the stagnant film:

$$N_{\mathrm{s}} = \frac{c_{\mathrm{ln}}\wp_{\mathrm{as}}}{\delta}\ln\left(\frac{1 - X_{\mathrm{s},\delta}}{1 - X_{\mathrm{s,INT}}}\right) \tag{76.22}$$

Constant concentration has been assumed and set to the log mean average. The variation in concentration is normally insignificant. There are two degrees of freedom in this model. The wall temperature can be fixed at a suitable sterilization temperature (121°C). The other variable is the amount of air in the boundary layer. A simple analytical solution may be obtained if a value of N_{s} is assumed. The value is constrained between zero and $N_{\mathrm{s,\,max}}$:

$$N_{\mathrm{s,max}} = -\frac{(Q/A)}{HM_{\mathrm{s}}} \tag{76.23}$$

which would exist when no resistance to mass transfer in the gas phase exists.

With the constant B defined as

$$B = \frac{(Q/A)}{N_{\mathrm{s}}M_{\mathrm{s}}C_{\mathrm{p}}} + \frac{H - C_{\mathrm{p}}T_{\mathrm{INT}}}{C_{\mathrm{p}}} \tag{76.24}$$

the integration of equation 76.21 can be expressed as

$$T_{\delta} = (T_{\mathrm{INT}} + B)\exp\left(\frac{N_{\mathrm{S}}M_{\mathrm{S}}C_{\mathrm{p}}\delta}{k}\right) - B \tag{76.25}$$

Given the temperatures at the boundaries, the partial pressures of steam can be evaluated from the following quadratic fit to the steam table over the range of 120–141°C:

$$P_{\mathrm{s}} = (8.91534 \cdot 10^5) - (1.76864 \cdot 10^4)T + 99.28\,T^2[P_{\mathrm{a}}] \tag{76.26}$$

The molar concentrations of steam can also be determined by a similar curve fit:

$$c_{\mathrm{x}} = \frac{0.8892}{134.829 - 1.60466\,T + 0.004999\,T^2}(\mathrm{kg \cdot mol \cdot m^{-3}}) \tag{76.27}$$

The concentration of air can be expressed from the ideal gas law, yielding the following relationship:

$$c_{\mathrm{a},\delta} = \frac{(P_{\mathrm{s,INT}} - P_{\mathrm{s},\delta}) + c_{\mathrm{a,INT}}R(T_{\mathrm{INT}} + 273.16)}{R(T_{\delta} + 273.16)} \tag{76.28}$$

Converting mole fractions to concentrations with

$$X_s = \frac{c_{\mathrm{s}}}{(c_{\mathrm{s}} + c_{\mathrm{a}})} \tag{76.29}$$

these relations can be solved simultaneously with equation 76.27 to find the concentrations at the two limits.

The total system pressure is then

$$P_{\mathrm{tot}} = P_{\mathrm{s,INT}} + 8313.7c_{\mathrm{a,INT}}(T_{\mathrm{INT}} + 272.16) \tag{76.30}$$

which is an approximate measure of the air trapped in the system. The exact fraction of the original air that is trapped can be expressed as

$$f_{\mathrm{a}} = \frac{\int_0^{\delta} c_{\mathrm{a}}dx}{\delta(P/RT)} \tag{76.31}$$

From equation 76.22, this can be derived as

$$f_{\mathrm{a}} = c_{\mathrm{a,INT}}\left[\exp\left(\frac{\delta N_{\mathrm{s}}}{c_{\mathrm{ln}}\wp_{\mathrm{as}}}\right) - 1\right] \cdot \frac{c_{\mathrm{ln}}\wp_{\mathrm{as}}}{\delta N_{\mathrm{s}}} \cdot \frac{298\,R}{1.015 \cdot 10^5} \tag{76.32}$$

Examining the equations, the solution space can be defined by two parameters δN_{s} and $(Q/A)/N_{\mathrm{s}}$. As these parameters increase, the gas-phase resistance increases. Because N_{s} is not of particular interest, the space is shown in terms of f_{a}, (Q/A), and D. Under the stated assumptions, the boundary layer thickness is related simply to D by

$$\delta = \frac{D}{2} \tag{76.33}$$

The parameters used in the analysis are shown in the list of symbols at the end of the section and reflect steam

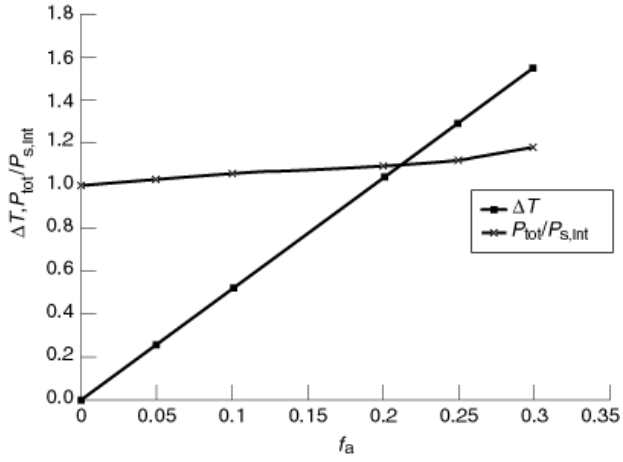

Figure 76.6. Magnitude of the gas-phase heat-transfer resistance. Conditions for pipe diameter D = 1 inch; T_{int} = 121°C; Q/A = 1550 W·m^{-2} (bare pipe). The air fraction f_a is calculated from equation 76.31. ΔT is the temperature span in the gas phase, and $P_{tot}/P_{a,\,int}$ shows the contribution of air to the total pressure. Adapted from Ref. 21.

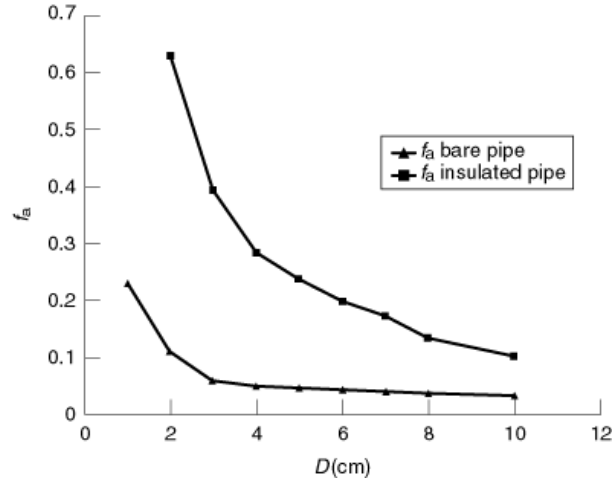

Figure 76.7. Limits of trapped air as a function of pipe diameter for a temperature drop of 0.5°C. For the gas-phase temperature span of 0.5°C, the interface temperature was fixed at 121°C. The trapped air is expressed as f_a, which is calculated from equation 76.31. Adapted from Ref. 21.

properties at 121°C. The diffusivity is estimated from a prediction developed by Slattery and Bird for low-pressure mixtures of steam and nonpolar gases, available in Bird *et al*. (23).

Figure 76.6 shows the magnitude of the gas-phase resistance. It is concluded that the amount of air trapped in a pipe would be low and $f_a < 0.1$. In Figure 76.7, it is shown that the gas-phase resistance in smaller pipes can be neglected because the air removal requirements are not large. In tanks it may be considered that gas-phase resistances may be significant, thereby resulting in nonhomogeneity of temperature. In reality, the gas layer would be close to the vertical walls. The lower temperature would be measured by an RTD thermometer at the vessel wall or else could be mapped using thermocouples attached to the vessel surfaces.

Dead legs in ports, nozzles and piping may harbor air which will cause significant gas-phase heat transfer resistance. When condensate can drain from dead legs, it can increase the mixing of steam and air through convection and aid in purging. In the worst case, dead-leg pockets will eventually reach temperature through diffusive heat transfer. Minimization of the *L*/*D* ratio at ≤6 is recommended to facilitate air purging and the ability to reach sterilization temperature in the dead-leg zone.

Use of double steam blocks on vessel inlet lines will enable sterilization through valves and longer lengths of piping.

Steam traps are important components in SIP and should be used in all low-point locations where condensate can accumulate.

In the final analysis steam-sterilization cycles are designed to provide significant overkill, providing greater than 30 logs of kill for a spore-forming organism. Through adherence to high standards for cleaning equipment, maintenance, and diligence in operation, the probability of contamination is virtually negligible. Small discrepancies in temperature (0.5°C) will have no significant effect on increasing or decreasing the very low probability that a contaminant survives the SIP process. Contamination is most frequently a result of operational errors during sampling and production. Equipment related contamination is usually through waterborne sources, for example, as a result of leaking cooling coils or faulty seals and gaskets.

76.1.2 Instrumentation

Instruments measure the parameters in the bioreactor and provide a means for adjusting the conditions. Adjustments are through manual intervention or by automated control of the bioreactor. A variety of sensors and probes are available (see Table 76.4).

Instrumentation has been an important part of bioreactor operation for over thirty years. At the start of the era, in-line instruments were confined to temperature control and simple indications of DOT and pH, enabling manual adjustments of aeration and acid/base addition. At that time, sensors were leading the control envelope. Computer-assisted bioreactor control applications emerged in the mid 1960s and then increased rapidly during the 1970s. Currently, powerful, compact computer systems provide an ideal partnership for the wide variety of the instruments that are available for use in bioreactors. The early concerns for

TABLE 76.4. Sensors and Measurement Devices

Physical Parameter	Sensor Principle	Features
Gas flowrate	Rotameter	Bouyancy position	Simple but limited use
	Mass flowmeters (Porter)	Temperature difference	Automatic, accurate, requires calibration; gas specific (C_p)
Liquid Flow Rate	Turbine, gear, and helical flowmeters (e.g., Hoffer,)	Positive displacement volume rpm	Common, simple, low–high flow rates
	Mass flowmeters (e.g., Porter)	Temperature difference	Automatic, accurate, requires calibration
	Load cells/Scales	Δ weight/time	
	Peristaltic pumps	Volume delivered/rpm	Requires calibration; tubing creep and wear can occur in prolonged use
	Platinum resistance RTD	Change in resistance with T ($^\circ$C)	Reliable linear response of resistance and temperature
	Thermocouple		
Temperature	Hg-glass thermometer	Expansion of fluid with increasing temperature	Standard for cross-checking using thermowell in vessel
	Galvanic DOT in-tank probe	Electrochemical reaction at cathode	Requires maintenance, post-SIP calibration, and checking
	In-tank probe	Change of pH in bicarbonate electrolyte (combined with pH probe)	Slow response; requires post-SIP calibration and checking
DOT (dO_2)	In-tank probe	Electrochemical	Requires pre-SIP calibration; check during run
pCO_2	In-tank probe	CO_2 diffusion and pH change in bicarbonate buffer	Calibration using known pCO_2
pH	In-tank probe	Hydrogen ion passage across ceramic pore	Requires calibration before sterilization Checking required off-line

the increased risk of contamination or failure through the use of multiple in-line devices are compensated for by the increases in productivity gained with reliable and reproducible process control. Nowadays, the use of control loops using mass spectrometer-based off-gas analysis is common in industrial manufacturing processes (26).

Data analysis, process control, and determination of physiological parameters in bioreactors depend on measuring chemical and physical variables. Measurements are obtained either by manual off-line measurements or else monitored by in-tank sensors. pH and DOT probes have been widely used in the industry for many years. Many new probe devices are available for in-tank sensing of pCO_2 and biomass, and new autosamplers can facilitate rapid in-line measurement of metabolites (glucose, glutamine) and waste products (lactate, ammonia).

Bioreactors include nozzles and ports for inserting probes and sensors and connecting lines for adding or removing liquids and gases. The number and type of ports are specified before the construction of the bioreactors. In jacketed bioreactors built as pressure vessels, the insertion of probes through the vessel wall results in a decrease in the jacketed surface area available for heat transfer. This is not a serious restriction for plant and cell culture with low metabolic heat generation compared to bacteria. Ports are placed to enable locating sensors and probes in appropriate positions in the vessel for monitoring the designated parameters. Ports designated for pH and DOT probes are located near the bottom of the tank so that the probes are submerged in media at all times during the process. This requires side entry ports on vessels 50 L or greater in volume. In fed-batch reactors, the initial volume could be 0.2–0.6 of the total vessel volume, and the minimum liquid height should cover the probes. In small-scale bioreactors ($\leq$20 L), it is possible to use a top-head plate probe insertion in combination with long probes to access the liquid media. Vessels with many internal features such as aeration tubing, baffles, agitators,

spin filters, or internal settlers impose limitations on probe location.

For larger scale vessels, probes are inserted through the side of the vessel at the base of the cylindrical section. In large, tall vessels, additional probes are placed at the middle or higher section of the cylinder. The commonly used probes, pH, DOT, and newer probe types, are designed to fit into the Ingold 25-mm probe port. The guide tube is stainless steel (SS316L) and is specified as DIN 1 4435. The probes are inserted in a metal support cage that fits the 25-mm port. The probe tip is exposed to the bioreactor media and the probe stem is sealed by an O-ring. The metal sleeve is sealed in the Ingold probe holder by O-rings and is secured by a threaded, drilled cap at the end of the probe holder cylinder. A typical arrangement is shown in Figure 76.8.

76.1.2.1 pH. Growth and production rates may be strongly influenced by pH. Components of the media may have limited stability outside of the physiological pH range. Degradation of glutamine in cell culture media is influenced by pH with a rate constant of degradation of 2.2×10^{-4} hr^{-1} at pH 7.0 and 2.8×10^{-3} at pH 8.0 at 37°C which is equivalent to a half-life of 7–8 days (27). Thus it is important to control the pH of the medium before inoculation, as well as during the production phase. Probes for measuring of pH were developed by Ingold in 1947. In-vessel, steam-sterilizable pH probes have been available for nearly 50 years. Use of an in-line pH electrode in a fermenter was reported in 1959 (28).

The glass probes used for insertion in bioreactors consist of combined reference and indicator electrodes. Probes are available 13, 16, 21, 26, 31 and 36 cm long. The range of measurement is 1–14 pH with a temperature range of −5 to 135°C and a pressure range (in housing) of 100 psig at 25°C and 30 psig at 135°C. The reference electrolyte is a silver chloride/potassium chloride solution. Internal temperature correction is achieved through an integral thermistor temperature sensor. The outer glass body of the probe is constructed of potash soda lead glass. The terminal glass bulb is a proprietary silica glass made with small percentages of alkali metals and rare earth metals. The porous ceramic liquid junction, through which the process and probe are connected, is made of silica plus complex mineral compounds, fired at high temperature to form an inert, porous ceramic matrix. The internal electrolyte gel is 3.8 M potassium chloride, a cellulose thickening agent, and butylparaben (0.005%), an antifungal preservative.

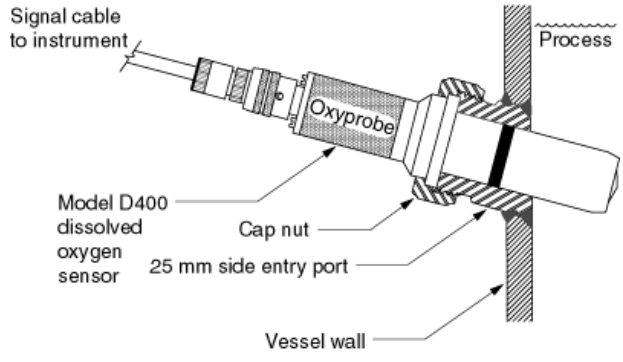

Figure 76.8. Vessel side port.

A standard Ingold probe measures pH with an accuracy of 0.04 pH ±0.01 and a reproducibility of 0.01–0.02 pH units. A drift of the pH signal may occur in a solution of constant (H+) concentration but should be less than 0.02 pH units hr^{-1}. Gel electrolyte (containing cellulose in the electrolyte) probes are the current, preferred choice, when SIP or autoclaving is required. Nongel electrolyte probes require housing pressurization to avoid boiling of the electrolyte during sterilization.

Following the insertion of the probe in the vessel port, the probe is ready for SIP or autoclaving. Control of pH is accomplished through a PID controller. Ideally, pH controllers should be split-range PID loop controllers. Split-range controllers have range-specific set points and provide separate PID outputs for actuating acid and base peristaltic pumps or valves. Split-range loop controllers are suited to pH control because they enable separation of the PID constants for the acid and base additions. With standard PID controllers, it is possible to have the acid pump overshoot the set point leading to a demand for base addition. This often leads to overadjustment of pH with a consequence of increased osmolality and potentially decreased productivity. When a common PID controller is used, a significant deadband and/or a decrease in the maximum addition rate of the acid and base can prevent the acid/base overcorrection. For large-scale reactors, acid and base may be added by using pneumatic tank pressure with actuating pulse-modulated solenoid valves.

76.1.2.2 DOT (dO_2 Probes). DOT is an important parameter to monitor and generally will be controlled in a bioreactor. Oxygen is required for cellular energy production and biosynthesis of product and cellular constituents. It is consumed at a rate of approximately 12×10^{-17} mol. $cell^{-1} \cdot s^{-1}$ (29). Oxygen is sparingly soluble in aqueous media (10 ppm or 260 μM) and may become limiting in high cell-density cultures. A high level of dissolved oxygen (hyperbaric DOT) is associated with oxygen-radical cell death (30). Two types of electrodes, galvanic and polarographic probes, are currently used for measuring dissolved oxygen. The major difference between polarographic and galvanic sensors is the source of the polarization voltage. The most commonly used probe is the polarographic probe, obtainable originally from Ingold, in which the voltage is supplied by a power supply in the amplifier. In the galvanic probe, the voltage is supplied by a separate electrochemical

reaction. In the polarographic probe, the cathode is platinum and the anode is a silver/silver chloride half-cell.

Cathode reaction (Pt):

$$O_2 + 2H_2O + 2e^- \rightarrow H_2O_2 + 2OH^-$$

Anode reaction (Ag/AgCl):

$$4Ag + 4Cl^- \rightarrow 4AgCl + 4e^-$$

Overall reaction:

$$4Ag + O_2 + 2H_2O + 4Cl^- \rightarrow 4AgCl + 4OH^-$$

The overall reaction produces alkaline conditions and consumes chloride ions. Silver chloride accumulates at the anode but does not impair the electrode. The chloride ions have to be replenished through periodic addition of fresh KCl. The electrode current depends on the oxygen partial pressure, not on the oxygen solubility in the solution. For a specific solution, the O_2 concentration C is proportional to its partial pressure (pO_2) according to Henry's law:

$$C = Kap O_2$$

where a = solubility factor of the solution and K is Henry's constant. The solubility factor is strongly influenced by the temperature and composition of the solution (illustrated in Table 76.5).

The cathode, anode, and the electrolyte of polarographic electrodes are separated from the measuring medium by a membrane permeable to oxygen but impermeable to most ions. The rate-controlling step is the diffusion of oxygen from the liquid medium through the membrane to the surface of the cathode. The current output of the probe is proportional to the activity or the partial pressure of the oxygen in the liquid medium.

DOT is controlled by using a staged control strategy. As the overall oxygen uptake rate increases, the DOT falls. In the first stage of DOT control, the agitation rate will be increased stepwise up to a maximum designated rpm. The next stage involves an increase in the airflow rate up to a designated maximum Lpm. The third stage involves decreasing the air flow rate and supplementing with oxygen gas up to a maximum Lpm. A fourth stage involves an increase in the bioreactor operating pressure. In cell culture, the rpm is generally fixed, and the DOT is controlled only through an increase in airflow rate and oxygen supplementation. Thus a DOT PID controller must provide output signals for rpm control and valve positioning for gas flow-rate control.

For lengthy perfusion mode operation, it is advisable to install a backup probe. In-line DOT probes may be readjusted by using off-line blood gas analyzer measurements. Daily off-line checks should be performed to monitor probe drift during culture processes.

TABLE 76.5. Oxygen Solubility and DOT Measurement

Medium Saturated with Air	Solubility of O_2 at 20°C and 760 mmHg (mg O_2/L)	% DOT (100% in water at 20°C and 760 mmHg)
Water	9.2	100
4 mol/L KCl	2.0	100
50% methanol/H_2O	21.9	100

76.1.2.3 Temperature Probes. Platinum 100-Ω resistance thermometers are used extensively in bioreactors. They can be inserted into an Ingold 25-mm standard probe holder. They may also be placed in the inlet and outlet of bioreactor cooling jackets to monitor heat removal/generation during culture operation. They need to be calibrated periodically to avoid large offsets. A temperature measurement accuracy of 0.1–0.2°C is achievable with RTD probes. Platinum RTD temperature sensors exhibit a linear, stable resistance versus temperature relationship. They are available in sanitary designs that conform to 3-A Sanitary Standards and feature product contact surfaces designed for CIP applications. Temperature control requires PID control of cooling jacket valves. In general, cooling is more likely to be required for large-scale vessels with lower surface area to volume ratios. Small vessels operating with animal or plant cells have low metabolic heat production, and control of culture temperature is likely to require heating the jacket. Unjacketed tanks may be fitted with heating bands (31) which operate as on/off devices and can be used with a pulse-modulating on/off PID controller. (Pulse modulation involves variation of the on-time/off-time and number of events/unit time).

76.1.2.4 pCO_2. CO_2 is toxic to CHO cells at levels >105 mmHg which is evidenced by reduced growth rate and productivity (32). It is likely that aqueous dissolved CO_2 influences the internal pH of the cell (pH_i). CO_2 may accumulate to high levels in bioreactors at high cell density and where removal of CO_2 from the broth is low due to low sparging rates and microbubble oxygenation. Absence of CO_2 or bicarbonate ions in cell culture media can also lead to repression of growth of animal cells (33). Therefore, it is important to monitor the CO_2 level in a bioreactor. Control of dCO_2 is usually not automated and is regulated through manipulation of sparging rates or vessel head-sweep airflow rate to reduce the headspace pCO_2. In sparged reactors, the total removal rate of CO_2 is limited by the maximum sparge rate that can be tolerated before foam or cell/bubble damage rates become limiting.

Cell culture media often use a bicarbonate buffer system. The reactions of the CO_2/bicarbonate buffer system are as follows:

$$CO_2 + H_2O \longleftrightarrow H_2CO_3 \text{ (at pH} < 8.0 \text{ reversible, forward reaction rate is slow)}$$

$$H_2CO_3 \longleftrightarrow HCO_3^- + H^+ \text{(rapid rate)}$$

$$CO_2 + H_2O \longleftrightarrow HCO_3^- + H^+ \text{(overall reaction } K_a = 5.2 \times 10^{-7} \text{ M)}$$

If a bicarbonate-buffered medium is allowed to stand in air, the carbon dioxide will leave solution, and the pH of the medium will increase. To prevent this, media should be stored below a 5% v/v CO_2 air mixture.

CO_2 can been measured off-line using blood gas analyzers (34) or by in-line sterilizable pCO_2 probes. In-line probes were described in 1980 (35). The Severinghaus type pCO_2 probe is essentially a combination of a pH probe with a CO_2 permeable silicone membrane. Dissolved CO_2 passes through the membrane into the NaCl/$NaHCO_3$ electrolyte where it dissociates and increases the H^+ concentration and hence decreases the pH. Response time is relatively slow (1–2 minutes) but decreases at higher pCO_2 levels. The probes are compatible with the standard 25-mm Ingold port. The probe is SIP and autoclave compatible.

Another approach has been the use of in-liquid silicone tubing through which N_2 is purged at a low flow rate (36). A mass spectrometer is used to determine the CO_2 concentration. This approach requires inserting silicone tubing into the liquid medium by using a modified 19-mm or 25-mm DIN 1 4435 Ingold-style fitting which is drilled and fitted to provide a SS316L tube connection inside the vessel and a sanitary connector externally. The tubing is connected on the inside and sterilized with the reactor.

76.1.2.5 Biomass Probes. Biomass is most often measured off-line using turbidity or direct visual counting to determine cell concentration. In-line measurement devices are now available and have been used in mammalian-cell bioreactors (37). The back-scattering in-line probes show a linear response to cell density in the range of 2–15 million cells per mL (38). Transmission laser probe types such as the Cerex (Cerex Corp., USA), Wedgewood (Wedgewood Technologies, CA, USA) and Monitek (Monitek Technologies, CA, USA), perform well in hybridoma suspension culture (39). The probes are Ingold 25-mm type design and are SIP compatible. Another in-line laser turbidimeter (ASR Co. Ltd., Tokyo) has been used to continuously monitor microbial culture (40) and can also be applied in cell-culture reactors.

Capacitance sensors have been examined for on-line biomass determination of attachment-dependent HeLa cells on Cytodex carrier beads (41). The biomass determination is based on the capacitance imparted by cell membranes. This type of sensor can distinguish biomass from the inert carrier matrix. Concentrations in the range of 2–3 million cells per mL were measured.

Biomass probes are calibrated outside of the bioreactor by using a high-density suspension of cells. The medium is used to zero (offset) the probe and a high concentration cell sample provides the span measurement. Calibration information is cell-specific and can be stored in the controller memory.

76.1.2.6 Flow-Rate Sensors. Flow measurement devices are required to control gas and liquid flow rates. In manual systems, gas flow rate can be adjusted and monitored by using rotameters. In automated control, gas mass flowmeters are used. These meters use a thermal sensing device, which is influenced by the gas density and specific heat capacity, to determine flow rate. Mass flowmeters require periodic calibration.

Precise liquid flowmeters are needed for perfusion culture feeds. Feed rates may be as low as 5 Lpd and cell removal rates in continuous culture may be as little as 1 Lpd. Turbine positive displacement meters and mass flowmeters can be used for measuring and controlling of flow rate.

The gas flowmeters are placed before the sterilizing filters and are not sterilized. The liquid mass flowmeters may have to be placed in the sterile fluid circuit and would have to be SIP or autoclave compatible.

76.1.2.7 Nutrient/Metabolite Sensing. External off-line analyzers such as the YSI Biolyzer are used for determining of glucose, glutamine, and ammonia. In-line detection requires using an external low-volume recirculation loop with a microporous tangential cross-flow filter. External loop recirculation rates of 50–100 mL/min are used to effect permeation of the soluble media across the membrane. The clarified filtrate is sent to an aseptic sampling module and then sequentially loaded to an off-line YSI type analyzer. A 12-L perfusion system was operated with a Millipore 0.22-μm cross-flow filter in an Applikon minimum holdup volume external cross-flow holder (38). At a laboratory scale (20 L), the device can be operated aseptically in-line. The vessel/device connection is made by using autoclaved tubing which is connected aseptically to the sterilized membrane device. Connection with a large-scale SIP-based bioreactor requires producing SIP compatible sample loop devices.

76.1.2.8 Pressure. Pressure influences the DOT and pCO_2 in the medium. Bioreactors are operated with

pressures in the range of nominal 0–10 psig. Inlet gas flowrate and outlet pipe diameter and filtration sizing must be compatible to prevent pressure buildup and thus enable control of pressure using a sterilizable, needle design control valve (42). Pressure should be measured in the vessel headspace and before the exhaust filter. Pressure sensors (43) are available in Ingold style fittings or in sanitary flush-mounted Triclamp designs. A simple pressure-indicating gauge can be installed at a vessel top-plate nozzle where simple pressure indication is desired. This may be useful in addition to a sensor for local and immediate indication for operators. Sanitary 3-A design gauges with flush-mounted designs are available (44).

76.1.2.9 Liquid Level. Liquid Level probes are used to measure liquid level and provide the sensor to control the bioreactor medium level. Control of medium level is important in perfusion-based cultures where a constant bioreactor volume is desired. Long batch runs should also be monitored for liquid level to provide a measurement for replacing evaporative loss or for monitoring vessel volume during fed-batch bioreactor processes.

The following approaches are available:

- determination of bioreactor weight using a load cell (45) for large reactors or floor-mounted scales for smaller reactors (46)
- magnetostrictive sensors (47)
- capacitance sensors (48)

Capacitance sensors measure the change in dielectric constant between the vessel wall and the probe and detect the liquid/air interface. They are fitted through the top-plate of the vessel through a 19-mm Ingold type or sanitary clamp fitting. They are steam-sterilizable and are fitted before SIP.

76.1.2.10 Others. Process control loops require actuators to respond to output signals from the controller. Peristaltic pumps can be activated and regulated by external signals. The flow rate must be calibrated with rpm to enable precise tuning of the control loop. Remote actuating valves and metering pumps play some part in large-scale process control loops. In regulating the gas flow rate, proportional valves are placed outside the sterile boundary with a sterile air filter between the nonsterilizable device and the bioreactor. A representation of a basic controlled-perfusion bioreactor is shown in Figure 76.9.

The level of sophistication of bioreactor sensors and instrumentation depends on goal. In manufacturing, the trend is more toward conservatism and minimal failure risk whereas in research, maximization of the information accrual rate dominates the strategy.

76.1.3 Maintenance of Valves and Changing of O-Rings and Gaskets

Valves are an essential element of any bioreactor system. They divert fluids through fixed piping manifolds and delivery lines in bioreactor skids. They isolate fluids from product and equipment in the production phase and are fundamental in ensuring the direction of steam, nutrients, gases, and product during the phases of the production cycle. Valves that are part of the primary product contacting system and the sterilizable zones of the bioreactor should comply with sanitary design standards. Several valve designs are used in a bioreactor system.

Diaphragm valves (49) are the most usual choice for on/off selection in the sanitary flow path. Ball valves are available in SS316L three-piece designs (50) and are used as absolute shut-off valves for utilities and to a smaller extent in the sanitary flow path. Simple plug valves (51) are useful in small diameter utility line applications and can operate with steam but are not regarded as a sanitary design. Several specialized valves are used for sampling, harvesting, and in automated CIP skids. Aseptic-designed tank harvest valves (52) have a steamable piston design and provide a flush-mounted, drainable face inside the vessel. The piston design produces a steam barrier while the valve is closed. When the valve is opened, the steam supply to the valve stem is cut off, and samples or product can flow out of the vessel. Sample valves are similar in design to harvest valves but are located in the vessel sidewall.

Diaphragm valves feature a smooth, crevice-free flow path free of any entrapment areas, and a self-draining design which is the key choice for SIP/CIP applications. The isolating diaphragm protects flow medium from external contamination while containing the medium within the valve bore.

All moving parts are isolated from contacting the flow medium. In addition to the standard two-way forged and cast valve bodies, the manufacturers of sanitary diaphragm valves offer many important process-related features:

- Multiport diverter valves divert or combine process streams.
- Close-coupled branch valves minimize the dead leg on sampling valve lines.
- Tee pattern valves provide excellent drainability and minimal deadleg for process sampling.
- The standard forged valve body provides the highest available surface finish and the optimum surface for electropolishing. Because these bodies are forged from wrought stainless steel bar (ASTM A -182 grade 316L), they have minimum porosity and low ferrite content (0.5% maximum). As a result, the migration of oxides throughout the system is minimized. These bodies comply with FDA guidelines as well as cGMP

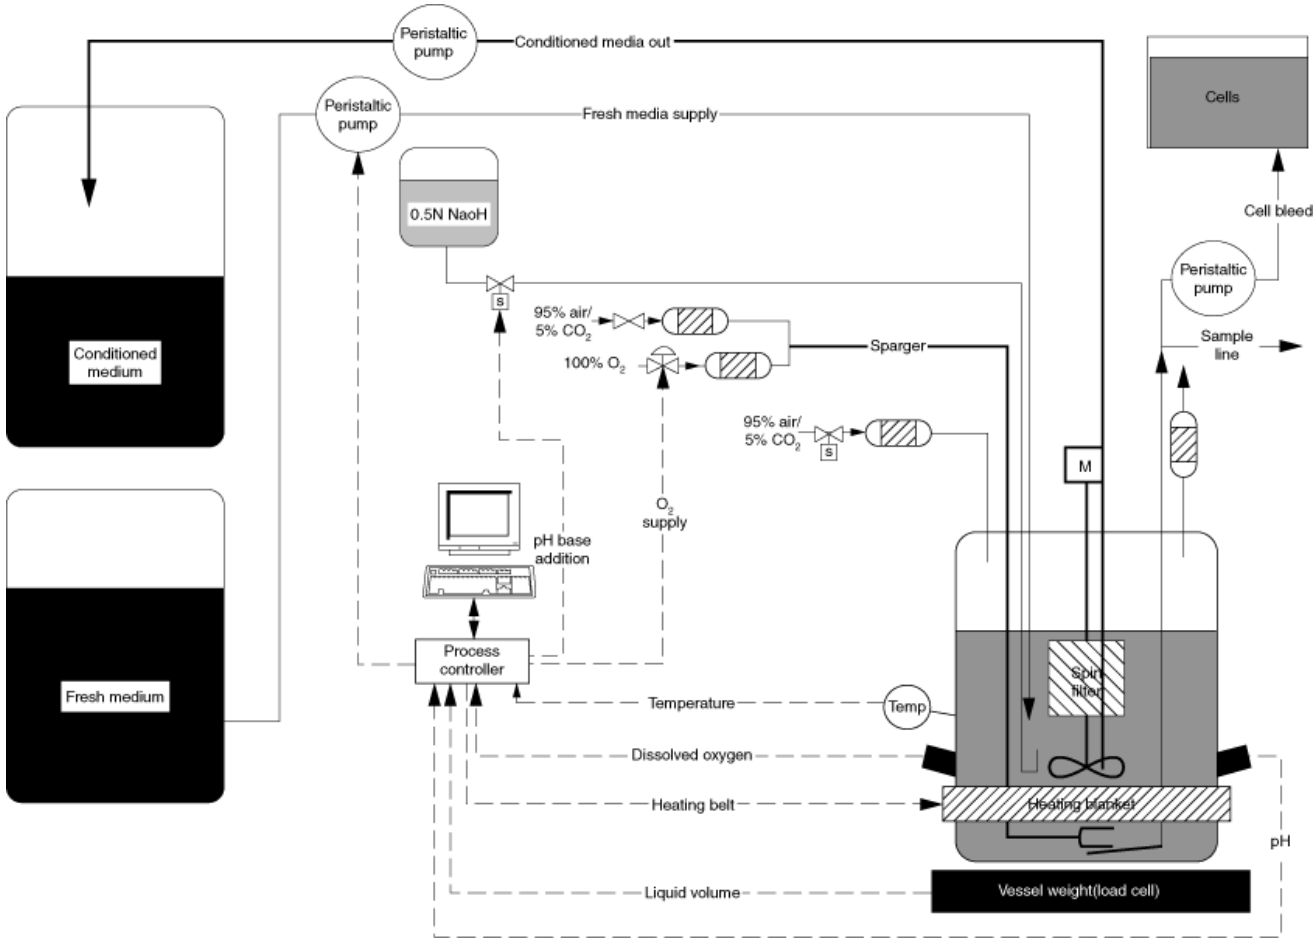

Figure 76.9. A perfusion bioreactor system. Liquid level control using a vessel load cell and regulation of a medium inlet pump.

principles and are ideal for high purity applications in the bioprocessing industry.

In addition to the stainless steel valve body, the diaphragm contacts the process stream and/or utilities. A variety of elastomers are available for bioreactor use in valves and as gaskets. The major elastomers used are given in Table 76.6. In bioproduct processes it may be important to pick an elastomer that possesses the right physical properties for the application and is also acceptable to the FDA for safety and nonleachables.

- EPDM is available for valve diaphragms and flat gaskets, but not in an O-ring format without the use of additives that render it unacceptable by the FDA for use in product-contacting applications in biopharmaceutical production. In this case EPR O-rings are used. An important consideration is the potential for toxicity of the materials to the cells in the bioreactor. Some materials such as PVC may be toxic to the cells in the reactor. Tests can be performed in shake flasks to evaluate the toxicity of particular polymeric elastomers. It has been shown that silicone, C-flex, and Teflon are noninhibitory to the growth of hybridomas (53).
- Teflon/EPDM-backed diaphragms are used in Saunders-type diaphragm valves for product-contacting vessels and lines.
- Buna-N material will handle most food, dairy, pharmaceutical, and sanitary services. It is the backbone of elastomer for the food and edibles industries and has excellent resistance to compression set, tear, and abrasion. It has good acid and mild alkali resistance.
- EPDM (ethylene propylene rubber) is excellent for hot water and steam service up to 325°F, and in addition it is very abrasion resistant and has excellent resistance to ozone, sunlight, weather, and deionized water. EPDM also has good tensile strength and good resistance to mild acids, alkalis, and alcohols (rated −65°F to 350°F and short term to 400°F).

TABLE 76.6. O-Ring and Gasket Elastomers

- Viton(fluorocarbon rubber) material has excellent mechanical, chemical, and heat resistance. It is particularly well suited for hot, fatty, and oil products. Viton has poor serviceability in steam contact application. EPDM is favored, for steam service. Viton is especially good for hard vacuum service because of its high molecular weight and low gas permeability. It has been used to −65°F in some static seals due to its high flexibility (temperature ranges 0°F to 400°F under continuous duty and will take 600°F for short periods of time).
- Silicone is known for its purity and nonleaching characteristics. Its ability to withstand many chemicals and combination of chemicals makes it a good choice in the pharmaceutical industry. Silicone has excellent low-temperature flexibility.

Harvest valves should be steam-sterilizable, piston-type valves with O-ring seals and should be flush-mounted to provide a smooth join with the vessel interior surface to eliminate dead pockets. In several designs, the valve housing can be pressurized with steam between operations to reduce the risk of contamination. A harvest valve should be sized to allow harvesting of the bioreactor and recirculation of CIP fluids.

In skid systems, there are many valves and gaskets which must be checked and installed before each batch run. EPDM-type gaskets, present in utility lines, are likely to be stable for months and are replaced during planned maintenance activities. The vessel and cell-culture-contacting gasket materials should be carefully inspected after each run. Flat Teflon gaskets are normally replaced after each process because they are prone to cold flow and deformation. Silicone rubber O-rings can be used for several cycles without problems and simple inspection and replacement are usual rather than regular replacement. After reinstalling gaskets, a low-pressure leak test will detect poorly seated gaskets and O-rings.

When replacing O-rings, it is important to clean the surfaces to eliminate small debris such as gasket particulates. Where circular O-rings are required to fit inside a tight sleeve, it is necessary to place a small amount of silicone gel on the O-ring to prevent any damage. If O-ring damage is persistent, then steel surfaces should be inspected. Any burrs or aberrations should be carefully machined away. Probe holders and other O-ring sealing systems are engineered to provide suitable seats and grooves. For O-rings, straight-sided grooves are best to prevent extrusion or nibbling, but 5° sloping sides are easier to machine and are suitable for very high pressure (15,000 psig.). The sides should be finished to a 32 μinch RMS (root mean square) with no burrs, nicks, or scratches. Any rubbing surfaces should be 8–16 μinch RMS.

When replacing flat gaskets, for example, sight glass gaskets, take care to prevent crimping the gasket. Tighten faces evenly by working with geometrically diapositioned nuts in a sequenced tightening procedure. Use a torque wrench that is correctly adjusted when it is stipulated that nuts are to be tightened to a set torque value.

76.1.4 Connections to Receive Charging Fluids

Several line connections are required for autoclaved and mobile vessels, after sterilization. For acid, base, antifoam, nutrients, inlet gases, and inoculation. Pilot-scale bioreactors may contain components that are disposable or are assembled using sterilized-silicone tubing. Assembly of components is specific to the vessel's particular design. In general, flexible silicone tubing can be used to link CO_2, air, oxygen, nutrient, and some utility lines to the reactor. These components need to be sterilizable by autoclaving because they will not tolerate steam under pressure in an SIP process. Tubing connections can be made to attach vessel stainless steel ferrules or dip tubes. These connections are secured by attaching external Tygon ties. The tubing is assembled and connected to the vessel before autoclaving. Sterilizing gas filters and liquid filters used in operating the bioreactor are also attached to the appropriate tubing and autoclaved. Final connections are made to the utility lines outside of the sterile boundary, for example, between the air filter inlet and the air utility line. When direct sterile tubing connections are to be made, a hot tubing weld must be used. This is accomplished by a sterile-tubing welder (Sterile Connection Devices-SCD) (54). The SCD device makes a sterile heat-fused connection of C-flex tubing. A vessel can be autoclaved with tubing, fitted with a terminal piece of C-flex tubing and a guarding sterile vent filter, and attached to various connections. A remote, sterile, C-flex capped line may be fused to the vessel C-flex line to form a complete assembly connection. This can be used for small-scale vessels on small tubing (up to size 16).

Larger bioreactor skid designs are made up of numerous connections for transferring the liquid medium, alkali and acid for pH control, antifoam, sterile quality air, carbon dioxide, and oxygen. Peripheral hard-piped connections, to be made within the sterile zone of the skid, must be from a sanitary design and must be steam-sterilizable. Instrument air, indirect utility lines, heating/cooling jacket water, and other non-process-contacting materials are also associated with the skid. Non-process-contacting connections are usually made with typical threaded pipe connections, swaged connections, or with plastic PVC glued pipe of ferrule or threaded design. Deionized water lines are usually constructed of schedule 80 plastic PVC (1–2″ pipe) which delivers the deionized water to tanks where it is batch-sterilized or else transferred to a stainless steel piped sterilizable filter unit to be sterile-filtered into aseptic equipment. Teflon-lined flexible hose with sanitary connectors can be used to transfer products, nutrients and other sterile components between equipment. Utility lines may be joined to process piping through quick-coupling fittings.

Sterile connectors are available in various forms, the most common of which is the Tri-clamp fitting. Pressure gauges, valves, pumps and other associated important skid equipment are available with sanitary design connections. The connectors most commonly used are described here and are illustrated in Figure 76.10.

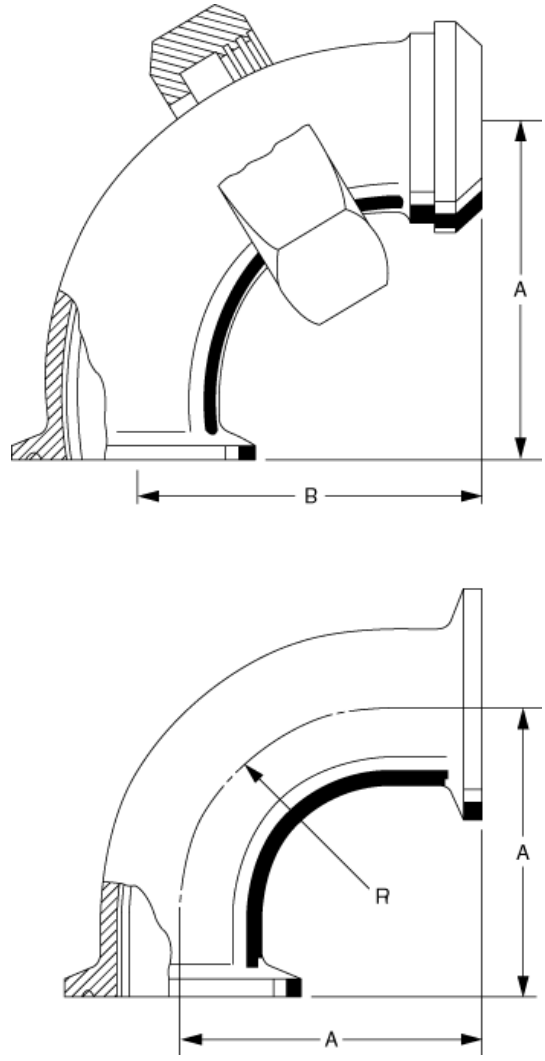

Figure 76.10. Sanitary design connectors.

76.1.4.1 Tri-Clamp. The Tri-clamp (TC) type fitting consist of a grooved, 316L stainless flange, an annular elastomeric gasket with a built-in O-ring that fits the flange groove, and a three-piece hinged 304 or 316 stainless clamp that fits around the assembled flanges and gasket. The fitting is self-aligning and easy to assemble or disassemble and in the 1.5–4 inch pipe diameter range provides a flush inside surface suitable for CIP. The fractional 0.5 and 0.75 inch fittings are useful in assembling small, fixed, stainless tubing. However, it is advisable to fit the 0.75-inch gasket into a 0.5-inch ferrule to facilitate CIP reagent access to the flat face of the ferrule (similarly fit a 1-inch ferrule with a 1.5-inch gasket).

76.1.4.2 Bevel Seat. Bevel seat fittings employ union nut assembly and Acme sanitary threads for connection (55). This fitting is more difficult to align and assemble than the Tri-clamp, and it is important to check the tightening of the exterior nut in lengths of pipe subject to vibration. The fitting is suitable for CIP, and the alignment and vibrational problems may be alleviated through correct use of pipe supports.

76.2 STERILIZATION

Sterilization inactivates potential contaminants and provides asepsis (the absence of bacterial contamination). Sterilization processes are designed to reduce the probability of survival of a single bacterial spore to less than 10^{-3}. The ability to achieve the low probability ($p \leq 0.001$) of contamination is met by the steam-sterilization procedure. In addition to wet heat sterilization with pressurized steam, dry heat (1800°C) for small equipment components, hot air (170°C for 2 h), radiation (γ rays, X rays, high-energy electron beams,) for serum medium, and nonionizing radiation (UV rays) for surface sterilization are potentially useful. Where high temperature sterilization is not feasible, such as where the vegetative organism surfaces must be sterilized (seeds, plant materials), chemical sterilization methods are required.

Empty vessel sterilization is used when cell culture media, containing temperature-sensitive nutrients and potentially cross-reactive components (glucose and amino acids). In this situation, the presterilization microbial loads are lower than situations in which an unsterilized medium is present in the bioreactor before sterilization.

Vessels which are in the 10 to 100-L range may fit into autoclaves and hence undergo programmed sterilization using a slow vacuum/steam cycle heat-up, a 60-minute sterilization cycle at 121°C, and a slow venting cool-down cycle. The vessel probes, addition line connectors, or silicone tube lines are unclamped and open but protected by a terminal, 47-mm, 0.45-μm gas-sterilizing grade disc filter.

SIP is the method for sterilizing vessels that are skid-mounted.

76.2.1 Theory

The destruction of microorganisms by heat implies loss of viability. The destruction of organisms by heat at a constant temperature follows a first-order rate equation given by

$$\frac{dN}{dt} = -kN$$

where k = Reaction rate constant, min^{-1}, $k = f(T)$ and N = number of viable organisms.

$$N = N_0 e^{-kt}$$

t = time (min)

76.2.1.1 Decimal Reduction Time (D). D is the time (min) of exposure to heat to reduce viable microbes by 90% at temperature T.

$$\frac{N}{N_0} = 0.1 = e^{-kD}$$

Thus

$$D = \frac{2.303}{k}$$

Spores are more resistant to thermal inactivation than vegetative organisms. The k value for spores is less than for vegetative cells. The rate constant k is a strong function of temperature. At 121°C, the value of k for *Bacillus stearothermophilus* is around 0.77 min^{-1} (56). The D value would then be calculated as 3.0 minutes. In other words, a log reduction in viable *Bacillus stearothermophilus* cell number would be obtained every 3 minutes during the sterilization hold period at 121°C. By contrast, the k values for heat intolerant organisms like *Escherichia coli* are very large at 121°C. The D values for *E. coli* RV308 in the temperature range of 56–62°C are shown in Table 76.7. The k values from this data are 0.75 min^{-1} at 56°C and 12.6 min^{-1} at 62°C, indicating a very steep curve for k versus temperature and clearly showing that such organisms are undetectable at 121°C.

The rate constant k is a function of temperature, and an Arhenius type expression can be used as follows:

$$k = ae^{-E/RT}$$

where

a = empirical constant, min^{-1}
T = absolute temperature, K
E = activation energy, $\text{cal} \cdot \text{g}^{-1} \cdot \text{mole}^{-1}$.
R is the gas constant = 1.98 $\text{cal} \cdot \text{g}^{-1} \cdot \text{mole}^{-1} \cdot \text{K}^{-1}$

On the basis of Eyring's theory of absolute reaction rate;

$$k = gTe^{\frac{-\Delta H}{RT}} e^{R\frac{\Delta S}{}}$$

where

g = factor including Boltzmann constant and Planck's constant

TABLE 76.7. Heat Kill *D* Values for *E.Coli* RV308

Temperature (°C)	*D* Value (s)
56	185
58	63
60	26
62	11

$\Delta H =$ heat of reaction activation
$\Delta S =$ entropy change of activation

In 1921 Bieglow published the Q_{10} theory (57) which said that

$$D = ae^{-b'}$$

where a' and b' are empirical constants.

Thus the reaction rate constant can be calculated.

76.2.1.2 Z-Value. The Z-value represents the number of degrees of temperature required to change the D-value by a factor of 10. The Z-value is defined as the slope of log D versus temperature. This is a straight-line graph.

$$\frac{\Delta \log_{10} D}{\Delta T} = \frac{1}{Z}$$

The D values determined for the various temperatures can then be used to calculate the Z-value for a sterilization process. Knowing the Z-value allows determining lethality at a particular temperature compared to a known lethality delivered at a reference temperature:

$$F_R = [\Delta T] \cdot 10^{\frac{(T-R)}{Z}}$$

where
$R =$ reference temperature having a known D-value (lethality)
$T =$ temperature
$F_R =$ the equivalent time at the reference temperature required to produce the level of lethality delivered at temperature T.

Dividing F_R by D_R gives the log reduction achieved at temperature T per unit time.

76.2.1.3 Del Value (∇). The Del value is frequently used in analyzing sterilization. The heating up and cooling down phases provide a finite kill effect of contaminant in addition to the sterilization hold phase. (The Del value accounts for this effect and can be described as the $\log_e$ of the population survival ratio throughout the whole sterilization cycle.)

$$\ln \frac{N}{N_0} = -Ae^{-E/RT \cdot t}$$

$$\ln \frac{N}{N_0} = \nabla$$

and,

$$\nabla = A \int_0^T e^{-E/RT} dT$$

Note that

$$N = \frac{N_0}{e^{\nabla}}$$

For a complete cycle, the overall Del value is determined according to the following equations:

$$\nabla_{TOTAL} = \ln \frac{N_0}{N} = \nabla_{HEATING} + \nabla_{HOLDING} + \nabla_{COOLING}$$

$$\nabla_{TOTAL} = a \int_T^{121} e^{-E/RT} dT + ae^{-E/RT} T_{121} + a \int_{121}^T e^{-E/RT} dT$$

In practice, the heating and cooling curves are integrated, and Del may be determined. Del factors represent the number of $\log_e$ (or $\log_{10}/2.303$) reductions in population throughout the whole sterilization cycle.

76.2.2 Principles (Unambiguous Flow of Steam)

The multiple addition lines and integral components that must be sterilized to ensure aseptic operation during the production phase complicate sterilization of fixed-in-place systems. It is important to design a sterilization cycle to ensure that saturated steam at 121°C contacts all of the equipment surfaces and areas for a specific duration to guarantee achieving design ∇ factor at all locations. It is not possible to sterilize all skid components concurrently because steam would be required to flow in multiple directions and would be difficult to direct. Sequential sterilization of systems is likely to be needed. Many valves will be needed to enable the flow of steam in the correct direction. The commonly used steam block valve arrangement is a key element in SIP. Steam blocks may be unidirectional or bidirectional (Fig. 76.11).

During the heat-up phase, condensate is produced and must be eliminated from the system to prevent cool spots and hindering steam flow. Steam traps are used at suitable points in the system, and piping is arranged with slopes to enable condensate drainage to the steam traps. Vents are placed at equipment high points to accelerate air displacement by steam. Steam supply pressure should be regulated to 20–30 psig to ensure that steam can enter sterilizing areas at 15–psig pressure when pulse control valves are opened.

76.2.2.1 Manual. Manual sterilization involves sequential operation of steam supply, steam trap bypass, and vessel-associated valves by an operator. The following simplified operations are the basic elements for achieving empty vessel sterilization.

- Open vessel drain valve.
- Open gas exhaust line valves (if pressure-regulating valve is in-line, open the valve manually at the controller).

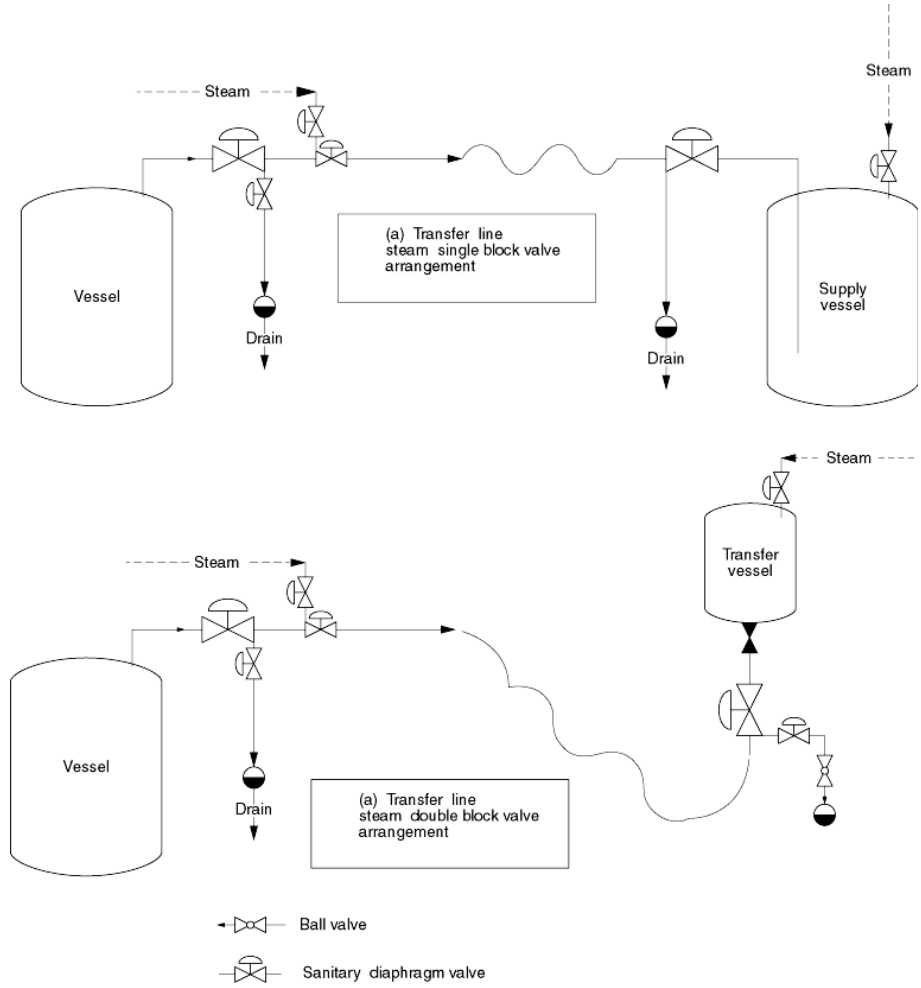

Figure 76.11. Steam block assemblies. Single block assembly (a) for sterilization of a media addition line. Double block assembly (b) for sterilization of a transfer line pre transfer and tank and transfer line post-transfer.

- Open all steam trap valves, and open steam trap bypass lines.
- Open up steam lines to vessel inlet nozzles (gas inlets, nutrient, acid/base) and the vessel jacket top valve.
- Close the exhaust line valve and steam trap bypass lines when steam is exiting the steam trap bypass lines and the vent lines.
- Ensure that steam is flowing into the vessel and is exiting through the drain-line steam trap and the exhaust filter line steam trap. Check that the individual TD steam traps are functioning correctly.
- Monitor the temperature during heat-up (use an external thermowell thermocouple or thermometer).
- After 5 minutes at 100°C close the exhaust line valve, and regulate the inlet steam supply pressure at 15–20 psig at the steam PRV valve.
- As the vessel temperature approaches 121°C regulate the supply steam pressure to 15 psig.
- Sterilize for 30–60 minutes for empty vessel sterilization.
- After sterilization shut off the steam supply, and allow the vessel to cool to 110°C. If there is a cooling jacket start the flow of cooling water through the jacket. Open the exhaust valve, and close the harvest valves.
- When the vessel temperature reaches 105–110°C, flow sterile air into the vessel to maintain 5–10 psig pressure during cool down.
- Cool the vessel to the desired run temperature using the jacket temperature control loop.

76.2.2.2 Automatic. Automatic SIP is most commonly used on skid systems where many valves are in the sterilizable zone. A sequential program that automatically opens

and closes valves during the progressive stages of the SIP cycle drives the sterilization cycle. Purging of air from the system can be accelerated by incorporating steam trap bypass lines that include a pulse open/closed solenoid valve. This is a suitable feature for automated systems. The pulsed valves open in the early heat-up phase and then close as the air and condensate are removed. A temperature sensor in the purge line could provide the threshold signal for opening/closing the solenoid valve. The valves are of the fail-closed design option, that is in the absence of electrical or pneumatic actuation they are closed.

A sequential program cycle for a bioreactor may be divided into the following nine stages.

76.2.2.2.1 Idle. This represents the vessel downtime configuration when SIP is inactive.

76.2.2.2.2 Heat to Purge. Vessel temperature is raised from ambient to a purge temperature (100–105°C). The next stage is initiated when the temperature reaches the purge temperature.

76.2.2.2.3 Purge. The vessel temperature is maintained at the purge temperature for a specified period of time. The trigger to move to the next stage is when the elapsed time equals the purge time entered in the controller. Purge time is in the range of 2–10 minutes.

76.2.2.2.4 Heat to Sterilize. In this stage, the air exhaust system is closed, and the vessel temperature is increased from the purge temperature up to the sterilization temperature. Steam passes into the vessel and vessel jacket, and condensate is removed through the steam traps. When the sterilization temperature (121°C) is reached, the next stage is initiated.

76.2.2.2.5 Sterilization. The vessel temperature is maintained at the sterilization temperature for a designated period of time. When the timer clock indicates that the designated duration has elapsed, the next stage is initiated.

76.2.2.2.6 Cool to Vent. The steam supply to the jacket of the vessel is shut off, and chilled water enters the jacket. The circulation loop is initiated, and the vessel temperature decreases to the stipulated vent temperature (∼105°C).

76.2.2.2.7 Vent. The air inlet valve opens to allow air to enter the vessel thereby preventing the possibility of a vacuum forming on further cooling.

76.2.2.2.8 Cool to Run. Temperature is decreased to the stipulated operating temperature.

76.2.2.2.9 Run. Run is the initial fermentation configuration, and the valves are positioned to allow the control loops to function. The system-specific valve-sequencing program is established, and a step logic program is entered into the sequence controller.

76.2.2.3 Steam. Some basic definitions for steam follow:

- Live steam is steam at temperatures greater than 100°C or greater than 1 atmosphere pressure.
- Saturated steam is steam at the dew point.
- Superheated steam is steam above the dew point.
- Service steam is steam used for general purposes; it may be contaminated with dissolved components of the feed water, rust, scale, water treatment chemicals, feed-water additives used to purify the boiler water, and volatile organic additives, typically amines and ammonia derivatives that help prevent corrosion. Examples of boiler water additives are sodium hydroxide (pH 13.2), sodium bisulfite, sodium sulfite, morpholine (pH 11.4), cyclohexylamide, and diethylaminoethanol (pH 11.2). The impurities present can be pyrogenic, (i.e., cause increased temperature) if present in pharmaceutical drug substances that are injected.
- Clean steam is steam free of pyrogens and chemicals, that is produced from demineralized and prepurified feed waters. Clean steam should be generated from stainless steel stills with stainless steel condensers and tubing.

Clean steam is characterized as dry saturated steam, having no additives, relatively low pH, and equal in purity (when condensed) to the water purity acceptable for final rinsing of drug contact surfaces.

When water changes phase from liquid to vapor in the form of steam at a given pressure, heat is added without changing the temperature of the fluid. By increasing the heat input into the water, the amount of steam produced is increased. Under constant pressure, the enthalpy value increases in proportion to the temperature until the boiling point is reached. While the water is changing phase, the temperature remains constant, but the enthalpy is increasing.

For a given pressure, enthalpy of water at the boiling point is commonly referred to as h_f. This is the value of enthalpy for water that is on the verge of boiling, also known as saturated water.

The temperature at which the phase change occurs is known as the saturation temperature.

At this point, heat can be added until all of the water is changed into steam without changing temperature. When this happens, the value of enthalpy is referred to as h_g, and

TABLE 76.8. Steam Table

Gauge Pressure (psig)	Absolute Pressure (psia)	Temperature (°C)	Heat Content			Volume Steam
			Sensible h_f (kJ/Kg)	Latent h_{fg} (kJ/Kg)	Total h_f (kJ/Kg)	V_g (m^3/Kg)

this is known as saturated steam. The values of h_f and h_g are tabulated in standard steam tables (Table 76.8).

Additionally, there is a value h_{fg} that indicates the amount of steam necessary to go from saturated water to saturated steam. This value relates to the quality of steam. When the amount of steam is half of the total weight, the steam quality is said to be 50%. When the amount of steam is equal to the total weight, the steam quality is 100%. Because this quality is generally not achievable in real circumstances, the accepted industry standard for steam quality is 99.5%.

76.2.2.4 Steam Traps and Drains. Steam traps are a critical component in SIP systems. A steam trap is a self-actuating valve that opens in the presence of condensate and/or noncondensable gases (air, CO_2, H_2 present in steam) and closes in the presence of steam (58). Steam traps are present in equipment that uses steam for sterilization. They are placed in lines draining condensate from the bioreactor. Several types of steam traps are available. Mechanical traps operate by the difference in density between steam and condensate. This category includes float and thermostatic traps and inverted bucket traps. Thermostatic traps operate on the principle that saturated process steam is hotter than either its condensate or steam mixed with noncondensable gas. When separated from steam, condensate cools below the steam temperature. A thermostatic trap opens its valve to discharge condensate when it detects a lower temperature. Balanced pressure and bimetallic traps and liquid and wax expansion thermostatic traps are included in this category.

Thermodynamic traps (TD traps) are the most commonly used traps in biotechnology applications. The TD trap uses the velocity and pressure of flash steam to operate the condensate discharge valve. The discharge valve is a simple flat disc (see Fig. 76.12). When closed, the flat disc is lying on the flat seat covering both the inlet and discharge orifices. Cool condensate at process pressure readily flows through the orifice, lifts the disk, and flows over the seat to the discharge orifices. When condensate reaches steam temperature, it flashes, which causes a decrease in pressure below the disk as the gas velocity increases, and the disk is forced down onto the seat which then seals the orifices. A TD trap can remove air from the system at startup but not if the system pressure increases very quickly because high velocity air, like flash steam, can force the disc closed and seal the orifice. Thus TD traps often require a separate air vent or bypass when used on batch applications that shut down and start up frequently and rapidly, for example, batch bioreactors. Because the TD trap has only one moving part, the disc, it is extremely rugged. TD disc traps are available in SS316L and with NPT or tube ends for ¼″, ⅜″, ½″, ¾″ and 1″ tubing (59). They may be installed in any position and are compact and easy to maintain.

Steam condensate is collected in the drain pan. A drain is essentially a fluid collection device that is separated

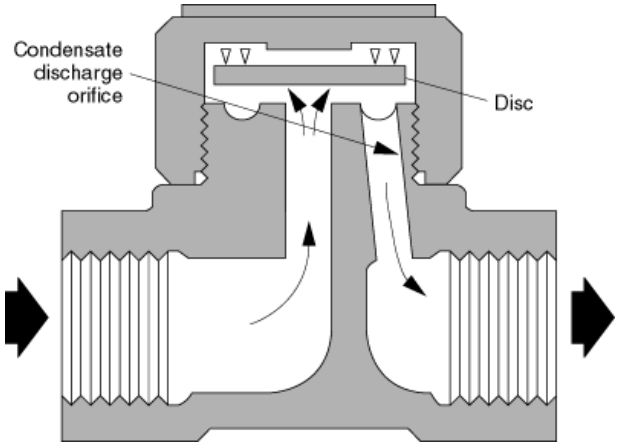

Figure 76.12. Representation of a TD steam trap.

from the process piping by an air gap which prevents pressure backup into the system. Drains should have sufficient capacity to handle full flow of fluids. Drains are connected to the facility floor drains. The air gap in a drain also prevents back-siphoning of waste into process equipment.

76.2.2.5 Ethylene Oxide. Ethylene oxide (EtO) can be used to sterilize materials that cannot be sterilized by heat. This may be performed by direct batch exposure to EtO or in a suitably designed gas-diffusion system (60). In a gas-diffusion system, a package is wrapped in a permeable material typically of low-density polyethylene (LDPE) film.

The direct batch gas sterilization process loses efficiency as product lot size increases as a result of the progressive increase in the load density. By comparison, product sterilized in a biological indicator evaluation resistometer (BIER vessel) has only one layer of protective barrier that separates the product from the critical process elements (temperature, humidity, and EtO concentration).

Ethylene oxide sterilization is effective only in defined humidity ranges. Moisture levels of 20–40% were used to inactivate spore samples (61). These levels are rarely employed by the sterilization industry. The original Kaye and Phillips experiment was performed directly on a microbial site that did not include multiple layers of packaging to hinder gas permeation.

A modern, industrial-size vessel typically injects steam into the headspace until a relative humidity of 50–80% is achieved. Additional steam is used to maintain the high level of humidity throughout the conditioning dwell. The same holds true for EtO concentration. Although a BIER vessel may inactivate spores with a sterilant concentration of 350 mg/L, industrial vessels use 600–1000 mg/L.

EtO gas-diffusion technology is a safety-conscious, effective, and efficient way for routine terminal EtO sterilization of small components. By controlling temperature and humidity and selecting packaging materials with compatible EtO permeation properties, a gas-diffusion sterilization system can be installed, validated, and operated to deliver six logs of lethality (SAL) in 10–12 hours of exposure.

76.2.2.6 Hypochlorite. Hypochlorite has frequently been used for surface disinfection. It has broad antimicrobial activity, rapid bacteriacidal action, is stable in water. Other advantages are high solubility and nontoxicity at use concentration. The active species is hypochlorous acid (HOCl). Spore-forming organisms are more resistant than vegetative organisms and viruses. It should be noted that heavy metals can reduce its sterilizing ability. Hypochlorite is used in water to prevent bacterial colonization. Hypochlorite contains chloride ions that can cause pitting of stainless steel or stress corrosion cracking around welds at temperatures greater than 50°C. In general, bleach is used reluctantly for the cleaning and sanitizing of stainless steel equipment. If fermenter cooling water is chlorinated, care should be exercised to drain and flush the cooling system before sterilization. In large vessels, the coils may be left filled with water during sterilization.

Vapor-phase sterilization of seeds can be accomplished by overnight chlorination. Seeds are incubated in the vapor phase of acid-treated bleach in a fume hood. Such procedures are limited to very small-scale operation due to the toxicity of chlorine.

76.2.3 Monitoring and Control

A bioreactor is a complex system that requires preventive maintenance to assure smooth operation. Leaky seals resulting from faulty O-rings and gaskets may result in loss of the process through contamination. Contamination control in production is based on initial good design and high standards of fabrication for the equipment and its support systems, piping, valves and seals. Operator training, adequate sterilization procedures, and ongoing preventive maintenance programs go a long way toward minimizing the risk of contamination. A laboratory logbook is useful for recording maintenance activity. Bioreactor skid supply lines contain numerous connections that depend on gaskets for correct functioning and maintenance of asepsis. Careful selection and checking of gaskets is important. All flanges and fittings should be checked routinely to ensure correct sealing and operation.

Once the basic procedures for SIP are in place, it is important to investigate the procedures through a testing method that will detect any potential flaws in the equipment setup or method. Flaws may exist in the components in the system, aberrant procedures, and operator errors, or in utility deficiencies.

Thermocouples can be placed inside equipment to monitor the SIP process. Special gaskets are available with

features that enable inserting a thermocouple through a sanitary standard flange (62). For example, it is possible to insert four probes through a single gasket-clamp connector. These devices, along with the temperature probes and data logging equipment, enable thermal mapping and validation of the sterilization process. Special gaskets, which accommodate biological indicator (BI) devices such as *Bacillus stearothermophilus* bacterial spore strips, can be used to investigate the SAL values at various places during the SIP cycle.

76.2.3.1 Dummy Runs with Bacterial Culture Media. System integrity may be tested using a sterile run method. This involves incubating the bioreactor system with a suitable bacterial growth medium to allow investigating system integrity. A carefully planned sterility test will enable the user to investigate the equipment and associated operational procedures. Growing bacteria doubling times range from 20 minutes for wild type *E. coli* to 6 hours for some yeasts and fungi in nonoptimal conditions.

Cell-culture media provide a rich nutritional environment for potential contaminating microbes. Using cell-culture medium is an expensive proposition for large-scale sterility testing at a cost of \$10 L^{-1}. Sterility can be checked economically by using simple microbial growth media in the bioreactor. Lauria Broth (LB) requires few components, involves simple preparation, is cheap, and will provide adequate nutrition for a range of bacteria. The LB medium consists of

- 10 g·L^{-1} Bacto tryptone
- 5 g·L^{-1} Bacto yeast extract
- 10 g·L^{-1} NaCl

To prepare the LB medium, fill the vessel to approximately 70% of the final operating volume, and add the solid media components with mixing. Heat the medium to 50°C to dissolve the components.

Adjust the pH with NaOH to 7.0, and add further DI water to final operating volume. The bioreactor should be set up with probes and associated systems in the same way as the intended culture process. The LB medium can be sterilized in place in the vessel at 121°C for 20 minutes. After sterilization the LB medium is cooled to 30°C. Add sterile glucose to the vessel to give a final 10 g/L concentration. The agitation is set to provide surface aeration, and the vessel is incubated for 1–2 days. A 250–1000 mL sample of medium can be removed after each stage of the test. This sample can be further incubated in a shaker flask to increase the sensitivity of detecting of contaminants in the bioreactor. In the subsequent step of the bioreactor sterility test, the aeration is activated (if it is part of the process being tested), and the vessel is incubated for a further 1–2 days. In the third stage the nutrient additions are activated, and a defined volume (0.1% v/V–1% v/V) of nutrient is added to the LB medium. Contamination is evident by growth in the shake flask samples followed by decreasing DOT in the bioreactor because O_2 is taken up by contaminating organisms. The sensitivity of the detection method depends on the contamination level that may be present after sterilization or after initiating the subsequent stages of the test.

Given:

- SOUR is approximately 1.5 mM. hr^{-1}· A 650^{-1} for bacterial contaminant (63).
- 1.0 OD 650 is $\sim 2 \times 10^6$ cell·mL^{-1}.
- Specific growth rate μ of contaminant of 1.0 hr^{-1} (i.e., a doubling time of 0.693 hr).
- DOT of 100% air saturation is 240 μM O_2 for air-saturated water.

We calculate that an A 650 of 0.02 (4×10^4 cells mL^{-1}) is required to give a 10% decrease of DOT per hour. This is a sensitive test of contamination in conditions where aeration is not provided.

Incubating samples from the reactor in shakers may increase contaminant detection resolution. The bigger the proportion of the sample relative to the bioreactor, the higher the sensitivity of the assay. If a single viable contaminant is present in the sample, it will be evidenced by the development of turbidity over the 7-day duration of the test. The most sensitive test would be to filter the entire test medium through a 0.2 μm sterile filter and then incubate the filter in nutrient agar to detect a single contaminant colony. This would be problematic because it may not be possible to filter the large volume of media aseptically and with typical test filters, and the test would be limited to one time. Removing a large volume into a shaker or sterile bag may increase sensitivity to 1–2 contaminants/L.

The LB medium does not provide a universal growth medium that supports a wide range of contaminants. This may be addressed by incubating the LB medium sample in small volumes of cell culture media after sampling or else into other selective media. Aliquots removed from the sterility test can be incubated under different conditions in other media such as indicated in Table 76.9. Tests should be incubated for at least 7 days.

Contamination can be detected by visual checking (A_{650}) or with a microscope at 400 × magnification. Contaminants detected should be typed using a commercial microbial identification kit. Typically, *Pseudomonas* sp. are of aqueous origin, *Bacillus* sp. airborne, and *Staphylococcus* sp. are typical of handling contamination.

76.2.3.2 Leak Testing. After completing the assembly of the empty clean bioreactor vessel, it is wise to perform

TABLE 76.9. Media and Conditions for Sterile Test

Medium	Temperature 20°C	Temperature 37°C	Aerobic	Anaerobic
Thioglycollate broth	+	+	+	
Sabouraud's medium	+	+	+	
Blood agar plate (streaked sample)		+	+	+
Deoxycholate plate (streaked sample)		+	+	+
Cell-culture medium (250-mL shake flask)		+	+	

a simple pressure test before the sterilization process to ensure that seals and gaskets are providing the necessary sealing. Internal vessel surfaces should be dry before a pressure test because small deformities may be filled with water, which is held by capillary action and will not be displaced by the 10–15 psig overpressure used in the test. First, make sure that all vessel fittings are securely fastened, caps are tightened, and silicone tubing is clamped shut. Attach a pressure gauge to the exit exhaust gas filter. Connect a 12-psig, regulated air supply line to the inlet air filter, and pressurize the vessel to 10 psig. When the vessel pressure has reached 10 psig, clamp the inlet gas line, and hold for 30 minutes. The pressure should not drop by more than 1 psig for a vessel of approximately 100 L in volume. For larger vessels, a longer period of time will be necessary to detect the drop in pressure caused by a small leak. During the pressure test, connections and probe holders can be inspected using a soapy-liquid squirt bottle. Dispense the soap around potentially suspect components, for example, probe insert ports, top port connections, and silicone tubing connections. A leak is detected by observing a foam layer around the leak. After pressure testing, slowly release the pressure in the reactor through the exhaust line.

A pressure test will indicate a poorly seated gasket and other faulty leaking components before sterilization, and so is worthwhile in leading to greater certainity of achieving successful asepsis after sterilization. For large-scale skid systems of high volume, a pressure hold test may not be entirely successful in identifying problems. Very sensitive testing is possible using tracer gases such as Freon or sulfur hexafluoride. Indeed such methods have been used for integrity testing of large-scale fermenters in the pharmaceutical industry and can detect the presence of microscopic leaks. The cooling coils in large industrial fermenters are likely to contain many welded sites that may develop microscopic leaks which can cause contamination of the bioreactor through ingress of cooling water contaminants. The coils can be pressurized (20–30 pisig) with a Freon 12 gas mixture. Leaks are indicated by the accumulation of Freon in the fermenter which is detected by a halogen gas detector (64).

76.3 CHARGING

Bioreactors and ancillary feed tanks are charged with liquid media components. Typical bacterial, yeast, and plant cell culture media can be autoclaved or sterilized in place. Some components, for example, vitamins, are heat-sensitive and would be added as poststerilization sterile additions. The cell-culture medium is not autoclaved and must be sterilized by filtration. Sterile media may be stored in commercially available (65) γ-irradiated polyethylene-vinyl acetate sterile bags or transferred to the bioreactor. Sterile media would normally be stored at cold room temperature (2–10°C). Sera supplied by various manufacturers are triple-filtered sterile solutions. Other manufacturers may supply γ-irradiated sterile serum. When serum is required in the medium, it is added to the bioreactor as a sterile addition using a sterile addition vessel through a sterile connection. Filter-sterilized protein additions, for example, growth factors, are similarly added as sterile additions.

Ancillary tanks are charged with base for pH control, specific nutrients for batch-fed and perfusion bioreactors, and may be antifoam. Addition tanks may be empty vessel-sterilized or autoclaved, and the component is added aseptically to the sterile tanks or vessel. Sodium hydroxide (0.1–1 N) is filter-sterilized into the storage vessel using a polysulfone-based 0.2-μm sterilizing filter. Potassium hydroxide is sterilized in place or autoclaved if it is to be used (rarely used in pH control). Antifoams such as PPG 2000 are diluted and sterilized in place or are autoclaved. If ammonium hydroxide is used, it is obtained as a sterile concentrated ammonia solution that can be diluted with sterile water and aseptically transferred to a presterilized vessel. Fluid is transferred by various simple methods, which are described in the following sections. The equipment layouts are illustrated in Figure 76.13.

76.3.1 Fluid Transfers

Following SIP or autoclaving, media can be transferred to the bioreactor. Small-scale bioreactors are assembled with sterile tubing connected to the inlet ports. This tubing will consist of a length of silicone tubing (size 15, 16, or 24) attached to a length of Pharmed tubing (size 15 or 24) and finally a short length of C-flex tubing (size 16) which is fitted with a terminal sterile 47-mm disposable vent-type filter that prevents ingress of contaminants after sterilization. This standard setup is present on all lines that use a peristaltic pump with a size 15, 16, or 24 head and require sterile connection to media or base or other fed tanks. Pharmed tubing is robust and suited for use in peristaltic pump heads. The soft C-Flex tubing can be sterilely welded to other tubes fitted with terminal C-Flex. In small-scale

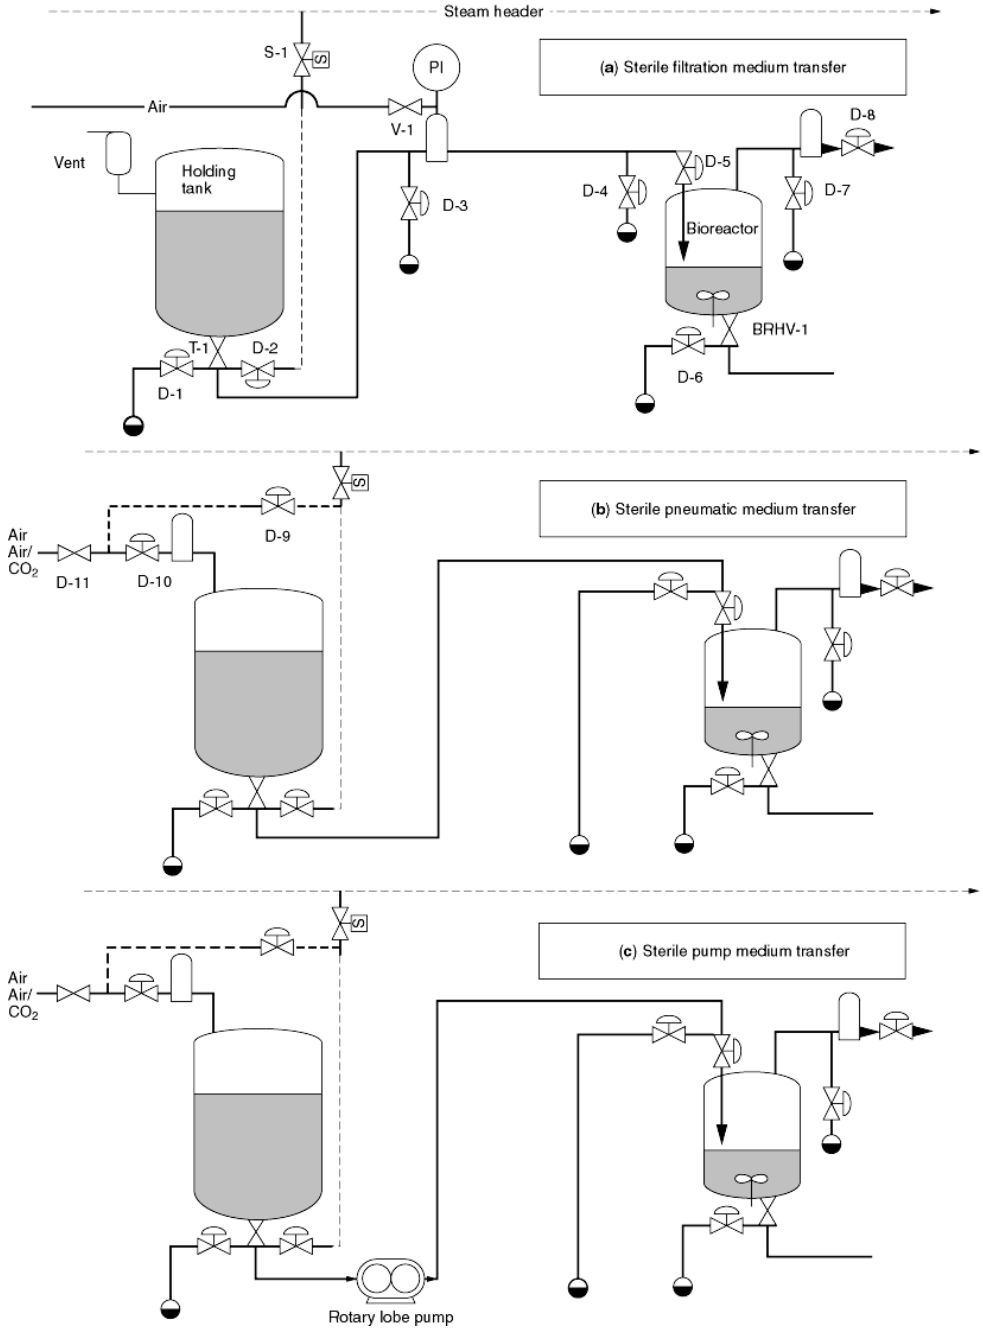

Figure 76.13. Charging media to bioreactor. Tank overpressure, pumping, and filtration are used for transferring media to the sterilized vessel. Valve arrangements provide a means to sterilize addition lines pretransfer.

and pilot-scale operation, medium may be stored in sterile bags thereby saving capital for the purchase of tanks. The sterile gamma irradiated bags have found much use in recent years for small-scale cell culture operation in conjunction with the sterile-welding technology. In larger scale systems, the media would be stored in sterilizable tanks or made fresh and 0.2-μm filter-sterilized into the bioreactor.

76.3.1.1 Overpressure or Sterile Air. Sterile media can be transferred from the sterile storage tank to the bioreactor using gas pressure as the driving force. This requires that the storage tank be designed as a pressure vessel. Because the storage tank would most likely possess a cooling jacket to preserve media at 2–12°C, it would already be rated for external pressure and be capable of

meeting the design criteria for internal positive pressure. Bicarbonate-containing cell-culture media are stored under 95% v/v/air, 5% v/v CO_2 to maintain the bicarbonate buffer system at a stable pH (7.2–7.4). The gas mixture is delivered through a steam-sterilized 0.2-μm hydrophobic gas filter to the top dish port. A pressure of 10–15 psig is applied to the vessel headspace. A steam-sterilizable transfer line is present between the medium vessel and the bioreactor. The fundamental operations for sterile transfer are as follows. (Fig. 76.13a):

- Charge the medium vessel with sterile medium, and close the drain port valve. The bioreactor media transfer port inlet valve D-5 is closed.
- Open steam supply valves S-1 and D-2 to medium vessel drain port and transfer line. Open the steam trap valve D-1 on the bioreactor transfer port steam block assembly and D-4 at the bioreactor inlet port.
- Steam the transfer line for 30 minutes at 121°C.
- Shut off the steam supply to transfer line valves S-1 and D-2, and allow the line to cool to ambient temperature. Pressurize the empty bioreactor with sterile air at 10 psig and open valve D-5, close D4, and allow air to push condensate out through D-1 until the temperature falls below 100°C.
- Close the steam trap isolation valve D-1 at the medium vessel.
- Maintain positive pressure (5–10 psig) in the transfer line during cooling.
- Pressurize the medium vessel to 15 psig with a sterile air/CO_2 mixture (if not, bicarbonate-based medium system air can used).
- When the line is cooled to ambient temperature, begin the medium transfer. Open the medium vessel drain port T-1 and the bioreactor inlet port D-5. Open the bioreactor exhaust line valve D-8.
- When the prescribed volume has transferred (indicated by bioreactor or media vessel load cell or level sensors), close the medium vessel drain port valve and allow the line pressure to dissipate into the bioreactor.
- When the transfer is complete, close both the bioreactor inlet port valve D-5 and the medium tank valve T-1.

76.3.1.2 Pump (Sterilized). Small volumes of sterile media may be transferred between vessels or from sterile media bags through sterilized silicone/Pharmed tubing. A peristaltic pump is used for the transfer. Flow rates are relatively slow, and this method may not be suitable for large scale operations. In small-scale operation, the method allows precise volume transfers. The highest flow rate possible with a peristaltic pump is 1000 Lph with large tubing sizes. More typically, flow rates for common peristaltic pumps are in the range of 0.1–1 Lpm.

In larger systems, the pump must be sterilizable in place. A steam-sterilizable rotary lobe pump can be used for this application (66). Transfer line steam-sterilization is as described in the example of pneumatic transfer.

76.3.1.3 Through Sterilizing Filter. Nonparticulate liquid media may be sterilized by filtration through an absolute 0.2-μm liquid filter. Manufacturers supply presterilized liquid filters. For small-scale operations, these filters may be setup with sterilized silicone/Pharmed tubing and used in a transfer line to the bioreactor. In large-scale operations, it is usual to insert the filter in a stainless steel housing located in the sterilizable transfer line. The filter is steam-sterilized in the forward direction and cooled with concomitant air pressurization on the upstream side of the filter cartridge to prevent backpressure on the cartridge. In clinical manufacturing, sterilizing filters must be validated by an integrity test after use (67). The integrity test is performed by either a bubble-point or diffusion-forward-flow measurement (68). In a bubble-point test, the filter is removed and placed in a test housing and wet. The micropores of the filter contain water held by strong capillary forces. Upstream air pressure is increased stagewise and held for a short period of time. At some pressure, the water will be pushed out of the capillaries by the air pressure, and the upstream pressure will collapse as air bubbles pass through the filter. The pressure at which this occurs is known as the bubble-point pressure and is a function of the size of the pores:

$$P = \frac{4k \cos\theta\sigma}{d}$$

where

P	= bubble-point pressure
d	= pore diameter
k	= shape factor corection
$\cos\theta$	= liquid-solid contact angle
σ	= surface tension

A 0.2-μm filter has a bubble point between 40–50 psig depending on the specific materials and manufacturer. In another test, the decrease in pressure as oxygen diffuses across a wetted membrane is measured over a fixed time period.

$$\Delta P = \frac{D \cdot (t) \cdot (P_a)}{V_h}$$

where

$D =$	diffusion rate (ml.min^{-1})
$t =$	time (mins)
$P_a =$	atmospheric pressure (psi)
$V_h =$	upstream reservoir volume of apparatus (ml)
$\Delta P =$	pressure drop (psig)

Filter integrity is validated by a suitable bubble-point result or by a diffusion test pressure drop within the manufacturer's specification.

Filters are available as 4″ and 10″–30″ pleated cartridges which provide approximately 5 to 15 ft^2 of surface area (69–71). Low protein binding filter materials should be used when filtering media that contain low levels of growth factors or other medium proteins. Bio-inert type materials are available from manufacturers (e.g., Pall with nylon 6, 6 polyamide.) Clean water flow rates of these cartridge style membranes are in the range of 0.2–0.5 $L \cdot min^{-1} \cdot ft^{-2} \cdot psig^{-1}$. Sanitary 3-A design housings are available with a double O-ring cartridge seal.

76.3.2 Volume Control (Weight, Level)

During transfer of media to the bioreactor, it is desirable to monitor the progress of the transfer by measuring the volume or mass transferred. As liquid enters the bioreactor, the weight increases as mass is added. A load cell can measure the mass of the reactor. Alternatively, a capacitance level probe (72) could be used to indicate when the liquid has reached a predetermined level and provide a signal to stop the transfer pump or close valves in the transfer circuit.

A floor load scale can be used for mobile vessels up to 500 L in operating volume. Fixed-in-place tanks require skid-mounted load cells to measure the vessel weight. Volume control can be achieved by activating of a feed pump to maintain a fixed volume. A common method of volume control in a perfusion system is to set the tank dilution rate by controlling the medium outlet continuous pump at a set flow rate and using a level sensor or load cell to regulate the flow rate from the fresh medium inlet pump. The flow control may be by PID pulsed on/off control or by PID regulated continuous flow rate. Continuous flow control is recommended in high-density cell culture.

Typical arrangements for simple liquid level control are shown in Figure 76.9.

76.3.3 Foam/Tangential Inlets

Foam results when bubbles persist at the liquid surface. Because the medium will contain proteins and other foam-generating materials (high surface tension), it is usual to experience foam in bioreactors that are sparged. When frit spargers are used, a stable fine textured foam may persist throughout a run (73). The foam layer will provide a gas mass transfer resistance between the headspace and the liquid surface. This may lead to a small increase of the pCO_2 of the culture during the production phase. Larger diameter bubbles do not tend to form stable foam packs and can be used to break down the foam layer to a certain extent. Foam may be entrained in the exhaust lines where it may coat and block exhaust filters and lead to a failure to control the bioreactor at optimal conditions. To avoid catastrophic foam-out problems, a break tank can be installed between the vessel and the exhaust filter. Foam may lead to specific CIP complications when the foam transports cellular material and media into the filter housing and top-plate nozzles.

Foam can be detected by a conductivity probe that can send a signal to alert operators or to initiate addition of antifoam in standard type bacterial culture. Antifoam agents are potentially toxic to cell culture and are rarely used in foam control. Mechanical devices are most often the choice for cell culture foam separation during the production phase. Defoaming has been achieved by inserting a preformed polysiloxane hydrophobic screen at the top of the liquid surface in an ascites suspension culture (74).

During transfer of the medium in the preparative phase, it useful to add the liquid components through vessel side ports. Ideally, these ports would be arranged tangentially on the side of the vessel. This minimizes the degree of splashing and air entrainment during addition and the formation of a foam layer on the surface of the media. There are also designs in the patent literature that describe abatement of foam using tangential inlets coupled with a low rpm centrifugal separator (75). Foam layers may impede the ability to adjust pH correctly if base is retained in the foam layer after addition through a top-plate nozzle. It is advisable to set the pH controller on manual or the integral function at a low value in attempting to adjust the pH when a foam pack exists.

76.3.4 Sterile Connections/Disconnections

Following sterilization, it is necessary to connect feed tanks, base tanks, sample lines, and perhaps gas lines to the bioreactor. Small autoclaved systems are usually set up with flexible tubing for later connections. Sterile tubing may be connected by using a sterile tubing welder. These devices are supplied as medical devices for connecting tubes aseptically (Terumo Medical Corporation Elkton, MD 21921 USA SCD IIB Sterile Tubing Welder). The type of tubing used to make a sterile connection can be PVC with a nominal OD of 0.21 inches and a wall thickness of 0.030 inches. Users of this equipment have had successful results in fusing thermoplastic tubing such as C-Flex (size 16). The equipment is portable and can be operated inside a class 100 hood if required. The SCD welder makes a sterile connection between the two lengths of tubing by thermal welding. Two pieces of tubing are placed in the tubing holder on the machine. The welding wafer heats to approximately 500°F ensuring sterility and melts through both pieces of tubing. With the wafer maintaining a functionally closed system, one tubing holder moves back to align the two pieces of tubing being connected. The instrument then simultaneously retracts the wafer and welds the tubes together. The two

pieces of tubing to be welded together should be previously autoclaved and have a terminal 0.2-μm 47-mm disc air filter. Because the tubing size is limited to size 16 with a nominal ID of 0.21 inches the flow rate of fluids is restricted. Exhaust gas flow rates of >5 Lpm may cause some pressure buildup in this small diameter tubing. If a line is to be severed or removed, place two tubing clamps over the line, and cut distally from the fermenter. If the line is to be reused, use a tubing welder to join a short C-flex tubing length to the vessel C-flex line.

For larger vessels, larger diameter tubing connections must be made. It is not possible to make a strict sterile connection between two hoses without steaming afterward. Where aseptic connections are required to link equipment, such as tanks, it is important to include steam-block arrangements in the interconnecting lines (Fig. 76.11). Steam-block arrangements enable sterilization of the transfer lines independently of the vessel sterilization cycle.

76.3.5 pH Priming

Before initiating automatic pH control, it is important to prime the acid and base lines. This involves filling the lines between the supply tank and bioreactor with acid or base, setting the controller to manual mode, and manually pulsing the addition pump or regulating valve to allow the base or acid to flow up to the vessel. An operator would have to visually observe the process of priming to assure that the lines are filled. In very large scale, use of a closed circulation loop or of an in-line conductivity probe could automate systems priming. A simplified example of a pH control loop is shown in Figure 76.14.

If priming is not done, it is possible that the initial pH control will overshoot and may cause the cells to experience wide pH fluctuations. Process control of pH is best achieved using PID process loop controllers. In PID control, the difference between the set-point pH and the actual measured pH would be used to generate a controller output signal for actuating of the base or acid pump. In a split PID control loop, the acid and base systems have individual PID controllers. In a standard PID control loop, the output signal is calculated from a control algorithm PID equation.

$$\text{Output} = K_c \cdot E + \frac{1}{t_i}\int_0 E dt + t_d \frac{dE}{dt}$$

where

E = set-point measurement value
K_c = controller gain (proportional)
t_i = integral time (integral)
t_d = derivative time (derivative)

This expression explains that an unprimed line will lead to an artificial delay in the change of the pH because base or acid is not present through the line. This will lead to an increase in the influence of the integral term, and a high output value will be calculated, which will likely lead to an overshoot in pH. To prevent this, the controller should be set in manual mode during priming and installation.

76.3.6 Instrumentation Checks

Sterilization may affect the calibration of various probes. Simple poststerilization checks can be made and any necessary readjustments can be made.

76.3.6.1 Temperature. The RTD probe can be checked by measuring the temperature of the medium with a mercury in glass thermometer in a thermowell port filled with a nonvolatile liquid such as glycerol.

76.3.6.2 pH. As mentioned earlier, a standard Ingold probe measures pH with an accuracy of 0.04 pH ± 0.01 and a reproducibility of 0.01–0.02 pH units. A drift of the pH signal may occur in a solution of constant (H^+)

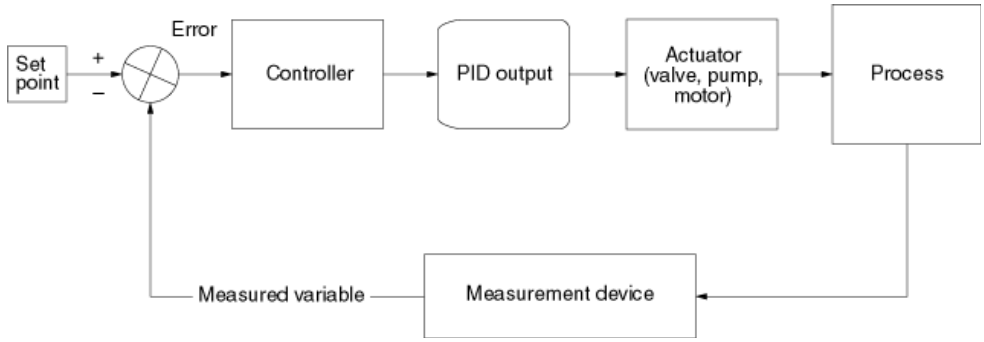

Figure 76.14. Process control loop. Feedback control loop showing PID controller. Comparison of the process pH to the set point value generates an error value. This electronic value feeds into a PID algorithmic calculation which generates a PID output to open a valve or to activate a pump motor resulting in the addition of acid (CO_2) or base to the process tank.

concentration. However, the rate of drift should be less than 0.02 pH units hr^{-1}. Larger rates of drift are usually due to clogging of the liquid junction.

The response of a pH probe should be 59.19 mV/pH at 25°C. The response time should be less than 30 seconds. Slow response time indicates thickening of the gel layer and accompanies increased electrical resistance, low slope, and zero-point drift. The aging of the probe is markedly increased by increased temperature. Normal probe life is 1–3 years at 20°C and less than a week at 120°C. Repeated dehydration, resulting from leaving a probe inside a dry vessel before or after a process, decreases the effective probe life. A dry probe gel layer may require days to rehydrate. The reference electrode is also adversely affected when the probe is allowed to dry out. Salt crystals may form in the reference electrode liquid junction causing an increase in the reference electrode impedance. Soaking in 3.8 M KCl may reverse this effect.

Because of potential problems due to poor storage and maintenance of probes, several points for maintaining and checking probes are provided here.

- During downtime, immerse the pH probe tips in 3.8 M KCl. Do not store at pH > 10 or in nonionic solutions for a prolonged time because pH sensitization of the glass may occur which renders the probe sluggish at low pH.
- When changing electrolyte or during cleaning, use an aspirator to remove the entire electrolyte from the inner and outer reservoirs.
- Clean diaphragm junctions regularly (2–3 process cycles) when immersion in high protein media occurs. Place the cleaning solution (supplied by manufacturer) in a probe cap over the tip, and invert the probe overnight. The inversion causes the small hydrostatic pressure to push the cleaning solution through the diaphragm ceramic frit. Rinse thoroughly and replenish the probe electrolyte. Allow 1–2 hours for stabilization before calibration and use. Preferably, leave the probe overnight in 3.8 M KCl.
- Never clean the probe with tissue. It can create a static charge that will render the probe very sluggish.

Probes are calibrated by a two-point calibration method. The probe is immersed in a pH 7.0 standard. The standard electrolyte is pH 7.0 ± 0.2 pH units at 20°C. The probe reading is adjusted to this value by adjusting the meter zero. The probe is rinsed and placed in pH 4.0 ± 0.2 pH unit buffer, and the meter span is adjusted to read pH 4.0. The process should be repeated once. At this point, the probe is inserted into the 25-mm Ingold-type vessel port. In lengthy perfusion-mode bioreactor processes, it is usual to install more than one probe as backup sensors. Probes are steam-sterilizable in place.

Several useful diagnostic tests can indicate the state of a before deciding whether it is reliable and suitable for in-line duty. Some practical tests are given here:

- A probe that gives a stable reading at pH 7.0 ± 0.2 pH should indicate a value of pH 4.0–4.15 within 30 seconds after placement in a pH 4.0 calibration buffer.
- An mV slope of <35 mV/pH unit indicates that a probe has an internal short circuit and should be discarded. This may be indicated by an unusually high span value (>140% normal new probe).
- Place a high impedance ohmmeter (10 MΩ) in parallel with the probe, which is immersed in 3.8 M KCl, by placing one electrode in the beaker of 3.8 M KCl and locating the other electrode in the probe electrolyte through the fill hole. Use only Ag/AgCl wires to prevent half-cell formation. The resistance should typically be 3–15 kΩ. If the reading is 20 kΩ or greater, the junction is blocked and needs cleaning.
- Electrical resistance between the reference element and the lead out signal wire should be too great to measure. However, any detected measurable resistance indicates cracking of the isolating glass and electrolyte leakage. This results in an inoperative probe.

Other indications and cautions for nongel electrolyte probes are as follows:

- Ensure that the sealing plug is removed from the probe before use to equalize the pressure of the probe within the housing. During sterilization at 121°C, the pressure will increase in the probe as the equilibrium vapor pressure increases.
- Maintain positive pressure on the probe housing to create a flow of electrolyte out of the electrode junction. The probe housing pressure should be approximately 6–8 psig greater than the sum of the positional hydrostatic plus vessel head pressure during operation. Note: A drop of electrolyte should form at the probe junction at positive housing pressure if the junction is not blocked. The electrolyte leak rate is 0.5–1.0 mL/day at 2-bar overpressure.
- For all pH probes, a normal drift of 0.05 pH/day can occur and is usually corrected by off-line grab sample and calibration measurement. It is important in this method that the sampling technique does not impart an error to the pH correction. This may be a problem in high cell-density cultures, high pCO_2 and changing sample temperature. To minimize errors of this nature, a contained sampling device such as a siliconized syringe is used.

76.3.6.3 DO_2. Ingold DOT probes give a current of 60 nA at air-saturation DOT. In N_2 saturated solution, the current should be less than 1% of the air saturation value. Response time from saturation to N_2 should be 45–90 seconds. Probes are stable at constant temperature and pressure, and the change in output in air saturated solution is less than 2%/week. The dissolved oxygen (DO) probe should be plugged in to the amplifier with the power to the control box on. If the probe has been unplugged from the amplifier or the power to the control box is off for more than one hour, the probe must be repolarized for 12 to 24 hours. Probes that have been unplugged or have had power interrupted for less than one hour must be repolarized for approximately two times the power off/unplugged time period.

Place the probe in air-saturated water, and record the dissolved oxygen value. This can be set-up using a 2000-mL graduated cylinder filled with deionized water and sparging the flask with air at approximately 5 Lpm for about 10 minutes. Next, place the probe in an oxygen-free atmosphere, that is, pure nitrogen. Use an empty 500-ml Erlenmeyer flask sparged with nitrogen at approximately 1 Lpm. The dissolved oxygen reading should drop to less than 2 to 5% of the saturated air value.

Leave the probe in the nitrogen atmosphere, and record the minimum steady-state dissolved oxygen value and the output current or amplifier voltage. If the voltage is greater than 0.04 volts, the probe must be rejected. If the probe passes the test, set the DO to zero. Placing the probe in air-saturated water can check the response time of the probe. On changing from nitrogen to air-saturated water, the probe should attain 98% of the air value within 45 to 90 seconds.

The DOT probe is calibrated in the vessel after sterilization and addition of sterile media. The bioreactor should be at the run temperature and sufficient media should be in the vessel to cover the probe. The rpm is set at a level that gives good bulk mixing. Attach a 95% v/v N_2/5% CO_2 gas line to the inlet sparger and headspace inlet filters. Sparge the mixture until the output signal is asymptotic for >30 minutes. Then adjust the probe zero on the DO controller amplifier. After the zero adjustment is completed, disconnect the N_2/CO_2 line, and flow 95% air/5% CO_2 through the gas inlet lines. When an asymptotic maximum is achieved, set the span to 95% airsaturation.

76.4 CULTURE INITIATION

76.4.1 Transfer of Cell Inoculum

Inoculum transfer essentially involves transferring an actively growing culture of cells from one growth vessel to another larger growth vessel containing fresh medium. The operation of transferring the culture should impose little or no physiological stress on the cells. The important aspects of inoculum transfer are as follows:

- Transfer in minimum time.
- Avoid DOT <20%.
- Avoid foam generation in transfer equipment.
- Preset receiving environmental conditions to run conditions.
  - Set pH at set-point value.
  - Set DOT at 95% saturation.
  - Set temperature at set point.
  - Set an initial low agitation rate (for bulk mixing).
- Sterilize transfer lines and allow them to cool ahead of time.

Ensure that the vessel valves are in the correct open/closed positions for the culture run conditions. Particular attention should be given to ensuring that the receiving vessel airflow rate is set at a low rate and that the gas vent (exhaust) line is open to avoid any elevation of backpressure toward the inoculum vessel or container. Any backflow of gas could result in foam production in the transfer lines or overpressurization of the inoculum vessel and subsequent breakage of connecting joints.

In small-scale vessels, it is possible to locate the inoculum inlet line below the initial liquid level line. This avoids the possibility that vessel headspace internal devices will hinder the inoculum. For larger vessels, a subsurface transfer line may impart hydrostatic pressure which must be overcome by pressurizing the inoculum sufficiently.

Overpressurizing an inoculum vessel can lead to transient high pCO_2 and O_2 concentrations and potential physiological shock to the cells. Transfer is achieved by using gravity feed or a peristaltic pump to avoid this problem. Small-scale cultures may be grown in small spinner jars or flasks that are set up with internal stainless tubing to facilitate transfer (Fig. 76.15). The inoculum can be transferred by gravity feed or by using a peristaltic pump. The spinner flask should be agitated by gentle swirling during the procedure. It is generally not possible to maintain the flasks at temperature in an incubator during the procedure when the vessels are separated by distance. The flask could be wrapped in insulating foam for the short inoculation duration if desired. Larger scale inoculum transfer may require using a slight gas overpressure to convey the inoculum. Using a minimum pressure, avoiding any large pressure gradients, and avoiding foaming are key design parameters.

76.4.2 Initial Mixing/Planting Conditions

After inoculation, a number of checks and controls are performed. The control and monitoring systems are

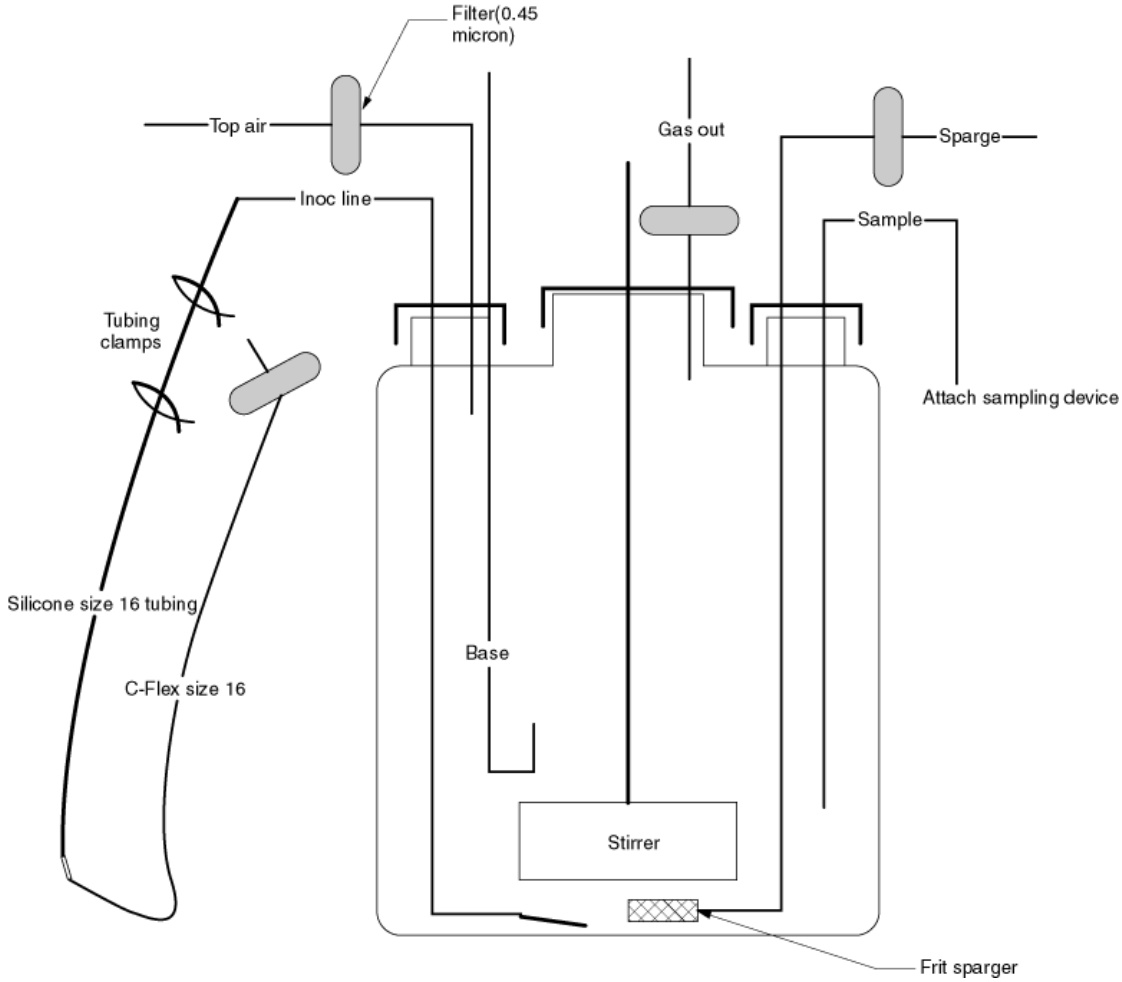

Figure 76.15. Inoculum transfer apparatus. A spinner jar (1 L–20 L) can be used to propagate and transfer an inoculum. The use of C-Flex tubing facilitates attachment to the bioreactor by using a SCD tubing welder.

switched from manual to automatic remote control mode. Initial aeration conditions are set for minimal flow rate to maintain the DOT and pH (CO_2). Overaeration during and just after inoculation can lead to production of a foam layer at the liquid surface which can trap cells and potentially inactivate them. In general, bubbles can inflict serious forces as they disengage at the liquid/gas surface, and through interfacial tension forces. These forces may irreversibly damage cells (76). In cell culture adding a low quantity of Pluronic Polyol F68 to the medium may very significantly decrease the rate of bubble damage (77). When cell density is low, this can lead to a significant lag phase through the reduction in viable cell concentration following an increased specific death rate. The agitation rate should be set to the lowest Rpm that keeps the cells suspended. The DOT will usually remain unchanged because the overall OUR is low relative to the volumetric OTR (Oxygen Transfer Rate).

The pCO_2 is a function of the % CO_2 in the aeration mixture and can be verified by checking the mixture component flow rates and the liquid pCO_2 using a BGA. In batch bioreactor operation, the volume will change only by a small amount, which would be the balance of loss through evaporation and entrainment and gain through the addition of base and other reagents. Nutrient feed should be initiated soon after the inoculation. The pump and hardware are checked to ensure that the lines are set up for the flow of nutrient feed to the vessel.

76.4.3 Initial Sampling

Samples are removed for sterility testing and off-line chemistry checks. A 100–200 mL sample of preinoculation medium is taken and stored at 2°–10°C before inoculation with postinoculation cells from the bioreactor. A small aliquot of the fresh sampled bioreactor medium is used to

TABLE 76.10. Postinoculation Sampling Matrix

	Sample	Medium (additions present)	Inoculation Cells	Comments
1.	Sterile sampling of medium	Sterile medium from supply vessel or bag pretransfer to bioreactor	None	Observe for any contaminant growth over 7 days
2.	Sterile sample of medium from bioreactor	Preinoculation medium from bioreactor	None	Observe for any contaminant growth over 7 days
3.	Test of growth medium	Sterile medium from supply vessel or bag pretransfer to bioreactor	Healthy growing stock cells (from culture deposit or research source)	Test medium for growth (specific growth rate μ and capacity—cell yield)
4.	Test of growth medium after transfer manipulations and residence in bioreactor	Preinoculation medium from bioreactor	Healthy growing stock cells (from culture deposit or research source)	Test for possible medium transfer effect on medium and bioreactor/medium interactions; any decrease in μ and yield from test 3 may indicate that changes to medium have occured
5.	Test of growth medium after inoculation manipulations	Postinoculation medium; aseptically centrifuge out cells, and decant and save medium	Healthy growing stock cells (from culture deposit or research source)	Test for possible inoculation effect on medium; any decrease in μ and yield from test 3 and 4 may indicate that changes to the medium have occured
6.	Test cells preinoculation	Sterile medium from supply vessel or bag pretransfer to bioreactor	Cells from inoculum vessel sample diluted to original inoculation density	Examine μ of cells to determine any decrease in cell function; tests health of inoculum
7.	Test cells postinoculation	Sterile medium from supply vessel or bag pretransfer to bioreactor	Cells from bioreactor postinoculation aseptically centrifuged to concentrate and then diluted to original inoculation density	Examine μ of cells to determine any decrease in cell function; compare with (7) to determine any effect on cell health during the inoculation process

determine preinoculation glucose, glutamine, ammonia, lactate, pCO_2 (BGA), DOT (BGA), and pH (BGA) values.

After completing the inoculation, a small sample of the inoculum is retained to determine viable cell concentration. The bioreactor is sampled to provide measure postinoculation viable cell count, pH (BGA), and pCO_2 (BGA). The culture is visually examined under a phase-contrast microscope to determine cell count and viability and to inspect the morphology of the cells.

76.4.4 Control Cultures Set Up

Various shake flask or small-scale incubation tests are setup. The tests are designed to detect any source of contamination that occurs during the inoculation and to compare and possibly troubleshoot differences in the cell growth rate in the bioreactor and the shake flask controls. The tests are depicted in Table 76.10.

76.5 HARVESTING

In cell culture, where the product of interest is secreted into the medium, the harvesting process should not result in cell damage or lysis. Operation at low temperature (4–12°C) is used to minimize enzymatic degradation of glycoproteins. In cell culture, sialadase may be active and cause degradation. It may be possible to minimize the degradation process by using inhibitors such as 2,3-dehydro-2-deoxy-*N*-acetyl neuramic acid (78). Prevention of mechanical damage and lysis involves chilling and using low-shear transfer systems. Peristaltic pumps with silicone tubing, pneumatic transfer through overpressure of the reactor, or gravity transfer in small-scale vessels are recommended. Additionally, static laboratory centrifugation is a gentle approach useful for clarifying relatively small volumes of culture liquid. The largest laboratory rotor capacities are 5 liters. The researcher can gauge the time needed to process the material with such an approach. It would be feasible to process up to 30 liters of culture broth in ~2.5 h using a laboratory batch centrifuge.

Filtration techniques may be used to separate the cells from the product. When cross-flow filtration is employed to separate cells and medium, it is important to minimize cell lysis, which could result in a decrease in yield and purity of the product, as well as decreased performance of the membrane system. Avoidance of average wall shear rates greater than 3000 s^{-1}, using membrane pore sizes of 0.2 um, and minimizing of shear rates (less than 25 $dyn \cdot cm^{-2}$) minimize the potential cell damage in cross-flow filtration

(79). Addition of Pluronic polyol F68 (0.1%w/v) prevents damage from gas bubbles generated by mixing and shearing. If small membrane systems of 1 ft^2 are used, then peristaltic pumps (Watson-Marlow or Cole-Palmer) are adequate. For larger systems, larger gap rotary positive-displacement pumps are employed (Flowtech, Waukesha). Cross-linked cellulosic membranes are available (Sartorius Hydrosart) which are useful in minimizing surface fouling and for facilitating high protein flux.

76.5.1 Discharge

The simplest methods for transferring the bioreactor contents from the bioreactor are mentioned in the next sections.

76.5.1.1 Gravity. In a facility in which tanks are arranged at multiple levels, gravitational force may be used to drain the bioreactor. The harvest valve is designed to allow sufficient flow from the tank. Harvest valve designs are flush-mounted with the vessel internal dish surface and use piston-type operation to open the closed positioning (Fig. 76.16). The flow rate from the tank will drop as the liquid height decreases. The following equation relates the time for reducing of the liquid height from the original height (H) to the empty vessel height designated as the reference height of zero.

$$T = \frac{1}{C_D}\sqrt{\frac{2}{g}} \cdot \left(\frac{D}{d}\right)^{0.5} \cdot (H^{0.5})$$

where D is the tank diameter, d is the outlet valve and piping diameter, and C_D is the discharge coefficient of the harvest orifice. Time restrictions limit this operation to small-volume systems (<500 L).

76.5.1.2 Sterile Air Overpressure. Sterile air overpressure at the bioreactor is frequently used to make liquid transfers. An air supply feeds a sterilizing inlet filter. The exhaust gas lines, inlet nutrient, and base lines are closed, and the vessel head pressure is increased to between 10–20 psig. Transfer is initiated by opening the harvest valve and the receiving vessel inlet and vent valves. When processing fragile cells, a minimum overpressure is chosen to minimize potential lysis caused by rapid pressure decreases through valves and fittings.

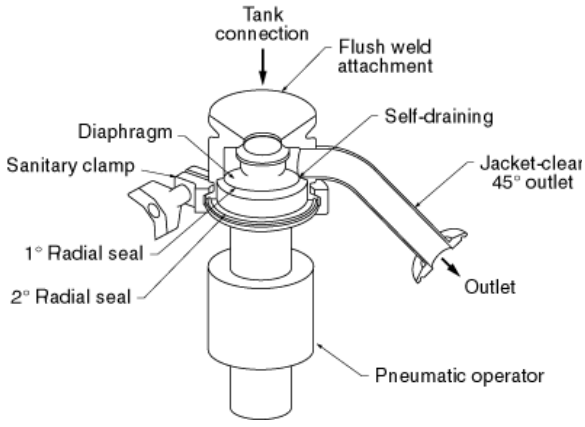

Figure 76.16. Typical flush-mounted tank harvest valve design.

76.5.1.3 Pump. To transfer small-scale bioreactor contents, it is possible to use a peristaltic pump with silicone tubing. Although peristaltic pumps are available up to 4″ in diameter and with deliverable flow rates of 1000 Lph it is generally not feasible to operate such systems smoothly. Placing persistaltic pumps at a distance from the reactor outlet may cause pressure losses that result in restriction of flow to the pump and subsequent tubing collapse. Rotary lobe pumps have been used for liquid transfer in cell culture. Recirculation of hybridoma cells through a recirculation loop of 0.75″ diameter and 8 ft long for 1 hour at flow rates up to 16.7 gpm did not cause any decrease in cell viability in the presence of Pluronic F68. The turbulent shear associated with flow through the system did not damage cells over a range of Reynolds numbers up to 71000, corresponding to a Kolomogorov eddy length of 12 μm (79). Cell damage at Kolomogorov eddy lengths of 3.5 μm or less at high power dissipation rates have been reported (80). Circulation of hybridoma cells through a rotary lobe pump showed cell damage at tip speeds of 350 $cm \cdot s^{-1}$ (79). When cell damage is to be avoided, the choice of pump should enable operation at low rpm with maximum tip speed in the region of 250 $cm \cdot s^{-1}$.

77.1 INTRODUCTION

77.1.1 Animal Cell Culture

Animal cells are widely used to produce recombinant glycoproteins such as hormones, enzymes, cytokines, and antibodies for human therapy (1). There has been a rapid increase in the demand for approved biopharmaceuticals produced from animal cell culture processes, especially the monoclonal antibodies (mAbs), which have become the most successful molecule modality in the development of modern biological medicine (2–4). In 2007, US sales of mAbs reached US$14 billion with an annual growth rate of 22% (5). MAbs also represent the second largest single category of biopharmaceutical substances under investigation as therapeutic drugs. Representative products from mammalian cell culture are listed in Table 77.1.

In the early 1980s, with the development of genetic engineering, it was possible to stably insert target DNA into mammalian cells and produce recombinant proteins, which were new kind of products in the pharmaceutical industry. Compared to the microbial expression systems, mammalian cell systems can produce larger, more complex proteins, which often require extensive posttranslational modifications, particularly glycosylation (7). About 60–70% of all recombinant protein therapeutics are produced by mammalian cells, primarily Chinese hamster ovary (CHO) cells (8).

Although animal cell culture technology has more than 100 years' history at the laboratory scale, its application as commercial bioprocess started from 1950s for the production of human viral vaccines (particularly for poliomyelitis) (9,10). In 1965, Telling and Elsworth demonstrated that baby hamster kidney (BHK) cells can be cultured in suspension by using a 30-L agitated, stainless steel bioreactor (11). The first commercial production of therapeutic recombinant protein from animal cells on a large scale was the human tissue plasminogen activator (tPA) by Genentech in 1986, which used suspended CHO cells in stirred-tank bioreactors (STRs) with sparger aeration. With the increase in the number and demand for biopharmaceutical products from animal cell cultures, the production capacity has significantly increased during last few years. Currently, a number of companies have a total capacity greater than 75 000 L (12). Nevertheless, for large-scale animal cell culture, key barriers including mass transfer limitations, shear sensitivity, the need for more sophisticated process control, and the challenges of growing adherent cell lines should generally be considered (6).

TABLE 77.1. Representative Products Generated In Mammalian Cell Culture Systems (Adapted from (6))

Product NameType of Product Cell Line Use			
Recombinant therapeutics			
Tenecteplase	Recombinant glycoprotein	CHO	Reduction of mortality associated with acute myocardial infarction
Antihemophilic factor(recombinant)	Recombinant glycoprotein	CHO	Control of hemorrhagic episodes
Interferon α-n1, lymphoblastoid	Endogenous glycoprotein	Human lymphoblastoid cell line	Treatment of chronic hepatitis C
Coagulation factor VIIa (recombinant)	Recombinant glycoprotein	BHK	Treatment of bleeding in hemophilia A or B patients
Etanercept	IgG1 fusion with TNF receptor	CHO	Treatment of rheumatoid arthritis
Trastuzumab	mAb, humanized IgG1, κ with murine CDRs	CHO	Treatment of metastatic breast cancer
Infliximab	mAb, mouse/human chimeric IgG1, κ	Murine myeloma cell line recombinant (NS0 based on medium components)	Treatment of Crohn's disease
Palivizumab	mAb	NS0, recombinant	Prophylaxis of respiratory syncytial virus
Basiliximab	mAb, mouse/human chimeric IgG1, κ	Murine myeoma cell line recombinant	Prophylaxis of acute organ rejection
Daclizumab	mAb, mouse/human chimeric IgG1	SP2/0	Prophylaxis of acute organ rejection
Rituximab	mAb, mouse/human chimeric IgG1, κ	CHO	Treatment of B-cell non-Hodgkin's lymphoma
Coagulation factor IX (recombinant)	Recombinant glycoprotein	CHO	Control of hemorrhagic episodes in patients with hemophilia B
Vaccines			
Rotavirus vaccine, live, oral, Tetravalent	Live viral vaccine	FRhL-2	Immunization for rotavirus
Rabies vaccine	Vaccine	Not revealed	Immunization for rabies
Hepatitis A vaccine, inactivated	Inactivated virus	Human MRC-5 diploid fibroblasts	Immunization for hepatitis A
Tissue-culture products			
Autologous cultured chondrocytes	Autologous cells	Chondrocytes	Repair of cartilaginous defects
Diagnostic products			
Human T-lymphotropic virus types I and II	mAb	Chronically infected human T and B lymphocytes	Enzyme immunoassay
Capromab pendetide	mAb, murine IgG1, κ	Murine hybridoma cell line	Cancer imaging agent
Nofetumomab	mAb, murine IgG2b FAb fragment	Mammalian cells	Cancer imaging agent
Imciromab pentetate	mAb, murine IgG1-κ FAb fragment	Murine hybridoma cell line	Cardiac imaging agent

BHK, baby hamster kidney; CHO, Chinese hamster ovary; mAb, monoclonal antibody. CDR, complementarity-determining region; FAb, fragment of antigen binding; FRhL-2, fetal rhesus diploid cell line; TNF, tumor necrosis factor.

77.1.2 Plant Cell Culture

Plant secondary metabolites are valuable, rich sources of various bioactive molecules, which play an important role in human medicine (13–15). Approximately 10% of all drugs considered to be "basic and essential" by the WHO are from plants (16). According to their biosynthetic pathways, the secondary metabolites are usually classified as three large molecule families: phenolics, terpenes, and steroids (17). Table 77.2 shows the plant-derived pharmaceuticals.

Many natural products are isolated from wild or field-cultivated plants; however, plants typically produce these compounds in low quantities, and purifying plant natural products is generally expensive, time-consuming, and not environmentally friendly. Compared to the traditional

TABLE 77.2. Important Plant-Derived Pharmaceuticals (Adapted from (18,19))

Product TypePlant Species		Therapeutic Use
Alkaloids		
Ajmalicine	*Catharanthus roseus*	Antihypertensive
Ajmaline	*Rauvolfia serpentine*	Antimalarial
Atropine, hyoscyamine, scopolamine	*Solanaceous*	Anticholinergic
Camptothecin	*Camptotheca acuminata* Decne	Antineoplastic
Capsaicin	*Capsicum*	Topical analgesic
Codeine, morphine	*Papaver somniferum*	Analgesic, antitussive
Cocaine	*Erythroxylum coca*	Local anaesthetic
Colchicine	*Colchicum autumnale*	Antigout
Ellipticine	*Orchrosia elliptica*	Antitumor
Emetine	*Cephaelis ipecacuanha*	Antiamoebic
Galanthamine	*Leucojum aestivum*	Cholinesterase inhibitor
Morphine	*Papaver somniferum*	Sedative
Nicotine	*Nicotiana*	Smoking cessation therapy
Physostigmine	*Physostigma venenosum*	Cholinergic
Pilocarpine	*Pilocarpus jaborandi*	Cholinergic
Quinine	*Cinchona*	Antimalarial
Quinidine	*Cinchona*	Cardiac depressant
Reserpine	*Rauwolfia serpentine*	Antihypertensive, psychotropic
Tubocurarine	*Chondodendron tomentosum, Strychnos toxifera*	Skeletal muscle relaxant
Vinblastine, vincristine	*C. roseus*	Antineoplastic
Yohimbine	*Apocynaceae, Rubiaceae*	Aphrodisiac
Terpenes and steroids		
Artemisinin	*Artemisia annua*	Antimalarial
Diosgenin, hecogenin, stigmasterol	*Dioscorea*	Oral contraceptives and hormonal drugs
Taxol and other taxoids	*Taxus brevifolia*	Antineoplastic
Glycosides		
Digoxin, digitoxin	*Digitalis*	Cardiotonic
Sennosides A and B	*Cassia angustifolia*	Laxative
Others and mixtures		
Ipecac	*Cephaelis ipecacuanha*	Emetic
Podophyllotoxin	*Podophyllum peltatum*	Antineoplastic
Shikonin	*Lithospermum erythrorhizon*	Antibacterial

methods of plantation, large-scale plant cell culture is more competitive as it offers two advantages: (i) controlled culture conditions without the variations in growing conditions that inevitably occur with plants grown in the wild, such as climate, pests, and pathogens; (2) well-defined production systems that result in higher yields and more consistent quality of the products (20). Furthermore, plant cell cultures have other advantages such as their intrinsic safety without foreign gene dissemination in the environment or contamination by mammalian pathogens, cost-effective bioprocessing, and the capability for posttranslation modifications. Recently, with the advances in culture technology, physiology, metabolism, and molecular biology of plant cells (21–23), plant cell cultures are being considered as a possible means for the production of various recombinant proteins. Such proteins include antibodies (24,25), industrial enzymes (e.g. trypsin) (26), technical proteins that are used in research (27), milk proteins that are suitable nutritional supplements (28), and new protein polymers with both medical and industrial uses (29). The first pharmaceutically relevant protein made in plants was the human growth hormone, which was expressed in transgenic tobacco in 1986 (30). Table 77.3 shows examples of recombinant proteins produced by plant cell suspension cultures.

The use of plant cell culture methodology as a means of producing medicinal metabolites has a long history. In the 1930s, it was first reported that plant cells could be cultivated in a synthetic medium in an undifferentiated state, and this achieved unlimited growth (56). In the 1970s, scientists began to make great efforts to use plant cell culture to produce natural products (57). At the laboratory scale, shake flask cultures are commonly used. However, the industrial scale requires a highly controlled culture environment, and various process variables such as mixing, shear force, and

gas content should be well controlled when the plant cell cultures are grown at different volumes (58).

77.1.3 Typical Bioreactors for Cell Cultures

In general, bioreactor systems for both animal and plant cell cultures can be classified into five main types as follows.

77.1.3.1 STRs. STRs are one of the most conventional bioreactors. Owing to its advantages such as easy scale-up, good fluid mixing, oxygen transfer ability, and alternative impellers and easy compliance with current good manufacture practice (cGMP) requirements, STRs are commonly used in cell cultures. However, this type

of bioreactor also has several limitations, such as high power consumption, high shear, and the concerns about sealing and stability of shafts in tall bioreactors. Compared to microorganisms, both animal cells and plant cells are shear sensitive, which results in remarkable efforts to modify and optimize the impeller system in order to balance mixing and mass transfer requirements and potential damage by hydrodynamic forces. Numerous modifications of conventional STRs have been made by developing new impeller designs (Fig. 77.1) (59–63). Several biopharmaceutical manufacturers have successfully implemented STRs at the 10 000–20 000-L scale for large-scale animal cell cultures (9).

77.1.3.2 Pneumatically Agitated Bioreactors. The pneumatic bioreactor is a type of gas–liquid dispersion reactor consisting of a cylindrical vessel, where compressed air or gas mixture is usually introduced at the bottom of the vessel through nozzles, perforated plates, or a ring sparger for aeration, mixing, and fluid circulation without moving mechanical parts (64,65). There are two main types of pneumatically agitated bioreactors: air-lift and bubble-column bioreactors, which are generally of low shear stress and simple design and construction. They consist of a main body, air bubbling device, steam generator for sterilization, air inlet, air vent system, various control systems for monitoring temperature, oxygen, and pH, and pipeline systems for transportation of steam, air, medium and product masses.

Air-lift bioreactors (Fig. 77.2 A, B, C, D) have some advantages over STRs: they distribute shear stress more gently as they do not have a mixer or impeller and they are easy to construct and scale-up at low cost. However, the lack of an impeller also brings some disadvantages such as poor fluid mixing for highly viscous culture and excessive foaming under high aeration (53). Air-lift bioreactors have been widely used in plant cell culture (66,67). Their application in animal cell culture has also been reported (68).

Compared to air-lift bioreactors, bubble-column bioreactors (Fig. 77.2 E,F and Fig. 77.3) have some disadvantages: backmixing in the continuous liquid phase and the decrease in interfacial area due to bubble coalescence in viscous liquids. These characteristics limit its application to a certain degree (69).

77.1.3.3 Membrane Bioreactors. Membrane bioreactors (Fig. 77.4), which utilize specialized membranes to retain cells in the reactors, are designed for *in situ* separation of cells from the medium and to integrate production and separation into a single step. The main advantages of membrane bioreactors are high cell density, high volumetric productivity, and low shear stress; therefore, membrane bioreactors are widely used in cell cultures (71–73). However, the disadvantages such as poor cell viability, poor process stability (membrane fouling and

clogging), product inhomogeneity, and diffusion gradients limit their large-scale applications. Despite the weaknesses, many membrane configurations have been tested (such as flat sheet and rotating bioreactors), and, among them, the hollow fiber configuration is a particularly interesting one (Fig. 77.5). It has been used for the commercial production of Capromab pendetide/ProstaScint™ (a cancer-imaging agent) with mAb, and murine IgG1 using murine hybridoma cells. It has been proved to be a good and economical alternative to *in vivo* production of antibodies at the lab scale or in large quantities required for diagnostic purposes (74). The bioreactors can reach high cell density with high product concentration. This type of reactor is generally used for small- and medium-scale antibody production. Oxygen delivery is considered to be the main factor limiting cell growth in hollow fiber reactors (75,76).

77.1.3.4 Packed and Fluidized-Bed Bioreactors. For the immobilization systems, packed and fluidized-bed bioreactors are frequently employed.

77.1.3.4.1 Packed-Bed Bioreactors (PBRs). PBRs, also called *fixed-bed bioreactors*, have been used for the cultivation and production of a wide range of cell lines and biologics such as mAbs, recombinant proteins, etc. (78,79). Typically, a PBR (Fig. 77.6) consists of a packed-bed that supports the cells on or within carriers and a reservoir that is used to recirculate the oxygenated nutrient medium through the bed. There are possibly two major configurations, with the packed-bed compartment located either external to, or within, the reservoir of the medium (80). Compared to STR, this type of bioreactor has the advantage of generating high cell densities with a low concentration of free cells in suspension, possibly due to the low shear forces present in the system, hence

high cell density and high productivity can be achieved. Yang *et al*. (81) reported that a fixed-bed bioreactor showed advantages in achieving high cell density and mAb concentration when using different culture systems for mAb production. The major problems of the PBR are their relatively poor mass and heat transfer coefficients due to low liquid velocities. By using intraparticle convective flow technology, this problem could be overcome, thereby significantly improving the transport of oxygen in the fixed bed (82).

77.1.3.4.2 Fluidized-Bed Bioreactors. The fluidized-bed bioreactor is the most widely used culture system for

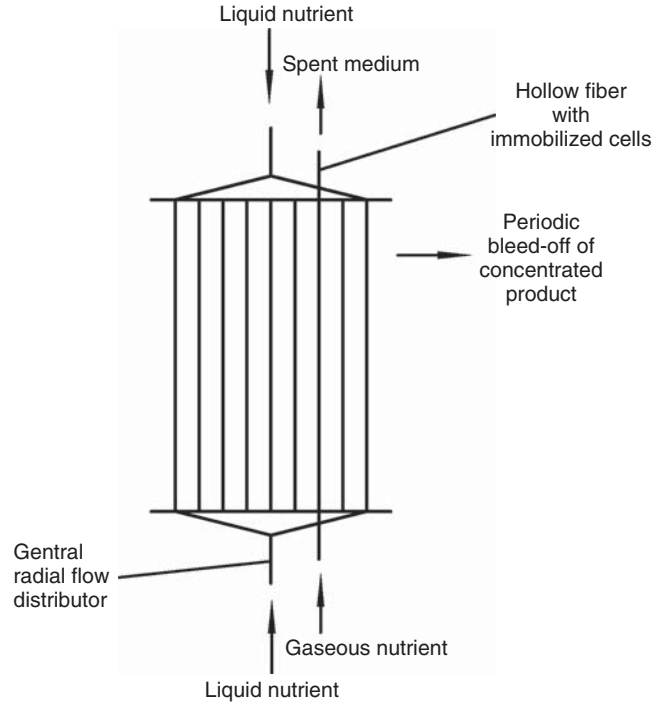

Figure 77.5. Hollow fiber bioreactor (77).

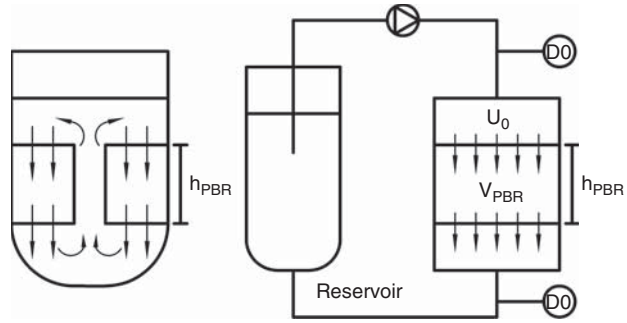

Figure 77.6. Packed-bed reactors with external and internal recirculation of nutrient medium (80). The main design variables for the packed-bed are its volume (V_{PBR}), height (h_{PBR}), and the linear velocity of the medium at the entrance of the bed (U_0). DO: dissolved oxygen sensor.

porous microcarriers (83). Because the density of the microcarriers is higher than that of the culture medium, the upward flow of the medium can suspend the microcarriers, which then circulate through the bed; therefore, the carriers are separated from direct aeration and agitation. As a result, the carriers can avoid local high shear forces. Furthermore, as both cells and fluid can move, fluidized-bed bioreactors provide a very high mass transfer interface, making it suitable for larger-scale production (84).

Goldman *et al*. (85) specifically used macroporous microcarriers in a perfused, fluidized-bed bioreactor

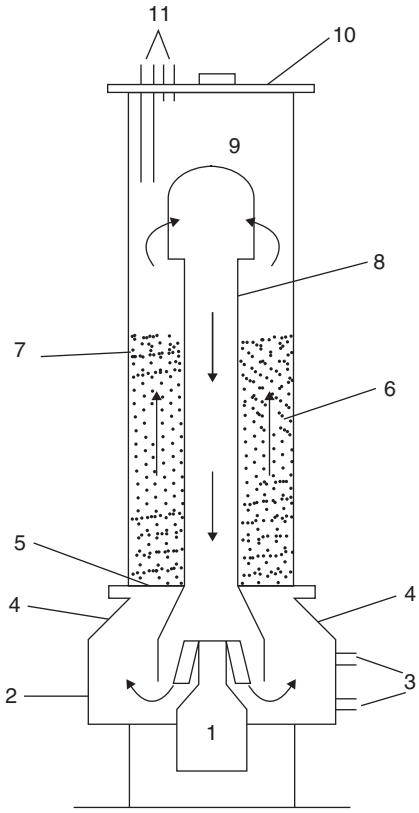

Figure 77.7. Schematic representation of Cytopilot mini fluidized-bed bioreactor (85). 1-magnetic stirrer, 2-stainless-steel double jacketed housing, 3-inlet and outlet for heating circuit, 4-probe nozzles, 5-porous gas/liquid distribution plate, 6-macroporous microcarriers, 7-glass cylinder, 8-downflow section of draft tube, 9-retention sieve, 10-headplate, 11-medium inlet and outlet for continuous-mode operation.

(Fig. 77.7), which have offered great potentials for the production of recombinant human interferon-γ (IFN-γ).

However, a major problem is that, with the fluidized-bed bioreactor, it is not easy to predict the back-mixing and fluidization patterns as it is quite difficult to maintain the nonfluctuating operation. This problem has made operation difficult and has hampered the efforts to scale up this type of bioreactors.

77.1.3.5 Wave Bioreactors. Wave reactors (Fig. 77.8) (86) have emerged and have been applied for cell culture in recent years. These reactors can generate a wave motion by mechanically rocking a culture-containing bag back and forth. These waves provide mixing and mass transfer, resulting in a suitable environment for suspension culture of both plant and animal cells. Several cell lines including CHO cells, NS0 cells, hybridoma cells, insect cells, as well as anchorage-dependant cells using microcarriers have been tested in the system.

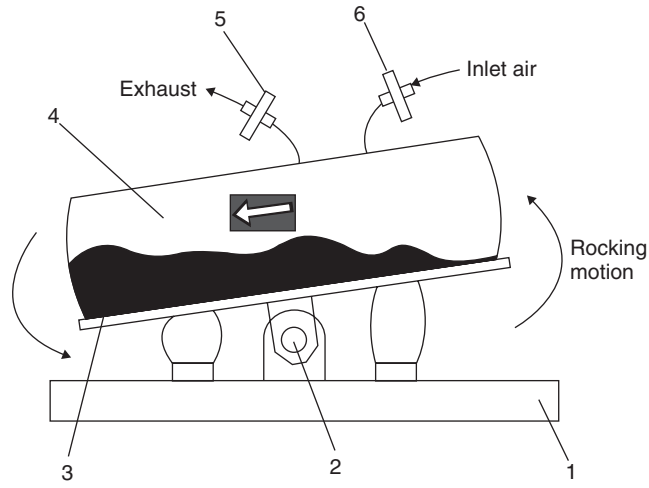

Figure 77.8. Schematic of disposable wave bioreactor (86).1-Base, 2-Pivot, 3-Cell culture media in bag, 4-Inflated plastic bag forms a disposable cultivation chamber, 5-Exhaust vent filter, 6-Inlet air filter.

In addition, the reactor uses a presterilized, plastic, disposable chamber, providing the ultimate ease in operation and protection against cross contamination. The chamber is placed on a special rocking platform that facilitates the compliance of cGMP regulations (87). On the basis of a similar principle, Terrier and coworkers (88) designed a wave and undertow (WU) bioreactor (Fig. 77.9) and a slug bubble (SB) bioreactor (Fig. 77.10). The WU bioreactor provides agitation while offering convenient mixing and aeration to the cell culture in the bioreactor. The SB bioreactor is a high-aspect-ratio bubble-column bioreactor, whose mixing and aeration are achieved through the intermittent generation of large-diameter bubbles. Both bioreactors can have application in various cell cultures on small-to-medium scales. Recently, such wave bioreactor systems have been scaled up to a capacity of 1000 L, and a cell density as high as 10^7 cells/mL was achieved (86,89).

In the following sections, the basic design principles for cell culture bioreactors, the process used to operate these bioreactors, and methods of scale-up for production are introduced and discussed.

77.2 DESIGN OF BIOREACTORS

77.2.1 Fundamental Design Principles

The basic function of a bioreactor is to provide optimum conditions for cell physiology and metabolism by regulating various chemical and/or physical factors. The design and selection of each type of bioreactors is unique but there are some basic fundamental principles. In general, the main

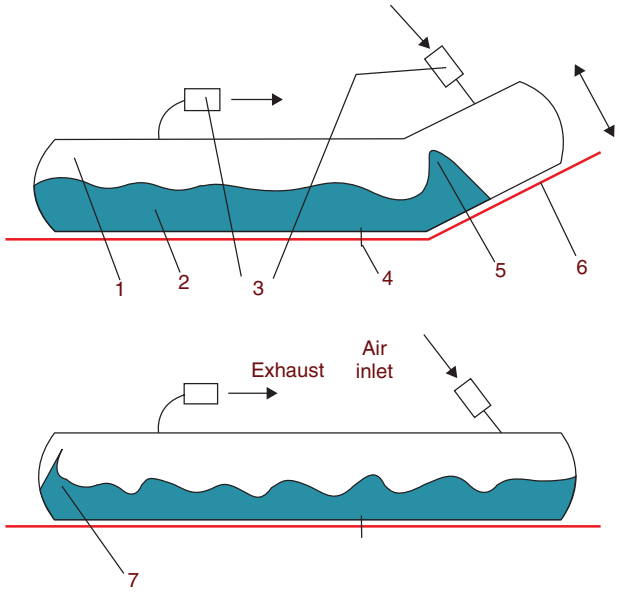

Figure 77.9. Schematic diagram of wave and undertow (WU) bioreactor (88). 1-Headspace, 2-cell culture, 3-filters, 4-harvest, 5-wave induction, 6-raising platform, 7-undertow formation. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

criteria for designing bioreactors should be adequate oxygen transfer, low shear stress, and adequate mixing (69).

77.2.2 Oxygen Supply

Oxygen is one of the most important nutrients for cells as it is a major factor in all aerobic metabolic cycles (90,91). Most nutrients required for cellular growth and metabolism are highly soluble in water, and sufficient and timely supply of these nutrients can be achieved in a well-mixed bioreactor; in contrast, oxygen is only sparingly soluble in aqueous solutions, especially in high-density and high-viscosity cell suspensions. Its supply to cells in liquid cultures usually becomes a limiting step to the optimal performance of biological systems and to the scale-up of cell culture processes (92). Maintaining a suitable oxygen concentration in the culture medium is equally important. Oxygen requirements of plant cells are relatively low, but may significantly increase during cultivation with increase of cell density (93).The optimal dissolved oxygen (DO) concentration may be different for cell growth and product formation in both plant and animal cells. In suspended cultures of *Perilla frutescens* for production of anthocyanin (red pigments) in a 2.6-L aerated and agitated bioreactor with a six-flat-bladed turbine, Zhong *et al*. (94) found that the oxygen supply and light irradiation exhibited significant influence on the production of anthocyanin by the plant cells. When the initial volumetric oxygen transfer coefficient ($k_L a$) value

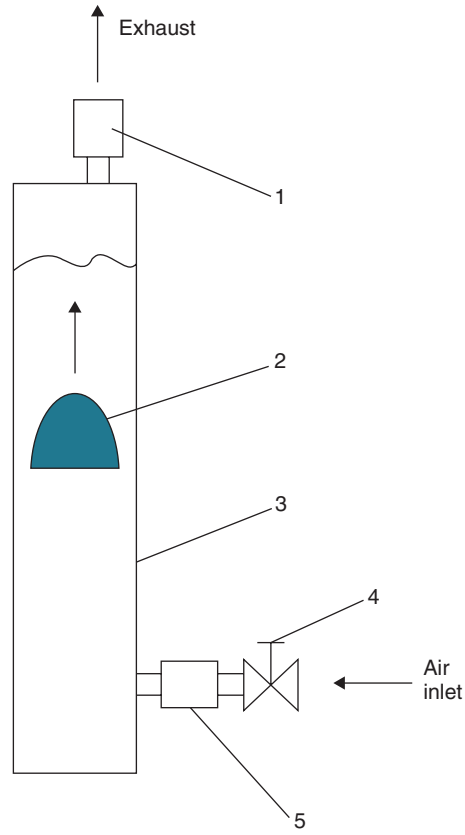

Figure 77.10. Schematic of slug bubble (SB) bioreactor (88). 1-Filter, 2-SB, 3-cell culture, 4-valve, 5-filter. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

was below 10 h^{-1} and light was not irradiated, the anthocyanin production was never over 0.6 g/L. By modifying a gas sparger, the oxygen supply capability of the STR was remarkably improved, and 1.65 g/L of anthocyanin was obtained at an enhanced $k_L a$ value of 15.4 h^{-1} (94). For bioreactor-based ginseng cultures, oxygen supplementation was also beneficial for biomass accumulation and saponin production (95).

Oxygen supply is also important for animal cell cultures, and recent developments in high cell density and high productivity fed-batch animal cell cultures have placed a high demand on oxygen supply and carbon dioxide removal in bioreactors. Usually, the high oxygen demand is met by increasing agitation speeds and sparging rates of air/O_2 in bioreactors. However, Zhu *et al*. (96) found that an increase in sparging resulted in cell damage at the sparger site due to high gas entrance velocities. The critical velocity for their NS0 cell line was found to be 30 m/s, above which low cell growth, low viability, and consequently reduced antibody production were observed. Increase in addition of pluronic F-68, a protective surfactant, from 0.5 to 2 g/L

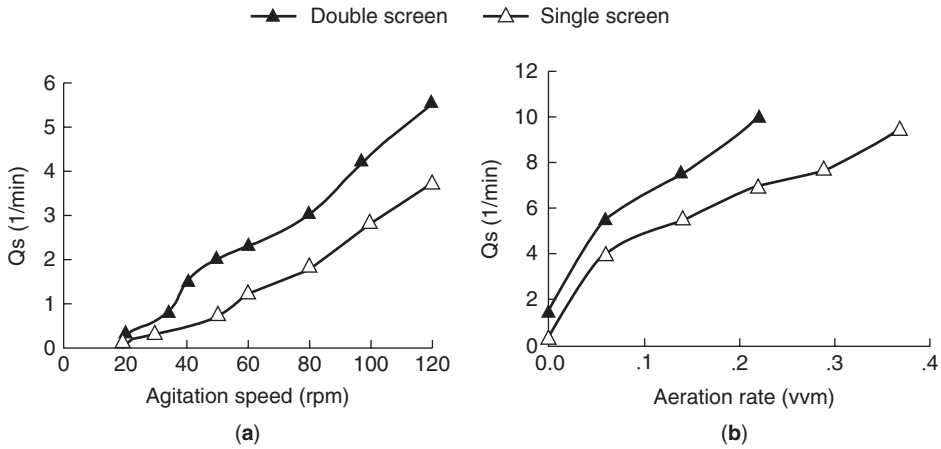

Figure 77.11. Effects of agitation speed (without aeration) (**a**) and aeration rate (at 50 rpm) (**b**) on the liquid exchange rate (Q_s) through the screen of a 20-L modified cell-lift bioreactor (13.5 L of working volume) with a double-screen cage (CellCul-20A) (103).

did not solve the problem. The sparger nozzle should also be carefully designed at pilot and large scale in order to accommodate high gas flow rate. The results of gas velocity analysis for cell damage helped a troubleshooting study in a 600-L bioreactor and successful scale-up of a process to a large-scale bioreactor (e.g. 10 000 L) for antibody manufacturing (96).

High cell culture density often causes a lower k_La value. The parameter k_La is so important in supplying oxygen to the medium that a very critical aspect of bioreactor design is to achieve a sufficiently high k_La. To meet a general oxygen uptake rate (OUR) of 5–10 mmol O_2/(L h), a typical k_La value required in bioreactor operation for plant cell culture is between 10 and 50 h^{-1} (97), while that for mammalian cell culture is around 0.25–10 h^{-1}. In addition, aeration rates in the range of 0.01–0.5 vvm (volume of gas per volume of culture per minute) are typically used in a STR and 0.1–2 vvm is applied in a pneumatic bioreactor. High aeration rates may result in severe foaming and gas stripping (of CO_2, ethylene or other volatile metabolites), which may inhibit plant cell growth (98,99). In another aspect, k_La is affected by many factors, including the geometrical and operational characteristics of the reactor vessel, agitation speed, aeration rate, fluid hydrodynamics, medium composition, cell type, morphology, and concentration. In mammalian cell cultures, gas sparge is also related to another issue: bubble-associated cell damage, which is mostly caused by high energy dissipation rate released during bubble rupture. Extensive studies have been conducted to investigate the mechanism and how to prevent it. Now preventative additives such as pluronic F-68 have been commonly used to alleviate it (100–102). However, aeration strategy still needs to be carefully considered.

For a better understanding of mass transfer mechanisms in the bioreactor, the effects of temperature, agitation speed, aeration rate, and the configuration of the cage screen on the k_La were investigated in a 20-L modified cell-lift bioreactor with a double-screen cage (CellCul-20A) by Wang *et al*. (103). Using a mathematical model based on the oxygen transfer in deep aeration, the value of k_La inside the cage was obtained, and the mass transfer resistances for the bubbling inside the cage and the transfer of liquid across the screen of the cage were also compared. Figure 77.11A shows the effects of agitation speed on the liquid exchange rate (Q_S) through the screen without aeration. The following correlations can be obtained through regression analysis:

$$\text{For the double screen: } Q_S = 3.42 \times 10^{-5}\, N^{1.49}$$
$$\text{For the single screen: } Q_S = 1.93 \times 10^{-5}\, N^{1.81}$$

where N is the agitation speed (1/s).

Figure 77.11B shows the effect of the aeration rate on the rate of liquid exchange through the screen. Under aeration and agitation, the liquid exchange through the cage screen can be regarded as the synergistic effect of these two factors.

Wen and Zhong (104) developed a simple and convenient technique for measuring OUR and CO_2 evolution rate (CER) of plant suspended cells in shake flask cultures, which are very essential and critical to bioprocess control and optimization on a reactor scale. This method was successfully applied to suspension cultures of rice (*Oryza sativa*) and *Panax notoginseng* cells, and some important bioprocess parameters, such as OUR, CER, respiratory quotient (RQ), specific oxygen uptake rate (SOUR) and specific CO_2 evolution rate (SCER), were quantitatively obtained (104). A model was developed for oxygenation in a PBR system, which was used to cultivate CHO cells at a high density of 6.1×10^7 cell/mL (Fig. 77.12), and, with

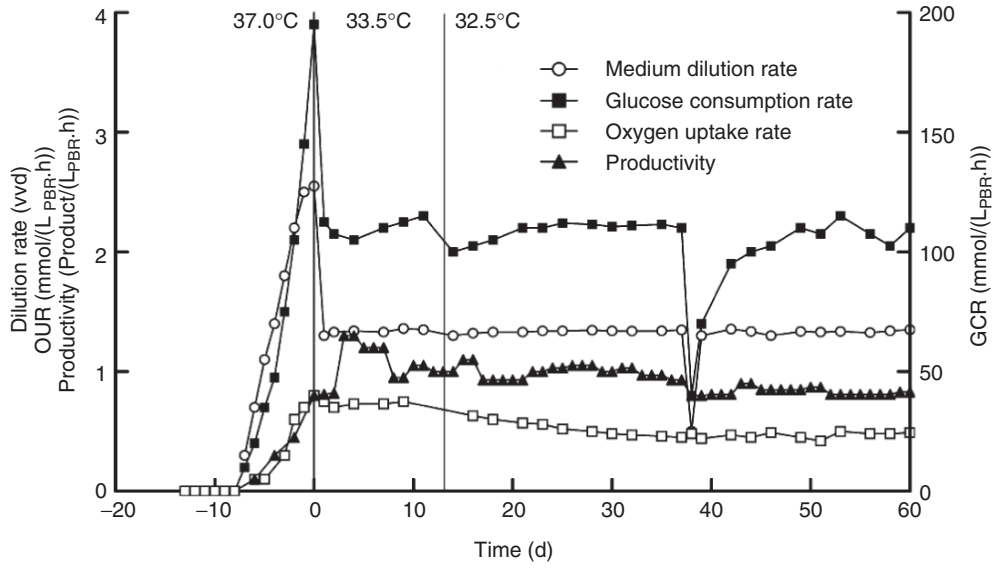

Figure 77.12. Time profiles of glucose consumption rate (GCR), oxygen uptake rate (OUR) productivity, and medium dilution rate during continuous culture of CHO cells in a fixed-bed bioreactor (105). Time 0 corresponded to the start of the production phase at 33.5/32.5°C; a deviation of dilution rate occurred on day 38 due to a technical failure of the feeding pump.

the help of this model, it was possible to identify if a PBR system is operated in optimal or suboptimal conditions. On the basis of this model, two options were proposed that could improve the performance of the basal system about twofold by increasing the density of immobilized cells from 6.1×10^7 to 1.2×10^8 cell/mL, or by increasing the packed-bed height from 0.2 to 0.4 m. Compared to the basal conditions, it would be possible to achieve a substantial improvement of about twofold higher productivity (105).

77.2.3 Shear Force

In order to maintain a homogeneous cell suspension and to provide effective nutrients (especially oxygen) transfer/supply, the cell culture system requires good mixing. Compared to microorganisms, both plant and animal cells are much bigger and more sensitive to shear force. Shear has been mainly considered in the technical literature as a destructive element, especially for plant cells. As cultured plant cells range from 20–40 μm in diameter and from 100–200 μm in length and embrace vacuoles up to 95% or more of cell volume (106), the primary cell wall contains parallel cellulose microfibrils embedded in a polysaccharide matrix. These features have led to the general belief that plant cells are shear sensitive, especially during the late exponential growth and early stationary phases when the cells are of relatively large size and contain large vacuoles (107). The shear sensitivity of plant cells has been observed in a number of cases (106,108–113). For example, Takeda *et al*. (114) reported a decreases in respiration rate, ATP content, and membrane integrity of both eucalyptus and safflower cells under hydrodynamic stress in a STR.

A couple of parameters are related to the shear-induced cell death, such as shear stress, shear time, power dissipation, and the growth phase of the cells. As mentioned earlier, sparging can also cause the shear damage, which can occur at different locations in a bioreactor: bubble generation zone at the sparger; the rising zone through the bulk liquid; and the surface of the suspension (it can either be covered with foam layer or be free of foam). The mechanism of cell damage at bubble disengagement zone is as follows: cells attach to the bubble surface (115), and then the bubble bursts at the suspension surface, which causes high shear (116). Small bubbles cause more severe damage than large bubbles (117). To analyze the effects of shear stress on plant cell cultures, a quantitative investigation of the influence of hydrodynamic shear on the cell growth and anthocyanin pigment production by *P. frutescens* was demonstrated by using a plant cell bioreactor with marine impeller of larger (85 mm) or smaller (65 mm) diameter (Fig. 77.13) (118). Figure 77.14A and B shows the effect of the average and maximum (represented by the impeller tip speed) shear rates on the specific growth rate of *P. frutescens* cells in a bioreactor. The specific growth rate was apparently reduced at an average shear rate over 30 s^{-1} or at an impeller tip speed of over 8 dm/s. Figure 77.14C and D shows the influence of shear on the maximum cell concentration. The maximum cell concentration was relatively higher at an an average shear rate of 20–30 s^{-1} or

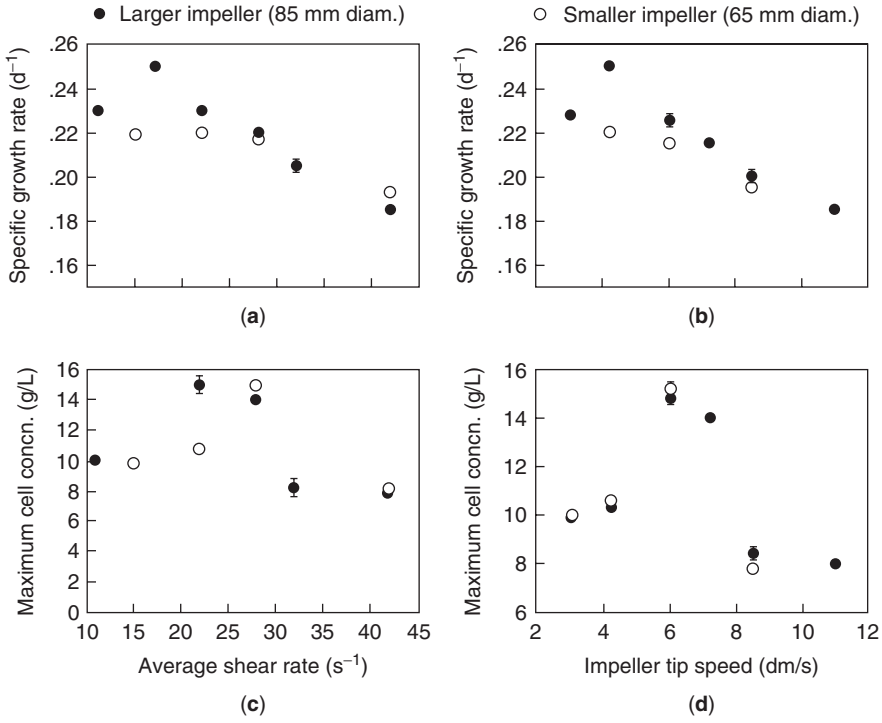

Figure 77.13. Influences of shear on specific growth rate and maximum cell concentration of *Perilla frutescens* cells in a plant cell reactor with a marine impeller (118). (**a**) and (**b**) show the effect of the average and maximum (represented by the impeller tip speed) shear rates on the specific growth rate of *P. frutescens* cells in the reactor. (**c**) and (**d**) show the influence of shear on the maximum cell concentration.

an impeller tip speed of 5–8 dm/s, and the pigment production and productivity as well as the yield coefficient of anthocyanin showed the same trends (data not shown). There have been abundant reports on shear damage suffered by animal cells grown in suspension, especially damaged by disengaging bubbles (119–123). Moreover, in the case of cells attached to microcarriers, limitations in the degrees of freedom for deformation lead to an increased sensitivity toward shear damage. Koynov *et al*. performed a detailed, high-resolution numerical simulation of bubble flows to analyze the stress and oxygen transport on a microscale (90). Different parameters such as gas holdup as well as bubble Reynolds, Morton, and Eotvos numbers were characterized. Better knowledge of the magnitude of the shear forces and DO distribution in sparged bioreactors can have a significant impact on their future design and optimization (90).

For shear-sensitive cell cultures, therefore, reducing the shear stress intensity by decreasing the agitation speed of the impeller is a general solution. However, this can also bring inadequate mixing and may conflict with enhancing oxygen and heat transfer rates in a high-viscosity cell culture broth. Furthermore, at high biomass concentrations, low agitation rates can also enhance the clumping of cells into cell aggregates of various sizes. However, appropriate bioreactor design and control can minimize shear damage from agitation and aeration. Wagner *et al*. (107) reported that anthraquinone production by *Morinda citrifolia* cells was lower in a STR than in an air-lift bioreactor, which implies the detrimental effect of shear force on plant cells. Wang and Zhong successfully designed a novel centrifugal impeller bioreactor (CIB) (Fig. 77.1F) for shear-sensitive biological systems including animal and plant cell cultures (63,125). As shown in Fig. 77.1F, this new impeller was designed on the basis of the principle of a centrifugal pump. During the impeller rotation, the center of impeller generates a negative pressure, drawing liquid and cells from the reactor bottom through the draft tube and centrifuging them toward the liquid bulk. This new type of impeller-reduced shear force, created much better mixing, and improved oxygen transfer capacity compared to the conventional STR with flat turbine and even with a relatively new, commercially available cell-lift impeller. This CIB has been demonstrated to be very successful in high cell density plant cell cultures (65,126–129). For example, in high-density cultivation of *P. notoginseng* cells, the production of the major, individual ginsenosides Rg_1, Re, and Rb_1 was significantly

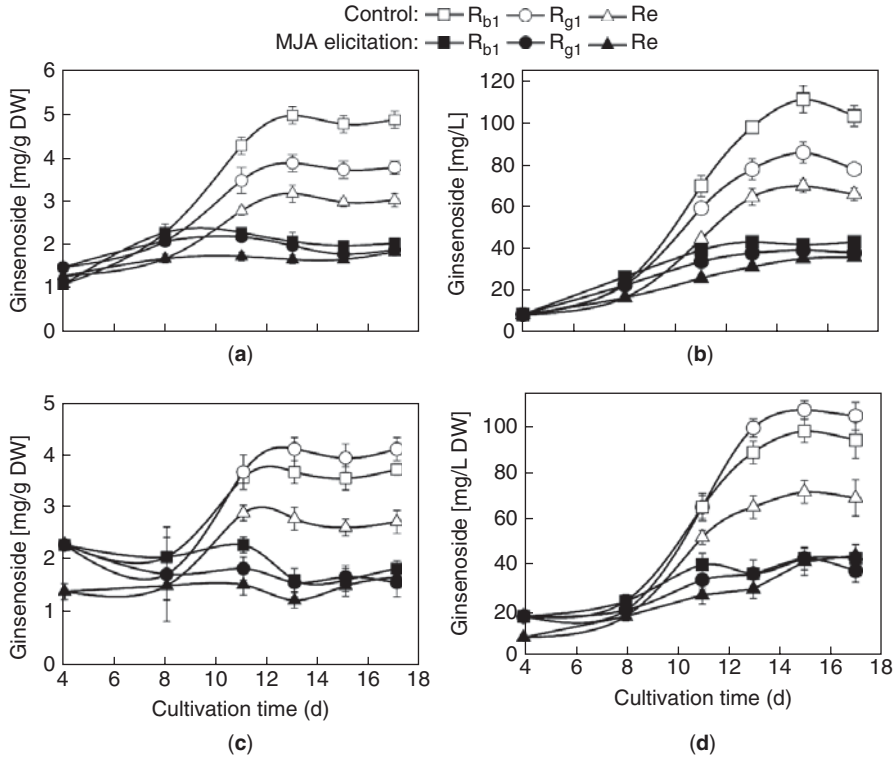

Figure 77.14. Effects of methyl jasmonate (MJA) elicitation (at 200 μM) on the content and production of the Rg_1, Re, and Rb_1 ginsenoside in high-density cultivation of *Panax notoginseng* cells in 3 L (**a**,**b**) and 30 L (**c**,**d**) CIBs (124).

enhanced in both 3- and 30-L CIBs (Fig. 77.14). The advantages of CIB were also confirmed by Prakash *et al*. They claimed that the CIB was less shearing and had higher O_2 transfer rate (OTR) than the setric impeller (a specially designed low-shear impeller (130)) bioreactor with respect to biomass and azadirachtin production in *Azadirachta indica* suspension cultures (124). Korin and coworkers designed a micro-wells/grooves bioreactor, which could protect sensitive cells from the detrimental effects of fluid shear stress by its microtopographical features. This is a promising approach to culture sensitive cells in perfusion microsystems (131). As mentioned earlier, based on advantages of wave-induced agitation, disposable wave bioreactors are also suitable for secondary metabolite production from suspension cultures, hairy roots, and embryogenic cultures (86–89).

Another possibility to overcome the problem of the rising air bubbles is bubble-free aeration using membranes for indirect aeration, in which the supply of oxygen is diffusion controlled and no bubbles arise. As the length of the membrane is limited, the average OTR is low. Also, the pressure inside the tubing has limitations. Therefore, this type of bioreactor is quite suitable for small-scale cell cultures but limited for large-scale cell cultures (10).

77.2.4 Fluid Mixing

In bioreactors, fluid mixing is another key variable because adequate mixing is essential to ensure a sufficient supply of nutrients (especially oxygen) and to prevent the accumulation of toxic or undesired metabolites like CO_2 in cultures. To maintain uniform concentration of chemical species (e.g. pH, gases, and nutrients) in the bulk phase and to increase the rates of mass transfer, mixing is normally carried out by sparging, mechanical agitation, or their combination (132). Global mixing quality in a bioreactor is usually characterized by measuring mixing time, which is defined as the time required in reaching a certain arbitrary level of uniformity in the mixed fluid (133). For the same power input per unit volume, mixing time in air-lift reactors is generally higher than that in STRs. On the basis of the time constants for oxygen conversion, oxygen transfer, and mixing, Doran compared the performance of air-lift and STRs and concluded that mixing became the limiting factor for pneumatically agitated reactors at high plant cell densities (134).

It is easy to maintain a homogeneous condition in a small-scale reactor; however, mixing often becomes one of the constraints during scale-up, as the magnitudes of hydrodynamic forces associated with mixing should be low enough so that they do not to cause cell damage.

In large-scale bioreactors, poor mixing often leads to undesirable concentration gradients and a decrease in mass transfer efficiency. In animal and plant cell cultures, which are typical shear sensitive biological systems, mixing could be enhanced by increasing agitation speeds and/or aeration rates in agitated bioreactors, but it has to balance with the increase of shear stress because shear force caused by intense agitation or aeration can bring damage to living cells. Furthermore, animal cells are very sensitive to pH changes. In large-scale suspension cell culture reactors, pH can also cause damage to cells, as a fast adjustment of bioreactor pH cannot be quickly mixed well with bulk liquid (135,136). Therefore, how to find the maximum agitation speed without causing cell damage is important. Baffles are recommended to be installed to increase mixing performance and eliminate detrimental center vortex. Cell damage in baffle zone should not be a concern generally as its hydrodynamic force is lower than that at impeller zone (137).

In the design of STR for cell suspensions, mixing has always been the focus of much attention. Doran (138) used an engineering analysis to identify whether the mixing situation in large-scale plant cell reactors can be improved by making different choices of impeller design, tank configuration, and operating conditions. On the basis of a novel mixing principle, Zhang *et al*. developed a new scalable helical track reactor for large-scale cultivation of mammalian cells. By simply using air for surface aeration, liquid-gas transfer was increased compared to standard STRs. This new type reactor with k_La around 10 h^{-1}, and capacity to support $8-10 \times 10^6$ cells mL^{-1}, meets the essential requirements for a cell culture system, that is, mixing without damaging shear-sensitive cells, sufficient gas transfer, and easy scale-up and process control (139). A novel wavy-walled bioreactor (WWB) was designed for tissue engineering (140). This bioreactor possesses a new geometry comprising walls with sinusoidal waves, which act as baffles and can potentially improve mixing and provide a lower shear stress.

77.3 PROCESS OPERATIONS

The design of a bioreactor system is an optimization procedure of balancing biological and engineering factors to obtain the required capacity and product quality at minimum production costs. At the heart of bioreactor control is the ability to monitor important process variables such as pH, DO, temperature, OUR, CER, and specific gravity. Mixing, oxygen transfer, and shear stress are the biggest challenges as far as the scale-up to industrial-size cell culture bioreactors is concerned (141). Control strategies, which range from the maintenance of basic parameters at constant levels to sophisticated computer-aided adaptive control systems, can often determine the overall output of the bioreactor. The important target of commercial process development and optimization is to minimize production cost by increasing product output and maintaining product quality. To realize this, unit operation studies are necessary toward maximum productivity. A comprehensive characterization of operational parameters must be conducted to support a robust commercial process.

77.3.1 Effects of Process Variables

77.3.1.1 Oxygen and Mass Transfer. Oxygen transfer is always a concern in aerobic biological systems. Most nutrients required for cellular growth and metabolism are highly soluble in water; sufficient and timely supply of these nutrients can be achieved in a well-mixed bioreactor. However, oxygen transfer often becomes a limiting step to the optimal performance of biological systems and also for scale-up because oxygen is only sparingly soluble in aqueous solutions. When oxygen supply is limited, both cell growth and product formation can be severely affected. Mass transfer is also an important factor for cell culture process; however, the overall mass transfer rate is not easy to measure because different phenomena are simultaneously taking place; also, the relative importance of these phenomena changes with the scale, the type of bioreactor, and so on. Therefore, the OTR is influenced by quite a number of factors (physical properties of gas and liquid, operational conditions, and geometrical parameters of bioreactor) and also by the presence of biomass, namely, the consumption of oxygen by the cells (139). Zhu *et al*. (142) were able to increase the mass-transfer rate by 17% by changing the impeller, and Puthli *et al*. (143) found that k_La value was affected by the stirrer configuration.

For animal or plant cell cultures, shortage of oxygen can be expected at a high cell density. As k_La is very important in supplying oxygen to the medium, a very critical aspect of bioreactor design is to achieve a sufficiently high k_La, which is affected by many factors, including the geometrical and operational characteristics of the reactor vessel, agitation speed, aeration rate, fluid hydrodynamics, medium composition, and biocatalyst properties, such as cell type, morphology, and concentration. It was estimated that oxygen transfer management accounts for about 15–20% of all operating costs for aerobic cultivation (144). Very high oxygen levels may become toxic to cells and cause localized oxidative stress (145).

For typical animal cell types, specific OUR is between 3×10^{-10} and 2×10^{-8} mg/(cell·h) (146). Generally, animal cell metabolism and productivity is consistent at a DO level between 10% and 100% of air saturation. Chotigeat *et al*. (147) studied the effect of environmental conditions, including the DO concentration and the level of sodium butyrate, on the expression levels, glycoform pattern, and

the levels of sialytransferase for human follicle stimulating hormone (hFSH) production by recombinant CHO cells. In steady-state perfusion cultures in an STR at different DO concentrations, it was found that both the specific productivity of hFSH and specific activity of sialyl transferase were increased from 0.7 to 2.6 ng $(10^6 \text{cells})^{-1}$ h^{-1} and from 1.0 to 4.9 mol (mg protein)$^{-1}$ h^{-1}, respectively, when the DO was increased from 10% to 90% of air saturation. The number of viable cells was found to be relatively constant, ranging from 4.5–5.7x10^6 cells/mL over the DO levels studied. Tang *et al*. (148) studied the effects of dissolved oxygen tension (DOT) and agitation speed on the Meth A tumor cell suspension culture process in a STR, and found that the heat-shock protein glycoprotein (gp96) biosynthesis was very sensitive to DOT and agitation speed. Compared to 50% of DOT, the production and specific productivity of gp96 was increased by 27% and 66% at 10% of DOT, respectively. Compared to the agitation rate of 100 rpm, the production and volumetric productivity of gp96 was increased by 48% and 144% at an agitation rate of 200 rpm, respectively. Low DOT (i.e. 10% of air saturation) and a relatively high agitation rate (i.e. 200 rpm) were identified to be favorable for gp96 biosynthesis. Low cell growth, low glucose/glutamine consumption, and high lactate production were observed when the DO level dropped below 10% (149). High DO level at 125% favored glucose consumption than glutamine and increased lactate yield (150), in which the shift toward anaerobic metabolism at high DO could be explained by oxygen toxicity. High DO also increased reactive oxygen species causing oxidative damage to cells and products.

In plant cell cultures, the deleterious effects of an oversupply of oxygen were demonstrated by Smart and Fowler (151). In suspension cultures of *Catharanthus roseus* in air-lift bioreactors, when the $k_L a$ value was 14.5 h^{-1}, a maximum biomass density of 14.3 g dry weight (DW)/L was achieved; however, it was only 8.9 g DW/L when $k_L a$ was increased to 39 h^{-1} (151).

77.3.1.2 Fluid Mixing. In bioreactors, adequate mixing is important to ensure sufficient supply of nutrients, especially oxygen (69). In cell culture processes, mixing has often been evaluated in terms of biological performance, such as cell growth rate and productivity. The control of temperature, pH, and substrate concentration is dependent on good mixing in the bioreactor. In plant cell cultures, Zhong *et al*. (128) studied the effect of mixing time on taxoid production in a novel CIB. In the agitation intensity range without damage to the cultured cells, two different mixing times (5 and 10 s) were applied by adjusting impeller agitation speeds. A higher cell density and taxoid productivity were obtained under a shorter mixing time. Poor mixing limited oxygen transfer and led to the formation of larger cell aggregates.

Many techniques and algorithms have been employed to solve fluid-based problems (152). Both Porter *et al*. (153) and Raimondi *et al*. (154) modeled the effects of perfusion to better comprehend the influence of perfusion and hence shear stresses on 3D cultures. Porter *et al*. used a code based on the Lattice–Boltzmann principle to approximately obtain solutions to the Navier–Stokes equations (153), whereas Raimondi *et al*. modeled their flows with the aid of a commercially available FLUENT package (154). Lappa (155) also developed equations based on the level-set principle to model fluid flow as well as to estimate soft tissue growth within a bioreactor. While the level-set method may provide higher levels of accuracy, it tends to be quite complex and might not always be feasible to apply.

77.3.1.3 Temperature. Temperature is one of the most critical parameters to be carefully controlled in a bioreactor. Regardless of the cell type, cell culture always has a quite narrow optimal temperature range for growth. According to van't Hoff's law, an increase in temperature causes an increase in the rate of endothermic reactions. Hence, an increase in the temperature should enhance the speed of conversions in the cells and contribute to the economy of the process (156). However, excessive increases in temperature lead to the enzyme (which catalyzes the reactions) denaturation, and hence reduce the speed of the reactions they catalyze. Therefore, there is an optimum temperature for any biological conversion process. The optimal temperature for plant cell culture (generally 23–30°C) depends on the plant species (157,158). Both the growth of plant cells and the biosynthesis of desired metabolites are influenced by the cultivation temperature with varied optimal values. Georgiev *et al*. found that the optimal temperature for growth of *Lavandula vera* cells was 30°C but the highest volumetric production of rosmarinic acid was at 28°C (159). The same trends were also found by Zhong *et al*. (160), who investigated the effect of temperature on suspended cultures of *P. frutescens* for optimizing the production of anthocyanin pigments. A higher (specific) growth rate was obtained at higher temperatures in a range of 22–28°C, while 25°C was optimal for the volumetric productivity of anthocyanin and the pigment production was remarkably reduced at the a relatively high temperature of 28°C. For animal cell cultures, typical operating temperatures are cell line specific. It varies between 36 and 38°C for mammalian cells, while it lies between 25 and 30°C for insect cells (161).

There are a number of reports on the effects of temperature on cell growth rates and product formation rates for different culture processes. In a conventional process, once the optimal temperature is determined, it is always maintained. This, however, may not always be the case for mammalian cell culture processes. In mammalian cell cultures, a large portion of the protein product is synthesized

during the post growth phase. As the cell viability drops quickly after the cell density approaches maximum in most cases, the cultivation of cells at a reduced temperature has been proposed to improve culture performances. It has been consistently reported that a decrease in cultivation temperature leads to prolonged culture viability (162,163). In CHO cell cultures, sometimes changes in temperature can induce desired effects as it can affect the cell cycle and a temperature shift from 37 to 30°C after 48-h postinoculation can retain cells in the G1 phase (a period in the cell cycle from the end of cell division to the beginning of DNA replication) longer and therefore delay the onset of apoptosis (163). The temperature shift was also successfully proposed by Ahn *et al*. to produce erythropoietin (EPO) (164). The CHO cells were cultivated using a perfusion bioreactor at 37°C until its viable cell concentration reached 1×10^7 cells/mL, and then the culture temperature was shifted to 25, 28, 30, 32, and 37°C (control), respectively. Lowering the culture temperature suppressed cell growth but was beneficial in maintaining high cell viability for a longer period. In a control culture at 37°C, cell viability gradually decreased and fell below 80% on Day 18, while it remained over 90% throughout the culture at a low culture temperature. The cumulative EPO production and specific EPO productivity q_{EPO} increased at low culture temperature and reached the maxima at 32 and 30°C, respectively (164).

77.3.1.4 pH. Medium pH affects the transport of ionized molecules between the cells and the medium. The buffering capacity of the medium and concentration of hydrogen ions in the medium affect the intracellular pH profile, the activity of the intracellular enzyme systems, and also the rate of diffusion of ionized molecules in the electrical field of the cells. The starvation of cells for several minutes brings about a prolonged change in the electrical field of the cells (165). Different biological systems have different optimal pH ranges. Most cells grow best at pH 7.2. During cultivation, the pH usually changes. As the cells grow, metabolites are released into the medium, and substrate consumption also changes the pH value of the medium. For example, ammonium is a common nitrogen source; when ammonium is utilized during cell cultivation, pH decreases. Therefore, the medium pH must be monitored and adjusted by base or acid addition in order to constantly maintain it at an optimum level (69). The pH monitoring and control is important to animal cell cultures, but it is not so in plant cell cultures as the medium pH value generally does not change so much in the latter case.

During plant cell cultivation for recombinant protein production, one of the main obstacles is product degradation by proteases that are produced by cells and/or the loss of biological activity of secreted (extracellular) products as a result of alteration in the recombinant protein conformation. To minimize these effects, Huang *et al*. (38) proposed a bioreactor strategy using a protocol involving pH adjustment and medium exchange during plant cell culture for improving the production of functional recombinant α1-antitrypsin (rAAT), a human blood protein. It was found that higher medium pH helped reduce protease activity derived from cell cultures and improve the inherent stability of rAAT as well, and both the productivity of extracellular functional rAAT and the ratio of functional rAAT to total rAAT were increased. Figure 77.15 shows the effect of pH control on the total and functional rAAT production for a chemically inducible, estrogen receptor-based promoter (XVE) expression system. Under pH control, extracellular functional rAAT reached approximately 60 mg/L in 9 days, compared to that of only negligible levels observed without pH control.

In animal cell culture processes, culture pH is often controlled by adding an alkaline reagent such as $NaCO_3$, $NaHCO_3$, or NaOH to neutralize the acidic effects of lactate and CO_2 production during cultivation (166). Another scheme for pH control in animal cell culture process is CO_2 aeration to decrease pH at the beginning of culture. Its usage decreases and ceases with the increase of lactate and dissolved CO_2 level in culture medium. Gramer and Ogorzalek (167) developed a mathematic model to correlate lactate concentration, pH, dissolved CO_2, and base addition, which helped them identify the reason for the need to add more base at pilot and large scale.

The medium pH is one of the most important process parameters in mammalian cell culture because of the cells' sensitivity. In hybridoma cultures, a pH value of 7.2 was found to be optimal for cell growth. When the pH value was decreased from 7.2 to 6.9, a twofold decrease in specific growth rate, specific glucose consumption rate, and specific lactate production rate was observed (168). On the other hand, Wayte *et al*. (166) reported that the final antibody concentration of two different murine hybridoma cell lines was increased 1.5-fold when the bioreactor pH was slightly reduced from 7.2 to 7.1. Xie *et al*. (169) studied PER.C6® cell growth, metabolism, and adenovirus production in STRs under different pH conditions. It was found that cell metabolism, in both infected and uninfected cultures, was very sensitive to culture pH. Dramatic changes were observed in glucose/glutamine consumption and lactate/ammonium production under different pH conditions. A more than twofold increase in adenovirus productivity was observed by reducing the pH from 7.6 to 7.3. Culture pH is an important environmental factor that should be precisely controlled to ensure the quality of a desired product. Its importance has been demonstrated in T-flask cultures without pH control. Borys *et al*. (170) found that culture pH significantly affected the expression rates and glycosylation of recombinant mouse placental lactogen-I (mPL-I) in CHO cells. Zanghi *et al*. (171) demonstrated the importance of culture pH and pCO_2 interactions, which altered

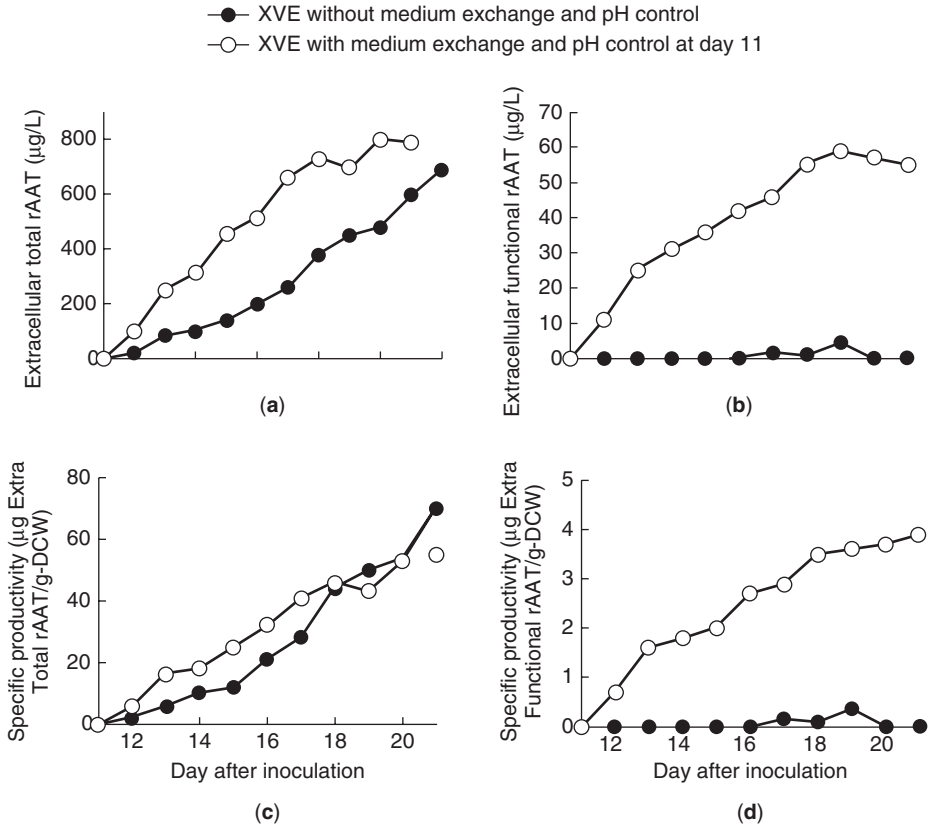

Figure 77.15. Effects of pH control on cell growth and recombinant α1-antitrypsin (rAAT) production in XVE cell cultures in a bioreactor (induction timing at day 11 after inoculation) (38).Extracellular functional rAAT reached approximately 60 mg/L in 9 days under medium exchange and pH control.

glycosylation of recombinant protein in CHO cells. Yoon *et al*. (172) studied the effect of culture pH on cell growth and EPO production at two different culture temperatures (32.5 and 37.0°C) in serum-free suspension cultures of recombinant CHO (rCHO) cells in a bioreactor with pH control (Fig. 77.16). At 32.5°C, q_{EPO} was significantly influenced by the culture pH, and it reached the highest [0.31 ± 0.02 μg/(10^6 cells h)] at pH 7.00, which was approximately 1.8-fold higher than that at pH 6.85, 7.60, or 7.80. At 37.0°C, however, the culture pH did not affect q_{EPO}, which suggested that the cells at low culture temperature were more susceptible to the pH change.

77.3.1.5 Light Irradiation. Light is usually important in affecting growth, organogenesis, and formation of plant products including primary and secondary metabolites. The spectral quality, intensity, and period of light irradiation have been shown to have significant effects on the secondary metabolism of plant cell cultures. Sakamoto *et al*. (173) demonstrated the stimulatory effect of light irradiation on the formation of compounds such as anthocyanins, vindoline, catharanthine, and caffeine in cell suspension cultures. The accumulation of anthocyanin was strongly stimulated by light in cell cultures of *Daucus carota* and *Vitis vinifera* (174). Mulder-Krieger *et al*. (175) found that illumination affected the composition of sesquiterpenes in callus cultures of *Marticaria chamomilla*. Illumination of *Coffea arabica* cell suspensions enhanced caffeine biosynthesis by a factor of 10 (176). Light irradiation had remarkable effects on callus growth of *Oldenlandia affinis* and biosynthesis of kalata B1 with an optimum intensity of 35 μmol/(m^2·s) (177). However, light can also have an inhibitory effect on the accumulation of secondary metabolites such as nicotine and shikonin (178). In addition, the biosyntheses of some metabolites, such as anthraquinone and ubiquinone, are not significantly influenced by light irradiation.

Zhong *et al*. found that the light irradiation and period under daylight irradiation greatly affected anthocyanin production by suspended cultures of *P. frutescens* (179). At a light irradiation intensity of 27.2 W/m^2, a high amount of anthocyanin pigments, 3.0 g/L, was obtained in a bubble-column bioreactor after 10 days of cultivation at an aeration rate of 0.1 vvm, while 2 g/L was obtained at

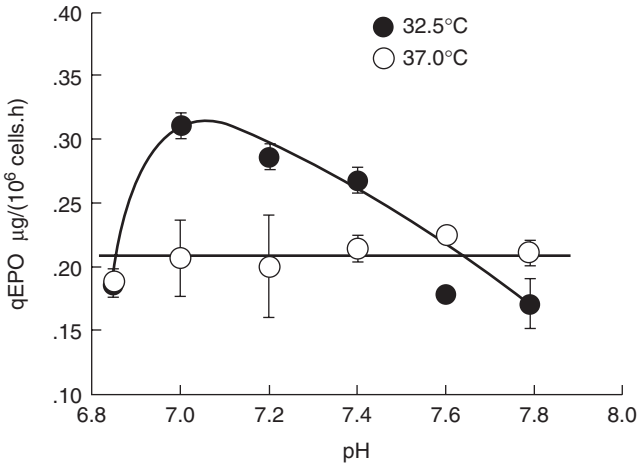

Figure 77.16. Specific erythropoietin (EPO) productivity in batch cultures of rCHO cells at different culture pH values and temperatures (adapted from (172)).

13.6 W/m^2, and very little at 54.4 W/m^2 (Fig. 77.17). A high amount of anthocyanin pigments, 2.9 g/L, was also produced using an aerated and agitated bioreactor with a marine impeller at an agitation speed of 130 rpm, an aeration rate of 0.1 vvm, and light irradiation intensity of 27.2 W/m^2 (179). The amount of anthocyanin produced was more than twice that without light irradiation.

Different types of spectral radiance can also influence the cell growth and secondary metabolite production. After 21 days of callus cultivation of *Saussurea medusa*, red light significantly improved its growth, but inhibited the biosynthesis of flavonoids (180). However, blue light was found to enhance the flavonoids' biosynthesis, although callus growth under this spectrum was comparable to that under white and other color spectra such as green and yellow. The accumulation of flavonoids in the cultures was related to the L-phenylalanine ammonia-lyase (PAL) activity, which was stimulated by the spectral composition of irradiation. Yu *et al*. found that the biomass of hairy roots was highest in the cultures grown under dark or red light, while ginsenoside accumulation was optimum in the cultures grown under fluorescent light during hairy root cultures of *Panax ginseng* (181). Similarly, the growth of hairy roots and betalain accumulation in *Beta vulgaris* (red beet) was also affected by different radiation sources—blue (B), red (R), R plus B (RB), B plus far red (BFr), and R plus far red (RFr), and Shin *et al*. found that BFr treatment induced betalain pigmentation in hairy roots (182).

77.3.2 Bioreactor Operation Strategy

An effective bioreactor operating strategy should provide a high volumetric productivity, which means more products can be formed per unit time per unit reactor volume. A major disadvantage of standard batch processes is that significant amount of time is taken up by the sterilization of system and medium, filling, emptying, and cleaning of the system. Thus, to improve the cost effectiveness of cell culture processes, various operational modes such as multistage batch, fed-batch, single- or multistage continuous (chemostat), semicontinuous (draw-and-fill or repeated batch), and perfusion (chemostat with cell retention) cultivations have been applied or developed so far (156,183–185).

77.3.2.1 Fed-Batch Culture. Generally, the final product concentration is primarily affected by the specific productivity of cells and integrated cell growth. Batch cultivations are characterized by constantly changing environmental conditions, and are capable of producing metabolites associated with any kinetic pattern. Batch studies are used to determine the conditions for maximum productivity. However, depletion of nutrients and a steady increase in toxic metabolites limits the final cell and product concentrations. With the resources available in a typical growth medium, cells are simply unable to attain and sustain high cell densities (133).

To overcome nutrient limitation, fed-batch processes have been widely practiced. This involves the addition of one or more nutrients continuously or intermittently to the initial medium after the start of cultivation, or from certain point during the batch process (13). Fed-batch cultures are currently the norm for most cell culture processes, especially for intracellular products of cell cultures that are stored within the cells. For intracellular products, a culture strategy that gives a high biomass output rate is most desirable (186). For example, in *P. ginseng* cell culture for ginsenoside production (187) and *Taxus chinensis* (188) cell culture for taxoid production, fed-batch cultivation has been successfully demonstrated. During the cultivation of *Coptis japonica* to produce berberine in STR, the biomass concentration was reduced due to high osmotic pressure of the culture medium and accumulation of inhibitory products during cell growth, and this problem was solved by a suitable fed-batch operation that enhanced both cell growth and berberine production at high cell density (189,190). Hu *et al*. (191) performed fed-batch cultivation of *P. notoginseng* cells in a concentric-tube air-lift reactor to study the effects of bottom clearance on cell growth and the production of ginseng saponin and polysaccharide. A fed-batch operational mode was also developed, in which sucrose was fed just prior to a sharp decrease in the specific OUR [>0.20 mmol/(g DW h)] (192). By applying this feeding policy to *P. notoginseng* cell suspensions, cultivated in a 10-L air-lift bioreactor (192) and a 30-L CIB (126), very high biomass productivity of approximately 1.5 g/(L·d) was achieved, and both saponins

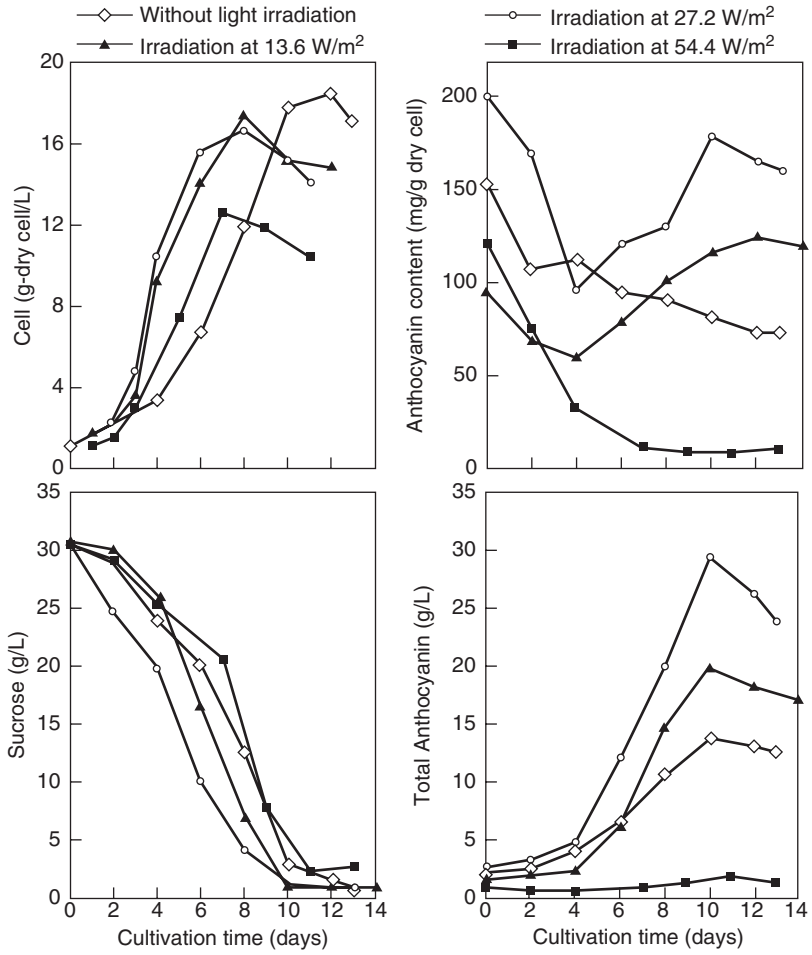

Figure 77.17. Effects of light irradiation intensity on production of anthocyanin pigments by suspension cultures of *P. frutescens* cells in a bubble-column bioreactor at an aeration rate of 0.1 vvm (adapted from (179)).

and polysaccharide productivities were also higher than those in a comparative batch process.

Fed-batch processes are also common in animal cell cultures and have been operated at scales up to 25 000 L working volume for large-scale antibody production (193). The titer from fed-batch mammalian cell culture has increased dramatically in recent years due to the improvement in cellular engineering, culture medium, and feeding strategy (8). High density of 3×10^7 cells/mL has been reached (194). Huang *et al*. recently reported up to 13 g/L of final titer and high volumetric productivity of 800 mg/(L·d) in an 18-day fed-batch process using a CHO cell line without the antiapoptosis gene (195). It can be predicted that more companies can achieve this level in future, which will increase the manufacturing capability dramatically and will put a positive pressure on downstream purification. In another case, because the forecasted market demand is beyond the designed capability of the first-generation process using packed-bed perfusion technology, Meuwly *et al*. (196) converted it to a fed-batch model at $15m^3$ and increased product output by 18-fold while maintaining a comparable product quality.

A comparison of different feeding modes is presented in Table 77.4. Among these, the most popular and successfully used ones are fed-batch and perfusion.

77.3.2.2 Continuous and Semicontinuous Culture. Theoretically speaking, continuous culture is the most promising mode for obtaining high culture productivity. In a continuous culture, the nutrients consumed by the cells are continuously replenished by an inflow of fresh medium. A constant inflow of fresh medium is balanced by a constant efflux of spent medium plus cells. Consequently, a steady state is developed at a dilution rate (equal to outflow rate/volume) less than the maximum specific growth rate of the culture. Under steady-state conditions, the average specific growth rate in the culture is identical to the dilution

TABLE 77.4. Comparison of Some Commonly Used Modes of Feeding Based on Product Yield and Process Economics (Modified from (197))

Culture Mode	Product Yield	Process Manipulation	Cost (Capital Investment and Labor)	Throughput
Batch	Low	Low	Low	Low
Repeated batch	Low	Medium	Medium	Medium
Fed-batch	High	Medium	Low	Low
Chemostat	Low	Medium	Low	Low
Perfusion	Medium	High	Medium	High

rate. The biomass concentration of the culture is then determined by the concentration of the growth-limiting nutrient in the influent. All culture parameters (biomass, biomass composition, and nutrients) remain constant for prolonged periods of time in a steady state. This "balanced growth" is a very attractive tool in studies on growth and production kinetics or cell physiology (185).

Seki *et al*. (198,199) and Phisalaphong and Linden (200) demonstrated the enhancement of paclitaxel production by continuous plant cell culture of *Taxus cuspidata* and by using a semicontinuous culture of *Taxus canadensis* with total cell recycle, respectively. However, due to the practical problems of cell line stability and requirement for long-term sterile operation of bioreactors, such work is still limited in the laboratory. On the other hand, as shown by Van Gulik *et al*. (201), a chemostat culture technique is useful in obtaining reliable data on the stoichiometry of the growth of plant cells in bioreactor. Several other groups have also studied growth kinetics, stoichiometry, and modeling of the growth of suspension-cultured plant cells by using semicontinuous or fed-batch cultures to achieve steady-state growth. In addition, Westgate *et al*. (202) presented fed-batch cultivation kinetics for continuous approximation in *Cephalotaxus harringtonia* cultures. Trexler *et al*. (203) used a cyclical, semicontinuous operation to produce rAAT in the transgenic rice culture; the process consisted of three cycles over a 25–28-day period, with each of the growth phases lasting 4–6 days and each of the protein expression phases lasting 2.5–5 days.

In animal cell culture, little work has been done by continuous cultivation. Nyberg *et al*. studied the glycosylation of IFN-γ produced in continuous culture of CHO cells to investigate the relationship between metabolism and glycosylation site occupancy (204).

77.3.2.3 Perfusion Culture. Perfusion model is normally chosen for the production of unstable proteins. This is because perfusion culture has low resident time in bioreactor and the product can be harvested and purified promptly (205). In addition, it can avoid the accumulation of toxic or inhibitory metabolites that might have a negative impact on the productivity of fed-batch cultures. Perfusion cultivation is carried out by continuously feeding fresh medium to the bioreactor and constantly removing the cell-free spent medium while retaining the cells in the reactor, thus a much higher cell density can be obtained in perfusion cultures compared to that in continuous cultures, as cells are retained within the reactor via a cell-retention device (206). The perfusion rate depends on the demand of the cell line, the concentration of nutrients in the feed, and the level of toxification. Table 77.5 summarizes the key assumptions in process inputs between fed-batch and perfusion modes of operation (207).

The overall advantage of perfusion cultures is that it requires a smaller scale compared to that required in batch cultures in order to obtain the desired amount of product, thus perfusion culture has been used in mammalian cell processes to produce at least seven commercialized products (208). However, it has low product titer compared to fed-batch culture, which brings challenges to downstream purification. Konstantinov *et al*. (209) proposed a "push-to-low" method, decreasing the perfusion rate until it failed to maintain high viability, in order to reach comparable titer as batch or fed-batch culture. Using transient gene expression (TGE) to produce large amounts of recombinant proteins within a short period of time has recently attracted considerable interest (210). Compared to the batch modes, in which the transfections are conducted at a low cell density, high-density perfusion culture has been used in the production of recombinant adenovirus with a significantly higher production (211,212). The cell densities achieved in perfusion culture (10^7–10^8 cells/mL) are typically higher than most fed-batch processes ((1–30) $\times$ 10^6 cells/mL). In specific cases, it has been demonstrated that continuous perfusion offers an approximately 10-fold

TABLE 77.5. Chemical and Physical Methods Used for Cell Synchronization

Assumption	Fed-Batch	Perfusion
Size of production bioreactor (L) (working volume)	5000	1000
Seed bioreactor train (L)	20; 100;500	20; 100
Duration of cultivation (days)	15	35
Cultivation titer (g/L)	1.0	0.35

improvement in volumetric productivities compared to that in fed-batch culture (207,213). Jardin *et al*. designed high cell density fed batch and continuous perfusion processes to maximize the productivity of stably transformed cell (Sf-9SEAP), with a total yield of 17.6 IU in batch process, of 46.1 IU in fed batch process, and of 394 IU in perfusion process (214). Deo *et al*. (215) reported a 500-L-scale spin filter perfusion hybridoma culture for antibody production that was run for 15–35 days. They estimated that the volumetric productivity of the perfusion process was approximately 10 times that of batch or fed-batch cultures. Coagulation factor VIII, licensed by Bayer, was the first biopharmaceutical produced by recombinant BHK cells using continuous perfusion culture. Bayer validated a 185-day production process. Compared to the batch culture, the advantage of Bayer's production process is a 30-fold increase in cell density that results in a 30-fold higher yield of factor VIII. This leads to significantly reduced requirements for plant capacity: a 100–500 L perfusion reactor versus a 5000–15 000 L batch reactor (216). Sun *et al*. established a high-density perfusion culture of 293 EBNA1 cells in a 2-L bioreactor. The process resulted in a longer posttransfection production phase and higher protein production (217).

Perfusion culture is also used in plant cell culture. Su and Humphrey (218) adopted the perfusion strategy for high cell density culture and enhanced secondary metabolite production. Chen and Lin used a fibrous scaffold from *Luffa cylindrica* in a PBR for dynamic seeding and perfusion culture of rat hepatocytes (219). In order to investigate the effects on the transgenic *Nicotiana tabacum* cell physiology and the human granulocyte-macrophage colony-stimulating factor (hGM-CSF) production, a perfusion culture was carried out in a 5-L STR with three different perfusion rates (0.5, 1.0 and 2.0 per day) by Lee *et al*. Owing to the lower protease activity caused by the perfusion, in all the cases, the hGM-CSF in the medium was significantly increased during the overall culture period (16 days), with maximum values 3.0-, 9.4-, and 6.0-fold higher than those obtained in batch cultures, respectively. Su *et al*. (55) grew *Anchusa officinalis* cells in a perfusion bioreactor with perfusion rates up to 0.4 L/(L day). With complete cell retention, the dry cell weight exceeded 20 g/L, and the packed cell volume exceeded 70%. It was concluded that perfusion bioreactor system showed high potential as an alternative to immobilized plant bioreactors.

77.3.3 Process Monitoring and Control

The maintenance of optimal conditions for cell culture in a bioreactor requires systematic qualitative and quantitative descriptions of cell culture processes by on-line and off-line process monitoring methods (31). Currently, process monitoring for cell culture processes is mainly applied for detecting cell growth and the related physiological status such as biomass concentration, nutrient consumption, OUR (220), CER, RQ, DO, and pH. To accurately characterize several plant suspension cultures (*O. sativa*, *Nicotiana benthamiana*, and *Trichosanthes kirilowii*), including biomass concentration and aggregate size, McDonald *et al*. (221) successfully applied a focused beam-reflectance method (FBRM developed by Lasentec Inc., Redmond, WA). By using a laser turbidimeter (at 780nm), the cell concentration of *P. frutescens* was successfully measured on-line and *in situ* (222). Furthermore, Zhong *et al*. established a computer-aided on-line monitoring system to analyze the response of *P. frutescens* cells during cultivation. The physiological and metabolic aspects such as cell growth and respiratory activity under different agitation speeds were also investigated (223). The system was useful for the selection of some informative process variables and for the identification of physiological states of plant cells during bioreactor cultivation. The process variables, such as RQ, pH, and SCER, could be used for the identification of the growth phase of the cells during cultivation. The experimental results also suggest that the process variables, that is, OUR and SOUR, may be related to the accumulation of anthocyanin in *P. frutescens* cell cultures (Fig. 77.18). Monitoring of the above variables including OUR and SOUR during bioreactor cultivation may be very useful for effective feeding and control in a high-density cell culture to optimize the product accumulation. The information provided by the work could be helpful for the control and optimization of plant cell bioprocesses (223). Zhou *et al*. (224) used on-line OUR measurement to determine the time for feeding as OUR dropped dramatically when nutrients depleted. Schoenherr *et al*. (225) found that the on-line OUR measurement was a sensitive and convenient way to determine the end of exponential growth phase, which can help optimize transfer time for inoculum expansion.

Spectroscopy is a useful tool for on-line monitoring of many biological species. Near-infrared (NIR) spectroscopy can be used to measure various chemicals in cell culture mediums such as glucose, glutamine, ammonia, lactate, and glutamate (226). Recently, Rhiel *et al*. (227) reported the application of mid-infrared (MIR) spectroscopy to detect glucose and lactate in CHO cell culture without recalibration in 60 days. With advances in electro-optics and computing power, two-dimensional fluorescence spectra can also provide information on many fluorescent species simultaneously (228). The recombinant protein that fused with green fluorescent protein (GFP) can provide an on-line monitoring method to rapidly observe the recombinant protein production kinetics as well as cellular dynamic responses (229). Schulze-Horsel *et al*. (230) utilized a sensitive and quantitative method for the flow cytometric detection of influenza A virus infection

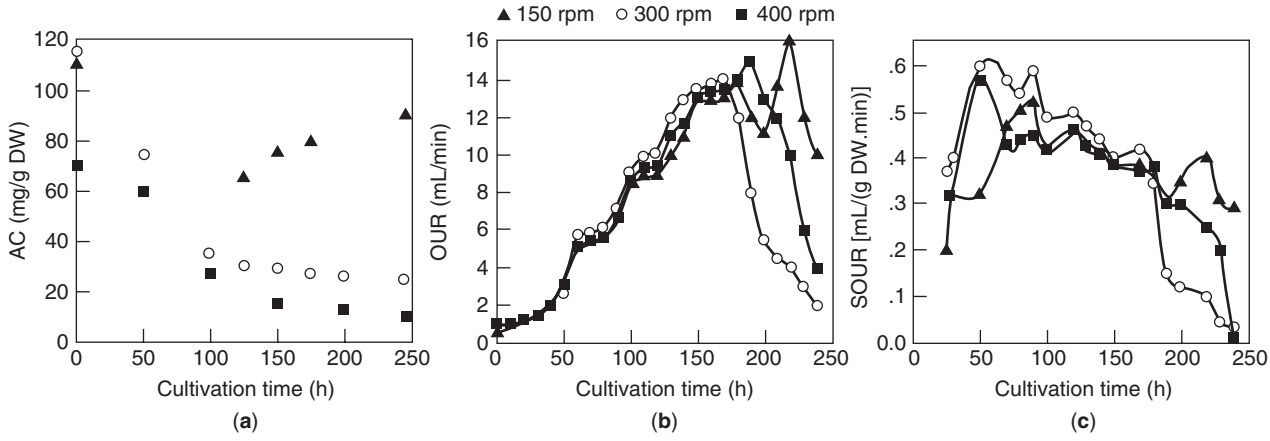

Figure 77.18. Dynamic behaviors of anthocyanin content (AC), OUR, and SOUR in a stirred bioreactor (adapted from (223)).

with mAbs in adherent MDCK cells fixed in ethanol and PFA/ethanol, and they demonstrated that this method was a valuable addition to other detection methods of influenza virus infection such as immunotitration and RNA hybridization. By using fluorescence probe, Srivastava *et al*. (231) investigated on-line biomass measurement during bioreactor batch cultivation of *A. indica* cells for azadirachtin (biopesticide) production; they established a linear correlation between viable cell concentration and net NADH fluorescence under balanced growth condition.

For mammalian cell culture, capacitance probe or dielectric spectroscopy is becoming a useful tool to monitor viable biomass. Under an electric field, the capacitance output is proportional to intact nonconducting cell membrane area where charge can be built up. Dowd *et al*. (232) applied it in a CHO perfusion process to assess viable cell concentration and adjusted the perfusion feeding rate accordingly.

In situ microscopy (233) has proven to be a suitable method for real-time inline monitoring in mammalian suspension cell lines (234–236). Important process parameters [such as cell concentration, cell size distribution, cell volume, and culture aggregation state that are distributed into single cells, double cells, and cell clusters (with more than two cells), respectively] can be measured. Rudolph *et al*. (237) utilized *in situ* microscope to measure the level of colonization of fibroblasts on microcarrier surfaces during cultivation, and then developed a neural-network-based algorithm for the estimation of the process parameters of plating efficiency (PE) and the level of colonization (LOC) from the segmented image regions of the microcarriers.

For production of antibodies, an upcoming trend in process control and online measurement is immunoanalysis of the produced antibodies to analyze the product characteristics regularly. The process can be monitored according to the concentration and quality of the desired product (238,239).

77.4 PROCESS SCALE-UP FOR PRODUCTION

The major challenge of process scale-up has been how to translate the laboratory-scale product designs into large-scale production. Bioreactor culture is the key step toward commercial production of bioactive therapeutics (145). During the scale-up of cell culture processes, reduced productivity has often been reported, which can be attributable to any of a couple of factors including shear stress, oxygen supply, and gas composition. With the aim of implementing an industrial-scale process, the behavior of cell cultures in bioreactors has been receiving much attention (127).

Bioreactors in general can be evaluated by the following physical characteristics: mixing time, shear, pH, heat transfer, and mass (oxygen) transfer. Although the physical characteristics are interrelated, in scale-up and reactor design, the mixing time, shear, and mass transfer aspects are coupled, while pH and heat transfer are considered separately (240).

Unlike mass transfer, which takes place throughout the broth, heat transfer occurs only at the boundary surfaces of heat exchange. It is possible to provide the required heat transfer capacity of a large-scale bioreactor by methods independent of process scale-up, such as by using a refrigerant rather than cooling water or by using an external heat exchanger. Consequently, traditionally equal heat transfer capacity has not been used as a basis for translating experimental results between different scales of operation. Similarly, proper pH control can be achieved independently by automatic addition of concentrated acids or bases into culture systems. Assuming an adequate mixing, pH itself does not constrain scale-up. pH gradient is an issue related to mixing on a large scale.

The process characteristics that have been suggested to be maintained constant or similar during scale-up include the following:

1. Reactor geometry
2. Volumetric oxygen transfer coefficient, $k_L a$
3. Maximum shear
4. Power input per unit volume of liquid, P_g/V
5. Volumetric gas flow rate per unit volume of liquid, Q/V or vvm
6. Superficial gas velocity, v_s
7. Mixing time
8. Impeller Reynolds number
9. Momentum factor.

To combat the problems of poor mixing in large bioreactors, especially with viscous non-Newtonian systems, people employ equal mixing times in bioreactors of different scales (241). Although important for fast chemical reactions, the requirement of constant mixing time is unnecessary for normal cell cultures. Furthermore, the volumetric power input required to maintain equal mixing time increases as the 2/3-th power of the system volume and can become prohibitive on scale-up. Experience proves that the power input thus determined is much more than that required for practical scale-up. Constant power input per volume commonly used in microbial fermentation, criterion 4, is also applicable to cell culture process as it has a great impact on mass transfer and hydrodynamic force distribution in a bioreactor (135). Criteria 8 and 9 are generally not used. One main reason is that no consideration is given to the effect of aeration on the process results. Consequently, only criteria 1–6 are commonly considered for scale-up of cell culture bioreactors.

Criterion 1 is based on the fact that almost all of the existent empirical or semiempirical correlations for scale-up are developed experimentally with geometrically similar reactors of different scales. When translating experimental results between reactors with different geometries, one needs to consider the validity of correlations chosen from the literature and the necessity of developing or modifying the correlations for the specific situation.

Criteria 5 and 6 address the importance of aeration rate to scale-up of aerobic cell cultures. Volumetric gas flow rate per unit liquid volume, due to its influence on mass transfer in bioreactors subjected to bubble aeration without mechanical agitation, has been accepted as a traditional scale-up criterion even for mechanically agitated vessels (242). On the other hand, the superficial gas velocity is also an important factor in reactor design. It strongly affects the mixing energy required to disperse the gas stream, and, in all the cases, has an upper limit before impeller overloading or liquid blow-out action begins. The upper limit of v_s is strongly system dependent. When overloaded, the impeller cannot disperse all the gas supplied, short-circuiting occurs, the gas rises as big bubbles to the surface, and the pumping action of the impeller diminishes.

Unfortunately, criteria 5 and 6 are contradictory to each other when applied to scale-up of geometrically similar bioreactors. If it is desirable to maintain equal vvm, then the superficial gas velocity through the vessel increases directly with the scale ratio, and consequently may lead to impeller overloading or liquid blowout. Therefore, the choice and/or compromise between criteria 5 and 6 has to be carefully evaluated for the individual process involved.

As mentioned above, without doubt, the bioreactor scale-up technology is critical to industrial application, for example, in plant root cultures (145). In some cases, the scaling-up factor may be quite different from the above-mentioned conventional ones. For example, in plant cell suspension cultures of *T. chinensis*, it was noted that a considerable drop in taxuyunnanine C (Tc, a novel bioactive compound) accumulation occurred when the cells were transferred from shake flasks to bioreactors; and, after a series of investigations, interestingly ethylene was finally identified as a key factor in scaling up the process (243).

77.4.1 Animal Cell Culture Scale-Up

Owing to high dose and multiple indications, the requirement of certain commercialized mAbs reaches 500–1000 kg per year. Therefore, large-scale manufacture with high productivity is of vital importance. Until the mid-1980s, the largest scale reported was 8000 L for the production of interferon from Namalwa cells (244). Currently, the manufacture scale can reach 25 000 L for a fed-batch process and 2000 L for a perfusion process. Table 77.6 shows large-scale processes of animal cells (10).

Even though large-scale mammalian cell culture has been routinely performed by biopharmaceutical companies, the literatures about scale-up are still limiting. Moran *et al*. (245) and Schenerman *et al*. (246) showed that very similar process performance and product characteristics are achieved for suspension cultures conducted at scales ranging from 3 to 10 000 L. Yang *et al*. (247) focused on the scale-up of a Sp2/0 mouse myeloma cell line–based fed-batch bioreactor process, from the initial 3-L bench scale to a 2500-L scale. A stepwise scale-up strategy that involved several intermediate steps in increasing the bioreactor volume was adopted. Consideration was also given to scale-up of the nutrient feeding, inoculation, and the set points of operational parameters such as temperature, pH, DO, dissolved carbon dioxide, and aeration in an integrated manner. They chose 65 rpm in the end to balance the mixing time and tip speed. The 2500-L process is currently in use for the routine clinical production of Epratuzumab in support of two global Phase III clinical trials in patients with lupus.

Xing *et al*. (248) performed cell-free mixing and mass transfer studies in production scale 5000-L bioreactors

TABLE 77.6. Large-Scale Processes of Animal Cells (Adapted from (10))

Cell LineScale (L) Reactor Product			
BHK 21	10,000	Agitated tank	Foot and mouth disease vaccine
CHO	10,000	Agitated tank	tPA
Namalwa cells	8,000	Agitated tank	Lymphoblastoid interferon
Bowes melanoma	7,000	Agitated tank/microcarrier	tPA
Murine hybridoma	2,000	Air-lift	mAbs
Vero cells	1,000	Agitated tank/microcarrriers	Killed polio vaccine
Murine hybridomas	1,000	Stirred-tank	mAbs against cell-surface antigens of adenocarcinomas
BHK	500	Agitated tank/perfusion	Factor VIII

with three Lightnin A100 impellers. It was found that pH and oxygen gradients might exist based on the difference between top and bottom probes. The oxygen transfer threshold analysis indicated that the current 5000-L configuration could only support a maximum viable cell density of 7×10^6 cells/mL. Empirical equations were developed to predict mixing time, oxygen transfer coefficient, and carbon dioxide removal rate. These equations indicated that increasing bottom air sparging rate was more efficient than increasing power input in improving oxygen transfer and carbon dioxide removal.

Van Berkel *et al*. (249) performed glutamine synthetase selection technology in suspension growing CHO-K1SV cells to test antibody expression. The N-linked glycosylation was highly consistent for the same cell line when grown extensively, indicating the robustness of the production and glycan analysis procedure. The N-linked glycosylation altered when batch production in a shake flask was changed to fed-batch production in a bioreactor, but was consistent again when the process was scaled from 130 to 5000 L. It may be due to uncontrolled environments in a shake flask such as pH and DO.

The level of dissolved CO_2 (dCO_2) should be carefully monitored during scale-up of mammalian cell cultures. Compared to O_2, CO_2 has high solubility, which also increases with scale because of hydrostatic pressure. For a single bubble, the gas composition changes, resulting from ongoing mass transfer while the bubble rises. The driving force to remove dCO_2 decreases more quickly than that to supply O_2. Mostafa and Gu (250) mentioned that dCO_2 level increased from the 68 to 179 mmHg level when scaling up a process from 4 to 1000 L resulting in a 40% decrease in productivity. The authors found that a decrease in the top impeller position and increase in the aeration rate could help lower the pCO_2 level and increase the final titer by 100%. Zhu *et al*. (251) also reported a high dCO_2 level of 120–150 mmHg observed in production scale as well as high osmolality, which caused quick viability drop and low titer compared to bench scale data. Therefore, the aeration and agitation strategy needs to be carefully designed to prevent dCO_2 accumulation on a large scale.

77.4.2 Plant Cell Culture Scale-Up

In 1959, it was first reported that plant cells were cultured in a 10-L bioreactor made of glass or steel (252). The first large-scale production of *N. tabacum* cells in a 20 000-L STR was reported in 1977 (253). Plant cell culture was industrially accomplished up to the 75 000-L scale (254).

Adventitious roots of *Echinacea purpurea* were cultured in air-lift bioreactors (20- and 500-L balloon-type bubble bioreactors and 1000-L drum-type bubble bioreactor) for production of chichoric acid, chlorogenic acid, and caftaric acid (255). On the basis of studies in a 20-L bioreactor, pilot-scale cultures were established and 3.6 kg and 5.1 kg dry biomasses were achieved in the 500- and 1000-L bioreactors, respectively. The accumulation of 5 mg of chlorogenic acid/g DW, 22 mg of chichoric acid/g DW, and 4 mg of caftaric acids/g DW were achieved with adventitious roots grown in a 1000-L bioreactor (255). OTR and the corresponding power requirement are vital for design and scale-up of surface aerators. Rao *et al*. (256) developed a simulation or scale-up criterion correlating the oxygen transfer coefficient and power number along with a parameter governing the theoretical power per unit volume. It has been demonstrated that energy can be saved substantially if the aeration tanks are run at relatively higher input powers. It is also demonstrated that smaller-sized tanks are more energy conservative and economical when compared to big sized tanks. The results presented have application in biotechnology areas with a particular emphasis on the design of appropriate surface aeration systems. Son *et al*. (257) demonstrated a novel type of bioreactor for the production of paclitaxel and its precursors by culturing cells of *Taxus cuspidata* on a pilot scale. The cells were inoculated in 20-L-capacity bioreactors of different types to test the growth performance, including a balloon-type bubble bioreactor (BTBB), a bubble-column bioreactor (BCB), a BCB with a split-plate internal loop, a BCB with a concentric draught-tube internal loop, a BCB with a fluidized bed bioreactor, and two different models of STRs. Among the reactors, BTBB appeared to be the most efficient in promoting cell growth. When yew tree cells were grown in

different sizes (100–500 L) of BTBBs, more than 70% cell viability was recorded at the time of harvest. The growth pattern of the cells in the pilot-scale BTBB appeared to be the same as that in a 20-L bioreactor. Approximately 3 mg/L of paclitaxel and 74 mg/L of total taxanes were obtained after 27 days of cultivation.

77.5 CONCLUSIONS

Currently, cell culture technology has had rapid development in application and technological innovation. It is used to produce a series of mAbs, hormones, cytokines, antiviral vaccines, effector cells, and so on. Cell culture at the laboratory scale does not seem to meet the production need; therefore, the bioreactor technology is necessary to meet the market need to get sufficient amounts of useful products. Most cell culture systems can be classified into one of the following types: STRs, pneumatically agitated bioreactors, membrane bioreactors, fixed and fluidized-bed bioreactors, as well as wave bioreactors. In bioreactor design, the mass (especially oxygen) transfer rate, production intensity, and dynamic characteristics should be considered. Biomedical research institute, pharmaceutical companies, and bioengineering companies combine different methods and bioreactor instruments to produce cells for different purposes, which also become the important driving force for bioreactor development, and here the cell or tissue could also be seen as a "super bioreactor" (69).

As we know, plant-derived natural products play a critical role in modern medicine. However, harvesting these products from the parent plant is expensive, requires large amounts of plant material, and is often harmful to the environment. Plant cell cultures have been established for a wide variety of species using nominal amounts of plant material, a particularly useful strategy for the production of valuable metabolites from endangered or rare plants. Although plant cell culture represents an important alternative for natural product production, at present only a small fraction of plant products are produced by cell culture on an industrial scale. However, with the development of biosynthesis and biochemical studies at cellular and molecular levels, metabolic engineering of plant cells is becoming more feasible, and the commercial prospects of plant cell culture will be improved. Further studies are also needed to develop correlations between cell physiology/metabolism and operating variables such as hydrodynamic forces in the *in vitro* culture environment, and to identify fluid dynamic parameters that are optimal for product accumulation and release, and so on. Such correlations will help improve our understanding of plant cell responses to cultivation conditions, and will provide a basis for more effective approaches to bioreactor design and optimization.

It is evident that the transfer of successful laboratory-scale results to large-scale industrial processes is still a challenge. Products from animal cell cultures such as vaccines, antibodies for therapeutic use, and recombinant proteins are mainly produced in batch reactors up to the 25 000-L scale. High amounts of antibodies and vaccines are in demand throughout the world to meet therapeutic or diagnostic needs. Ongoing development and optimization of fed-batch and perfusion processes are required to meet the worldwide market at an economically and socially acceptable price. For large-scale cell culture processes, cell retention and separation is still ineffective; the devices undergo fouling very quickly; the cells are stressed to some extent by retention or separation, and viability drops. The latter is also a problem for batch cultures when the product is harvested and separated from the cells. Dead cells release a variety of proteins into the supernatant, which might alter the product quality and DNA might also contaminate the product and has to be carefully removed.

Meanwhile, the bioreactors for mass production of regenerated tissues and organs have already been proposed by a few companies. New horizons have been opened, and clinicians, scientists, engineers, and other individuals, whether in private or in public industries, should begin to work in teams as a multidisciplinary approach is required. Numerous applications have been proposed, but many more are expected. Biomaterials and artificial organs increase life expectancy and improve the quality of life of millions. Currently, bioreactor engineering is also moving forward toward new challenges and aims to turn them into industrialization achievements for the benefit of human beings and the society.

NOMENCLATURE

$k_L a$	Volumetric oxygen mass transfer coefficient, h^{-1} (or s^{-1})
N	agitation speed, s^{-1}
Pg/V	power input per unit volume of liquid, kW/m^3
Qs	liquid exchange rate, m^3/s
Q/V	volumetric gas flow rate per unit volume of liquid, $m^3/(m^3\ s)$
v_s	superficial gas velocity, m/s

ACKNOWLEDGMENTS

The experimental results from the JJ Zhong Lab (Molecular Biochemical Engineering Group) were mainly obtained by Wei-Wei Hu, Zhi-Wei Pan, Zhi-Gang Qian, Hong-Qiang Wang, Si-Jing Wang, Zhi-You Wen, Cai-Jun Yue, and Zhan-Ying Zhang. Financial aids from National Natural

Science Foundation of China, Ministry of Education of China, Shanghai Municipal Science & Technology Commission, ECUST, and SJTU are also appreciated. The authors also thank the referees for their constructive comments.

BIOTRANSFORMATION, PROCESS OPTIMIZATION

Department of Chemistry, Rostock University, Rostock, Germany

78.1 INTRODUCTION

The use of biotransformations in the food, pharmaceutical, and chemical industries has increased steadily since the early 1970s. Applications range from synthesis in the milligram scale for precious oligosaccharides up to multiton scale for bulk chemicals either using whole cells or isolated enzymes. These processes have been documented in numerous reviews and textbooks (1–5). When new processes are being developed, the special properties of the biocatalyst must be considered, as well as the basic elements of chemical engineering. There is a strong interaction among the individual aspects, which may be considered for process optimization. These are summarized in Fig. 78.1.

The intention of this contribution is to outline the basic strategy for the development of industrial process of biotransformation including the beneficial role of biochemical engineering. For some selected examples the beneficial role of biochemical engineering is demonstrated. A more detailed description can be found in textbooks of biochemical engineering (1,3,6–8).

78.2 WHOLE CELLS OR ISOLATED ENZYMES?

Whole microorganisms or their components, enzymes, may be used for biotransformations. Both approaches have specific advantages and requirements, as summarized in Table 78.1. Commonly, the word *biotransformation* is used to describe the transformation of a substrate or precursor into a certain product in only a few steps. Fermentation processes, for example, production of amino acids from glucose and ammonia or production of (recombinant) proteins, are normally not regarded as biotransformation. Literature describing those processes can be found elsewhere in this volume or in external references (2,9–13).

Examples for industrial biotransformations using whole cells or isolated enzymes are given in Table 78.2. Some special information about process characteristics is given as well. When isolated enzymes are used for biotransformations, the purity must only be such that no side reactions occur. There is no need to purify the enzyme to homogeneity, as required for biochemical characterization. On the contrary, many enzymes show reduced stability with increasing purity. In some cases, the addition of inert proteins, such as bovine serum albumin, may be used as a simple way to increase the stability of the production enzyme. In others, the enzyme stability may be increased by immobilization on a support. Covalent attachment fixes the conformation of the enzyme often preventing denaturation. However, the increase of stability has to be balanced against the losses during the immobilization step, as well as the additional work and materials costs. A method introduced in the 1990s for the stabilization of enzymes and their immobilization is the formation of cross-linked enzyme crystals (CLECs) (21). A simpler approach uses cross-linked enzyme aggregates, as they are easier to obtain.

Reactors for immobilized enzymes are discussed elsewhere. However, the engineering approach as outlined in

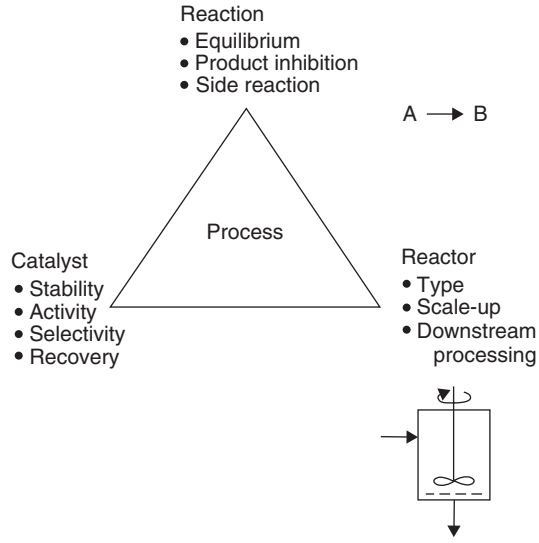

Figure 78.1. Elements of process development.

the following sections is the same for all forms of biocatalysts. Specific requirements and properties such as oxygen delivery, mass transport limitations, or particle size must be considered for individual cases.

78.3 CLASSIFICATION OF DIFFERENT REACTORS

There are three basic types of reactors, which have several variations (Fig. 78.2):

1. Stirred tank reactors (STRs) or batch reactors
2. Continuously operated stirred-tank reactors (CSTRs)
3. Plug-flow reactor s (PFRs)

Unlike the STR, which is operated batchwise, the latter two are operated continuously. By knowing the main characteristics of these fundamental reactors and some of their variations, for example, the cascade reactor of Fig. 78.2, it is possible to choose the appropriate reactor for a specific application. This is especially important when dealing with a kinetically or thermodynamically limited system, as demonstrated later. In the following analyses only the basic terms are explained. For more details the reader is referred to textbooks (6–8).

The STR is operated in a nonsteady state (Fig. 78.2a). Assuming ideal mixing characteristics, the instantaneous concentration of every species is the same in every volume element. With advancing conversion, the substrate concentration is decreased and the product concentration is increased. A steady state is only reached at equilibrium conversion.

TABLE 78.1. Comparison of Biotransformations Using Whole Cells or Isolated Enzymes

Whole Cells	Isolated Enzymes
Large amounts of catalyst easily available	Additional step for obtaining the catalyst required
No stability problem when growing cells are used	Catalyst stability strongly influenced by reaction conditions
Limited volumetric catalyst activity	High volumetric catalyst activity possible
Multistep processes	Multistep processes difficult
Cofactor recycling solved	Cofactor recycling so far only for NADH and ATP
Side reactions may occur	No side reactions
Toxicity of substrate/product	Enzyme stability may be influenced by substrate or product, but can be enhanced choosing the appropriate reactor
Problem of oxygen supply	Nonnatural substrates and reaction conditions possible
Normally no cosolvent possible leading to low concentration of hydrophobic compounds	Cosolvents possible, but often reducing enzyme stability
Transport in and out of the cell may be limit	Mass transport limitations only with immobilized enzymes

In the PFR, the product concentration increases slowly over the length of the reactor (Fig. 78.2b). Therefore, the average reaction velocity is faster than in the CSTR. In each single volume element in the reactor, the concentration is constant in the steady state, whereas in different volume elements along the reactor the concentrations are different. In other words, the dimension of time is exchanged with the dimension of place in comparison to the STR.

The CSTR works under product outflow conditions, meaning that the concentrations in every volume element are the same as those at the outlet of the reactor (Fig. 78.2c). If the steady state is reached, the concentrations are independent of time and place. The conversion is controlled by the catalyst concentration and the residence time, τ.

$$\tau = \frac{V}{F}$$

where τ (hour) is the residence time, V (liter) is the total reactor volume, and F is the (liter/hour) substrate feed rate.

One very common variation of the CSTR is the cascade of n CSTRs (Fig. 78.2d). With an increasing number, n, of reaction vessels, the cascade approximates the PFR (22). The product concentration is increased stepwise from vessel to vessel.

78.3.1.1 Mass Balances. The performances of the different reactor types concerning the reaction can be simulated

TABLE 78.2. Examples for Industrial Biotransformations

Product	Substrate	Catalyst	Comments	References
Acrylamide	Acrylnitrile, H_2O	Nitril hydratase in whole cells of *Rhodococcus rhodochrous*	Very high substrate concentration	14
Chiral hydrophobic alcohol	Ketone	Whole cells of *Zygosaccharomyces rouxii*	XAD-resin as substrate reservoir	15
β-Tetralol derivative	β-Tetralone derivative	Whole cells of *Trichosporon capitatum*	—	16

[a] KDN = ketodeoxynonulosonic acid

mathematically. This is also the verification of the kinetic model of the reaction, because it should describe the course of the concentration for each compound with only a small error. The main part of the simulation model is the coupled system of differential equations of first order, which are the mass balances of all substrates and products. The change in the concentration of one compound in time and in a volume element (called the accumulation) is the sum out of convection, reaction, and diffusion (Eq. 78.1).

$$\text{accumulation} = \text{convection} + \text{reaction} + \text{diffusion} \quad (78.1)$$

The convection term describes the change of the concentration of one compound in the reactor as difference of the influx into the reactor and the efflux. The reaction term describes by use of the kinetic model the change of the concentration of one compound as result of the reaction. The reaction velocity, v_S, is the sum of individual reaction velocities describing consumption of a substrate or formation of a product. Diffusion occurs only in the case where no ideal mixing is stated.

With regard to the chosen reactor type the mass balance can be simplified assuming ideal mixing or ideal plug-flow behavior.

Stirred-Tank Reactor.

Diffusion = 0 At a defined time the concentrations are the same in every volume element.

Convection = 0 There is no influx or efflux of substrates or products to a single volume element in time.

The mass balance is simplified to:

$$-\frac{dc_S}{dt} = v_s \rightarrow t = c_{S,0} \int_0^{\text{desired conversion}} 1/v \; dx \quad (78.2)$$

Continuously Operated Stirred-Tank Reactor.

Diffusion = 0 At a defined time the concentrations are the same in every volume element.

Accumulation = 0 In the steady state the concentrations will not change with time.

The mass balance is simplified to:

$$0 = -\frac{dc_S}{dt} = \frac{c_{S,0} - c_S}{t} + v_S \quad (78.3)$$

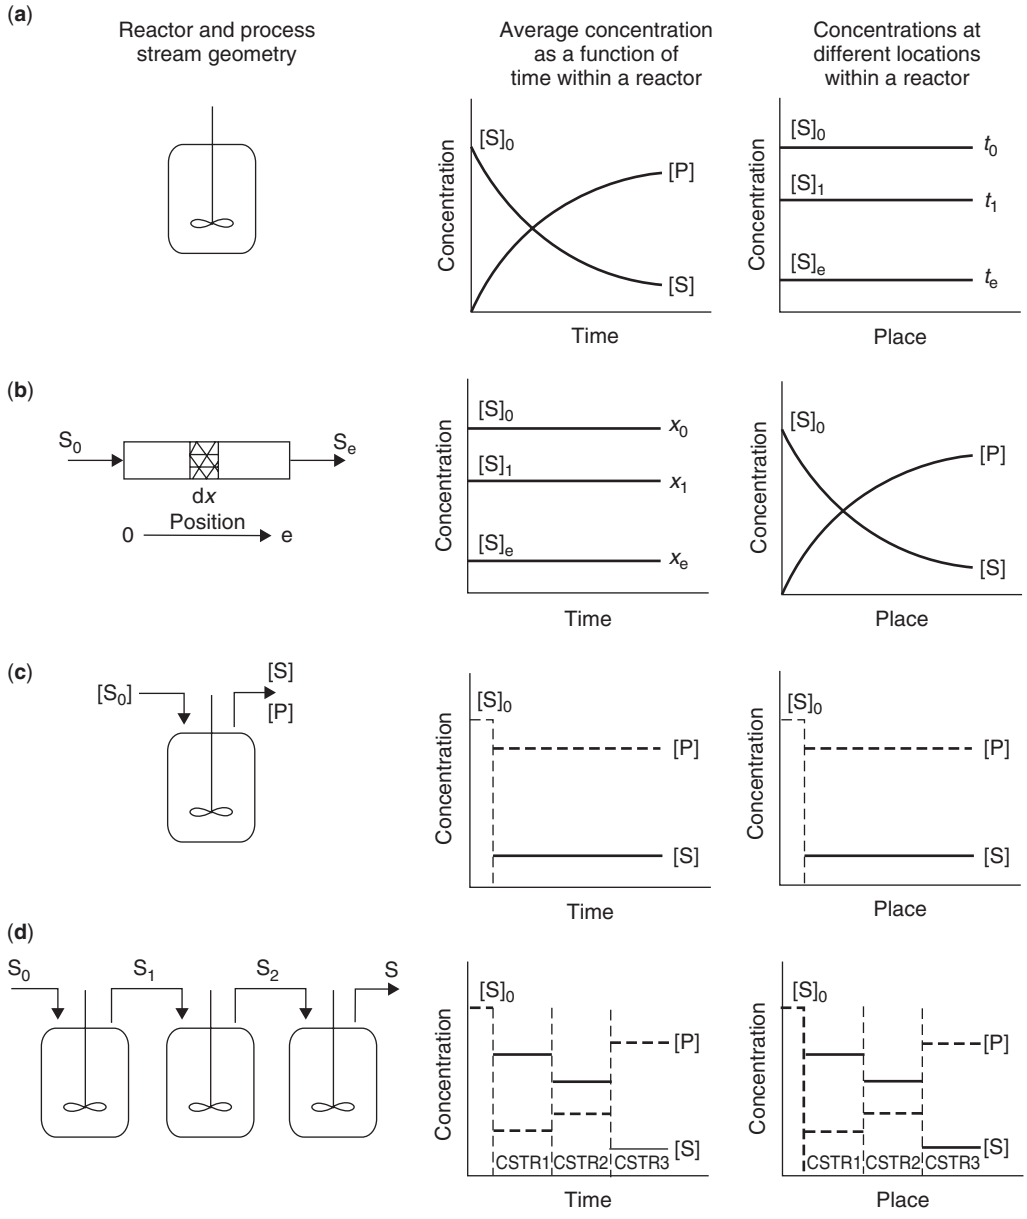

Figure 78.2. Characterization of different reactors.

Plug-Flow Reactor.

$$\text{Diffusion} = 0 \quad \text{Diffusion is neglected in an ideal PFR.}$$

$$\text{Accumulation} = 0 \quad \text{In the steady state the concentrations will not change with time.}$$

The mass balance is the same as for the STR. In the integrated form the time, t, has to be replaced by the residence time, τ.

78.3.1.2 Kinetics. The fundamental equation (Eq. 78.4) for the description of enzyme kinetics was derived by Michaelis and Menten (24).

$$v = c_{\mathrm{E}} \times \frac{v_{\max} \times c_{\mathrm{A}}}{K_{\mathrm{M}} + c_{\mathrm{A}}} \tag{78.4}$$

The enzyme activity is expressed as a function of the substrate concentration for an irreversible one-substrate reaction without inhibition. As this is hardly found in nature, Equation 78.5 gives the rate for a reversible reaction A $\rightleftharpoons$ B. In this form the product inhibition is considered as a competition of A and B for the active sites, as expressed by the two K_{M} values. This form might

be extended to cover substrate surplus inhibition as well as multisubstrate reactions by adding additional terms to the numerator and denominator (6,25–27).

$$v = c_E \times \frac{\frac{v_{max,\ A} \times c_A}{K_{M,A}} - \frac{v_{max,\ B} \times c_B}{K_{M,B}}}{1 + \frac{c_A}{K_{M,A}} + \frac{c_B}{K_{M,B}}} \qquad (78.5)$$

The determination of the kinetic parameters can be performed either by initial reaction velocity measurements or by batch experiments at different substrate concentrations. The kinetic parameters are determined by fitting the kinetic model to the experimental data by use of nonlinear regression; in the case of the batch experiments, numerical integration of the reaction velocity equations is required.

78.4 PROCESS DEVELOPMENT STEP BY STEP

Figure 78.3 shows different phases and topics to be addressed during development and optimization of a biotransformation. The main focus is on the use of isolated enzymes, but for whole cell processes a similar scheme must be followed. A more detailed description can be found in (6). In practice, some of the investigations listed here stepwise will be performed simultaneously. For example, experiments should first hint possible problems from side reactions. Other factors may be considered as well.

- Buffer compounds may be important for enzyme stability, but must be removed during product isolation. Avoiding them may simplify product isolation and save costs.
- Any reaction exhibiting substrate surplus inhibition should not be carried out in a batch-reactor setup, since this results in longer reaction times due to the high substrate concentration at start-up which lowers the initial reaction velocity. In such a case, a CSTR that is operated at a high conversion in the steady state is preferred, resulting in a low substrate concentration. Another possibility is the use of a fed batch, which means that the substrate is added in small portions as a function of time, also resulting in a small substrate concentration. One example for such systems is the enzymatic synthesis of L-phenylalanine by reductive amination, which can be found in literature (24,28).
- If product inhibition occurs, either an STR, a PFR or a cascade of n CSTRs should be chosen. In all these reactors, the product concentration increases over time. Another possibility is the use of a differential reactor with integrated product separation (29). These two possibilities will be discussed in detail in the section titled "Examples."

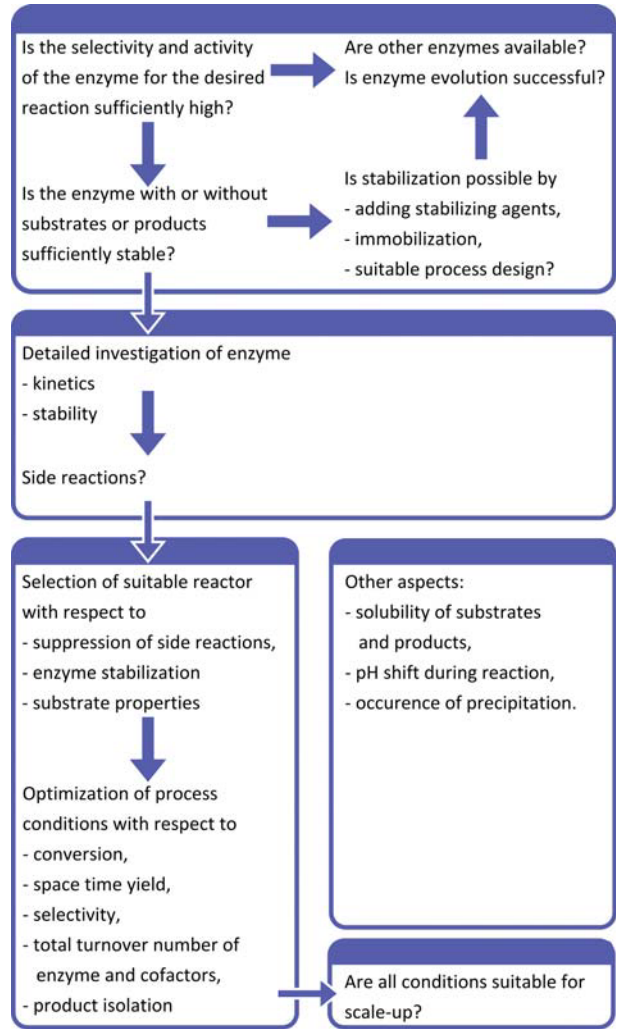

Figure 78.3. Process development step by step. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

- The biocatalyst may be recirculated in and between the reactors by various means to enhance catalyst concentration. Whole cells are often concentrated by microfiltration membranes or centrifugation. Isolated enzymes are much smaller, but can be retained by an ultrafiltration membrane. This type of equipment is commercially available for the processing of volumes of a few microliters up to the cubic meter scale. If the enzyme is immobilized on a support, its size determines the separation step. For example, penicillin amidase is immobilized on a support suitable for separation using a stainless steel mesh in an STR. Also, whole cells might be immobilized on a support, most often simply by adsorption, or by entrapment in alginate gel or similar material.
- The optimization process shown here and discussed later (see section titled "Examples") is based on a

kinetic model of the whole reactions system, including side reactions. This model, together with the mass balance for the reactor, can be used for simulation. By a variation of feed concentrations, catalyst concentration, and residence time, conditions can be found that result in high conversion and space-time yield. When enzyme deactivation is known, the product-specific catalyst consumption may be calculated as well. Alternatively, an empirical optimization can be performed using a simplex method or a generic algorithm. The latter have been successfully applied to fermentation processes (30), but only tested preliminary for optimization of multienzyme systems. These methods are especially powerful for optimization of processes where a direct connection between input- and output-values cannot be given.

- A discussion of the influence of organic solvents onto the solubility of reactants and on enzyme stability can be found in literature (31–35).

Figure 78.4 summarizes some measures that can be taken to overcome or modulate against enzyme deactivation caused either by thermal inactivation or by the reaction partners. Whereas in the first case lowering of the temperature, application of stabilizers, or immobilization on a support may be helpful, the deactivation caused by the reaction partners, may be overcome with the help of the tools of reaction engineering. For the deactivation caused by substrates or products, different tools can be used. The different reactor types are discussed in section titled "Classification of Different Reactors."

78.5 EXAMPLES

By choosing the appropriate fundamental reactor type on the basis of the individual reaction kinetics, the production of the fine as well as bulk chemicals as given in Table 78.3 is possible even in processes that exhibit either a strong inhibition by one of the reaction compounds or limitation by thermodynamics.

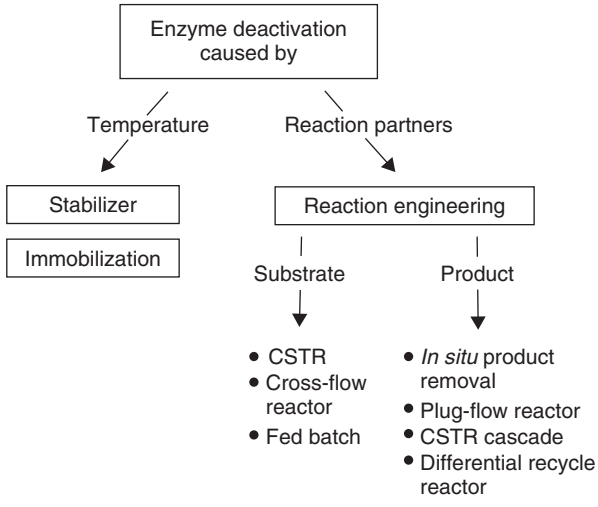

Figure 78.4. Tools to overcome enzyme deactivation.

78.5.1 Product Inhibition

The product inhibition is the consequence of the competition of a substrate and a product for complexation in the active site of a catalyst. This kind of inhibition is not only observed in enzymes, but is also found in reactions which are catalyzed by homogeneous soluble and heterogeneous chemocatalysts (27). Whereas the reaction velocity is reduced by product bonding in the case of an irreversible reaction, the situation is more complex for reversible reaction (*principle of the microscopic reversibility*). In terms of the mathematics, product inhibition is expressed as an additional term in the denominator of the Michaelis–Menten equation (Eq. 78.6). This form of the equation describes competitive inhibition. An explicit discussion of other types of inhibition can be found in the textbooks of enzyme kinetics (6,24,25). By transformation of Equation 78.6, Equation 78.7 can be obtained, which is similar in its structure to the common reaction velocity equation (Eq. 78.5), derived for chemical systems by Hougen and Watson in 1947 (40,27).

$$v = c_E \times \frac{v_{max} \times c_S}{K_M^{substrate} \times \left(1 + \frac{c_P}{K_i^{product}}\right) + c_S} \tag{78.6}$$

where v (catalytic activity/liter) is reaction velocity (1 kat = 1 mol/s), c_E(gram/liter) is enzyme concentration, c_S(mole/liter) is concentration of substrate, v_{max}(catalytic activity/gram, Unit/milligram) is maximal mass specific activity of the reaction, $K_M^{substrate}$ (mole/liter) is Michaelis–Menten-constant of substrate, and $K_i^{product}$ (mole/liter) is competitive product inhibition.

$$v = c_E \times \frac{\frac{v_{max}}{K_M^{substrate}} \times c_S}{1 + \frac{c_S}{K_M^{substrate}} + \frac{c_P}{K_i^{product}}} \tag{78.7}$$

$$v = \frac{(\text{kinetic term}) \times (\text{potential term})}{(\text{adsorption term})^n} \tag{78.8}$$

where n is the number of centers, which are part of a velocity limiting elementary reaction

The decrease of the reaction velocity with increasing product concentration is described by the ratio of K_M to K_i. The relative reaction velocity is plotted as function of the conversion in Fig. 78.5. Three different ratios of K_M to K_i are plotted, which relate to a strong (curve A), moderate (curve B), and weak (curve C) product inhibition.

TABLE 78.3. Examples for the Contribution of Biochemicalengineering

Product	Catalyst	Problems	Solution	References
(S)-1-Phenyl-1,2-ethanediol	Glycerol dehydrogenase	• Product inhibition • Chemical side reaction	Differential batch with continuous product extraction	29
GDP-mannose	GDP-Man pyrophosphorylase	• Product inhibition • Chemical complexation of reaction compounds	Cascade of continuously operated stirred-tank reactors	36
CMP-Neu5Ac	CMP-Neu5Ac synthethase	• Substrate surplus inhibition	Fed-batch reactor	37
Oxindol, chiral sulfoxide	Chloroperoxidase	• Catalyst deactivation	H_2O_2-dosing with closed loop control	38
Chiral lactone	Mono-oxygenase	• Oxygen delivery	Bubble-free aeration using silicone tubing	39

In 1985, Lee and Whitesides suggested, using the example of an oxidoreductase-catalyzed alcohol oxidation, that the feasibility of a process can be judged by the ratio of $K_M^{substrate}$ to $K_i^{product}$ (41):

- If $K_M^{substrate} : K_i^{product} \leq 1$, it is, in principle possible that the reaction can proceed with practicable conversions (Fig. 78.5, curves B and C).
- If $K_M^{substrate} : K_i^{product} > 1$, the reaction is unusable with regard to preparative syntheses (Fig. 78.5, curve A).

This is clearly a simplified view. It is also important to note that the kinetic parameters of a given reaction cannot be changed.

78.5.2 Overcoming Product Inhibition by Product Extraction

Chiral diols are important building blocks, for example, for the synthesis of chiral ligands, agrochemicals and pharmaceutical intermediates (42–44). Using the example of the oxidative resolution of 1-phenyl-1,2-ethanediol, it is demonstrated how the product inhibition can be overcome in case of hydrophobic products.

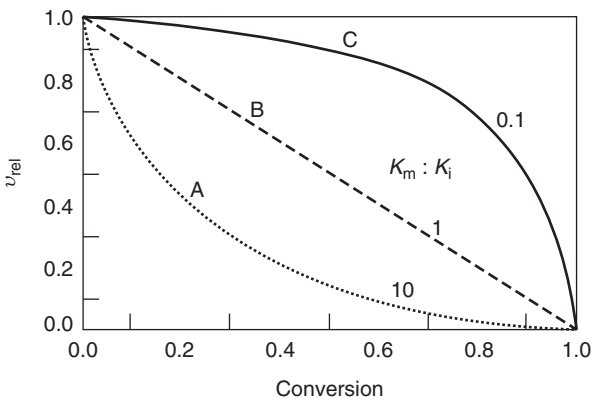

Figure 78.5. Influence of product inhibition on reaction velocity as function of conversion and ratio of K_M and K_i.

The enantioselective oxidation of the (*R*)-enantiomer to ω-hydroxyacetophenone (1-oxo-1-phenyl-2-hydroxyethane) is catalyzed by the glycerol dehydrogenase (GDH) from *Enterobacter aerogenes* (EC 1.1.1.6) (45). Because the GDH needs β-nicotinamide adenine dinucleotide (NAD^+) as a cofactor, a cofactor regeneration carried out by lactate dehydrogenase (LDH) (EC 1.1.1.27) was incorporated as depicted in Fig. 78.6. LDH reduces pyruvate to (L)-lactate enantioselectively. The cofactor regeneration must proceed faster than the racemic resolution in order not to become the limiting step. The remaining (*S*)-enantiomer of the diol is the desired product for further synthesis.

The detailed investigation of the reaction conditions and the kinetics revealed that a strong product inhibition by the hydroxyketone as well as by the NADH was given (29). This resulted in a ratio of $K_M^{substrate} : K_i^{product} = 43.2$ for the ω-hydroxyacetophenone. The inhibition by NADH was not taken into account, because NADH is converted *in situ* to NAD^+ by LDH. Utilizing the above determined criteria, the reaction as investigated here would never proceed efficiently. Additionally, it was observed that the hydroxyketone reacted in a chemical side reaction with NAD^+. Thus, ω-hydroxyacetophenone not only reduced the GDH activity due to its inhibition, it furthermore reduced the available NAD^+ concentration. Therefore it is very important, that the ω-hydroxyacetophenone concentration is kept as low as possible. One possibility is an integrated extraction of the inhibiting compound. Best results were obtained for hexane. In contrast to phenylethanediol which was not extracted, up to 98% of the hydroxyketone was extracted after eight extraction steps.

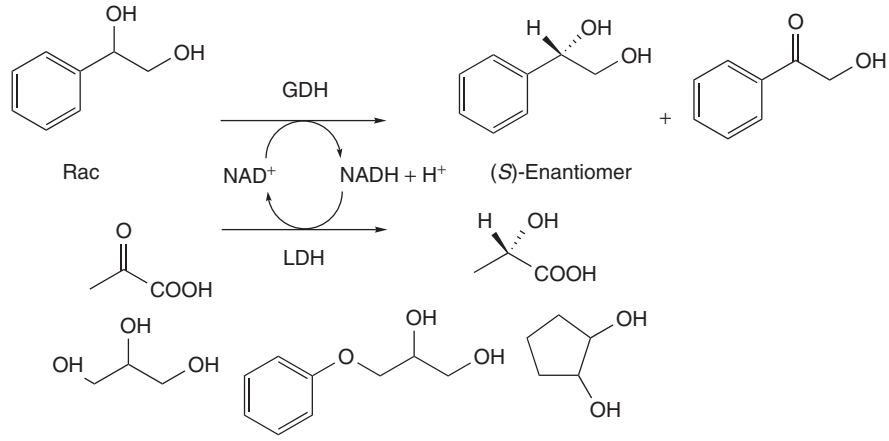

Figure 78.6. Enzymatic resolution of racemic 1-phenylethan-1,2-diol; GDH = glycerin dehydrogenase; LDH = lactate dehydrogenase. Relative activities: glycerol 100%, 3-phenoxypropan-1,2-diol 31%, 1-phenylethan-1,2-diol 8%, *trans*-cyclopentan-1,2-diol 3%.

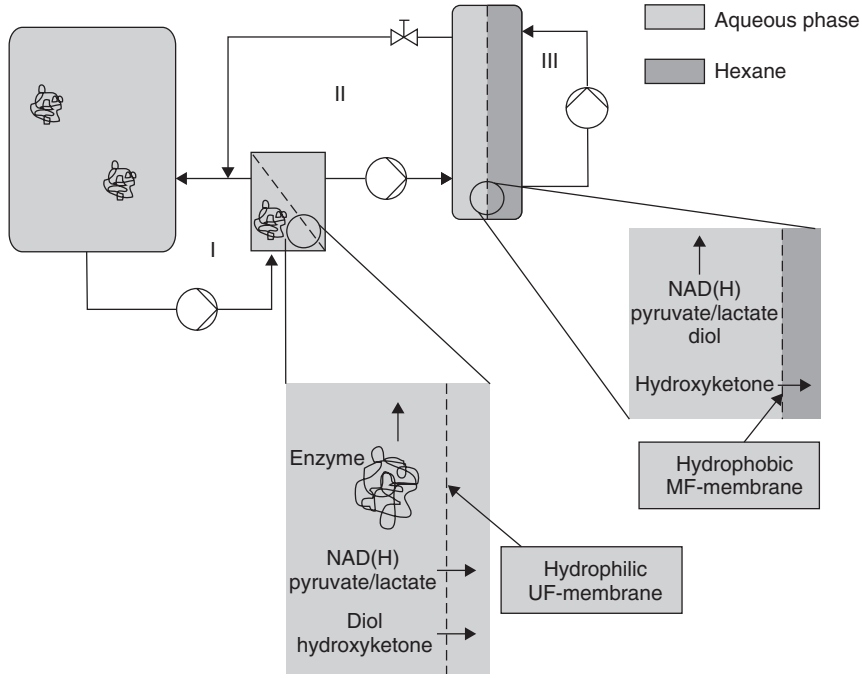

Figure 78.7. Flowsheet of the two-phase membrane reactor; I membrane reactor loop, II extraction loop, aqueous phase, III extraction loop, organic phase. For details refer to (46,53).

The flow sheet of the two-phase membrane reactor is shown in Fig. 78.7. The reactor consists of three different loops. The membrane reactor (loop I) integrates the stirred-reaction vessel and the membrane module (47,48). A hydrophilic ultrafiltration membrane (YM 10, cutoff 10,000 Da, Amicon GmbH, Witten, Germany) is used to retain the GDH and the LDH. The consequence is the decoupling of the residence times of the catalysts and the reactants. Prior to the membrane reactor, an extraction module was positioned in a closed loop arrangement (loop II). The aqueous phase is continuously extracted by means of liquid/liquid extraction, using a hollow fiber module (Liqui-Cel® 5PCM-106, Hoechst, Frankfurt, Germany), consisting of Celgard® microporous, hydrophobic hollow fiber membranes (49). The module was circulated countercurrently by a hexane stream. The best ratio of the flow rates of the aqueous phase to the organic phase was determined to be 1: 6. To reduce the amount of organic solvent used, a distillation (not shown) is incorporated in the extraction loop III. The oxidation

product ω-hydroxyacetophenone is collected in the bottom of the distillation.

The entire reactor behaves as a batch reactor with recirculation, meaning that only a low conversion per cycle is reached corresponding to a small amount of oxidation product, which is directly extracted (29). The consequence is a continuous low concentration of the ω-hydroxyacetophenone in the membrane reactor. This reactor represents a modification of the continuously operated bimembrane reactor which was constructed for the conversion of sparingly soluble substrates (46,50,51).

In Fig. 78.8, two experiments are compared, one with the integrated extraction and the other one without. When no extraction is incorporated, an enantiomeric excess of only 58% and a conversion of 37% was reached after 170 h. The reason for this unsatisfactory result was the accumulation of the reaction product, which lowers the reaction velocity of the GDH and also reduces the concentration of the NAD^+ by the chemical side reaction. With integrated product extraction a conversion of 50% and an enantiomeric excess >99% is reached after 64 h.

This process example demonstrates that by means of reaction engineering, kinetically unfavorable reaction can still be used on a preparative scale. By application of the integrated extraction, a transition from curve A to curve C in Fig. 78.5 is reached.

78.5.3 Overcoming Product Inhibition by a CSTR Cascade

D-Mannose can be found as building block of numerous glycoproteins and glycolipids, for example, in the

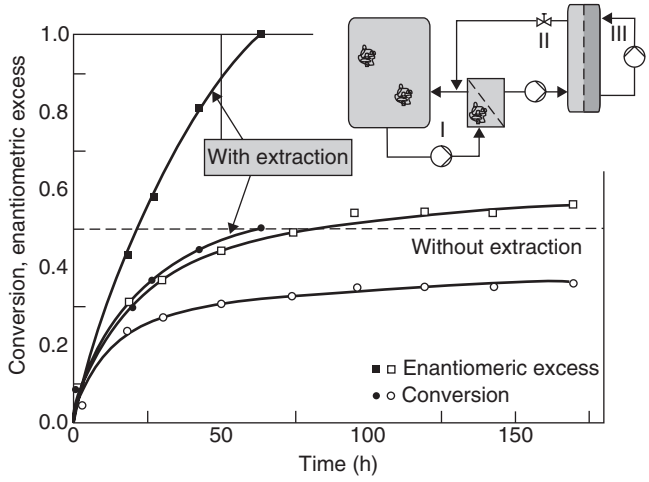

Figure 78.8. Increase of enantiomeric excess and conversion for the kinetic resolution of 1-phenyl-1,2-ethanediol due to product extraction. Residence time in the membrane reactor: 15 min; pressure difference: 2 bar; total volume 500 mL; 100 m*M* glycine/KOH buffer; pH 9; $T = 25^{\circ}C$; 0.054 U/mL GDH; 0.6 U/mL LDH; 200 m*M* ammonia; 40 m*M* (R,S) 1-phenyl-1,2-ethanediol; 2 m*M* NAD^+; 25 m*M* pyruvate).

common core structure of *N*-glycans (52). For the enzymatic *in vitro* synthesis of oligosaccharides guanosine-5′-diphospho-α-D-mannose GDP-Man is used as donor for mannosyltransferases. Recombinant mannosyltransferases have been used for the synthesis of the trisaccharide Man β1-4GlcNAcβ1-4GlcNAc (53). The enzymatic synthesis of GDP-Man starting from mannose-1-phosphate (Man-1-P) and guanosine-5′-triphosphate (GTP) using a recombinant GDP-Man pyrophosphorylase (E.C. 2.7.7.13) has been described (54) (Fig. 78.9). Both reaction products show a very strong inhibition on the GDP-Man pyrophosphorylase. The inhibition by pyrophosphate can be overcome by cleaving it to phosphate using an inorganic pyrophosphatase (E.C. 3.6.1.1). The product inhibition by the product GDP-Man itself can be reduced in a CSTR cascade as shown below. Additionally, the cofactor Mg^{2+}, required by the GDP-Man pyrophosphorylase, is complexed by the substrate GTP. Its influence of the enzyme activity and the preferable use of a continuously operated reactor to establish a constant Mg^{2+} to GTP ratio, together with a complete set of kinetic data for the pyrophosphorylase, has been published (42). For the ratio $K_M^{Man-1-P}/K_i^{GDP-Man}$, a value of 4.4 is obtained. According to the classification outlined in the section "Product Inhibition," this reaction would be only of limited use. Unfortunately, the substrates and products are quite similar with respect to size, hydrophilicity, or charge, prohibiting a selective removal of the inhibiting product. However, simulations on the basis of the kinetic model and various reactor configurations revealed, that a cascade of two CSTRs in series is reducing the required amount of enzyme by >50% (22). A two-stage cascade is a good compromise: plug-flow behavior is approximated to a large extent, whereas the experimental setup does not require too much effort (7). Figure 78.10 compares the conversion of Man-1-P as function of the product of enzyme concentration and residence time for a single CSTR and a two-stage CSTR cascade. In a two-stage cascade 98% conversion is reached for 4.5 (U/mL)min, whereas a single CSTR requires 9.0 (U/mL) min. That means that at a constant enzyme concentration the residence time can be cut in half, resulting in a doubling of the space-time yield. When the enzyme deactivation is only a function of time, by an increase of the space-time yield at constant enzyme concentration, the product-specific enzyme consumption can be decreased. The experimental verification revealed a good agreement between calculated and experimental values (36). At a conversion at 98%, a space-time yield of 28 g(L day) and an enzyme consumption of 900 $U/kg_{product}$ was obtained. For a single CSTR, an enzyme consumption of 2000 $U/kg_{product}$ was reached due to the higher enzyme concentration required to reach the desired conversion under otherwise identical conditions. The relatively low space-time yield is caused by the low substrate concentrations. Complex interactions

between K_M values of the substrates and the K_i of GDP-Man require simulation to show that the space-time yield can be increased 10-fold by a corresponding increase of the substrate concentration (Fig. 78.11). In order to keep a high conversion at >98%, the enzyme concentration must be increased at the same time, but only 2.5-fold. This clearly demonstrates the potential of process optimization based on a model and a complete set of kinetic data.

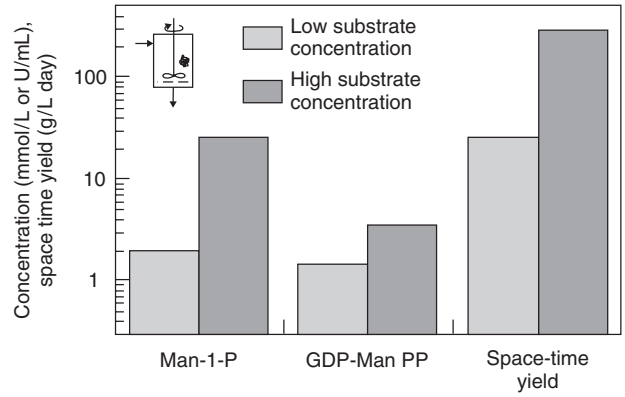

Figure 78.11. Improvement of space-time yield of GDP-Man by higher substrate and enzyme concentration in a one-stage CSTR; (GTP) 2.5 mmol/L or 25 mmol/L, (Mg^{2+}) 1 mmol/L or 9 mmol/L, residence time 1 h; conversion >98%.

78.5.4 Overcoming Thermodynamic Equilibrium by Side-Product Removal

The production of surfactants from high-viscous or high-melting reactants, for example, diglycerol, polyglycerol, or other polyols, illustrates the need to overcome limitations caused by thermodynamic equilibrium. The enzymatic synthesis of fatty acid esters can be carried out as a solvent-free reaction in a PFR. However, the produced water has to be removed from the reaction medium to obtain total conversion by shifting the thermodynamic equilibrium. This is possible by a sequence of a PFR containing the biocatalyst and an evacuated stirred-tank reactor for water removal. In this case the reaction progress is limited by the liquid/gas interface. Additionally, a PFR is restricted to raw materials and products having a viscosity which is low enough to allow its pumping through the bed of immobilized enzyme, resulting in a low differential pressure drop.

The enzymatic synthesis of polyglycerol-3-esters starting from polyglycerol-3 and lauric acid using an immobilized lipase B from *Candida antarctica* (Novozym 435) has been described in detail (55) (Fig. 78.15). Both substrate and the product show a very high viscosity, therefore, removal of the formed water by vacuum only is not sufficient. The limitation of the low surface to volume ratio applying vacuum can be overcome by using a bubble column reactor. The side-product removal can be enhanced in this reactor type but is strongly dependent on the aeration rate and size of the formed gas bubbles (Fig. 78.13). Additionally, aeration enables mixing of the two liquid reactants as well as of the immobilized biocatalyst. The detailed description of the benefit of the bubble column reactor regarding reaching minimal reaction time and the preferable use also for low viscous products like myristyl myristate was recently published (56). Comparing the effective reaction times ER_n

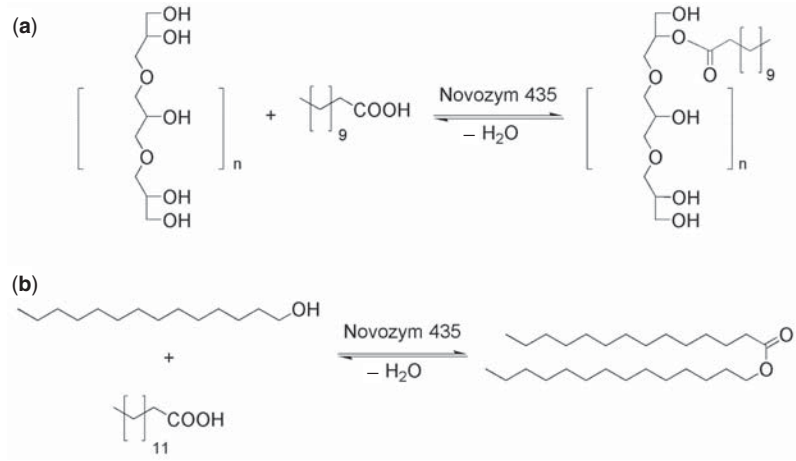

Figure 78.12. Reaction systems carried out within the bubble reactor: (a) polyglycerol-3/lauric acid; (b) myristic alcohol/myristic acid.

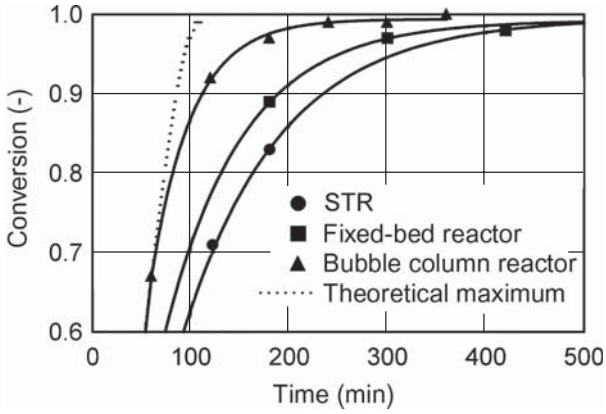

Figure 78.13. Comparison of different reactor setups for the synthesis of myristyl myristate with the theoretically calculated reaction time. All reactions with 0.4% (w/w) of Novozym 435 at 60°C.

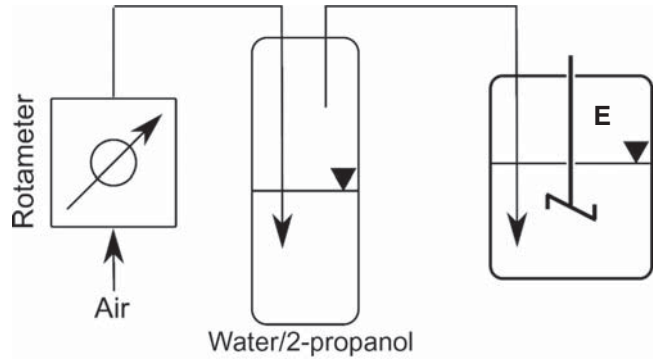

Figure 78.14. Flow scheme of the stripping process.

with the theoretical reaction times TR_n and calculating the efficiency quotients EQ_n revealed the high efficiency of this reactor setup in the case of enzymatic esterifications for a given conversion n:

$$TR_n = \frac{c_{S,0} - c_S}{v_{max}} + \frac{K_m}{v_{max}} \times \ln\left(\frac{c_{S,0}}{c_S}\right)$$

$$EQ_n = \frac{ER_n}{TR_n}$$

The efficiency quotients $EQ_{99.6}$ of 8.3 when using a PFR are significantly reduced to 3.3 when applying the developed bubble column reactor. This means that at a constant enzyme concentration the space-time yield can be doubled. At a conversion at 99.6%, a space-time yield of 6.7 kg(L day) and a biocatalyst consumption of less than 4 $mg/g_{product}$ was obtained.

A second example for overcoming thermodynamic limitations by reaction engineering is the asymmetric reduction of prochiral ketones with alcohol dehydrogenases and substrate-coupled cofactor regeneration. Here, the maximum conversion in ketone reduction depends on the thermodynamic properties of the system (57). A possibility to overcome this limitation in the case of 2-propanol/acetone as coupled reactants is the integration of an ISPR technique, thereby shifting the equilibrium toward the desired product (58,59). As the coproduct acetone is the most volatile compound in the reaction system, it is possible to remove it by applying the stripping process (Fig. 78.14).

A continuous air stream—saturated with water and 2-propanol—is passed through the reaction mixture. Moreover, the air flow causes a mixing of all components, so that additional stirring is not required. To prevent an excessive foaming of the protein suspension, polypropylene glycol was added as polymeric additive. The efficiency of the method on the asymmetric reductions of acetophenone catalyzed by *E. coli*/ADH-"A" was evaluated. The conversion increases up to over 99% in comparison to

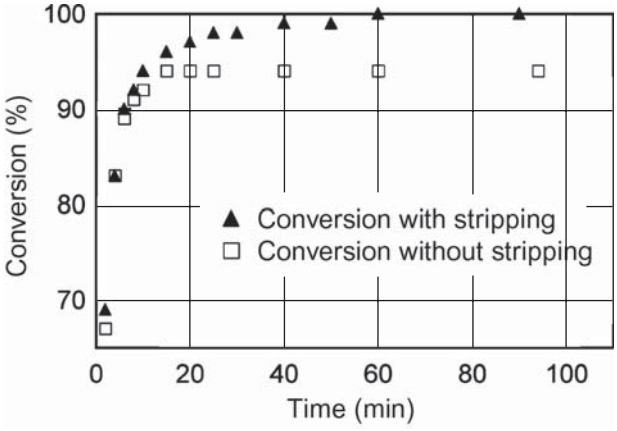

Figure 78.15. Conversions as a function of time. Asymmetric reduction of acetophenone (80 m*M*) with recombinant *E. coli* cells (80 mg) at 30°C in phosphate buffer (50 m*M*, pH 7.5) containing 1 m*M* NADH with a 2-propanol concentration of 2.355 *M* in an overall reaction volume of 20 mL. The biotransformations are carried out with and without stripping.

94% without applying the outgassing method (Fig. 78.15). During the reaction no substrate or product was outgassed from the reaction vessel, which could be proven by determining the mass balances for these compounds during the course of the biotransformation. The technical complexity of the coproduct separation via application of the stripping process is rather low.

As outlined by Prins and van't Riet (1), foam in bioprocess operations has received little attention compared to other engineering problems such as mixing and mass transfer.Hence, as reported in a recent review, the problem of foam formation in fermentation processes is not yet well controlled (2). Most of the progress has been made at the level of the knowledge of the physicochemical mechanisms and only a few experiments have been performed on the tools needed to control foaming during a bioprocess. This knowledge has notably led to the conception of chemical antifoams. However, the use of such chemicals in bioprocesses must be carefully monitored considering the microorganisms' sensitivity to extracellular changes. A second source of important data comes from the investigation of the hydrodynamic effect leading to the appearance of foam in bioreactors.

79.1 AN OVERVIEW OF THE MECHANISMS OF FOAM FORMATION IN BIOREACTORS

In bioreactors, the intensification of the aeration process and the protein content of the broth are at the basis of foam formation. Indeed, in aerobic cultures, oxygen is provided by the injection of compressed air into the lower part of the reactor. Oxygen solubility being very low in aqueous media (about 7–8 mg/L in fermentation conditions) and oxygen requirement by the microorganisms being very high, the oxygen transfer from air bubbles to the liquid phase must be strongly optimized. This is achieved in practice by increasing the air flow rate through the reactor and, in the case of stirred bioreactors, by increasing the stirrer speed. In all cases, the oxygen transfer process is optimized by increasing the gas–liquid dispersion inside the vessel. The rising bubbles (being as fine as possible) cross the surface of the liquid inside the reactor and in the presence of surface-active molecules, induce the formation of foam. In general, the surface-active molecules found in fermentation media are proteins that are at the basis of most of the industrial complex media or being released by cell autolysis during the process (3). Other compounds exhibiting a surface-active behavior can also be secreted by microorganisms, for example, Escherichia coli, which is known to release lipopolysaccharides (LPS) in a culture when exposed to starvation stress (4), and Bacillus subtilis, which is able to synthesize several lipopeptides (5). A wide variety of compounds excreted during the culture of Penicillium herqueii have been characterized. These include pigments and non-identified lipophilic surfactants released from cell lysis and accumulated in the foam (6). However, proteins are the most frequent surface-active agents encountered in bioprocesses. Proteins are adsorbed at the gas–liquid interfaces, and according to their surface-active properties (i.e. the constituent

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

chains of amino acids each exhibiting hydrophobic or hydrophilic properties) are able to promote foam at very low concentrations (as low as 1 mg/L (1)). In addition, it has been shown that the sterilization procedure of a protein solution significantly increases the foaming capacity of the medium (3). Considering the isoelectric point of the protein, that is the pH for which the global charge of the protein is null, the pH of the medium plays an important role on foam formation. However, the pH is also an important parameter which affects microbial growth and is usually controlled during the culture; therefore, in practice, it cannot be modified to limit foam. In some specific cases, surface-active molecules, named *biosurfactants*, can be released by the microorganisms' secondary metabolism (7,8), leading to an increase of the process difficulties promoted by the foaming media. To illustrate this problem, some research involving a Bacillus subtilis strain overproducing a surfactin (a surface-active molecule belonging to the lipopeptide class), has necessitated a special reactor configuration where oxygen is provided by surface aeration in order to avoid the problem associated with air injection (9). Foam, owing to the amount of precautions to be taken to prevent its formation, is a big challenge for the process engineer. The problems generated by a foaming medium are multiple (10): decrease of the working volume of the reactor, removal of microbial cells and metabolites, contamination, decrease of the oxygen transfer rate subsequent to the addition of antifoam, toxic effects on cell physiology, and so on.

Two spatial scales are involved in the understanding of the underlying mechanisms associated with foam formation in bioreactors. First, the microscopic scale involving molecular arrangement at the gas–liquid interfaces. Second, the macroscopic scale involving gas–liquid flows at the level of the bioreactor.

79.2 DESCRIPTION OF THE FOAM AT THE MICROSCOPIC LEVEL: MOLECULAR MECHANISMS AT THE INTERFACES

An extensive amount of data involving the physical and molecular mechanisms of foam formation is available in the literature. In this section, only the basic molecular mechanisms will be presented. The molecules comprising a hydrophobic and a hydrophilic part are termed as surface-active and are preferentially located at the interfaces. The surface tension, that is the interfacial free energy per unit area, represents the force of cohesion that maintains the molecules in each phase. A surface-active molecule is able to significantly reduce the surface tension after adsorption at the interface. One of the major macroscopic effects resulting from this adsorption, is the stabilization of the dispersion of one phase into the other. In aqueous solutions, when the air–water interface is saturated the adsorption stops and the surface excess of surface-active molecules is arranged in micelles in the solution. This point corresponds to the critical micellar concentration (CMC), that is the surfactant concentration leading to the saturation of the interfacial film. Above the CMC, the surfactant concentration has no influence on the surface tension (Fig. 79.1). The formation of micelles is also a mechanism by which the contact between water and hydrophobic parts of molecules is minimized, leading to a reduction of the free energy of the system. However, this is not the magnitude of the surface tension drop that influences formation of foam. Indeed, there are surface-active molecules that greatly reduce the surface tension but lead to unstable foams. The concept of foam stability is thus important and appears to be strongly correlated to the rate of surface tension variation $d\sigma$ (11). An important parameter controlling the stability of the interface against mechanical action is the force of elasticity (12,13). The effect of surface dilational elasticity (N/m and generally in the range of 10–100 mN/m for protein solutions) was first described by Gibbs, using the following equation:

$$E = \frac{d\sigma}{d\ln A} \tag{79.1}$$

With σ being the surface tension (N/m) and $d\ln A$ the relative change in surface area. Surface elasticity is a parameter allowing the quantification of mechanisms conferring mechanical strength to an interface stabilized by proteins or small molecular weight surfactants. Proteins are able to form a strong viscoelastic network at the interface because of their ability to modify their conformation to readjust the surface equilibrium after a perturbation. But in the case of small molecular weight surfactants, surface elasticity has a different origin. Indeed, in this case, the readjustment of

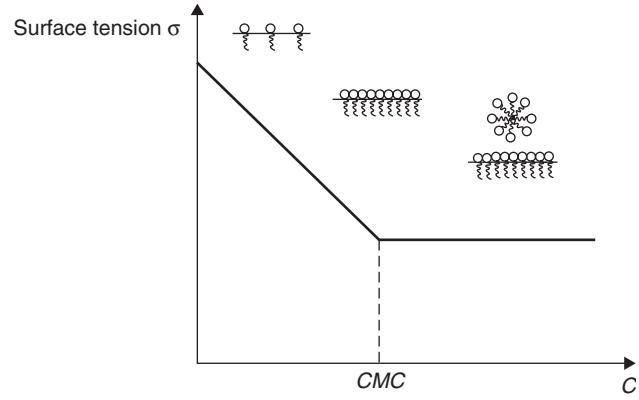

Figure 79.1. Ideal system in which the surface tension σ decreases linearly with the surfactant concentration C.

surface properties is attributed to the mobility of these small surface-active molecules at the interface. Equation (79.1) is very relevant since the flow properties of liquid/air interfaces are strongly influenced by elastic forces. As pointed out above, it is important to highlight the molecular differences between foam produced by low molecular weight surfactants and by proteins. Indeed, proteins differ from low molecular weight surface-active molecules in several aspects: it is very difficult to desorb a protein from an interface except with a low molecular weight surfactant; proteins can change their conformation at the interface conferring some amount of elasticity to the foam and consequently increasing the foam stability; more than one layer of protein can adsorb at the interface (1). In summary, the interfacial effect induced by protein adsorption is strongly linked with its conformation at the interface. (Fig. 79.2 for a comparison of the conformation of a low molecular weight surfactant and a protein, at an interface.) Under dynamic conditions, such as those encountered in bioreactors where bubbles continually flow through the media and burst at the free surface, proteins can change their conformation in order to readjust the surface tension and equilibrium. This effect is enhanced by the sterilization process leading to a loss of conformation at the level of the protein structure. This is a good example of elasticity leading to foam with high stability which can be quantified by the Gibbs dilational modulus (Eq. 79.1). Indeed, in the case of protein-stabilized foam, this modulus is very high, which means that the surface tension gradient can persist for a long time in a surface onto which a protein is adsorbed. However, the adsorption of surfactants at the interface is not the only condition required for the formation of foam. Depending on the intensification of the aeration process in the reactor, the gas–liquid mixture is a very important factor, the surfactant being required only in order to stabilize the bubbles bursting at the level of the free surface. These hydrodynamic phenomena will be described in the next section.

79.3 DESCRIPTION OF THE FOAM AT THE MACROSCOPIC LEVEL: GAS–LIQUID DISPERSION IN THE REACTOR

In the previous section, it has been shown that at the gas–liquid interface the adsorption of surfactant molecules is required to produce foam. However, this is not the only condition. Indeed, the gas–liquid mixture inside the bioreactor is also important, the surfactant being required only to stabilize the bubbles bursting at the liquid free surface. Several authors have pointed out the fact that the turbulent motions in the reactor are important, these motions being strongly linked with the dispersion of bubbles and other gas–liquid phenomena (14).

From a chemical engineering point of view, the foam is considered a special case of gas–liquid dispersion with a large air/liquid ratio (15). Foam formation in a sparged bioreactor is a dynamic phenomenon involving two competing processes, that is the rate of disintegration of bubbles in the foam and the rate of bubbles entering the foam. Freshly formed foam is composed of spherical bubbles separated by liquid films which are up to a few millimeters in thickness.Foam stabilization occurs if the bubbles remain separated from each other by a liquid lamella, a mechanism favored by the presence of surface-active molecules. During ascension of the foam column in the headspace of the bioreactor, the liquid contained in the lamella is drained. At this stage, the aged foam is morphologically different from the fresh foam as it contains polyhedrals in which three bubbles intersect at a corner with an angle of 120° (15) (these corners are called *Plateau borders*). The drainage of the liquid in this lamella is responsible for the collapse of the foam. Like other gas–liquid dispersions, the destabilization of foam involves the aggregation of gas bubbles known as the *coalescence phenomenon*. The evolution of gas bubbles from the bulk of the reactor to the headspace, as well as shape modification of the air bubbles entrapped in the foam phase, is depicted in Fig. 79.3. As shown in this figure, the generation of foam depends on the rate of

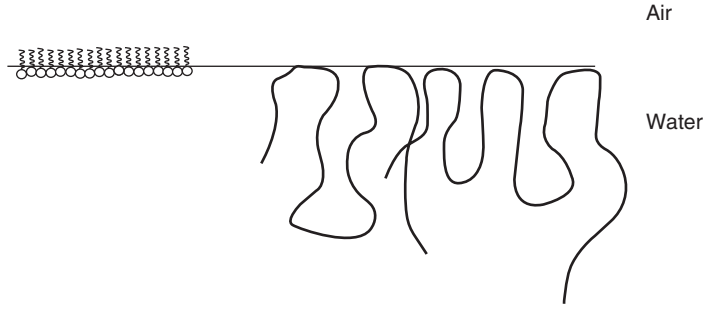

Figure 79.2. Difference of conformation of low molecular weight surfactant (left) and protein (right) at an air/water interface.

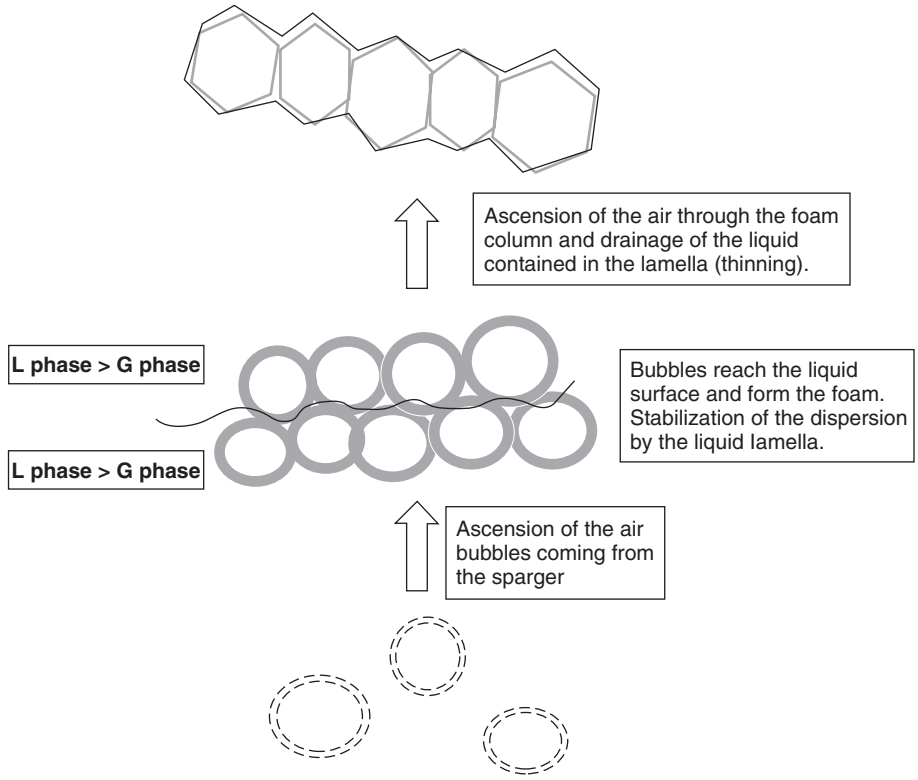

Figure 79.3. Macroscopic mechanisms involved in the generation and the aging of foam in an aerated bioreactor.

alimentation of air bubbles through the liquid surface. The foam rise velocity in the headspace of the reactor is thus strongly dependent on the gas rise velocity in the bulk of the reactor.

$$V_{\text{foam}} = f(V_{\text{g}}) = f\left(\frac{G}{S}\right) \tag{79.2}$$

The gas superficial velocity is described as the ratio of the air flow rate G (m^3/s) to the reactor's cross-sectional area S (m^2).

To limit the foam formation in bioreactors, that is the gas–liquid dispersion at low liquid fractions occurring in the headspace of the reactor, it is important to understand gas–liquid dispersion at high liquid fractions occurring in the bulk of the reactor. This is a large problem owing to the incompatible nature of the two dispersions. Indeed, the gas–liquid dispersion is favored in order to maximize oxygen transfer, but in turn, this dispersion induces the appearance of foam. These two phenomena will be discussed in the following lines by highlighting the interactions between oxygen transfer efficiency and foam intensity. Air is injected into the bioreactor in order to ensure a continuous oxygen supply, with oxygen playing the role of final electron acceptor in microorganisms involved in aerobic processes. The oxygen transfer in bioreactors is described by the general equation:

$$\frac{\mathrm{d}C_L}{\mathrm{dt}} = K_L a(C_L^0 - C_L) \tag{79.3}$$

With $K_L a$ (s^{-1}), defined as the volumetric rate of oxygen transfer, and being the main performance parameter used to estimate the gas–liquid transfer efficiency, C_L^0 being the dissolved oxygen concentration at saturation (typically around 8 mg/L) and C_L being the actual dissolved oxygen concentration. The bioreactor gas–liquid hydrodynamics is optimized to minimize the bubble size and to increase the specific surface available to transfer oxygen (represented by a in the $K_L a$). In the literature, two kinds of correlations using $K_L a$ in function of the operating parameters of the bioreactor have been proposed (16).

For bubble column or airlift bioreactors:

$$K_L a = C\left(\frac{G}{S}\right)^{\alpha} \tag{79.4}$$

For stirred tank reactors:

$$K_L a = C\left(\frac{P}{V}\right)^{\alpha}\left(\frac{G}{S}\right)^{\beta} \tag{79.5}$$

With G being the air flow rate (m^3/s), S being the reactor's cross-sectional area (m^2), P being the power drawn at the level of the impeller (W) and V being the volume of the reactor (m^3).

The gas–liquid dispersion in relation to K_La is far better described in literature than the foaminess, owing to the strong relation existing between the two kinds of dispersion (17) and the operational parameters influencing oxygen transfer that can be used to discuss about foam-influencing parameters at the process scale. In general, the critical condition for foaming in a bioreactor (with or without stirrer) is reached when the gas velocity exceeds a critical value depending on the liquid velocity in the bulk of the reactor (14). The ratio between these two velocities can be modified by the operational parameters. In pneumatic reactors (e.g. bubble column and airlift), the gas–liquid dispersion is quite simple to describe because the air flow rate alone can be considered in order to improve oxygen transfer (Eq. 79.4). It has been shown that the foam appears in a bubble column bioreactor when the gas superficial velocity V_g is larger than a critical value for a fixed liquid velocity V_l (14). Thus the difference between the gas superficial velocity and the liquid flow rate is correlated to the turbulent motions in the reactor which are, in turn, governing the appearance and ascension of foam in the headspace of the reactor. The critical gas superficial velocity above which foam appears can be described by Equation (79.6):

$$V_g = a \cdot V_l + b \tag{79.6}$$

With a and b depending on the nature of the foaming solution.

From this equation, the foam increases when V_g increases for a fixed V_l, and the foam decreases when V_g decreases for a fixed V_l; no foam is produced when V_l is large enough. Similar results have been obtained in the case of 10 m^3 jet loop bioreactors with a draft tube for which a stronger liquid circulation is correlated to a reduction in the foaminess of the medium (18).

The situation is a little bit more complicated in the case of a stirred bioreactor for which the gas–liquid dispersion is governed by two operational parameters: the stirrer speed and the air flow rate (Eq. 79.5). These two parameters must be considered together in order to describe the quality of gas–liquid dispersion (19). If the air flow rate is too important and/or if the stirrer speed is insufficient, the reactor is in the flooding regime. The air bubbles coming from the sparger cross the impeller cross-sectional area without being dispersed, leading to a weak specific area (a) and thus a low K_La. The dispersion can be optimized by increasing the stirrer speed and/or by lowering the air flow rate. At this stage, the reactor is in the loading regime and the bubbles are mechanically broken when passing the vicinity of the impeller, leading to an effective gas–liquid dispersion. Our personal findings suggest that there is a direct relationship between the foam rise velocity in the headspace of the reactor and the gas–liquid dispersion regime in stirred bioreactors (Fig. 79.4). These considerations suggest that the operational parameters of bioreactors can be optimized in order to reach an acceptable level of oxygen transfer and to limit the foaminess to some extent. It has led, for example, to the "stirring as foam disruption" (SAFD) concept (20) that will be discussed in detail later in the text.

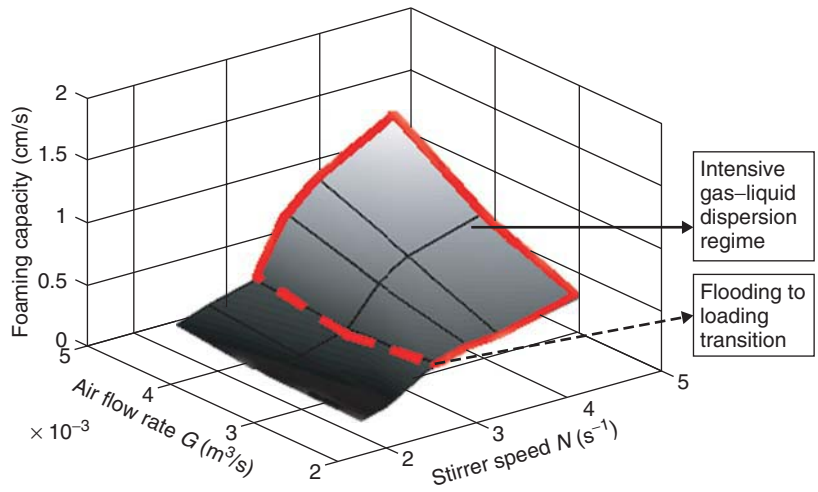

Figure 79.4. Relation between foam rise velocity in a stirred bioreactor as a function of the air flow rate and stirrer speed. The transition between the flooding and loading regime of the impeller has been highlighted. Experiments have been performed in a 300 L stirred tank reactor equipped with a Rushton disk turbine having six blades. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

However, in case of intensive foaming, a foam control procedure has to be considered (as is discussed in the sections on Chemical Methods Used to Prevent Foamand Physical Methods Used To Prevent or Reduce Foam Formation in Bioreactors).

79.4 METHODS USED TO EVALUATE THE FOAMING PROPERTIES OF A SOLUTION

To estimate the problems associated with the formation of foam, it is important to have a technique for measuring some parameters linked with foaming intensity. The foaming properties of proteins or surfactant solutions can be classified into two main categories: the foaming intensity (foaminess or foamability) and the foam stability. These two properties seem to be complementary, but can diverge under some conditions. For instance, increase in temperature leads to an increase of foaminess and decrease of foam stability (21). In general, the foamability of a surfactant solution refers to its overall capacity to produce foam, irrespective of some given characteristic of this foam (e.g. its liquid content and bubble size distribution). On the other hand, the foam stability is a parameter that takes into account the rate of change of foam properties (13). It is thus important to consider these two properties in order to characterize the foaming behavior of solutions.

Three main techniques have been used to determine the foaming properties of surfactant solutions. The first one, based on the volume of foam generated as a function of time, is known as the *Bikerman method* (22). The foam can be generated by whipping or bubbling, but considering the lack of reproducibility of the former, the bubbling apparatus is preferred (23). This apparatus comprises of a glass column equipped with a porous sparger in order to uniformly disperse the air bubbles at the base of the column. The second method is based on the measurement of the liquid drainage from the foam (23). This method can be used only to measure stability of foam and not foaming intensity of a medium. The third one is based on the conductivity of foam, since foam with a high water content exhibits a higher conductivity. A more sophisticated method involves the combination of both the volume and conductivity measurements, the two techniques being known to produce complementary results (5,23). The conductivity method is the most sophisticated and permits the measurement of conductivity at multiple points of the foam column allowing us, for example, to have a precise description of foam behavior in the headspace of a bioreactor (24). This principle is currently under investigation in order to elaborate probe able to measure on line the development of foam inside a reactor (more details are given in the next section). This kind of probe is based not only on foaminess (which is related to the height of foam inside the reactor), but also on foam stability, giving a clearer picture of what can be done to destroy the foam.

These techniques can also be used to test the efficiency of chemical antifoam (25). In this case, foam is generated and when it reaches the top of the column, given quantities of an antifoam are added. The frequency of antifoam addition within a given time interval can be exploited in order to measure the efficiency of the antifoam, the frequency of addition being inversely proportional to this efficiency.

79.5 DETECTION AND REGULATION OF FOAM IN BIOPROCESSES

The detection of foam is generally performed by using a resistivity probe located in the headspace of the bioreactor. The foam level is then detected by a contact probe inducing the automatic delivery of the antifoam. The contact between the probe and the foam close the electrical circuit supplying the antifoam delivery pump. However, this simple on/off control does not take into account the dynamics of foam formation and can lead to the delivery of an inappropriate dose of antifoam. Current research involves more sophisticated probes that are able to measure the conductivity at different levels of the foam column. The conductivity value can be exploited to measure the liquid content of the foam at a given point (24); this method is used mainly to estimate the foaming properties of solutions, as explained in the section on "Methods Used to Evaluate the Foaming Properties of a Solution". This measure is more representative of the properties of foam especially its stability, and gives a robust parameter that can be exploited to improve the dynamic control of foam during a bioprocess. However, such types of sensors are sensitive to fouling by the residual foam. This problem can be avoided by an appropriate processing of the signal at the level of the transmitter. In this way, some companies (e.g. Charis) propose a sensor technology that will be able to detect foam intensity and deliver a precise dose of antifoam. For example, combination of the multi-conductivity probe with a neural network processing of the signal, has allowed effective control of the foam during Pseudomonas sp. cultivations performed in laboratory-scale stirred bioreactors (26).

When using a physical defoamer, the automatic controls can be based on the power input variation required by the turbine of the foam breaker, when being exposed to foam (15).

79.6 CHEMICAL METHODS USED TO PREVENT FOAM

An agent that inhibits initial foam formation is often called *antifoam* whereas an agent that ruptures already-formed

foam is called a *defoamer* (27). We will however use the word "antifoam" in a general way, whether it is used as antifoam or defoamer. Typical antifoams or defoamers consist of oil, hydrophobic solid particles or a mixture of both (28–31). Nonpolar and polar oils have been described while solid particles can be either organic or inorganic. Nonpolar oils are based either on silicone oils (PDMS, see *vide infra*) or organic oils. The most important organic nonpolar oils are water-insoluble paraffinic mineral oils, vegetable oils (such as tall oil, soybean oil, or rape seed oil) or polymeric oils (such as polyisobutylene). Although some nonpolar oils may exhibit some antifoaming performance on their own, mixtures of nonpolar oils with hydrophobic solid particles perform much better than each component, which in some cases can be ineffective when used alone. Hydrophobic solid particles which are the most widely used in the making of antifoam formulations, consist of treated silica (either fumed or precipitated) (32,33), organic waxes (such as ethylene bis-stearamide) or so-called metallic soaps (Aluminum or Calcium stearate) (34). There is a whole class of soluble foam control agents, mostly based on polypropylene (PO) or polyethylene-oxide (EO) (or copolymers such as EO-PO-EO or ethoxylated fatty alcohols) which function by phase separating above their cloud point to form insoluble droplets of a hydrophobic liquid (35). Some soluble polymeric surfactants are thought to destabilize the foam stabilized by proteins or macromolecules by entering the surface as a soluble surface-active species and decreasing the surface elasticity. Antifoam with surfactant structures use this principle (36). A list of selected antifoam agents is presented in Table 79.1. This table includes the main antifoam classes found in the market and for each class, several examples of commercial products are given.

79.6.1 Modes of Action of a Chemical Defoamer

Many foam control agents are added to the foaming medium after being predispersed in water, either as self-dispersible neat materials, oil-in-water emulsions, or self-dispersible mixtures and compounds. The main reason justifying this kind of formulation comes from the fact that, to be efficient, the antifoam must be dispersed as small droplets in the liquid medium. Indeed, in order to destroy a foam film, it is critical that a hydrophobic particle droplet emerges from the aqueous phase into the air/water interface (this process is termed as *entering*). Subsequently, after the entering process, the oil coming from the droplet is able to spread on the air/liquid interface. The two phenomena are not independent as spreading of the oil at the solution/air surface can change the so-called "barrier to entry", which is related to the forces which prevent the emergence of predispersed oil drops on the foam film surface (37,38). Two coefficients, that is the entering and the spreading coefficients, are thus used to characterize the change in free energy of the system when the antifoam droplets emerge from the

TABLE 79.1. List of Selected Antifoam Materials (Neat oil, Emulsion and Powder)

Antifoam Class	Trade Name	Vendor
100% Silicone-based active		
	Dow Corning® Antifoam 1500	Dow Corning
	Silfar® 100	Wacker
Oxylated fatty alcohol or acid		
	Range of Clerol or Agnique defoamer	Cognis
	Acepol 42 Ester	Emerald
	Range of ethoxylated fatty alcohol material	OUVRIE
Organic oil based		
	Acepol 183E	Emerald
Polypropylene glycol or polyethyleneglycol polypropylene glycol copolymer		
	Range of Pluronic	BASF
	Range of Genapol	Clariant
	Range of Polyglycol	Dow
	Polypropylene glycol	BASF, Dow
Emulsion of polydimethylsiloxane		
	Dow Corning Antifoam 1510	Dow Corning
	Silfar SE 4	Wacker
	Acepol 15	Emerald
	Antifoam FD 30	Basildon
Powdered antifoam		
	Dow Corning 1920 Powdered Antifoam	Dow Corning
	Agnique Soap L	Cognis

This list is not exhaustive and is given only as an example of material currently available on the market.

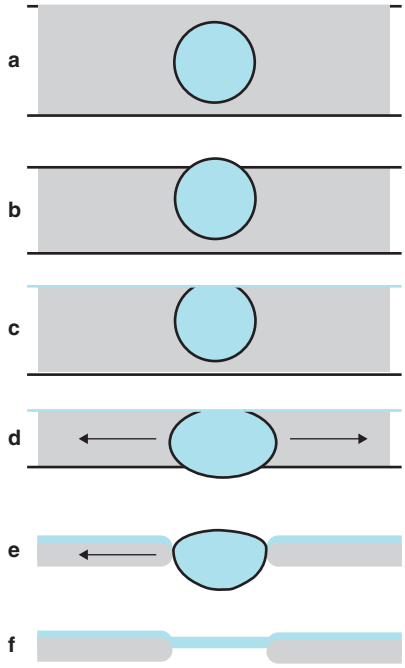

Figure 79.5. Schematic presentation of the bridging of a foam film by a spherical antifoam droplet. (a) The antifoam droplet is entirely in the liquid film. (b) The antifoam droplet has entered the surface. (c) The antifoam droplet bridges the film. (d) The process of bridge de-wetting occurs, leading to destabilization of the foam film and eventually to foam rupture (E and F). (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

solution to the solution/air surface (entering, see step B in Fig. 79.5) and when oil from the droplets spreads on the solution-air surface (step C, Fig. 79.5). In the latter process, solution-air surface is replaced by solution-oil interface and oil-air surface.

The entering coefficient can be described by the following equation:

$$C_{\text{entering}} = \sigma_{A/W} + \sigma_{O/W} + \sigma_{O/A} \qquad (79.7)$$

A positive value for this coefficient means that the surface tension of the antifoam liquid ($\sigma_{O/A}$) is lower than the sum of the surface tension of the foaming solution ($\sigma_{A/W}$) and the interfacial tension between the antifoam and the foaming solution ($\sigma_{O/W}$). This also means that the change in free energy of the system when the antifoam droplets emerge from the solution to the solution/air surface, is negative.

When oil from an emerged drop spreads over the air/water interface (step C, Fig. 79.5), it leads to a change of free energy which is the opposite of the spreading coefficient given by the following equation:

$$C_{\text{spreading}} = \sigma_{A/W} - \sigma_{O/W} - \sigma_{O/A} \qquad (79.8)$$

During this step, the water surface is progressively replaced by the oil. A positive value for the spreading coefficient means that the surface tension of the foaming liquid ($\sigma_{O/W}$) is greater than the sum of the surface tension of the antifoam ($\sigma_{O/A}$) and the interfacial tension between the antifoam and the foaming liquid ($\sigma_{O/W}$). Entering is obviously essential to rupture the foam, and it is generally recognized that the entering coefficient must be positive to cause this rupture. A recent study suggests that the spreading of a layer of oils facilitates the foam breaking mechanism, suggesting that the ability to spread is an important property for an oil used in an antifoam formulation (37). To get a positive value for both the entering and the spreading coefficient, it is important to have a liquid with a low surface tension condition which is met for example, in the case of silicone oils. It has been shown that hydrophobic particles facilitate the penetration of the antifoam droplets in foam films, explaining the benefit associated with their addition to antifoam formulations. Hydrophobic particles were shown to decrease the so-called "barrier to entry", thus the barrier which prevent the droplet to emerge from the solution (39). On the other hand, the dispersion of hydrophobic particles in a reactor is an efficient method to control foam (40). After a silicone droplet has penetrated the double air-water interface, a bridge is formed between the two surfaces of the foam film (Fig. 79.5). At this stage, one of the mechanisms invoked in the literature involves the de-wetting of the solution, away from the antifoam droplet associated with the low surface tension of the oil and eventually leading to the rupture of the film (Step E, Fig. 79.5). By no means, is this the only mechanism proposed in the literature, but it helps to better understand how antifoam droplets can eventually lead to foam rupture. For example, another mechanism proposed in literature is "Bridging-stretching" which is illustrated in Step F (Fig. 79.5). In this mechanism, the bridge stretches till a thin, unstable oil film forms in the center of the bridge. Rupture of this oil film results in the perforation of the entire foam lamella (41,42).

79.6.2 Polydimethylsiloxanes as Surface-Active Ingredients in Antifoams

Silicone oils, and more specifically polydimethylsiloxane (PDMS) materials, because of their molecular characteristics, combine many unusual properties such as the flexibility of the Silicium-Oxygen-Silicium backbone and the very low cohesive energy existing between methyl groups (Fig. 79.6). PDMS polymers have low surface tension, and most of them are nonvolatile and remain liquid even at fairly high molecular weights. They are also highly insoluble in water (43). Because of the extreme flexibility of the siloxane backbone and ease with which various polymer

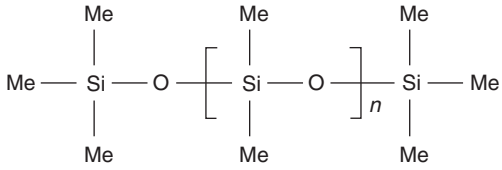

Figure 79.6. Polydimethylsiloxane backbone of a silicon-based antifoam.

configurations can be adopted (despite the siloxane backbone's considerable polarity), it is the side groups that are the primary surface-active entities in the polymer structure. The pendant groups in PDMS are methyl groups, which show the weakest intermolecular interactions known: the London dispersion forces. The low surface tension, which is a direct manifestation of low intermolecular forces, confirms that the interactions between two PDMS chains occur only through their methyl groups. The polymer backbone controls the organization of the side groups at the surface, and its flexibility has a major effect on the ease with which the pendant groups can adopt preferred configurations. Thus, from a surface tension standpoint, the more flexible the backbone, the more readily will the lowest surface energy configurations be adopted. PDMS is a particularly favored case of very low intermolecular force pendant groups anchored along the most flexible backbone, thus allowing the methyl groups to be ideally presented to the external world (44). It is often observed that neat silicone oil shows low efficiency as an antifoaming agent. But mixtures of such oils with hydrophobic particles such as treated silica or finely divided high melting point waxes, are generally much more effective than the individual components (27–29,39). In fact, the mixture performs well even if each component is ineffective when used alone. This synergy is observed for most combinations of oils and solids and in various types of foaming media. It is now widely accepted that the main role of solid particles in antifoam formulations is to facilitate the entry of antifoam droplets. The "barrier to entry" is much lower when the oil drop contains hydrophobic particles. The main role of solid particles is then, to facilitate the entry of the antifoam droplets (39). Effective foam control agents continue to be developed using such combinations to adjust for different types of foam problems.

79.6.3 Formulation Trends

The delivery vehicles, by which the antifoam is delivered to the foaming system, are a key aspect of the antifoam formulation. Practical aspects such as the physical state of the foam control agent (liquid, pasty, or solid), its viscosity (which can be a limit for the pumping or dosing systems), the required cost efficiency, and the addition method will all impact the way the foam control can or need to be added in the fermentation system. There are interactions between the parameters which control foam formation (air incorporation, chemical composition of the broth, presence of surface-active species or pH of the solution) and the antifoam's characteristics (formulation of the antifoam) and how it is delivered to the foaming system. These interactions are illustrated in Fig. 79.7.

79.6.3.1 Neat. Almost all foam control agents sold and used on the market are liquid. As discussed in a different section, they can belong to different chemical families (silicone, aliphatic oil, triglyceride, polyglycols, ethoxylated fatty alcohols, etc.). Their chemical composition will drive

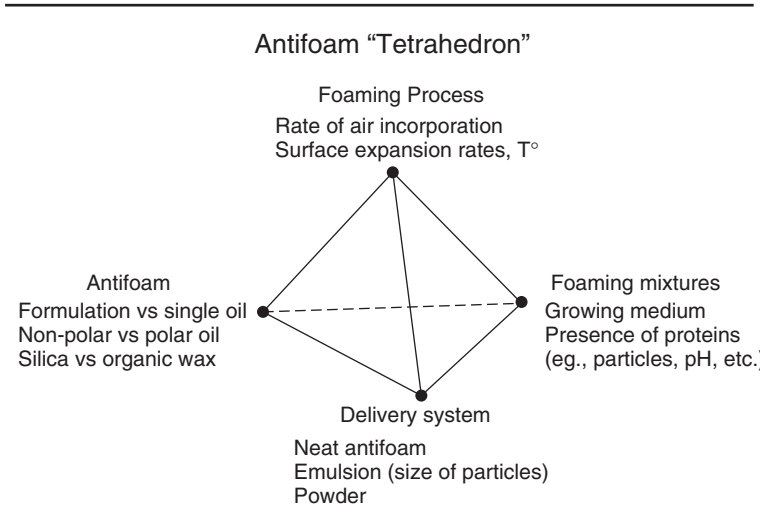

Figure 79.7. Scheme illustrating the different parameters taken into account in the elaboration of a chemical antifoam.

the physicochemical properties, especially the ease of dispersion into water. This is the main characteristic which will dictate if the foam control agent needs to be further formulated or can be used as such; we will characterize this as the neat active agent. If the foam control agent has a low interfacial tension with water (or with the foaming solution), it may be used as such, as it may "disperse" in such a way that it can reach the desired particle size and start to control the foam. If the foam control agent shows a high interfacial tension with water (like PDMS or aliphatic oil with water), some further formulation will be required, such as the addition of surfactant for the making of self-dispersible blends or as emulsion for easier handling.

79.6.3.2 Emulsions. Emulsions are dispersed systems consisting of two (or more) mutually insoluble or sparingly soluble liquids (45). The liquid, usually present in excess, is termed the *continuous* or *external phase*, while the liquid dispersed in it is termed the *internal* or *dispersed phase*. If the external phase consists of water and the internal phase of an organic liquid, for example mineral oil, the term *oil-in-water* (o/w) emulsion is used. In the field of foam control agents, emulsions are generally aqueous, which means they are made by dispersing a nonaqueous foam control agent (dispersed phase) into water (the continuous phase).

Emulsions are prepared industrially to improve the effect of the foam control active substance during the application, by using it in a more or less finely dispersed form. The external phase assumes the role of a transporting and/or diluting agent while the dispersed foam control agent is present as tiny droplets.

Emulsions are used for easy handling of foam control agents which are sometime greasy, highly viscous, organic liquids. Stability of the emulsion is obtained from the proper use of surface-active agents (surfactant) which reduce the interfacial tension between water and the foam control agent in such a way that, the high interfacial area between the dispersed phase and water can be achieved. Thickeners such as functionalised cellulose or some other natural or synthetic materials reduce creaming and further stabilise the emulsion. The latter can have some detrimental impact on downstream treatment of the fermentation broth.

79.6.3.3 Self-Emulsifiable or Self-Dispersible Systems. Self-dispersible systems are blends of foam control agents with surfactants which are designed to readily disperse into the foaming system or, readily emulsify and stabilize the foam control agent in aqueous solutions prior to addition in the foaming liquid. Various systems are described in the literature such as dispersion of antifoam in silicone polyether (46), glycols (47) or organic surfactant (48). Although apparently simple, the compatibility between the foam control agent and the surface-active agent needs to be good enough to achieve stability of the self-dispersible systems, and yet effective enough to ensure ready dispersion during the final application.

79.6.3.4 Powdered Antifoam. The last means by which a foam control agent can be added is as a solid form, most often this will be a powdery material which can be conveniently dosed or handled. Various methods exist to transform a liquid foam control agent into a solid powder. A simple adsorption of a liquid on an absorbing solid is sometime enough to obtain a nice free-flowing powder (49). When improvement of the physical properties of the powder is required (i.e. free-flowing powder with improved shelf stability), more complex formulations and methods of manufacturing will be used. This can imply the preliminary dispersion of the foam control active followed by spraying on a powder acting as carrier and water evaporation (50).

79.7 PHYSICAL METHODS USED TO PREVENT OR REDUCE FOAM FORMATION IN BIOREACTORS

Various physical principles have been proposed in order to prevent foam formation (10). It includes thermal, ultrasound methods and more classically, the mechanical method which involves a special turbine designed to break the foam bubbles by rotating. Considering that the latter is by far the most widely used at the process scale, only this method will be investigated here (the ultrasonic method is actually under investigation but presents some adverse effects notably at the level of the influence of ultrasound on the viability of the microorganisms). To reduce the costs associated with the electrical motor, several turbines have been designed in order to be effective when placed directly on the shaft of the bioreactor. Finally, a new method, based on the management of the bioreactor hydrodynamics in stirred tanks (to reduce foam formation), will be considered. This new method is termed *stirring as foam disruption* (SAFD). These three physical alternatives are presented at Fig. 79.8.

It is important to point out the fact that the first method proposed in this section can be used in order to suppress foam, whereas the second and third methods can only be used to limit its formation.

79.7.1 Mechanical Foam Breakers

79.7.1.1 Classical Mechanical Foam Breaker. Considering the limitations associated with the chemical antifoams (see section on "Impact of Foam Formation and Prevention"), the use of a mechanical foam breaker can in certain cases be a good alternative. It can be used simultaneously with the addition of chemical antifoam

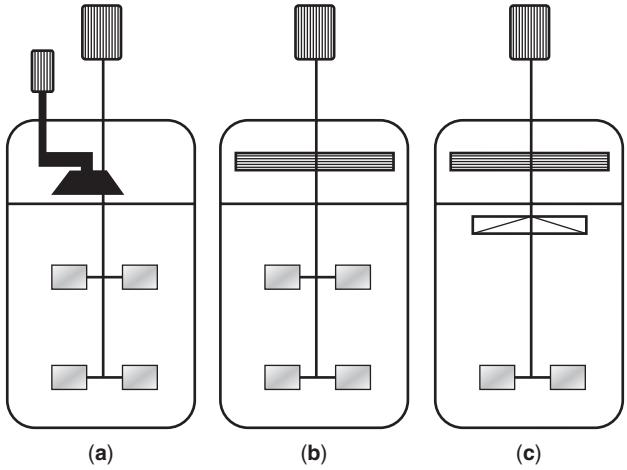

Figure 79.8. Different concepts of mechanical foam breaker. (a) classical concept with the defoamer mounted on a separate shaft, (b) defoamer with the turbine mounted on the shaft of the bioreactor, and (c) "stirring as foam disruption" (SAFD) concept for which the liquid flow pattern generated by the upper impeller tends to destabilize the foam.

in order to reduce the amount of antifoam added in the bioreactor. There are numerous systems available which have been extensively reviewed in the literature (10), and their actions are based on pressure change, shear force and compressive force leading to the destabilization of the foam film. A good example of commercially available and effective mechanical foam breaker is the Fundafom system developed by Chemap (Fig. 79.9) for which the turbines (inverted cones) have been especially designed in order to enhance the shear effect. This apparatus is typically centrally mounted on the bioreactor cover and allows an effective separation of the gas and liquid phase (the volatile part of the collapsed liquid film is collected in a cooled condenser and injected back into the reactor). Other systems including foam breakers with rotating disks (51) have also been experimentally investigated. The main limitations of the mechanical systems is the energy cost associated with the motor of the defoamer. In the case of a stirred vessel, two motors are required, one for the mixing system and another for the defoamer, leading to a significant increase in the installation, functioning and maintenance costs. These costs become unacceptable in large-scale bioprocesses (1). The following sections involve the description of some low cost alternatives to this system.

79.7.1.2 Mechanical Foam Breaker and Mixing System Mounted on the Same Shaft. To reduce the costs associated with power consumption, the turbine of the mechanical defoamer can be mounted directly on the shaft of the impeller system of the bioreactor. In addition, this method presents a lower risk of contamination because the foam

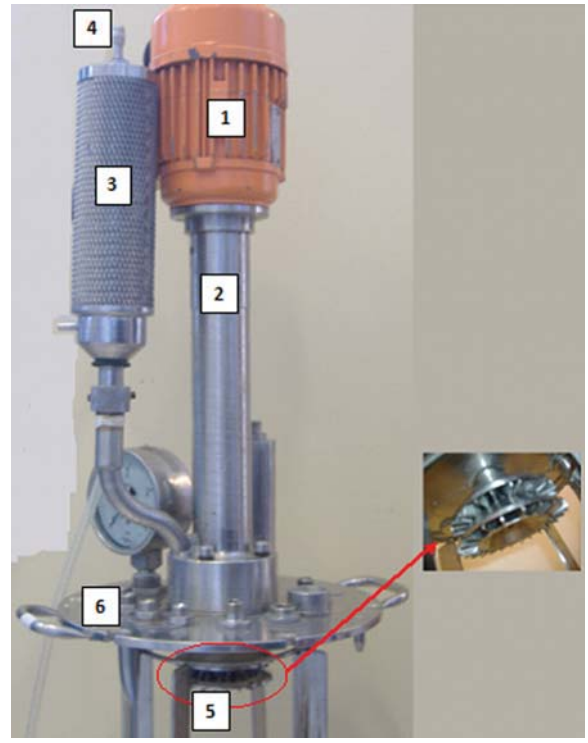

Figure 79.9. Classical mechanical foam breaker equipped with a rotating turbine and installed on a 20 L bioreactor. (1) motor, (2) shaft, (3) cooled condenser, (4) condenser outlet back to the reactor, (5) turbine (conical disks), (6) cover part of the bioreactor. (This figure is available in full color at http://onlinelibrary.wiley.com/book/10.1002/9780470054581.)

breaking apparatus is directly integrated on the shaft of the bioreactor (no mechanical seals are required). Considering the strong interrelation existing between oxygen transfer and foam generation (as reported in the section "Description of the Foam at the Macroscopic Level: Gas–Liquid Dispersion in the Reactor"), this method is only valid if the critical speed for foam control is lower than the required speed for gas dispersion in the bulk of the bioreactor (52). In this context, the turbine of the defoamer must be appropriately designed. A comparison has been done between classical impellers (originally used for the mixing operation in the bulk of the reactor) and some newly designed turbines. It has been shown that these new turbines (thin needles and large paddle turbines) were more efficient in the sense that they lead to a significantly reduced critical speed for foam control (52–55). A more recent system based on hollow inverted cones has been tested in a pilot bioreactor (56). This system is derived from the autonomous foam breaker Fundafom (see section "Classical Mechanical Foam Beaker") and has allowed efficient foam control during a Bacillus culture (a culture generally associated with strong foam problems considering the surfactant synthesis capabilities of this microorganism) at a 0.5 m^3 scale.

79.7.2 Stirring as Foam Disruption (SAFD) Techniques

As discussed before, the bioreactor's hydrodynamics can be optimized to limit foam formation and ensure a given level of oxygen transfer. Further studies have led to the consideration of hydrodynamics as a primary factor in preventing foam in stirred bioreactors this is known as the *stirring as foam disruption* (SAFD) concept. As mentioned before, the foaming intensity in relation to the gas–liquid dispersion in the reactor is governed by the ratio V_L/V_G. The SAFD technique consists simply of designing the impeller system to enhance the liquid velocity near the free surface. To achieve this, the impeller configuration must be modified, that is the height of the upper impeller must be increased for it to be closer to the free surface. Several impeller geometries have been tested (20,57,58) and it has been shown that up-pumping hydrofoils (and notably the A340 hydrofoil commercialized by Lightnin) are the most effective because their flow pattern gives rise to high liquid velocities in the vicinity of the free surface. Considering the complexity of gas–liquid dynamics inside stirred bioreactors, the SAFD mechanism is not completely understood. In addition to the shear effects induced by the liquid flowing through the dispersion surface, the distortion of this surface under the action of liquid waves propelled by the hydrofoils can also play a role in the mechanism of foam rupture (59,60).

79.8 IMPACT OF FOAM FORMATION AND PREVENTION

Foam formation has several impacts at the level of a bioprocess design. In this section, the impact of foam formation will be reviewed by considering three distinct parts of the process: the cell growth and metabolites production, the bioreactor optimization and scale-up and the downstream processing operations. The appearance of foam induces a direct and an indirect negative effect on the bioprocess. The direct effect is attributed to the appearance of the foam which induces cell loss and sterility problems. Indeed, the flow of foam outside the reactor can lead to a significant reduction in reacting volume (and in some extreme cases, to the loss of the entire volume), and can lead to the incorporation of contaminating microorganisms. Subsequently it can result in obstruction of the filters, valves, piping, and so on, by the foam itself and/or the liquid from the collapsing foam. The indirect effects are linked with the antifoam strategy. Mechanical foam breakers can induce shear damages at the level of the cell membrane. Like the other stirrer dependent variables, the shear damages are proportional to the specific power input $\varepsilon = P/\rho V$ [P being the power dissipated by the stirring device (W), ρ being the fluid density (kg/m^3) and V being the volume of the agitated fluid (m^3)] (19). It is generally assumed that the microbial cells are exposed to shear effect when they are of a size approaching the Kolmogoroff microscale of turbulence λ_K. This scale can be directly calculated from the local specific power dissipation:

$$\lambda_K = \left(\frac{\varepsilon}{\upsilon^3}\right)^{-1/4} \tag{79.9}$$

where υ is the kinematic viscosity (m^2/s).

Hewitt and Nienow (61) have calculated that, for water-like media and for a specific power dissipation of 1 KW/kg, the Kolmogoroff microscale has a value of 30 μm, which is largely below the mean size of a bacterial cell (about 1 μm). This result suggests that, in most cases, the shear stress has no effect on the microbial cell. However, the picture is not the same if the power drawn by the impeller is increased in order to improve the mixing and the oxygen transfer efficiency of the bioreactor. Differences can also be noted for microorganisms other than bacteria and for which the average size can approach the critical size for shear damage (e.g. budding yeast and filamentous fungi). This effect is also enhanced in the case of a mechanical foam breaker designed to destroy the foam by shear effect. However, in this case the application of the Kolmogoroff equation (Eq. 79.9) is not straightforward, since the nature of the foaming medium is difficult to characterize.

On the other hand, the chemical antifoams also exhibit several problems as they can alter the microbial metabolism, reduce the oxygen transfer efficiency and compromise the downstream processing operation.

79.8.1 Impact of Foam Formation and Prevention on Microbial Growth

The direct and indirect effects of foam on the bioprocess have to be distinguished. Foam directly affects the process by removing the cells from the medium by flotation. In addition, foam indirectly affects the process performance by the elaboration of a foam suppression strategy. Indeed, the addition of chemical antifoam has an impact on the microbial growth process. The non-metabolizable antifoams, such as silicone oils and polyglycols, have little effect on microbial metabolism (11), although a noticeable exception occurs in the case of exopolysaccharides production with the addition of a polypropylene glycol antifoam (62). However, the process-related problems associated with the use of such antifoam agents (i.e. principally oxygen transfer limitation and membrane fouling as it will be explained in the next sections), has led to the consideration of natural oils as an alternative. In particular, the use of vegetable oils has been investigated (63). As the organic compounds contained in the oils (e.g. triglycerides and free fatty acids) can be used as a carbon source, the course of fermentation is altered when using

such products as antifoam agents. Their impact at the level of the metabolism depends on the microorganism cultivated and the composition of the oil: in certain cases, they can increase the cell mass yield because they are incorporated as carbon sources (63), and in other cases they can induce toxic effects related to the release of specific fatty acids (11). A major disadvantage related to the use of natural oils as antifoam agents is their relatively low efficiency when compared to their synthetic alternatives. In addition, the natural oil has to be added continuously during the culture as it is metabolized by the microorganism. Vardar-Sukan (63) has made a comparison of the efficiency of several natural oils (castor, corn, cotton seed, linseed, olive, sesame, soybean, and sunflower) and has found large variations in their efficiency which is a function of the composition of the culture media, suggesting that the use of natural oils must be carefully tested before being applied to large-scale bioprocess.

79.8.2 Impact of Foam Formation and Prevention on Bioreactor Performances and Scale-Up

The use of chemical antifoam is known to reduce the oxygen transfer efficiency and in general, the gas–liquid dispersion performance of the reactor. Indeed, the adsorption of antifoam molecules at the gas–liquid interface induces a resistance to oxygen diffusion. In addition to this surface effect, antifoam addition has a bulk effect interfering with the mixing mechanism and leading to reduced gas–liquid dispersion, larger bubbles and reduced gas hold up and interfacial area (64). As mentioned before (section 2), many surface-active agents are added as emulsions of suspended oil droplets in order to break the foam structure by formation of hydrophobic bridges and displacement of proteins at the interface. However, these conditions induce, at the same time, the coalescence of air bubbles in the bulk of the reactor (65). This adverse effect is enhanced at higher aeration rates, leading to problems when the aeration process has to be scaled up (3). This effect has been investigated and confirmed on 55 and 770 L external loop airlift bioreactors with the addition of silicone-based antifoams (65) and on bubble column bioreactors (66). During the culture of plant cells, a significant decrease of K_La (see Eq. 79.2) has been observed in laboratory bubble column reactors and stirred tank reactors when little quantities (as low as 20 ppm) of polypropylene glycol and Pluronic PE6100 were added to the culture to control foam (67).

79.8.3 Impact of Foam Formation and Prevention on the Downstream Processing Operation

In general, the addition of antifoam during the culture leads to several problems at the level of recovery procedures. The addition of antifoam modifies the suspension capabilities of the cells, leading to problems during centrifugation and induces fouling of the micro and ultra filtration membranes (68,69). Considering their surface-active properties, antifoams tend to stay at the interface, increasing their tendency to accumulate onto the membrane surface or pore walls. The antifoam polymers can easily spread on this surface, inducing the formation of a gel layer which causes fouling of the membrane. From a physicochemical standpoint, several mechanisms are involved in membrane fouling by antifoams, for example, hydrophobic interactions between emulsified antifoam and the membrane, cloud point effects of polyglycols, and formation of a gel layer at the surface of the filtration membrane (70,71). The prevalence of one of these mechanisms over the others depends on the nature of the filtration surface and the antifoam used. Pretreatment of polysulfone membrane surfaces has been proposed in order to reduce the fouling effect (72). The treatment of the membrane with a wetting agent tends to decrease the hydrophobicity of the surface of the membrane. The hydrophylisation of the membrane can be achieved by chemical modification of the surface charge or by physical precoat of the membrane.

On the other hand, in some specific cases, the foaming behavior of the broth can be exploited to perform a downstream processing operation. Indeed, proteins of interest can be recovered by foam fractionation (73). Specific methods for the direct purification of biosurfactants based on foam generation from the culture media have also been proposed (74,75). Along the same lines, the process of foam separation has been applied to separate microbial cells from the fermented medium in order to reduce the costs associated with centrifugation (76).

79.9 FOAM IN BIOTECHNOLOGICAL PROCESSES: PRESENT KNOWLEDGE AND FUTURE PROSPECTS

It is clear that foam formation in bioreactors is a complex physicobiochemical phenomenon that may induce a huge amount of technological problems. Foam prevention in biotechnological processes requires a thorough understanding of the microscopic, as well as the macroscopic, mechanisms involved in foam generation. The microscopic mechanisms are based on the molecular interactions of the surfactant with the gas–liquid interfaces. The picture is more complicated in the presence of microorganisms since the biomass leads to a modification of the nature of the broth and subsequently to substrate consumption and the release of metabolites; some efforts must be allocated to the investigation of the effect of the biophase on evolution of foaminess of the broth. The latter is of particular importance to better understand the impact of addition of

chemical antifoam on the course of the bioprocess. Indeed, silicone-based antifoams are actually the best alternative for an effective antifoam strategy, but in several cases they cannot be used due to biological constraints (toxic effect on the microorganisms, reduction of the oxygen transfer efficiency, etc.). At this stage, some efforts remain to be made at the level of antifoam formulation in order to increase their efficiency along with low adverse effects on the culture. On the other hand, the macroscopic mechanisms are related to the gas–liquid hydrodynamics of the bioreactor. It has been shown that bioreactor hydrodynamics (e.g. by the inclusion of a SAFD strategy) and/or operational parameters can be adjusted in order to reduce the generation of foam. However, these changes can only be performed on a limited range, since they directly affect the transfer performances (i.e. oxygen transfer, heat transfer and homogenization efficiency) of the bioreactor. A lot of experimental methods are available to study the gas–liquid dispersion in the bulk of the reactor (e.g. local gas hold up and K_La measurements), but only few are available to make similar observations at the level of the gas–liquid dispersion below the liquid free surface. It is important to have some techniques to better characterize the foam generated in the bioreactor, and not simply consider the level of foam. At present, they are several techniques that can be used at the laboratory scale to measure the liquid content of the foam. This principle has been adapted at the level of the bioreactor by a specially-designed probe for the online monitoring of foam characteristics during a bioprocess (i.e. the foam level, as well as the foam stability at different levels of the foam column in the headspace of the reactor). This kind of probe will be very useful in the future for the control of addition of antifoam and will allow the combination of chemically-based antifoam strategy (microscopic mechanisms) with those based on the knowledge of gas–liquid efficiency of the reactor (macroscopic mechanisms) such as adjustment of the air flow rate and/or stirrer speed.

In conclusion, at this point in time, foam still poses a serious threat to biotechnological applications, but a reasoned application of antifoam strategy along with a precise characterization of foam properties and integration of biological constraints associated with the process, would lead to better control over this problem.

PILOT PLANTS, DESIGN AND OPERATION

Beth H. Junker
Bioprocess R&D, Merck Research Laboratories, Rahway, New Jersey

80.1 INTRODUCTION

Several diverse roles, objectives, and purposes are associated with a bioprocessing, biochemical, or biopharmaceutical pilot plant. These include, but are not limited to, the manufacture of early- and late-phase clinical supplies, process development (including process characterization, validation, and comparability (1)) for new products in the company pipeline, process improvement including technical support for existing products in the market, and production of biologically produced materials (which are not intended for the clinic) to support basic research efforts such as screening, assays, and disease mechanism elucidation. Despite desires to design pilot facilities for diverse differences in scale, products, processes, clinical phases, and capacity, limited capital and operating budgets force value engineering decisions about "must have" and "nice to have" capabilities (2). Unlike chemical pilot plants, pharmaceutical pilot plants are used not only to scale-up laboratory processes, but also to produce developmental quantities of chemicals (and biological substances) for safety, toxicological, and clinical studies (3). Thus, balancing of the demands for scale-up and development research with those for clinical production is a key dilemma for pilot plant operation (4). This tension has resulted in an increased recent attention to the development of scale-down models to mimic larger scale performance and thus reduce demands for pilot scale process development runs (5). Another challenge is to determine what proportion of the material requirements for each phase of a product's development has to be outsourced to contract manufacturing organizations (CMOs). Some CMOs are even targeting clinical-scale production clients, essentially building pilot plants for hire (6). The timing and reliability of clinical material production is critical as expensive and time-consuming clinical programs can be delayed, thus postponing product application filings, approvals, and launches (7). Although traditionally pilot plants have not manufactured material for sale, accelerated launch dates, deferred manufacturing facility capital commitments, and other areas of project uncertainty have prompted consideration and use of pilot plants for manufacturing in recent years. In addition, rising fermentation titers, isolation yields, and overall process streamlining has expanded the capabilities of smaller sized facilities to satisfy larger kilogram material demands (5).

The types of products manufactured using biologically based methodologies include primary metabolites, secondary metabolites (ranging from pharmaceuticals to biopolymers), constitutive proteins, recombinant proteins, intracellular/extracellular enzymes and biocatalysts, antigens, viruses, polysaccharides, and plasmid DNA itself. These products are made using a wide range of cell cultivation and isolation techniques suitable for bacteria, yeast, fungi, actinomycetes, suspension animal cells, anchorage dependent animal cells, insect cells, and plant cells. Processing equipment considerably varies among these diverse systems.

Designing for extensive processing flexibility can be expensive, potentially in excess of $100 million, depending on the specific process requirements, size, and intended use of the pilot plant. In addition, processing requirements can change drastically as products are de-emphasized

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

and re-emphasized in development. These decisions on priorities often are not usually caused by process robustness but rather by the state of the clinical data or potential market share. The ability to process multiple products in an acceptable manner is typically desirable to maximize facility use. Although designers may need to predict future types of processes and products, they should be cautious about over designing the facility in terms of containment and flexibility (8). Designing for future expansion with minimal disruption to operations can help in reducing initial capital expenditures (9).

The general areas required in a pilot plant might include support labs for bench scale development and quality control, production suites for scale-up, utility areas, personnel offices, as well as ample storage areas for raw materials, supplies, product, samples, and documentation (4). There should be a clear division between controlled and noncontrolled areas utilizing signs at a minimum and perhaps by physically restricting access. General design criteria might focus on modularity, simplicity, future growth provisions, redundancy, construction costs, operating costs, and air/water waste containment (10). Future operating costs are important considerations for pilot plants as ample funds are necessary for raw materials, staffing, maintenance, and additional capital modifications to permit improvements.

80.2 OPERATIONAL CONCEPTS AND PROCESSING REQUIREMENTS

Several operational concepts influencing design requirements need to be agreed upon prior to the initiation of design activities. Agreement should be sought among end users, operations staff, compliance auditors, environmental consultants, safety officers, as well as appropriate levels of management who are directly or indirectly influencing or controlling capital expenditures. A written document summarizing consensus on these issues may then become the basis for conceptual design activities.

Major decisions influencing pilot plant capabilities include whether the facility will produce bulk drugs (thus falling under the regulation of Center for Drug Evaluation and Research (CDER) and following guidelines from 21CFR 210/211) or biologics (thus falling under the regulation of Center for Biologics Evaluation and Research (CBER) and following guidelines from 21CFR 210/211 and 600) (11). The level of validation and the validation philosophy are directly related to the end use of the resulting pilot plant products, specifically whether they are used for process development, clinical supplies (presafety/basic research, safety, phase I, phase IIa, IIB, phase III), or material for sale. Validation strategies, as well as other operational and design issues, are also influenced by whether the pilot plant is administratively located within the manufacturing or research division. Individual company preferences and guidelines for similarity between manufacturing and pilot plant areas need to be identified and evaluated for their impact on the proposed pilot plant facility. Typical areas targeted for standardization within a company might include vessel designs, computer systems and interfaces, equipment vendors, and construction specifications.

Design requirements center on the desired initial and end product stages of processing, specifically the forms of the pilot plant inputs and outputs, as well as in-process hold steps. Example stages include master/working seed preparation, fermentation broth, initial captured product (e.g. microfiltration retentate, ultrafiltration concentrate, cell paste), crude product (e.g. rich ion-exchange fraction), finished isolated/sterile bulk, and filled vials. Ambient, refrigerated, and frozen storage requirements based on these inputs/outputs then need to be addressed in the areas of seed, raw materials, intermediates, clinical supplies, and process samples.

The scale of the pilot plant relative to current or proposed manufacturing scale and relative to laboratory scale needs to be established. Generally, a 1:5 or 1:10 scale-up is common (1), but smaller ratios can be advantageous in terms of minimizing risk during factory start-up. The appropriate level of biosafety also must be considered with GLSP being sufficient for most recombinant work. Some pilot plant areas may require BL1-LS and/or BL2-LS, and careful consideration of multiple use/decon issues for BL1 and BL2 containing facilities is necessary. Solvent-use areas need to be identified and minimized if possible as cost implications for explosion proof design can be substantial.

Primary motivations to design a multiuse pilot plant are the conservation of capital and improved response time for clinical manufacturing requirements for new product development. The strategy for multiuse should be identified and considered throughout the design process. Common strategies (12) include (i) using totally dedicated equipment and limiting production to one product at one particular production stage, (ii) using campaigned equipment in which multiple products are sequentially processed in the same equipment "campaign style," with documented product changeover procedures completed to minimize cross-contamination potential, and (iii) conducting concurrent manufacturing in dedicated equipment in which several products are simultaneously produced in segregated areas with segregation achieved via physical separation or closed systems. These strategies result in the minimization of cross-contamination potential through engineering controls, SOPs, and/or temporal segregation (13). Typical pilot plants combine the second and third strategies by providing segregated and dedicated areas for certain types of processing (e.g. virus and nonvirus

areas, GLSP versus BL1/BL2 areas, beta-lactam antibiotic processing, heat-resistant spore former cultivation) (14), and maintaining flexible areas that can be reconfigured efficiently to suit their multiproduct portfolio needs. Example layouts for product-specific and common areas depending upon the strategy selected have been described (15).

To increase the speed and number of products entering clinical trials, platform processes are becoming increasingly more common to achieve high throughput for early-phase products, avoiding large amounts of individualized process development effort. Platform processes are based on classes of products with similar processing requirements and/or properties. Less optimized processes (e.g., lower yields, longer cycle times, higher cost) are accepted for early material deliveries (i.e. prior to Phase IIB) in exchange for reduced resource requirements. A platform for cell cultivation for monoclonal antibody production has been developed by IDEC based on their own in-house medium and feed formulations (16). In addition, a platform for monoclonal antibody downstream processing based on Protein A capture has been described by Amgen in which a flexible, generic process is used, which predefines most operating parameters and requires only a small subset of other operating parameters to be defined via product-specific process development (17–19).

Guidelines concerning the use of open versus closed systems for various processing stages need to be devised and justified based on available and cost-effective technologies as well as quality requirements. In a closed system, the product is not exposed to the immediate environment. The quality of materials entering a closed system (such as water, steam, and air entering a bioreactor) is controlled by its quality as well as the manner in which these materials are entering the closed system (such as filter sterilization, autoclaving, and/or steam sterilization of system connections) (12). In an open system, the product is directly exposed to the surrounding environment, thus necessitating the creation of a controlled or sometimes even a closed system around the open system. One example of this latter strategy is the transfer of seed vial contents in a biosafety cabinet. Other examples might include the supply of higher quality filtered area to areas for the cool down of autoclaved materials and assembly of clean equipment. Thus, levels of containment can be constructed until all open systems are contained within controlled or closed systems to meet quality requirements for the specific processing stage.

The specific issue of potential exposure of product to spore-forming organisms has been extensively debated. The closed system concept appears to minimize the concern for airborne spores that are typically found in the environment. Cultivation guidelines for spore-forming organisms within a multiuse facility appear to have been redefined to evaluate the robustness of the spore type formed. The careful consideration of segregation has been given when cultivating organisms that form spores that are difficult to be killed, such as *Bacillus*. A separate, self-contained area with no shared equipment, air systems, or entrances minimizes exposure concerns for other products. The relatively heat-sensitive, substantially larger, fungal spores have not been highlighted as a substantial cross-contamination concern. Thus, segregation of these types of processes is not as critical, though it still might be implemented due to company preferences for separate bulk drug and biologics processing areas.

80.3 DESIGN

The initial generation of flow charts for a bioprocessing, fermentation, and/or isolation pilot plant is best conducted based on model processes that are developed and critiqued by several end users of the equipment and facility. These model processes are carefully selected so that they give adequate and appropriate representation to current and reasonable future needs of the pilot plant. Specifically, current and future projections for fermentation titers should be modeled to establish the potential operating range for downstream steps. Because model processes form a preliminary but sound basis for equipment and utility sizing, they should include specific unit operations, equipment scales, and expected cycle times. In some cases, simulation (17,20–23) and/or actual laboratory/pilot scale testing (24) of critical equipment under typical processing conditions or with expected process streams may be warranted to further define design specifications. Time and effort expended to identify and change the design on paper is more efficient (i.e. causing fewer delays) and less expensive than modifications during construction or after start-up (25,26). The proper level of criticality must be assigned to each system; attention to too many critical systems results in unnecessary expenses and too few critical systems results in design changes, delivery delays, and validation challenges (25). Example model processes and throughput evaluations have been published for vaccines, antibodies, and other intracellular/extracellular products (26–31). Resulting flow charts can focus on raw materials for fermentation/isolation, seed development, fermentation, recovery, crude product isolation, final product isolation, product finishing, buffers, utilities, and waste (including chemical waste, biological waste and any necessary off-gas treatment) (27).

The requirements for these model processes, coupled with an estimate of the required facility output, can be used to construct a preliminary architectural layout that divides the facility into sections (commonly termed as *modules, cubes, or suites*). These sections are surrounded by controlled corridors and accessed via airlocks (8). On the basis of this initial layout, flow patterns are developed to permit the logical, usually unidirectional, flow of personnel,

raw materials, product, waste, and clean/used equipment throughout the facility. Flows are primarily designed to minimize cross contamination from multiple products and from used equipment while maintaining access and flexibility (8). This separation is often accomplished using clean and return corridors located on either side of the processing area as well as via temporal segregation using appropriate SOPs. Evaluation of these flow patterns should be conducted carefully and incorporate end users as well as quality auditors. In some cases, companies may solicit outside GMP reviews of the project at this time from external consultants, a second design firm, or even FDA representatives. Gathering and organizing up-to-date, accurate information and comments about the design's impact on model process requirements are critical factors in forming a successful basis of design (32).

Example layouts for process flows for biotech facilities have been published (6,12,33,34). An extensive reference (including piping and instrument diagrams (P&IDs), layouts, and flow diagrams) for the design of biopharmaceutical plant equipment, utilities, heating, ventilation, and airconditioning (HVAC), and waste treatment also has been published (35). Although it was based on acceptable practices in 1991, the strategies and concepts for design presented are still relevant. Adequate space around the equipment needs to be reserved for operations and maintenance access as well as for process-related portable equipment. Specifically, the movement, segregation, storage, and cleaning of portable equipment such as vessels, skids, hoses and carts should be fully examined.

Various reports of successful and problematic aspects of facility design, construction, start-up, and validation have been published. Often, cost estimation for pilot plants is more difficult than that for manufacturing plants owing to incomplete understanding of processes, equipment, and technology (36). Pressure to meet initial schedules and budgets can result in higher initial and subsequent costs, particularly for retrofitting projects. Cost control issues and the benefits of formulating a master schedule (37) need to be reviewed in terms of their potential validation impact. Construction concerns and "lessons learned" from multiple biotech installations also have been summarized (38). One case study of a laboratory facility highlights the need for teamwork among the client, design firm, and construction manager (39). This trio can be extended to include validation contractor in an effort to minimize "finger pointing" and "blame storming" when unforeseen problems are uncovered. Regardless of who may actually be perceived as being "at fault," the company owning the facility ultimately is adversely affected by substantial start-up and validation delays. A comprehensive overview of biochemical pilot plant design and operational guidelines appeared in the mid-1980s (40). A more recent review focuses on best practices for design and operation to reduce bioreactor contamination, a key type of abnormality typically resulting in batch termination (41).

80.3.1 Process Equipment

For a pilot plant, the major decision regarding process equipment is that of similarity versus diversity as it applies to multiple process steps as well as multiple products. The extent of commonality required in equipment specifications is an important operational factor to be considered, as equipment specifications are devised based on the inputs from model processes. For a pilot plant to accept a manufacturing interface role, at least a portion of the equipment (and automation) design and selection should be representative of the factory that the pilot plant is intended to support (1). For example, if the factory is intending to use continuously sterilized medium for large scale fermentation, then there should be provisions in the pilot plant to perform continuous sterilization as products get closer to their transfer to production. Alternatively, depending on individual company preferences for the pilot plant role, later clinical batches (Phase IIB and beyond) might be manufactured in the factory to facilitate eventual process transfer upon commercialization and ensure consistency of equipment.

Skid-mounted or packaged equipment is a common selection in recent pilot plant installations because it puts the design, delivery, and start-up burden entirely on one vendor (25), who specifies the appropriate quality, supply rate, and/or pressure of the required utilities (e.g. steam, cooling water, instrument air). Skid-mounted equipment can be fixed or portable, the latter permitting different types of processing to occur in the same space as necessary. Several skid-mounted unit operations can be mounted together to create "super skids," further streamlining construction, start-up and validation, and placing even more responsibility on the vendor (9). Customization of skid designs with respect to components and spare parts may be a drawback as vendors might not be willing to build skids to individual company specifications without added costs. This situation can be particularly problematic if the skid manufacturer has arranged a low cost deal with a vendor (e.g. diaphragm valves) or developed a programmed software on a PLC that may not be the vendor of choice for the rest of the facility. There also may be incompatibilities in piping, utility requirements, or software when the skid is connected (42) if miscommunications occurred between the skid vendor and the facility designer. Typically, a team, consisting of representatives from the vendor, facility owner, facility user, validator, procurement, engineering/construction management firms, and facility maintenance organization, is assembled.

The traditional alternative to skid-mounted designs is to request the facility designer to purchase the equipment

components separately and assemble the piping and equipment on site (25). One advantage to this "stick build" approach is that total flexibility in equipment selection now rests with the pilot plant designers who may be quite confident in their ability to design the equipment based on their extensive prior experience. Drawbacks of this approach include placement of the design burden on the facility as well as added design costs for one-of-a-kind systems. Specific references for fermentation equipment flow charts, detailed design, and qualification are available (43–46) as well as for filtration units (47), chromatographic equipment (33,48–50) and centrifuges (51,52). A list of typical process, utility and support equipment that might be required in a bioprocessing pilot plant has been compiled (Table 80.1).

A third alternative for pilot plants is the use of disposable, single-use equipment now available for solution preparation and storage, bioreactors, filtration, and chromatography (53,54). Several authors describe how disposables reduce fixed capital costs (often at the expense of variable operating costs), operational effort (recleaning and often sterilization are not needed which decreases turnaround time and effort) as well as space and utility requirements (2,53,55–57). Specific analysis tools for stainless versus disposable equipment selection for clinical material preparation based on manufacturing strategy have been developed (58,59). In fact, one company has designed a biopharmaceutical pilot plant based on disposable systems to maximize flexibility and speed of cell line process development and early-phase clinical material supply (60).

For any type of bioprocessing facility, certain aspects of equipment and piping specifications should be uniform throughout the installation where possible; this goal is particularly challenging for a pilot plant containing a large variety of equipment from multiple vendors. These specifications might include requirements for orbital welding of lines, documented weld inspections, passivation, pressure testing, self draining (sloped) piping, minimal lengths for dead legs and pockets, restricted use of flanged connections, level of polish on product-contact surfaces, stainless steel quality (typically 316 L for product-contact surfaces) and use of FDA-approved polymers in specific applications (gasket, o-rings, valve seats, and distribution piping) (61). Proper storage of fabricated piping awaiting installation as well as prominent identification of valves and lines also

TABLE 80.1. Types of Processing Equipment and Utilities Possibly Required for a Bioprocessing Pilot Plant

Fermentation and Harvest	Isolation	Utilities	Support
Culture storage freezer	Low pressure chromatography	Clean steam generator	Sterilizing autoclave
Incubator/shaker	High pressure chromatography	USP-purified water system	Decontamination autoclave
Biosafety cabinet	Membrane chromatrograhy	WFI system	Depyrogenation oven
Laminar flow hood	Solvent blending and delivery	Deionized water	Laminar flow hoods for cool down and equip. assembly
Seed fermenter	Viral filter	Process (city) water	Glasswasher (glassware, vial, stopper)
Production fermenter	Sterile filter	Compressed clean air	Buffer preparation tank
Nutrient feed tank	Laminar flow hood	Compressed instrument air	Media preparation tank
Harvest tank	Liquid transfer pumps	Compressed plant air	In-line mixer
Microfilter	Dispensing machines	Compressed gases (O_2, N_2, CO_2, NH_3)	In-process sample refrigerator/freezer
Ultrafilter	Chemical fume hood	Electricity	Raw material cold/frozen storage
Centrifuge	Portable tanks	Chilled water	Floor and bench scale
Depth filter	Laboratory scale centrifuge	Cooling tower water	Process and equipment monitoring/alarm system
Expanded bed absorption	Ultrafilter/ultracentrifuge	Plant steam	Uninterrupted power source (UPS)
Homogenizer	In-process refrigerator/cold room/freezer	Glycol	Off-gas analyzer (mass spectrometer)
Continuous sterilizer	Product refrigerator/freezer	HVAC and building automation system	Bar code system
Filter integrity tester	Syringe/vial filling equipment	CIP skid	
Sterile tubing welder	Lyophilizer	Biowaste inactivation system	
		Environmentally potent chemical destruction system	
		Dust collection system	

must be considered. Valve specifications can be important to determine early in the design cost estimation phase (62). Valve capital cost contribution is high due to the large numbers required and any installed valves (either diaphragm or ball) require subsequent maintenance. Consideration should be given as to whether live steam, set up as a steam block, should be used to continually purge the back side of product-contact valves and/or whether live steam should be used for tracing between double o-rings on a port or manway (43). Although such designs traditionally have increased sterility assurance for lengthy secondary metabolite fermentations, they may create detrimental localized hot spots during animal cell cultivations conducted in the same pilot plant fermenters. Neither the equipment itself nor its disposable/replaceable parts should release any extractable substances (after the initial postinstallation rinsing and cleaning steps) into the product (43). An overview of sanitary piping design, installation, and validation concerns is available (63).

Transfer piping strategy is another major design decision. One common strategy for several transfer lines is to meet at a transfer panel or process manifold, typically located at a high point between two or more areas, and be connected using spool or "jumper" pieces to move material in the desired fashion (8). Steam entry is at the high point and condensate drainage at the low point for steam-in-place (SIP) during sterile transfers. Clean-in place (CIP) solutions are passed along the direction of the previous transfer. Advantages of this approach include reduced piping distribution costs and space requirements (which can multiply fast when multiple tanks and multiple types of process transfers are required). Disadvantages center on operational restrictions concerning the elapsed time between successive transfers through a common manifold system, as well as cross contamination associated with transfers of nonsterile media/buffer, sterile media/buffer, inoculum, harvested broth, CIP solutions, and/or water through common lines. Ring headers with automated or multiport valves are one recent alternative design being introduced to avoid "jumper" connections (53). A listing of product and nonproduct transfer line/utility piping that might be required in a bioprocessing pilot plant has been compiled (Table 80.2).

Sterilization, sanitization, cleaning, and draining sequences need to be carefully defined and documented during the equipment and transfer piping specifications because retrofits postinstallation can be time consuming and expensive. P&IDs should be traced through these process sequences prior to approval by both operational and validation personnel. Requirements for validation testing and in-use monitoring of equipment operation also need to be identified during the equipment specification phase. Examples include sizing condensate lines to permit adequate drainage of condensate when spore strips are present, specification of additional validation ports for thermocouples on vessels and condensate lines, installation of product-contact utility sampling stations (especially at worst-case locations), and installation of temperature sensors on critical lines to monitor sterilization and/or proper trap operation.

TABLE 80.2. Transfer Lines and Utility Piping Possibly Required for a Bioprocessing Pilot Plant

Product Contact	Nonproduct Contact
Utilities	**Utilities**
Clean water	Chilled/cooling water and/or glycol
Clean air	Instrument/plant air
Clean steam	Plant steam
CIP solutions	Contained sewer
Other compressed gasses (CO_2, O_2, N_2, NH_3)	Chemical (noncontained) sewer
Process	Sanitary sewer
Sterilized medium or buffer	Vacuum system
Sterilized nutrient/acid/base/antifoam feeding	Natural gas
Nonsterilized medium or buffer	
Inoculum	
Harvest	

80.3.2 Utilities

Similar to any bioprocessing facility, product-contact utilities in a pilot plant might include water, clean steam, compressed air and other gases, and CIP systems. Nonproduct-contact utilities generally include chilled water, instrument air, plant steam and plant air, although for some products plant steam may be appropriate for product contact based on its quality (Table 80.3). A listing of product and nonproduct-contact utilities is compiled in Table 80.2. Multiple utility use points are located within and among suites for both product and nonproduct utilities. These are organized into utility stations for each equipment skid. To minimize piping, it might seem convenient to use product-contact utilities in nonproduct-contact applications

TABLE 80.3. Comparisons of Example Plant Steam and Clean Steam Achievable Quality

Quality Attribute	Clean Steam	Plant Steam
Bioburden	<0.1 cfu/mL	<0.1 cfu/mL
TOC	<0.5 ppm	<2.0 ppm
Endotoxin	<0.25 EU/mL	<0.5 EU/mL
pH	5–7	5–8
Conductivity	Meets USP 23 supplement 5 standards	N/A

such as compressed clean air on a vessel jacket, relying on a check valve for back flow prevention. This approach can risk disaster because the operation and quality of product-contact utilities can affect processing throughout the entire facility.

Peak utility loads should be based on carefully investigated assumptions for anticipated pilot plant processing portfolios, which are transferred from design directly to validation testing. Although it may be probable to operate several large fermenters simultaneously each at their maximum air flow rate, it may be less likely that several large fermenters will be cooled simultaneously after completion of sterilization. Thus, air compressors might be sized assuming maximum load, while process chillers might be sized based on an operationally realistic fractional load. Assumptions about processing cycle times and fermenter working volumes are important particularly when sizing CIP and liquid waste decontamination systems. Shorter (50 h) *Escherichia coli* fermentations might require a smaller tank volume (5000 L) but are run more frequently, compared with longer (400 h) animal cell or fungal fermentations, which might require a larger tank volume (20,000 L) but are run less often.

80.3.2.1 Product Contact. The most critical product-contact utility for a bioprocessing facility often is water due to the sheer volume required during typical processing steps. It is well known that the quality of water needs to be appropriate for the intended application, but higher than the necessary water quality often is designed and system capacities underestimated, particularly when actual pilot plant processing portfolios exceed the design basis. In many installations, purified water is utilized for upstream processes and early CIP steps, and WFI is reserved for cultures that are sensitive to endotoxin such as animal cells and for downstream isolation steps (64). A brief overview of various methods to produce pure water is available (65).

Water for injection (WFI) is often favored for the entire pilot plant facility for uniformity and to avoid mix-up. Specifications are set for parameters such as bioburden (typically 0.1 CFU/mL), endotoxin (typically 0.25 EU/mL), conductivity (1.3 μScm at 25°C), and total organic carbon (TOC) (<500 ppb). WFI systems containing stills are the most predominant and are generally designed as a hot 80°C loop (66). Recently, 65°C loops have been sanctioned to reduce cooling costs and to permit the use of thermostable plastics in construction (67,68). Point-of-use coolers provide water at a user-selected temperature. These coolers can form deadlegs and require substantial flushing prior to use, thus increasing waste water. It is also possible to design a cold or ambient WFI loop with periodic (typically daily) heating to 80°C or ozonization for sanitization purposes.

USP-purified water is an attractive alternative to WFI for various applications that do not require WFI. Specifications include bioburden (typically 100 CFU/mL), conductivity (1.3 μScm at 25°C), and TOC (<500 ppb) (69). Ion-exchange, distillation, and/or reverse osmosis (RO) systems are used (66). Although such systems can be operated hot or cold, success with ambient systems that are sanitized with ozone or chemically (70) has been reported. Examples of the design and validation of two ambient USP-purified water systems for pilot plant use are available (70,71).

Other noncompendial grades of water also may be utilized. In these cases, quality attributes are typically set by the facility to address the requirements of specific processing steps (Table 80.4). Examples might be deionized water with bioburden (<500 cfu/mL) and resistivity (>1 Mohm) specifications or process water (municipal water passing through a break tank) with TOC (<10 ppm) or particulate (≤ disk #1 standard) specifications. Using the lowest quality of water appropriate for the quality of the process step reduces operating costs, assuming running multiple water systems in the facility is acceptable (68).

General design elements for water systems include the desired flowrate at each use point and the expected number of simultaneous use points in operation. These values are combined to obtain the total "take-off" flow rate; the system and piping are then sized such that velocity of remaining flow rate is sufficient to minimize bioburden and biofilm growth. Suggested methods for obtaining this residual velocity have been outlined (72). Use point positioning should consider the height of the take-off valve, automation of take-off valves, sink or sewer location for flushing, as well as cleaning, sanitization, and acceptable noncoiled storage racks for associated use-point hoses. In addition, water systems should be designed with specific sanitization procedures identified at the outset. Steam, ozone, or chemical sanitization methods are most common, although steam

TABLE 80.4. Comparison of Example USP-Purified Water, Deionized Water, and Process Water Achievable Quality Attributes

Quality Attribute	USP-Purified Water	Deionized Water	Process (City) Water
Bioburden	<100 cfu/mL	<500 cfu/mL	<500 cfu/mL
Coliforms	Absent	Absent	Absent
TOC	<0.5 ppm	<2.5 ppm	<5 ppm
Endotoxin	<0.25 EU/mL (for info. only)	N/A	N/A
pH	5–7	5–8	5–8
Conductivity/resistivity	Meets USP 23 suppl. 5 standards	>1 Mohm	N/A

sanitization is generally not recommended for plastic loop systems due to concerns about distribution pipe sagging. Plastic systems utilizing PVDF instead of stainless steel are becoming more common and effective for achieving even WFI conditions. A direct comparison of plastic piping with stainless steel with respect to ion leaching, smoothness, and CFU counts has been made (73).

By using plant steam for supplying heat of vaporization, clean steam can be generated from a purified water feed. Increased heat exchanger fouling may occur if a controlled feed water supply is not utilized. Clean steam distribution piping is designed with regulators to reduce the pressure from 5 atm down to about 2–2.5 atm needed for typical SIP operations. Sanitary pressure gauges, placed near or on equipment skids, can assist in monitoring dynamic pressures during SIP cycles. Steam sampling stations generally encompass a removable sanitary trap to which a sample cooling device (typically a heat exchanger) is attached. Consequently, a source of cooling water is necessary, either piped from local lines or transported by gravity via a portable holding tank about 20 L in volume. Steam traps are placed in header branches and equipment supply lines such that when skid equipment is isolated for repair, condensate buildup does not occur. Most importantly, steam traps and pressure regulating/control valves should be selected and sized properly to remove excess condensate during SIP operation (74). Periodic cleaning of the clean steam system assists in cleaning fouled heat exchange surfaces and minimizing rouging.

Compressed air in product contact is generally used for fermentation sparger air supply, pressurized transfers, and other positive pressure requirements. Oil-free compressors are favored with intakes positioned away from other building effluents. Heating up to and holding at 200°F (93°C), typically accomplished by design of the compression ratio and residence time in a receiver, is desirable to minimize airborne biological contaminants such as bacteriophage, although there is some evidence that submicron (0.1 μ) filtration also can be effective (41). Humidity then can be reduced from the compressed air using refrigeration and/or desiccant dryers. Moisture removal is desirable down to a dew point of −40°C. Air then is microfiltered (0.2 μ) at the point of use to remove microbes/particulates. Compressed air may be sampled for any or all of the following depending on the application: identity, hydrocarbon level, microbial content, and particulates. Other gases may be required for the facility such as oxygen enrichment for microbial cells, carbon dioxide for pH control of bicarbonate-buffered animal cell media, nitrogen, and oxygen supplementation for animal/insect cells, along with appropriate gas blending and control systems. Planning should consider the storage of bottled gas cylinders or tanks outside the facility or in segregated maintenance areas to minimize the transport of unclean cylinders into controlled locations.

Clean-in-place (CIP) skids can be portable and moved into place in the suite at a designated utility location and/or one or more fixed supply skids can be located permanently in the utility area. CIP systems are composed of supply and return pumps, one or more cleaning agent dilution tanks, provisions for heating cleaning agents, and a PLC for sequence control and associated data acquisition. Specific aspects of CIP design guidelines, cleaning agents, and step sequences are documented (75). Owing to the tankage and pumps required (33), these skids often are located in utility areas where acid/caustic-based cleaning agents arriving in drums can be suitably diluted. More than one CIP skid may be necessary to provide product segregation and minimize cross contamination. Multiple skid requirements depend on design decisions concerning the level of containment and product segregation (8), as well as capacity.

80.3.2.2 Nonproduct Contact. The type of vessel jacket cooling/heating system selected, although not in product contact, has widespread design implications, and ultimately may limit pilot plant fermenter versatility. Recirculating temperature control loops, containing high surface area/unit volume heating and cooling heat exchangers, an expansion tank, and a circulation pump, are common. These systems rely on indirect heating/cooling of jacket fluid so that their response can be slow, particularly if heat exchangers were not sized according to user expectations. The involvement of heat exchangers suggests that practical application may be limited to vessels of few thousand liters in size. Jacket fluids can be water, glycol, or novel fluids with wide temperature ranges. Reliable operation of the circulation pump and internal (as well as external) integrity of the heat exchangers are also critical. Cooling heat exchangers can use either chilled water and/or glycol, while heating heat exchangers generally use plant steam. Dual parallel filter housings, containing 10–50 μm elements, are advantageous to reduce cooling heat exchanger fouling. Sediment buildup on filters can be monitored using measured pressure differentials across the filters, and the assembly can be designed so that one filter set may be replaced while maintaining flow to the second filter set.

Direct application of heating or cooling fluids to process jackets is the traditional alternative. Consecutive application of chilled water and steam on the jacket is acceptable if the design evacuates the jacket using higher pressure compressed air such that banging is minimized. Regardless of the indirect/direct mode of heating/cooling fluid application, jacket design can greatly affect the effectiveness of heat transfer. Dimple or straight jackets are preferred for smaller vessels, and external half-pipe cooling coils are used in larger vessels. The largest manufacturing scale vessels utilize internal cooling coils, but these coils present

additional internals for cleaning and increased sterility risks, particularly at welds, because cooling water can be at a higher pressure than the fermenter contents.

Filtered dried instrument air, typically at a pressure near 100 psi, is required for solenoids valves on bioprocessing skids. Pressure specifications for control valve operation considerably vary among vendors and inversely affect valve actuator size. Plastic hosing, although convenient and cost effective, should be carefully evaluated for instrument air lines, especially on hot equipment where heat-induced leaks can develop and in solenoid cabinets where crimping can slice the tubing. A back-up instrument air compressor and expansion tank can minimize operational consequences from supply pressure dips. A separate compressed air source, at a higher pressure than chilled/cooling water and jacket steam, is desirable for the evacuation of vessel jackets to minimize risk of backflow into the instrument air system.

Natural gas usage, if required, might be best addressed using bottled gas for safety reasons, which discourage distribution piping throughout the facility. Favored for flaming of openings in many microbiological procedures, the use of Bunsen burners or propane torches in a biosafety cabinet or laminar flow hood should be examined with company safety department representatives. Care should be taken to minimize the potential for reaching the lower explosive limit near the motor of the cabinet or hood. Compatibility of plastic laboratoryware with flames also should be insured.

80.3.2.3 HVAC. HVAC is the key and costly component of a pilot plant facility owing to its multiproduct nature. Its design and operation needs to be understood by operating, maintenance, and quality personnel. Requirements for air cleanliness, as well as the ability to achieve them, are determined by HEPA filtration, airflow volume, pressurization room design as well as the type of operation being conducted (Table 80.5) (8). HEPA filters are oftrn used for inlet air but only used for exit air when required by biosafety containment.

The specific classification of processing areas depends on processing step quality requirements as they are related to equipment design. Where possible, support equipment (or portions of thereof) is located in cheaper gray utility space, reducing disruptions for alterations needed as pilot plant processes change. Gray space does not require classification and thus has reduced gowning, cleaning, and monitoring requirements, as well as lowered HVAC construction and operating costs (53,56). As closed system operation in processing spaces increases, trends toward smaller classified core areas enveloped in nonclassified space are emerging (9,53,76). The use of contained sampling devices that permit sampling by maintaining a closed system also helps in supporting this trend.

Classification level, representing the maximum number of particles permitted per cubic foot of air sampled, of an area increases from fermentation (class 10,000–100,000; 20–40 room changes per hour) to purification (class 1000–10,000; up to 100 room changes per hour) (8). Within a room, there are cleaner areas surrounding open transfers (e.g. biosafety cabinets or laminar flow hoods) which are class 100 (540 changes per hour) (77). For viable particles, the range is from class 100,000 which permits 2.5 cfu/ft^3 down to class 100 which permits 0.1 cfu/ft^3 with intervening levels that are generally determined by the individual processing application being conducted (77). Sufficient air velocities also are necessary to dilute particulate contaminants. In some cases, separate air handlers are considered for critical sterile areas, inoculum preparation areas, high particle or dust areas, and segregated product areas. In most other instances, air flow is designed in a once-through pathway which may substantially increase heating and cooling utility costs.

Inlet air enters from the top of the room, flows downward, and exits from ducts near the floor. Any recirculation, which may be desirable to minimize the capital costs for heating and cooling equipment as well as operational costs, should be only from the room where the air originated, limited to areas that do not generate substantial amounts of particles, and pass through inlet HEPA filters again. This strategy is beneficial to the life span of the HEPA filters and the ease of maintaining constant temperature and humidity (8). Exit ducts should be placed near equipment within a

TABLE 80.5. Comparisons of Example Controlled and Noncontrolled Area Achievable quality Based On Room Design in a Pilot Plant Facility

Type of Area	Pressurization	Airflow Changes (#/h)	Inlet Filtration	Nonviable (#/ft^3)	Viable (cfu/ft^3)
Bulk fermentation processing	None	5–7	Coarse	<250,000	<25
Laboratory	Positive	60	Coarse	<100,000	<2.5
Laboratory	Positive	10	HEPA	<100,000	<2.5
Laboratory-clean construction	Positive	25	HEPA	<100,000	<2.5
Laboratory-clean construction	Positive	20	HEPA	<10,000	<0.5
Laboratory-contains autoclave	Positive	100	HEPA	<100,000	<2.5
Laboratory-contains glasswasher	Negative	50	HEPA	<100,000	<2.5

processing area, which generates the most particulates or aerosols so as not to spread them throughout the area. Specific examples include autoclaves, glass washers, and cell disrupting homogenizers.

Room pressurizations should be higher for cleaner areas and lower for areas that generate particles (8). Higher pressurization levels should be assigned to airlocks between adjacent areas for which it is desired to minimize cross contamination. Relative pressurizations between rooms sharing a common wall should be considered to supplement and/or minimize reliance on completely sealing rooms during their construction. The use of door sweeps and gasketted ceiling tiles to achieve and maintain pressurization should be evaluated relative to floor cleanability and ceiling maintenance access, respectively. Pressure differentials might be as high as 0.03 inches water between classified areas and as high as 0.05 in. water between classified and nonclassified areas. Lower pressure differentials might be acceptable depending on the specific product as long as the direction of airflow remains consistent. Interlocks, control, monitoring, and alarm building automation systems may be designed to reduce pressure losses when doors are opened and to alert users to unsatisfactory conditions. When desired pressurization has been lost, affected areas are recleaned and in-process materials are evaluated for quality impact, delaying schedules, and increasing manpower.

Facility temperature is generally maintained on the cool side because gowning requirements tend to make workers warm. Inaccurate assumptions concerning the impact of radiant heating from windows may cause higher than desired temperatures on certain days of operation. Humidity should be comfortable to avoid drying of workers' respiratory membranes during extended processing hours. Care should be taken to specify tolerance limits that have quality implications appropriate for the processing steps expected to be conducted in the area to avoid unnecessary additional facility costs. Although specific example guidelines are 23 $\pm$ 3°C and 40–60% relative humidity (78), substantially larger ranges may be acceptable for many processing applications. An extensive P&ID of HVAC design for clean spaces is available as a published Ref. 77. In addition, consideration should be given to Federal Standard 209E, Airborne Particulate Cleanliness Classes in Clean Rooms and Clean Zones, as well as EC regulations which establish parallel categories of Grade D (100,000), Grade C (10,000), and Grades A+B (different designs of class 100) (77,79).

80.3.3 Containment

Similar issues exist for product, environmental, and personnel protection, and these issues are heightened due to constantly changing pilot plant processes. Often the resulting design specifications overlap with those items necessary for sterile or sanitary operation. This concept is addressed in the literature (80), which compares solutions to prevent microbial transport to attain containment with those to maintain sterility for fermenters. A unified approach is recommended to minimize unnecessarily stringent specifications, which can substantially augment capital and operating costs. Environmental and personnel protection issues are evaluated for each new pilot plant process undertaken by the facility, along with product protection quality concerns. Samples of broth, and other product, intermediate, and waste streams, are submitted for aquatic (and sometimes human) toxicity testing in advance of processing in the pilot plant when appropriate. Preliminary test data might be then available to evaluate potential hazards in conjunction with published documentation concerning the similarity of the questionable compounds, raw materials, or organism to known hazards.

80.3.3.1 Product Protection. The major concept surrounding product protection is the closed system in which all material entering or leaving the process must be controlled in a specified and documented manner. This requirement extends to product-contact utilities such as purified water, clean steam, compressed air, and controlled/monitored room air so that when equipment is opened for cleaning the quality of surrounding environment is consistently at a known and documented level. The equipment is then cleaned to an acceptable quality level. Several elements are typically included as part of closed system operation. After sterilization, material enters the closed system via a sterilizing filter, steamed connection to an autoclaved bottle assembly, and/or sterilized transfer line. Off-gas passes through a 0.2 μ steam-sterilized vent filter, often contained in a low pressure, steam-jacketed housing preceded by a coalescing filter, condenser, and/or vent heater to avoid pluggage from moisture. Double mechanical seals are utilized with a barrier fluid of a controlled quality (typically condensed clean steam) at a higher pressure than the vessel. A closed system also can be used to surround an open operation such as the use of isolator technology (i.e. glove box) as an alternative to clean rooms or biosafety cabinets (81,82).

80.3.3.2 Environmental Protection. Environmental protection concerns focus on emissions from air, liquid, and solid waste. Typically, state air permits are required for new vessels and need to be altered if additional air treatment devices such as vent filters, incinerators, or scrubbers are added to existing vessels. Hydrophobic vent filters can provide emergency foam control and prevent external product or organism release. These filters can be monitored for pluggage over cultivation time using pressure differentials with plugged filters replaceable during a run only if a bypass line exists. Liquid emissions include accidental spills/sewerings, which can be minimized by locking vessel

bottom valves, blocking open sewer connections, collecting sample line flush waste, and providing clear written instructions to personnel regarding batch disposition. Dikes, troughs, and vaults can be used to contain large spills or divert inadvertently sewered material. Sample waste can be minimized using low volume sampling devices. Thermal or chemical (less common) batch or continuous kill tanks need to be considered for biological hazards. For chemical hazards, other appropriate waste destruction and minimization systems may include hot caustic hydrolysis, reverse osmosis, and evaporative condensers. Batch leakage into cooling water utility systems can be minimized by operating utility systems at a pressure higher than the batch, but this differential might introduce contamination if jacket cooling coils develop leaks. Alternatively, the utility system return headers can be isolated from general use until their contents are treated and/or tested. This solution might be attractive for cooling water as well as condensate, especially when it is returned to river sources. Care must be taken to avoid sequestering large quantities of potential waste for long periods of time. Solid waste can be controlled procedurally using clearly labeled containers.

80.3.3.3 Personnel Protection. Personnel protection requirements are reduced now that several recombinant organisms can be grown under typical operating conditions of GLSP. For other pilot plant processes requiring personnel protection, either the culture is rated at or above BL1-LS or a compound produced by the culture adversely affects human heath (e.g. a genotoxin, mutagen, teratogen, or carcinogen). Environmental monitoring of the operating area is necessary for the compound or culture of interest using air and/or swab sampling techniques. For optimal recovery, swabs should be soaked in a solvent that is known to dissolve the compound of interest. Screening and monitoring of personnel potentially in contact with the process (operator, mechanics, janitors, engineers, visitors) must be arranged and notification must be given to those personnel at unacceptable levels of risk. A key element of personnel protection is personal protective equipment (PPE). This equipment can include gowns, uniforms, safety glasses, lab coats, and gloves at a minimum, but can be extended to include face shields, goggles, and respirators as required. Spill response equipment, procedures, and training are also necessary.

Reduction to practice techniques are presented in the literature for general biocontainment issues (83) as well as biocontainment regulations and requirements (84,85). Specific examples are available for the design of waste inactivation systems (86,87), contained facility design and operation (88,89), design details for cleanliness and containment for floors, walls, ceilings and penetrations (90), and contained sampling systems (91).

80.3.4 Instrumentation

The main purpose of a pilot plant is to collect data as comprehensively as possible. Thus, a large fraction of the pilot plant capital allocation might be devoted to instrumentation. Use of in-process measurements and controls to improve product quality is a key foundation of the FDA's recent process analytical technology (PAT) initiative (92). Traditional instruments for on-line monitoring, particularly for fermentation, include pH (93), dissolved oxygen (DO) (94–96), temperature, agitator speed, agitator power draw, back pressure, foam detection, batch level or weight, air flow rate, and vent gas analysis via mass spectrometry (97). Redundant instrumentation is desirable for critical parameters such as pH and DO. Instrumentation for isolation processes includes the monitoring of conductivity, pH, ultraviolet wavelength intensity, and refractive index. Useful utility instrumentation includes on-line TOC analysis and resistivity/conductivity meters. Local readouts of transmitter values can be particularly useful for pressure and possibly temperature, although the potential for differences between field and control room values may have to be addressed.

Many novel sensors have been developed including dissolved carbon dioxide probes (93,98), redox sensors (93), glucose sensors (99), near infrared detectors (100,101), fiber optic biosensors (102), fluorometry of intracellular NADPH (103) and cell density probes (104–106). Another novel measurement device example incorporates fermenter side streams to measure viscosity on line (106). A description of useful sensors may be found in the literature (92,107). Characteristics of on-line and *in-situ* devices include cleanability, minimal drift, minimal interferences, versatility, sterilizability, and ease of calibration. Implementation of any sensor should be evaluated for its effect on bioreactor sterility as well as product quality.

80.3.5 Automation and Control

Automation and control can reduce manual work and operator errors, as well as raise operational consistency (9). The need for flexibility and change within a pilot plant (as compared with production) needs to be apparent in control schemes, event sequencing, data collection and presentation, and alarming (108). Increased amounts of automation restrict the abilities of the end user to implement changes, but do reduce the number of manual operations and thus possibly headcount. Specifically, the control system should readily permit set-point and alarm changes. Control systems can be distributed or centralized with distributed control systems (DCS) favored because there are individual controllers/computers for each unit connected via a high speed network. Thus, the loss of one centralized computer is not catastrophic (108).

Although there can be "islands of automation" within a pilot plant owing to automated skids purchased from different manufacturers, connectivity in a centralized location for data monitoring, set point/alarm changes, and data archiving typically is desirable. Substantial advantages exist for localized controls on skids when there are large numbers of inputs required based on an operator's evaluation of field conditions. A local readout of data versus a centralized "control room style" monitoring area (or even both) is dependent on the expected degree of operator supervision versus intervention required during processing. This decision is directly related to the flexibility of operators to move in and out of the field in terms of gowning procedures and access restrictions. The ability to remotely input set point and/or alarm changes can be useful when containment and/or product protection levels are high. Multiple areas for setting parameter values should be carefully considered from an operational control viewpoint to avoid duplication of desired changes and to batch record log omissions. Verbal communications between the field and control room using hand-held radios, intercoms, or phones also can minimize unnecessary movement within the facility.

Distributed control systems are favored for process management in some pilot plants. System architecture requirements vary depending on the processing requirements, but examples for a non-PC-based system are present in the literature (109). Distributed control systems also can be PC-based using commercial PC control/data acquisition software (110). In either case, some type of process-level controller is required such as a PLC (programmable logic controller), LC (loop controller), or PCBC (personal computer-based controller) (47). The ability for the noncomputer expert to easily modify and understand control sequences using newly developed, commercial control software is attractive but requires effective change control and documentation procedures. The ability to readily configure the data acquisition system to download and archive data is an important consideration for process performance evaluation.

There are several types of computer inputs/outputs (108) which include: (i) digital inputs in the form of an on/off signal used for foam probe, pressure, flow, and/or temperature switches, (ii) digital outputs in the form of an on/off signal used for the flow of antifoam, open/close valves, and/or pump/motor start/stops, (iii) analog inputs in the form of an amplified output in the range of 4–20 ma used for temperature, pressure, pH, dissolved oxygen, flow, and power draw, and (iv) analog outputs in the form of a proportional signal which controls the valve opening via an I/P conversion (typically used for back pressure, cooling, and/or airflow valves) or else signals such as motor speed.

The most frequently utilized type of control is the PID (proportional integral differential) control loop. It is tuned using three parameters to minimize oscillations, which can change depending on the specific process (e.g. for dissolved oxygen cascade control of a fermenter cultivating faster growing *E. coli* versus slower growing animal cells) or over the course of the same process (e.g., for glucose and ethanol consumption phases of a Bakers' yeast fermentation (111)). These three parameters are the (i) size of the error relative to proportional band with smaller bands resulting in more sensitive systems, (ii) integral of the error over time with longer error durations resulting in greater corrections, and (iii) rate of error change with time with larger increases in correction with time calculated the faster the error is growing with time (107). Typically, the third parameter is at a minimal value near zero for the optimally tuned loop.

A conscious decision needs to be made concerning the level of automation for CIP, SIP, and vessel-to-vessel transfers desired for a pilot plant. Higher levels of automation may insure reproducibility of operation, reduce reliance on operational staff, and simplify SOPs. However, raising the level of automation increases capital, validation, and maintenance costs, while reducing flexibility to quickly adapt to changing pilot plant processes. Familiarity with the details of automated versus manual equipment operational sequences may be lower among operating personnel routinely observing automated processing steps. A domino effect may exist in that automation of one valve may lead to the automation of several related valves, severely increasing design complexity and cost. Limit switches are often installed which confirm to the control system that the desired automatic valve has opened or shut as requested. Automatic pulsed diaphragm valves have been successful for nutrient feeding as well as for sterilization of transfer lines in automatic plants (112). A prominent example of a highly automated but apparently reliable fermentation facility is operated for the manufacture of cephamycins as well as for pilot use (113). Typical diagrams for the monitoring and control of a fermenter (33,108) and for the monitoring and control of an ultrafiltration unit (47) have been published.

80.3.6 Data Acquisition and Archiving

The collection and management of data obtained during pilot plant operations (as well as laboratory experiments) is a critical facet of knowledge management for the speeding implementation of cost-effective manufacturing processes (114). Capture, storage, and retrieval of critical product/process knowledge, including pilot scale process development and scale-up data, also is a key challenge to implementing quality by design strategies (115). The data collection interval is dependent upon the nature of the processing step. For fermentations, intervals might be in every 15–20 min during secondary metabolite or animal cell cultivations but might shrink to 5–10 min for faster growing bacterial or yeast cultures, especially when a key

process addition or change is planned based on off-gas or dissolved oxygen measurements. Typically, 5–10 min intervals are appropriate for microfiltration or centrifugation operations and continuously for chromatography systems especially during loading and elution. Smaller data collection intervals may create substantial data archiving demands, which may be alleviated by only saving those data substantially different from previous values based on some user-defined value.

In-process trending of data is attractive to permit the timely evaluation of process status and trouble shooting of processing problems, which are the two factors critical to continuous improvement efforts. Specifically, multivariate analyses can be performed for critical variables and results can be used to adjust the process (116). Automatic recording of alarms and changes to the control system, preferably sorted according to the equipment and/or batch for which they occurred, also can help to trace back processing problems and actions taken. On-line data might be archived on a common server by some unique batch delimiter, according to the established facility SOP for archiving data. Two formidable challenges are to capture off-line data electronically (without manual re-entry) and then incorporate it within the same or a closely related reference database, which is preferably located in a central repository. Otherwise, this off-line data can get fragmented among the notebooks and files of individual researchers. Novel customized systems for bar-coding samples taken from the field and creating a database for results can be helpful, permitting possible use of robotic systems for sample analysis. Remote access is an attractive option for monitoring process performance from off-site locations. Remote alarming can be triggered to a satellite pager thus removing the necessity for round-the-clock on-site coverage. Remote control of operations can be administratively challenging to regulate and document as well as a potential safety issue. Security issues must always be considered for any established remote capability.

80.3.7 Warehousing

Warehousing requirements for the facility need to be determined based on expected pilot plant production capacity and desired batch lead times. Common items that might be stored include ambient, cold and/or frozen solid/liquid hazardous and nonhazardous raw materials (controlled temperature and/or relative humidity storage), disposables, equipment, spare parts, as well as sample and product storage. Computerized inventory systems, organized by process or equipment, can be useful for most of these items with reminders to reorder when supplies decline to a critical level or discard when items expire. Marker equipment also might be purchased for long lead replacement parts for which redundancy was not desired during the original facility design. Sizing of these storage areas should match typical lot volumes of prepared culture media and solids to minimize repetitive release testing for multiple lots. For a pilot plant, in which several diverse processes may be run, additional process-specific storage often is required. The relative amount of storage necessary within or near the building should be compared with other available on-site and off-site options. Vendor manufacturing schedules often require the purchasing of larger quantities of rare raw materials to avoid future shortages. In this instance, if on-site storage is not available, vendor storage, or a third party warehouse alternative may be required. Warehouse access may need to be restricted depending upon the nature of its contents. Within the warehouse, there should be segregation for released, unreleased, and quarantined materials either by physical separation or by designated labels.

Although the entire facility should have a comprehensive pest monitoring program (as well as an SOP), there may be a need to directly address pest control, particularly for flours and meals used in certain secondary metabolite fermentations. These food ingredients when purchased for pilot scale fermentation purposes may not pass through fumigation unless specifically requested on the purchase order. Typically, larger customers in the food industry have invested capital for on-site fumigators, but commercial nutrient vendors may not have this type of equipment due to their high rate of inventory turnover.

Staging areas should be available for collecting raw materials and supplies in advance of a specific batch. Some method of inventory assessment and control should be available; one convenient method is to use computerized bar coding to check inventory as well as to confirm the use of specified materials when charging occurs. In addition, controlled sampling areas (to provide raw material, environmental, and/or personnel protection) for the sampling of raw materials may be necessary.

80.3.8 Back-up Systems/Redundancy

A critical design decision centers on the level of backup and/or redundancy required in the pilot plant. Equipment sharing to reduce services for less critical tasks can be cost effective to increase the amount of backup available for critical tasks (117). Although typically none of the material created in the pilot plant is "for sale," mechanical problems can delay processing and thus material production, which may interrupt clinical supplies and compromise the success of ongoing studies. Even if no clinical material is at risk, process development efforts are hampered when experiments are frequently interrupted for mechanical support-type equipment failures (10). Scenarios that might be protected against include loss of clean steam lubrication to agitator seals, positive air pressure on a sterile tank, and electrical power to a controller. Corresponding equipment

needs might include redundant clean air compressors, clean steam generators, and/or purified/WFI water generation systems with the peak plant capacity requirements split between two systems rather than relying on a single system sized for peak usage. Such redundancy usually is achievable because utility costs are low compared to equipment costs (10). A UPS system sized to include the most critical equipment (typically controllers and data acquisition devices) might also be installed. Back-up power for large electrical loads such as motors might not be economical; however, consideration might be given to installing connections for a gas-powered generator if future evaluations altered the economic assessment.

80.3.9 Future Expansion/Modification

As future processing needs may change, the pilot plant must adapt to maintain its usefulness to the company. Large initially underutilized spaces might be outfitted with utility headers to minimize processing disruption during future installation. Oversizing of utilities for anticipated future loads (10), as well as unforeseen procedural modifications warranted based on future validation testing results (such as additional rinsing cycles), assures subsequent flexibility. Selection of portable equipment permits exchanges for new pilot plant processes, provided there are procedures developed for storage, cleaning, and start-up of this equipment.

Modular design and central spine approaches facilitate expansion and adaptability with minimal impact on existing operations when new components are added (9,117). One aggressive approach to increase versatility is a modular, mobile, validated pilot plant (118), comprised of a system of interconnected and integrated modules. Modules are selected according to processing needs and can be rapidly assembled to form a processing plant capable of undergoing validation. Example processing modules include fermentation, recovery, and purification; the utility module includes clean water and clean steam; the personnel support module includes lockers and changing areas; and the HVAC module houses the air handling and filtration equipment. Additional modules can be then added or deleted as required.

80.4 OPERATION

Each pilot plant facility must decide for itself whether it is required to operate in a continuous mode of GMP compliance or whether it can selectively apply GMP practices to certain batches (but not to other concurrently run batches) or during certain specific processing periods. A conservative solution might be to operate continually in GMP compliance, thus insuring facility readiness and preventing the omission of a required procedure for an actual batch destined for the clinic. Dual GMP and nonGMP operation serves to create two standards and may cause confusion among operating and maintenance staff. If dual operating modes are implemented, then a clear distinction between GMP and nonGMP operation must be established, documented, and maintained.

80.4.1 Maintenance

80.4.1.1 Preventative. Preventive maintenance, performed during an annual facility shutdown, is probably the most important factor influencing smooth pilot plant operation throughout the upcoming year. The scheduling of an annual facility shutdown is desirable for several reasons including the ease of lock out of hazardous energy sources, the time economies of concentrating several maintenance workers in a single area, and the ability to supervise and document completion of a large fraction of maintenance work at one time. This yearly PM documentation can then serve as the model for maintenance personnel for the following year's shutdown. Individual PM work orders, spread over the course of a year, result in substantial time and effort expended in scheduling, preparing, and documenting the work done. Interspersing of annual PM work among batch processing inevitably results in PM delays due to equipment and/or manpower unavailability. Guidelines for planning and executing an annual plant shutdown are available (119).

All PM work orders can be categorized and then listed according to trade, equipment, material, or time requirements. They can be reviewed prior to the facility shutdown and augmented with any modifications or "one-time" replacement work orders that are requested. As PM work is completed, documentation should be signed by the tradesperson as applicable and reviewed by mechanical and operational staff for completeness. Problems that are identified with equipment or instrumentation should be highlighted as they occur and then entered into change control work order systems so that they can be tracked for their effect on validation.

Before the annual shutdown, transfer line manifolds and/or utility supply lines, that typically cannot be shutdown entirely for maintenance throughout the year, might be leak tested to identify faulty valves in need of replacement. After the annual shutdown, equipment start-up procedures should be documented, preferably through the use of equipment start-up batch sheets. These procedures might include equipment cleaning, testing of instrument calibrations such as level, temperature, and pressure (120) and vessel integrity testing for leaky valves. Instrument calibration accuracy should be evaluated for random or systematic errors with random error within accepted tolerances being the expected outcome.

Some general PM procedures can be applied to several areas in a pilot plant, both product and nonproduct contact.

Sanitary fittings, which tend to loosen during repeated heating and cooling cycles, should be checked, gaskets replaced, and clamps tightened as required. Any flanges in product contact should be tightened to a specified torque. PM inspections of vessel internals should be conducted and lock washers installed on external nuts that may loosen due to repeated heating and cooling. A PM should be developed for the inspection of vessel cooling coils for leaks, which can result in inadvertent cooling water contact with product (121). For agitated systems, there should be a regular examination of foot bearings, motor/drive vibration, oil analysis, and shaft runout. Double mechanical seals, the failure of which can lead to condensate buildup and/or batch contamination, should be tested regularly and replaced preventatively based on a minimum life expectancy (122). An outline of specific PM procedures for laboratory fermenters can be applied to larger scale fermenters (123). An example of the documentation for the maintenance of horizontal laminar flow hoods is also available (124) which can be readily adapted to other HEPA filter units. PMs should be conducted on all utility systems and may include the rebuild of air compressor heads, descaling of heat exchange surfaces, and replacing of air dryer desiccant, among other items recommended by the equipment manufacturer. Finally, novel predictive maintenance evaluation techniques should be explored and implemented as appropriate to identify imminent equipment failures (125).

It is most appropriate to perform any annual validation work (e.g. fermenter SIP, autoclave load pattern, controlled temperature unit) at the conclusion of the annual PM shutdown. In this manner, proper equipment operation can be documented and the effectiveness of PM procedures can be evaluated. Often inadvertent mistakes or omissions during maintenance can be identified prior to having an adverse, and possibly widespread, quality impact on pilot plant batches destined for clinical trials.

80.4.1.2 Ongoing. A reliable system of tracking outstanding maintenance by equipment or by process should be designed and implemented, particularly for a pilot plant in which equipment is used less regularly. Each piece of equipment has a clearly distinguished tag name. Work orders are initiated, evaluated for their effect on validation, marked as complete when mechanical work done, then finalized when process personnel have checked the job. A computerized database can readily track maintenance and identify repetitive maintenance problems. Such a system permits easy review of outstanding work orders for each piece of equipment prior to getting it ready for service. All maintenance work orders need to be tracked within one system; care should be taken not to bypass the operations area when maintenance needs are identified by those directly controlling the mechanical staff.

Interim maintenance work, such as calibrations and subannual preventative maintenance (PM) activities, should be documented and filed in a manner equivalent to the yearly PM results. PM schedules should be reviewed based on the frequency and results of interim maintenance work. Unusually common equipment failures can be identified through maintenance database searches and appropriate longer term repair efforts or replacement justified and undertaken.

80.4.1.3 Calibrations. Calibrations of pilot plant equipment have additional concerns associated with them because important processing decisions for early scale-up batches may be based on the accuracy of the instrument readings. In some cases, specific instruments are designated as "critical" for a processing step; in other cases, desired specification ranges for the processing step are targeted based on certain noncritical instruments. These two methods provide assurance that product quality is not compromised if any of the other instruments that are present in the equipment utilized fail.

Although some facilities distinguish between calibration procedures for "critical" and "noncritical" instrumentation, it may be prudent for a pilot plant to calibrate all instruments in a reliable and documented manner because their accuracy ensures useful process development data. Calibrations should be performed using NIST traceable instruments and include full loop calibration to the process monitor as appropriate. A specific calibration and maintenance SOP for the instrument is most desirable but a general SOP referencing vendor manuals might also be acceptable, particularly in the interim period while instrument calibration SOPs are being developed. The "as found" (or "before") and "as left" conditions should be documented along with the serial number of the standard used (126). Establishment of an acceptable tolerance for each instrument insures consistency. When an instrument is found outside the tolerance specified, the impact of this calibration "as found" error on previously executed batches may need to be evaluated. Thus, a confirmation of the error might be warranted prior to correcting the calibration. Records should be evaluated for the amount of instrument drift, which may indicate the need to either recalibrate on a more frequent basis or else replace/upgrade aging equipment. An example calibration sheet is available (127).

80.4.1.4 Modifications/Change Control. Any validated facility needs to devise procedures for tracking changes on equipment as well as on processes and computers. This requirement is heightened for a pilot plant because a large number of changes are expected owing to its rapidly changing portfolio and processes. Incomplete documentation of changes can obviate extensive time and money spent on validation testing. Although the exact contents may change, such a procedure starts during the

initial design phase as equipment specifications are altered, continues through the facility start-up and qualification phases, and then moves directly into the facility operational phase. Adherence to change control procedures may be difficult during facility start-up as many unexpected items are found to be incorrect and management pressure may mount to have the facility operational quickly. Depending upon the philosophy of the individual facility, the scope of this change control procedure may include product and nonproduct equipment to varying degrees. The procedure identifies the individuals who need to approve changes and determine prior to or in concert with the change implementation what additional validation testing is required. Often, processing personnel, being most familiar with the equipment being modified and the reason for its modification, can provide valuable leadership in this area and initiate contact with quality and validation personnel as required for input.

Generally, replacements of this kind are accepted without additional testing unless the item being replaced was specifically tested or calibrated during the initial validation effort. Example items and associated testing might include a replacement or rebuilt motor or associated drive (measure motor amperage draw at various agitator speed settings) or replacement instrumentation (calibrate sensor and transmitter). Replacement items in this category need to be tagged appropriately in the field with the same tag number as the original item and serial numbers updated in any centralized maintenance data bank as well as recorded on installation documentation.

Modifications or obvious changes in equipment or instrumentation need to be evaluated for their potential impact on the validated state of the equipment. This impact is particularly important for SIP and CIP cycles. Such modifications may be minor, such as a change in gasket or o-ring material of construction, or major, such as a change in piping. An example procedure is available which can insure proposed changes are reviewed by operations, maintenance, and quality for their potential impact (128). Specific attention should be given to alterations needed in P&IDs, SOPs, PMs, batch sheets, and/or training programs. Equipment modifications, necessary to accommodate a new process, need to be identified early on and their impact also should be evaluated (4). It is critical to balance the request for change with an evaluation of its validation impact. Changes cannot be discouraged in a multipurpose pilot plant, but they need to be controlled and managed in a logical yet expedient manner.

80.4.2 Staffing

Personnel requirements are best defined based on the production process (129) but in a pilot plant setting, production processes change rapidly and substantially (130). Both short- and long-term planning tools and models are necessary to plan manpower for the preparation, execution, and finalization of various campaign efforts (130). A decision needs to be made early in the design process concerning the level of off-shift activity that is reasonably expected in the facility as it can severely impact items such as utility capacity and operation. Round-the-clock coverage, although demanding for personnel involved, may be necessary almost throughout the process to insure success and timeliness of production. The use of unionized personnel, technicians, or process development staff should be incorporated into the educational requirements and manual workload expectations for the operating staff to ensure appropriate job fits and reduce potential drivers for turnover. A core operations group, responsible for the facility, can insure continuity in areas such as SOP updates, maintenance work order tracking, batch sheet content, and equipment operation. Such a group might be supervised by an area manager, responsible for coordination and scheduling, who might interface with those directly involved in process development. Then, the processing groups might rotate through the pilot plant as their projects demanded are accompanied by a member of the operations group. Alternatively, a dedicated pilot production process development staff might be instituted, responsible for the translation of laboratory processes into GMP batches.

80.4.3 Laboratory Support

To provide adequate and accurate sample analyses, laboratory support needs to be identified and addressed through either on-site or contract laboratories. Targets for testing might include final product, in-process samples, raw materials, sterility, culture purity, environmental quality of controlled environments, and utility quality (Table 80.6). Although the goal of these laboratories may be to work toward using validated methods and approved SOPs for all assays, this goal might not be attainable for project-specific assays until the later stages of a successful development project. Initially, in the early project stages, only notebook procedures might be available to guide laboratory testing. Information directly impacting quality should be communicated directly to both quality and operating personnel and appropriate investigations conducted both in the field and laboratory for failing or out-of-specification (OOS) results.

A microbiological laboratory is critical for fermentation-based operations to prepare seed cultures and test new culture seed vials for culture purity and productivity in lab-scale processes. An examination of up-to-date sterility/culture purity results prior to vessel-to-vessel transfers should be undertaken as close to possible to the time of transfer to minimize the adverse impacts of contaminated cultures. In a pilot plant setting, tension may exist between

TABLE 80.6. Types of Testing (Sampling and Analysis) Possibly Required by On-Site or Off-Site Support Laboratories for a Bioprocessing Pilot Plant

Facility Monitoring	Sterilization Cycle Validation	Cleaning Cycle Validation	Process Monitoring
Total organic carbon (TOC)	Indicator spore strip incubation	Total organic carbon (TOC) (swab and rinsewater)	Spectrophotometer
pH	Indicator water spore suspension incubation	pH	pH meter
Conductivity	Indicator media spore suspension incubation	Conductivity	HPLC for organic acids, amino acids, sugars
Endotoxin (LAL)	Sterility	Endotoxin (LAL)	HPLC for product/impurity analysis
Bioburden and coliforms	Bacterial and fungal culture purity-	Bioburden (swab and rinsewater)	LC-mass spec
Airborne viable particles	Filter integrity testing	Ultraviolet light absorbance	Protein gel analysis
Airborne total particles	Microbial identification	Visible light absorbance	Osmometer
Surface viable particles	Gram stains	Filtered solids	Microscope
Compressed gas viable particles		Dissolved solids	Cell counter/viability monitor
Compressed gas nonviable particles			Conductivity
Compressed gas identity			Metabolite analyzer
Noncondensable gases in steam condensate			Plate readers
			Blood gas analyzer
			Laboratory scale-down control/trouble-shooting experiments

the time required to adequately test new cultures and development pressure to use the latest mutant or transformant in a pilot scale cultivation to evaluate its capabilities. Reasonable procedures need to be established in advance for the introduction of new processes and/or new cultures into the pilot plant. Laboratory prepared nutrients, trace ingredients, and/or sterilized additions should be evaluated for their quality impact and the procedures used for their preparation should be documented where possible.

80.4.4 Standard Operating Procedures (SOPs)

SOPs are essential for the planning and standardization of various procedures conducted by operational staff and maintenance personnel that need to be completed before, during, and after pilot plant batches (4). Typical categories include SOPs for equipment operation, facility and equipment cleaning, sampling, sterilization/sanitization, maintenance, and documentation procedures for tasks such as product changeover, change control, and batch sheets (Table 80.7). When referencing SOPs as part of the batch record, working versions of SOPs can be helpful to track progress and ensure accuracy of step execution in the field. An SOP on the requirements for writing, issuing, and inactivating an SOP also is useful. SOPs focus operation, guide operations staff, document the order and scope of activities, standardize approaches, define regulatory needs and constraints, and increase the speed of new personnel training (4). They should be written by a person familiar with the facility or equipment operation that is the subject of the SOP, reviewed by another person who might be asked to follow the SOP, and approved by a quality group. Each SOP should have an effective date of issue, be available to those who need it, and be archived when a future revision is created.

The need for structure and consistency within an SOP must be balanced by the need for flexibility in a pilot plant when unexpected process requirements arise. Procedures must be defined for what to do when an SOP is altered intentionally to accommodate a new process or an unexpected development in an existing process. Consideration of SOPs should be given during the equipment design phase so that tasks can be performed in a logical clockwise or counterclockwise fashion (129). SOPs should be clear so that the expected outcome is insured. Specific examples of often omitted details include (i) statements regarding settings for pressure switches and acceptable calibration error tolerances, (ii) diagrams, part numbers, and manual references to aid in following the procedure, and (iii) relying solely on valve numbers, not valve purposes, to describe the procedure. Although SOPs should be reviewed periodically in every few years to determine if they are in need of clarification, care should be taken to minimize the number and frequency of similar versions of the same SOP issued to the field. Operational clarification memos, issued to all operational staff and signed off when read, might be used to provide additional noncritical SOP clarification without

TABLE 80.7. List of Example Types of Procedures that are Possibly Required for a Bioprocessing Pilot Plant

Administrative	Process Equipment	Lab Equipment	Maintenance	Operations
Processing abnormality	Sterilization-in-place	Autoclave operation-sterilization and decon	Instrument calibration	Gowning
Investigation of contamination	Cleaning-in-place	Autoclave load patterns	Equipment preventative maintenance	Water system flushing/sampling
Product changeover	Sanitization	Glasswasher operation	Utility preventative maintenance	Steam system sampling
Writing of an SOP	Vessel set-up and operation	Glasswasher load patterns	HVAC preventative maintenance	Spill containment
Personnel training on equipment/operations	Transfer line/panel operations	Working in biosafety cabinet	Equipment change control	Facility housekeeping and cleaning
Personnel training on assays	Batch harvest (noncontained)	Working in laminar flow hood	Equipment start-up after processing hiatus	Facility start-up after processing hiatus
Personnel training on computers	Batch harvest (contained)	Incubator/shaker operation	Equipment start-up after major mechanical work	Daily utility checkout
Issuing and review of batch sheets	Equipment integrity test	Freezer	Equip. storage during processing hiatus	In-process sampling and analysis
Raw material release and storage	Utility systems operation	Refrigerator/cold room	Computer system change control	Data archiving
Investigation of monitoring excursions	HVAC systems operation	Tubing welder use and cleaning	Computer system failure recovery	Computer system operation
Forklift certification	Media/buffer preparation	Manual washing	Shutdown/interim maintenance document	Monitoring- controlled environments
Pest control	Specific equipment SOPs	Usage of scales and checkweights	Equipment isolation for maintenance	Tracking of process/equipment status
Ongoing validation testing		Calibration of pH meter	Issuing and tracking of work orders	
Ongoing facility monitoring		Facility monitoring assays		
Introduction of new products/processes		In-process monitoring assays		
		Fume hood use		
		Seed preparation		

reissuing the SOP during the interim period between SOP reviews. All major SOPs changes should be documented, evaluated for their effect on validation, and communicated to staff in a documented manner.

80.4.5 Safety

Because concerns regarding product exposure to personnel are similar to concerns for personnel exposure to product, GMP guidelines overlap with safety regulations in many respects such as training, SOPs, preventative maintenance including calibrations, and validation/change control (4). In fact, specific procedures for managing change to conform to process safety requirements (131) match the rigor of those required to confirm with GMP requirements. By the definition of a pilot plant's mission, change is an integral part of its existence. Consequently, comprehensive yet reasonable safety procedures must be established.

Safety captions can be required for certain raw materials based on the review of MSDS documentation. Broths, as well as isolated compounds, might be submitted for toxicity testing as soon as they are cultivated in laboratory bioreactors so that results are available prior to pilot plant scale-up. Safety is a component of installation qualification(IQ) because pressure vessel documentation and utility connections are reviewed. HAZOP (hazard operability) reviews for pressure vessels (e.g. fermenters, autoclaves) and utilities (e.g. clean steam generators) often are required by company policy and summaries included within equipment qualification reports. HAZOP action items need to be addressed promptly and any necessary modifications to equipment and/or procedures made to minimize risk. Equipment design needs to be reviewed for the ease of lockout and removal of hazardous energy sources (e.g. bleed valves for the evacuation of process and utility lines, local field-mounted pressure gauges to confirm depressurization), as well as the individual

isolation of skids/units for maintenance. In addition, equipment-specific SOPs for preparing the equipment for maintenance might be required.

Regular safety inspections with documented action items that are communicated to all affected personnel (i.e. operating staff, technicians, engineers, management) can identify and correct nonoptimal working conditions and cluttered processing areas. Tracking systems can be effective to ensure that corrective actions are taken and are effective. Specific attention should be given to the purchase of ergonomic lifting devices such as material elevators, drum lifters, and vacuum assist arms. Exposure of personnel to excessive sound, heat, or dust also should be considered during facility design as well as monitored during facility operation. Although personal protective equipment is available such as ear plugs, heat-resistant gloves, and respirators, when possible engineering controls such as sound dampeners, insulation, and dust collectors may be better solutions. Safety during validation testing should always be considered, particularly when groups outside of operations are involved in setting up/operating equipment and when sources of hazardous energy are involved. Whether during validation testing or operational use, fittings of any sort should be tightly secured and should not be tightened when equipment is under pressure and/or hot, specifically during SIP and CIP procedures. Summaries of generally accepted laboratory and pilot plant safety procedures to consider are available (132).

According to ASME code, overpressurization protection using relief devices is required for vessels over six inches in diameter. The background for this regulation as well as details of pressure relief valves and rupture disks is available (133). Although sanitary rupture disks are most desirable for product contact, once blown, processing must stop until they are replaced. Sometimes, a rupture disk may be installed followed by a pop-safety valve rated at a slightly higher pressure with a pressure gauge or other type of sensor in between to indicate rupture of the disk (84). If this arrangement is used, then the cleanliness of the area between the rupture disk and the pop-safety valve must be demonstrated for the batch quality not to be adversely impacted if the disk ruptures but the pop-safety valve does not release. Removal of entire rupture disk assembly (not the removal of the disk out from the assembly) for cleaning should be checked with company policy but may be acceptable in most cases.

Another key concentration is that the outlets of safety relief devices (which might be unexpectedly spewing steam, hot water, or broth after relief) should be oriented such that personnel safety is considered for those who may be standing near them. One method is to pipe outlets to outside containment troughs, but it may not be desirable to have a potential connection to the outside. A second alternative is to create a designated area within the pilot plant processing area. Although piping outlets to the floor beside the equipment should be minimized, if they are found to be necessary, they should be carefully situated outside the normal path of personnel.

80.4.6 Training

Initial and ongoing training programs need to be developed and documented for each individual associated with the facility based on the facility needs. The number of different individuals associated with pilot plant processing can be high unless a dedicated group is established regardless of product. A training SOP should be established, which might include a training manual containing useful items such as copies of key SOPs, facility layouts, equipment diagrams, and policies. Initial training might include items ranging from vendor supplied training sessions to validated load pattern arrangements. Often this training falls at a peak workload period during the facility start-up and validation (or during subsequent batch preparation) when attentions can be diverted into seemingly more urgent areas. In other cases, more individuals require training than can be reasonably accommodated in the area surrounding the equipment. When permitted, such training might be recorded for later review by the staff once they have fully assumed responsibility for operation. Another alternative is for those just trained to provide training to others, which may be suitable for certain operations. For best results, training should occur with written reference documentation available to those being trained.

Ongoing training should be done on a regular basis with sessions once in every one or two months, which seems to be most appropriate for an active pilot plant facility. Training should include supervisors, operators, engineers, and maintenance personnel, as well as validation and GMP staff. Training might include a process review that highlights critical steps and equipments, SOP reviews, identification of personnel safety and environmental containment issues, review of PM and ongoing maintenance needs, as well as what operational personnel should anticipate with respect to proper equipment function (127). Training sessions are one method to communicate recent SOP changes and to explain why certain procedures are necessary. They also might be used for periodic SOP reviews to obtain feedback from those using the SOP frequently. Attendance should be required, sessions recorded when possible, and those new to the facility should review prior training sessions for the past few years as applicable.

80.4.7 Validation

When manufacturing clinical materials, pilot plants are evaluated under the guidelines for investigational new drug

products, among other regulations, which clearly state that GMPs applying for drug products are approved for clinical trials in humans and animals (134). The recent guideline issued by the FDA (135) makes pilot plants eligible for product licensure should company needs require a product launch from a pilot plant facility. Individual company philosophies vary on the suitability or desirability of their pilot plants for this task because using a pilot facility for manufacturing reduces its availability for the production of clinical material. The level of validation effort required is best considered during the initial facility design. Prospective validation is the preferred option, owing to the association of document collection and equipment testing with facility start-up. Validation can be done retrospectively although the collection of the required documentation may be more challenging and modifications that are necessary for testing may be costly.

The major steps for validation ensure that installed equipment and utilities operate in a manner acceptable for the process to be run in that equipment. Because multiple processes, many of which are not necessarily identified at the time of validation, may be conducted in a pilot plant, operational ranges need to be set to accommodate a wide range of reasonably expected processes. For example, an incubator might be validated for temperatures between 25 and 37°C to accommodate common bacterial, yeast, and fungal cultures, but not necessarily at 45°C to accommodate unusual thermophiles. The selection of "worst-case" scenarios can be difficult for a pilot plant if the associated "worst-case" conditions are unduly burdensome for normal operation. Specifically, the cleaning procedures required after a three week fungal production cultivation are significantly more involved than those required after a two day fungal seed cultivation of the same culture or for a two week animal cell cultivation. Similarly, the sterilization cycle hold time for a concentrated sugar solution is substantially longer than that required for a heat-sensitive waterlike growth medium (136). Approaches for efficiently resolving these multiproduct validation issues can be complicated by desires to follow manufacturing validation guidelines, which most likely were established based on a single product.

Often validation, qualification, verification, commissioning, and start-up are used with specific definitions in mind for individual facilities and organizations. Generally, validation implies the highest rigor of direct reproducible testing of a specific procedure. Qualification encompasses a wider range of documentation collection and testing of capabilities. Verification might imply a single test against an identified standard. Commissioning can refer to documented trouble shooting of newly installed equipment, and start-up might refer to initial equipment checkouts directly after installation. The major validation phases are divided to focus on qualification followed by validation. IQ focuses of the verification of proper installation, appropriate utility connections, and adherence to manufacturers' and purchase order specifications (137). Operational qualification (OQ) includes testing of equipment function and an acceptance criteria for equipment performance (135). Performance qualification (PQ) centers on process-specific testing for SIP, CIP, and autoclave sterilization and decontamination load patterns. For computers, a system life cycle methodology incorporating specifications, program design, coding, testing, start-up, operation, and maintenance has been adopted (137,138).

Process validation centers on the reproducibility of the process in the manufacturing area (139). Parameters influencing this reproducibility might be initially identified at the laboratory scale then studied in the pilot plant to obtain acceptable operating ranges for those processing parameters, such as cultivation temperature, pH, and dissolved oxygen, are found to influence product quality. The set of criteria for proceeding to the next processing step, specifically volumetric/specific productivity, yield and purity, must be validated in a documented fashion. The critical processing steps important to process quality should be identified and validated (137). Other noncritical process steps may be studied for their impact on manufacturing productivity. Process validation may require multiple identical pieces of equipment (such as fermenters) at the laboratory and process scales to define acceptable processing ranges in a parallel rather than sequential manner.

80.4.8 Facility Records and Manufacturing Execution Systems (MES)

Documentation associated with a new pilot plant facility and its equipment can be extensive initially and increases substantially during the time that the facility operates. Although centralizing all documentation in a single archive can be attractive, duplicate copies of some items are often needed in other locations during every day operation. For example, equipment manuals and facility drawings may be needed near the actual location of the equipment, in the maintenance shop, and archived in the centralized documentation repository. Validation documentation, consisting of IQ/OQ, PQ, and load pattern/SIP/CIP reports, is generated both during the initial validation and during annual retesting and ongoing environmental monitoring programs. Storage of change control documentation might be accomplished through notebooks/file folders designated for individual pieces of equipment or individual suites. SOPs might be archived in a centralized location but also posted near equipment for ready reference. Access and sign-out procedures for the control of documentation need to be developed. Electronic on-line access is one way

to minimize space requirements and facilitate locating documentation.

A robust system for batch records needs to be created, based on individual batch sheets for processing steps or for individual pieces of equipment or for some appropriate combination of the two approaches. Issued batch sheets should be tracked by a unique sequential number with the product, processing step, and/or equipment number clearly identified. There is a need to track the use of equipment by product and batch, particularly for multipurpose pilot plant facilities. Although this might be done through individual equipment use logs, it is also helpful to include such tracking within the batch record itself.

Newly authored or completed batch sheets should be reviewed by the pilot plant operations area and may be required to be approved by a quality group prior to execution. Batch sheets should have clear written instructions as well as a signature, date and time, as required, for each step. Handwritten instructions, likely to be added during the processing of pilot scale batches, may need to be reviewed by representatives from operation and/or quality groups. Brief justifications for alterations in batch sheet instructions also should be considered. A written explanation documenting that the material from the current step is acceptable for continued processing in a subsequent step is recommended. Care should be taken to use common templates wherever possible to simplify successive batch sheet differences and minimize the review effort. Executed batch sheets should be reviewed for completeness by the operations area, by those in charge of the batch, and by a quality group as required. A tracking system should be instituted to monitor the review of completed batch sheets as well as to ensure that all issued batch numbers are accounted for in the batch record filing cabinets. Photocopying, microfilming, or scanning of completed batch sheets serve to provide a backup in case of loss or damage. Paperless electronic batch records, as well as electronic signatures, can minimize documentation volume and guidelines for implementation and validation are published (140).

Manufacturing execution systems (MES) control manufacturing processes. These include areas such as inventory, batch sheets, scheduling, and calibration management (141), as well as mechanical and operational status of equipment. Bioprocess facilities in general have been slow to implement these systems owing to their large initial costs, need for knowledgeable IT support, challenges with melding with paper-based systems, and validation requirements (55). Bioprocessing pilot plants have been even slower because their inherent need for flexibility can make scoping of MES systems difficult. However, there are several benefits deriving from MES tools and they should attain successful implementation and be readily maintainable (142). In the case of a pilot plant, frequent changes in batch-associated procedures make it challenging to gain the benefits of electronic batch records that utilize computerized cross-checking to ensure that steps are completed in the proper order (55).

SHEAR SENSITIVITY

YUSUF CHISTI
School of Engineering, Massey University, Palmerston North, New Zealand

81.1 INTRODUCTION

Depending on its intensity, a shear field may be stimulatory, inhibitory, or outright destructive. Intense shear fields will disintegrate even the most robust of microorganisms (1). Lesser levels of turbulence impact upon cellular morphology (2,3), biochemistry and physiology (4), floc size (5), and attachment and detachment from surfaces (6,7). These influences of shear stresses are reflected in the industrially important aspects of production rate, productivity, product spectrum, and characteristics. Among the most susceptible to shear effects are the animal cells, plant cells, and cells of some microalgae and cyanobacteria. Shear-associated problems have the greatest economic impact in the animal cell culture industry because it is the largest amongst ones based on shear-sensitive cells and because of the high-value nature of most cell culture–derived products (8). Damaging consequences of intense shear fields are well documented for other microorganisms also. For example, shear effects may alter characteristics of extracellular microbial polysaccharides by affecting the secretory processes in some bacteria (9,10). Considerations of shear stress levels are also important in design and operation of biomedical devices such as dialysis machines, heart–lung machines, and transfusion filters. The shear stress associated with implanted devices such as artificial heart valves can have medically significant implications. Increasingly, shear-sensitive human cells are being used to regenerate damaged tissue *in vitro* for later implanting or grafting. In other instances, susceptibility to shear may be beneficial; for example, during recovery of intracellular material by mechanical disruption (1,11,12). Some of the factors that determine shear sensitivity are summarized in Table 81.1. In the future, it might be possible to correlate the mechanical properties of cells with their susceptibility to damage by shear stress. Data is becoming increasingly available on mechanical strength of cells and organelles (13–16).

81.2 SHEAR FORCES IN BIOREACTORS

Substantial information exists on the effects of hydrodynamic forces on cells in defined flow geometries such as viscometers and capillaries (5,17–22), but little is known about shear fields in bioreactors (23–25). While selection

of more shear-tolerant cell lines can be helpful, successful culture of shear-sensitive biocatalysts requires attention to bioreactor design and operation.

The magnitude of the fluid mechanical forces is often expressed as shear stress τ or shear rate γ. These quantities are related; thus, in laminar Newtonian flow,

$$\tau = \gamma \mu_{\mathrm{L}} \tag{81.1}$$

where μ_{L} is the viscosity of the fluid. Shear rate is a measure of spatial variation in local velocities in a fluid. Cell damage in a moving fluid is sometimes associated with the magnitude of the prevailing shear rate or the associated shear stress, but these quantities are neither easily defined nor easily measured in the relatively turbulent environment of most bioreactors. Moreover, shear rate varies with location within a vessel. Attempts have been made to characterize an average or a maximum shear rate in various types of bioreactors and process flow devices, as discussed in the following text for the more common cases.

81.2.1 Bubble Columns and Airlift Bioreactors

Expressions for mean shear rate in bubble columns have been summarized by Chisti (25), Chisti and Moo-Young (23), and Shi *et al*. (26). These expressions generally correlate the average shear rate with the superficial gas velocity; thus,

$$\gamma = kU_{\mathrm{G}}^{a} \tag{81.2}$$

where the parameter a equals 1.0 in most cases, but the k value has been reported variously as 1000, 1500, 2800, 5000 m^{-1}, and so on (24). The enormous disagreement among various authorities is obvious in Fig. 81.1, where the shear rate calculated according to several available equations is shown as a function of the superficial aeration velocity in an air–water system in a bubble column. Theoretical analysis suggests the following dependence between average shear rate and superficial gas velocity in bubble columns (27):

$$\gamma = \left(\frac{g \rho_{\mathrm{L}} U_{\mathrm{G}}}{K} \right)^{1/(n+1)} \tag{81.3}$$

where U_{G} is the superficial gas velocity, g is gravitational acceleration, ρ_{L} is the density of the fluid, K is the consistency index, and n is the flow index.

Equation 81.2, which was originally developed for bubble columns, has been applied also to airlift bioreactors using the superficial gas velocity in the riser zone as a correlating parameter; however, that usage is incorrect (23). A more suitable form of equation 81.2 for airlift reactors is

$$\gamma = \frac{kU_{\mathrm{Gr}}}{1 + \dfrac{A_{\mathrm{d}}}{A_{\mathrm{r}}}} \tag{81.4}$$

where U_{Gr} is the superficial gas velocity in the riser, A_{r} is the cross-sectional area of the riser, and A_{d} is the

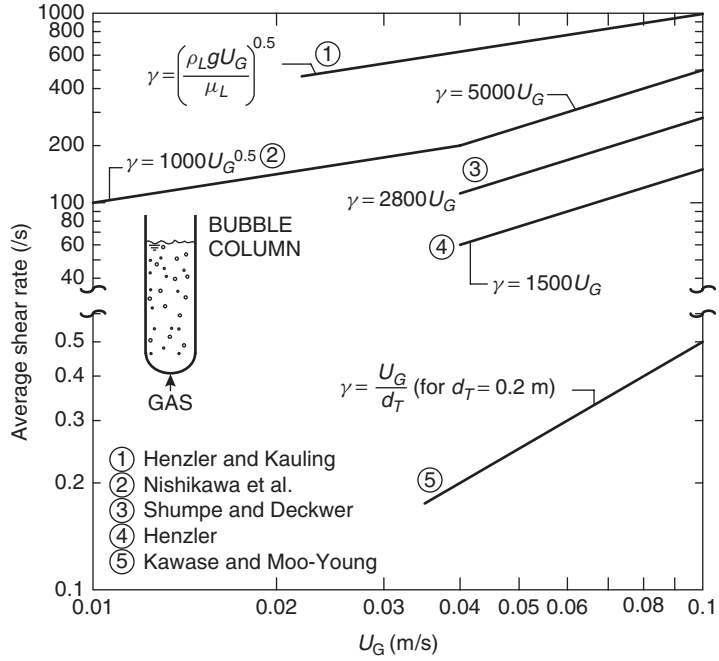

Figure 81.1. Average shear rate in air–water system in a bubble column according to various sources. Based on Ref. (25).

cross-sectional area of the downcomer. In addition to the discrepancies already noted (Fig. 81.1), Equations 81.2 and 81.4 have other significant flaws. The shear rate should depend also on the momentum transfer capability of a fluid, that is, on the density and the viscosity of the fluid;but Equations 81.2 and 81.4 show no such dependence. Indeed, it is well known that the bubble size in a turbulent field depends on the viscosity and the density of the fluid as well as on the specific energy input rate. It is therefore reasonable to assume that correlations that express the shear rate as a function of U_G (or U_{Gr}) alone are incomplete (23). Furthermore, correlations such as Equation 81.2 have generally been based on observations of phenomena at solid–liquid interfaces (e.g. heat transfer from coils or jackets), and their extension to phenomena at gas–liquid interfaces or the bulk fluid is absurd at best. Shear stress and, hence, shear rate at walls of riser and downcomer zones of an airlift device are readily calculated using methods developed for pipes and channels as discussed in a later section.

Another equation for estimation of an "effective" shear rate in airlift reactors is

$$\gamma = 3.26 - 3.51 \times 10^2\, U_{Gr} + 1.48 \times 10^4\, U_{Gr}^2 \qquad (81.5)$$

which was developed for $0.004 < U_{Gr}$ (m/s) < 0.06 (26); the shear rate range covered was 2–35 s^{-1}. Equation 81.5 was developed in an external-loop airlift reactor. First, the effect of viscosity on the induced liquid circulation velocity in the downcomer was established using Newtonian glycerol solutions at various gas flow rates. The maximum Reynolds number in the downcomer was about 3200 or barely in the turbulent regime. In a second step, pseudoplastic media were used in the reactor, and the effective viscosity (μ_{ap}) of these fluids in the circulation loop was determined as being equal to the viscosity of the Newtonian glycerol solutions when the two systems were at identical aeration and liquid circulation rates. The effective viscosity and the known values of K and n were used in the power law equation to calculate the prevailing shear rate:

$$\gamma = \left(\frac{\mu_{ap}}{K}\right)^{\frac{1}{n-1}} \qquad (81.6)$$

The calculated shear rates were correlated with the superficial gas velocity in the riser as noted in Equation 81.5 (26). Although written in terms of the superficial gas velocity in the riser, Equation 81.5 may be usefully expressed in terms of the specific power input in the reactor, as recommended elsewhere (23).

Because the procedure employed by Shi *et al*. (26) equated the viscosity-associated reduction in the liquid circulation velocity in different fluids, it gave in some sense a shear rate in the vicinity of the interface between the fluid and the walls of the reactor; shear rate in the bulk flow, which is the quantity of interest in most cases, was not quantified. Furthermore, the method of analysis used (26) applies strictly to a laminar flow regime, quite unlike the flow situations encountered in most practical operations.

Compared with bubble columns, Equation 81.5 yields quite low values for shear rates in airlift reactors, as noted by Shi *et al*. (26). In such comparisons, care needs to be taken to ensure that the devices are being compared at identical values of specific power inputs (23,25). Although Shi *et al*. (26) did not adhere to this criterion, the specific geometry of the reactor they used was such that the error was small. Unlike what Shi *et al*. (26) concluded, Equation 81.5 is not suitable for correlating mass transfer from gas bubbles or suspended solids because it does not give shear rates at gas–liquid or particle–liquid interfaces. Similarly, the usefulness of the shear rate calculated using Equation 81.5 for correlating survival of fragile biocatalysts remains questionable.

Following a methodology identical to that of Shi *et al*. (26) but in a 0.7 m^3 external-loop airlift device, Al-Masry (28) obtained the equation

$$\gamma_w = 14.9 + 11.1\, U_{Gr} + 24.392 \times 10^3\, U_{Gr}^2 \qquad (81.7)$$

for an A_d/A_r value of unity, in a 1.6-m tall reactor operated such that the superficial gas velocity in the riser remained below 0.07 m/s (28). The wall shear rate values were almost always less than 120 s^{-1}. Equation 81.7 is subject to the same criticisms as Equation 81.5. To account for effects of reactor geometry, Al-Masry (28) correlated their data and that of Shi *et al*. (26) with the equation

$$\gamma_w = 3.36\,(1 - U_{Gr})^{-32.56}\left(1 + \frac{A_d}{A_r}\right)^{0.89} h_D^{0.44} \qquad (81.8)$$

which applied to $0.0018 \le U_{Gr}$ (m/s) ≤ 0.07; $0.11 \le A_d/A_r \le 1.0$; and $1.4 \le h_D$ (m) ≤ 6. Equations 81.7 and 81.8 disregard effects of momentum transport properties on shear rate, even though such effects are known to exist (29–32).

An alternative, mechanistic approach to quantifying the bulk shear rate in various zones of airlift bioreactors has been advanced by Molina Grima *et al*. (18). Because the hydrodynamic environment in various zones of airlift reactors tends to be quite different, characterization of shear rate by a single global value is not sensible. The overall shear rates can be deceptively low even though damaging levels may be experienced in the high shear zones (18); hence, the approach of Molina Grima *et al*. (18) is preferred. This method computes shear rates using reliable expressions for energy dissipation in various zones of airlift reactors (25,33).

Some directly measured shear rate data in an airlift bioreactor for hybridoma culture have become available (34). At aeration power input of ~9 W/m^3 in the

BSA-supplemented medium (bovine serum albumin (BSA) concentration = 1 g/L), the mean shear rate values in the downcomer were ~100 s^{-1}, and were independent of height (34). For the same conditions, the mean wall shear rate values in the riser zone varied axially from a high of ~600 s^{-1} at 0.06 m from the sparger to ~100 s^{-1} about midway up the riser. Measured average wall shear rate values were reduced by BSA supplementation; but this effect was largely independent of the BSA concentration over the range 0.1–1 g/L. Although the BSA concentration over the range 0.1–1 g/L did not further affect the mean wall shear rate value, the concentration affected the probability distribution of the shear rates 0.06 m above the sparger; higher concentrations produced narrower distributions (34). These results were obtained in a concentric draft-tube airlift device that was sparged in the draft-tube. The aspect ratio of the vessel was ~7 and the A_r/A_d ratio was ~0.7. Significantly, these observations regarding the axial variation in the mean wall shear rate (γ_w) do not agree with Equation 81.8, which predicts a hyperbolic increase in γ_w with increasing height h_D of dispersion.

Other attempts at characterizing the hydrodynamic forces relied on measurement of noises associated with events such as bubble formation at the sparger, bubble disengagement at the surface, and liquid flow over the baffle into the downcomer (35). Spectra of acoustic signals were measured in water, a salt solution, and aqueous glycerol media in a bubble column and split-cylinder airlift reactor (35). Because several events occur simultaneously in bubbling reactors, there were substantial ambiguities in assignment of the noise signals to specific events. The practical significance of the results was unclear even though the intended aim was to somehow relate the data to damage of fragile cells that has been reported by others in such reactors. Other work (36) examined the structure of turbulence in water and power law solutions ($K = 0.0194^{0.973}$ Pa $s^{0.973}$ and 0.0596 Pa $s^{0.958}$) in an external-loop airlift reactor. The reactor achieved complete gas–liquid separation, and there was no gas in the downcomer. Measurements of local root mean square velocity fluctuations as an indicator of turbulence intensity showed a slight decrease from the center of the riser to the wall. These measurements were at a constant gas velocity of 2.05×10^{-2} m/s. The magnitudes of the velocity fluctuations were similar for all media; however, the velocity fluctuations were much lower in the gas-free downcomer than in the riser despite similar values of Reynolds numbers in the two zones. On the basis of measurements of one-dimensional energy spectra in the center of the riser (36), turbulence could not be considered isotropic, particularly in power law fluids. Other substantial evidence for the absence of isotropic turbulence in airlift and bubble column reactors has been documented (37,38).

81.2.2 Stirred Tank Fermenters

The local velocity at a fixed position in any vessel fluctuates around a mean value; hence, the shear rate fluctuates. The extent of fluctuations is position dependent. In stirred tanks with radial flow impellers such as Rushton turbines, the velocity fluctuations are greatest near the impeller tip and decline rapidly as one moves radially outward from the tip. Elsewhere in the vessel, the velocity fluctuations are reduced even further. The time-averaged mean shear rate generated by a six-bladed Rushton turbine agitating a Newtonian fluid in a baffled vessel of diameter d_T is given as (39):

$$\gamma_{av} = 4.2N \left(\frac{d_i}{d_T}\right)^{0.3} \frac{d_i}{W} \tag{81.9}$$

where W is the width of the impeller blade, d_i is the impeller diameter, and N is its rotational speed. The time-averaged maximum shear rate value is 2.3 times γ_{av} (39). Another expression for the maximum shear rate at Rushton turbine blades is (30):

$$\gamma_{max} = 3.3N^{1.5} d_i \left(\frac{\rho_L}{\mu_L}\right)^{1/2} \tag{81.10}$$

which applies to Newtonian and non-Newtonian liquids when $100 \le \left(N d_i^2 \rho_L / \mu_L\right) \le 29,000$. The uncertainty in the coefficient (Eq. 81.10) is said to be ±20%. For non-Newtonian fluids, μ_L in Equation 81.10 is the zero shear viscosity. A different equation has been proposed by Wichterle *et al*. (30):

$$\gamma_{max} = N\,(1 + 5.3n)^{1/n} \left(\frac{N^{2-n} d_i^2 \rho_L}{K}\right)^{1/1+n} \tag{81.11}$$

Equation 81.11 provides the maximum shear rate on a Rushton turbine blade. An average shear rate expression applicable to a broader range of impellers and media is (40)

$$\gamma_{av} = k_i \left(\frac{4n}{3n+1}\right)^{n/n-1} N \tag{81.12}$$

where n, the flow index of a fluid, equals 1.0 for a Newtonian liquid. In Equation 81.12, k_i is an impeller-dependent constant. Some typical k_i values are noted in Table 81.2.

TABLE 81.2. The k_i Values for Use in Equation 81.12

Impeller	k_i
Six-bladed disc turbines	11–13
Paddle impellers	10–13
Propellers	~10
Helical ribbon impellers	~30

Shear stress encountered near the wall of a stirred tank is discussed by Wichterle *et al*. (41,42). According to Wichterle *et al*. (41), the friction factor C_f and the wall shear stress τ_w in a stirred tank are related as follows:

$$C_f = \frac{\tau_w}{\rho_L N^2 d_i^2} \left(\frac{d_T}{d_i}\right)^2 \tag{81.13}$$

The value of the friction factor was found to depend on position at the tank wall (42). In both Newtonian and pseudoplastic media, the maximum value of the friction factor correlated with the impeller Reynolds number, as follows:

$$C_{f\,max} = (15n + 1)\, Re_i^{-1/(1+n)} \left(\frac{d_T}{d_i}\right)^{2(1-n)/(1+n)} \tag{81.14}$$

where the Reynolds number is $Re_i = \frac{N^{2-n} d_i^2 \rho_L}{K}$. According to Equation 81.14, the maximum shear rate at the wall in a standard stirred tank ($d_i/d_T = 1/3$) containing a Newtonian fluid ($n = 1$) is nearly 30% of the maximum shear rate near the impeller, calculated with Equation 81.11.

The various shear rate correlations discussed here are compared in Fig. 81.2, for water in a standard stirred tank (43) agitated with a 0.1-m diameter six-bladed Rushton turbine. For some context, the shear rate around a rising bubble may be approximated as the ratio of the terminal rise velocity to the bubble diameter (or radius); hence,

$$\gamma_{av} = \frac{2U_B}{d_B} \tag{81.15}$$

In air–water, under conditions typical of bubble columns and airlift reactors, the bubble rise velocity is about 0.2 m/s and the bubble diameter is about 0.006 m. Thus, the interfacial shear rate approximates to 67 s^{-1} if the interface is nonmobile. Lower shear rates are expected at circulating interfaces. Shear rate in stirred tanks is further discussed elsewhere (27,41,42,44).

81.2.3 Spin Filter

Spin filters—rotating cylinders made of wire screen with openings that are significantly bigger (e.g. 25 μm openings) than the cells—are used to retain suspended animal cells in perfusion culture continuous bioreactors. Most of the cells are kept on the upstream side of the wire mesh by a hydrodynamic mechanism that depends on rapid rotation (e.g. 500 rpm) of the cylindrical screen (Fig. 81.3). The spent, largely cell-free medium is withdrawn from the zone within the rotating screen. Shear stresses associated with rotation of spin filters do not generally damage animal cells (45). Sometimes the cell-free zone within the confines of the screen are also used for submerged aeration.

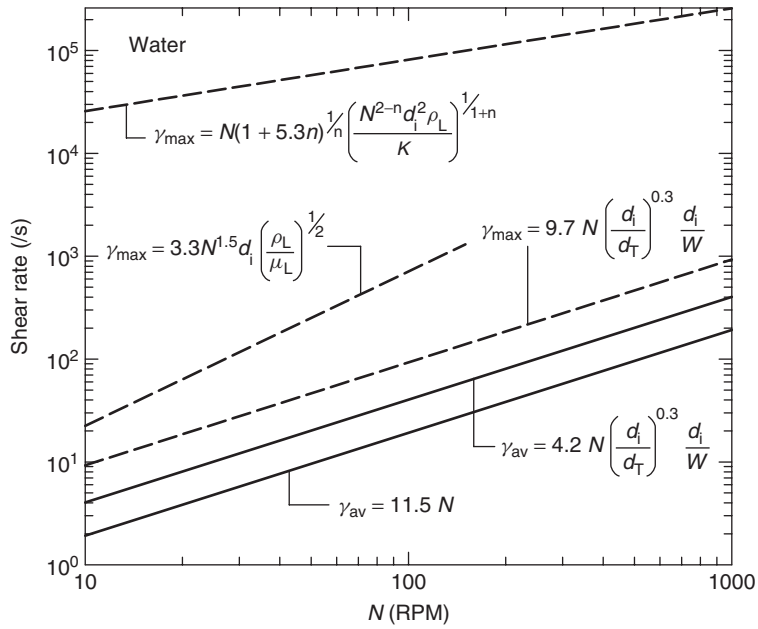

Figure 81.2. Comparison of the various shear rate correlations for water in a standard stirred tank agitated with a 0.1-m diameter, six-bladed Rushton turbine. The dashed lines are for the maximum shear rate; the solid ones are for the average shear rate. See text for additional details.

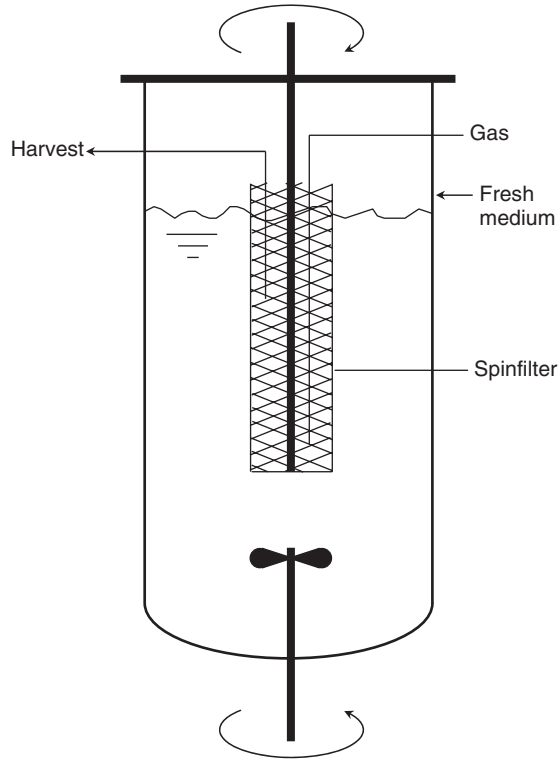

Figure 81.3. Perfusion culture with spin filter for hydrodynamics-based cell retention in bioreactors.

81.2.4 Other Flow Devices

Bioreactors and process vessels are where much of the shear-sensitive material is processed; however, at least part of the processing usually requires transfer of material between vessels. Transfer is accomplished through pipe work and centrifugal pumps are sometimes used. Methods of estimating shear stress levels in these devices are briefly summarized next.

81.2.4.1 Pipes, Tubings, and Flow Channels

81.2.4.1.1 Newtonian Fluids. In developed laminar flow of a Newtonian fluid through a straight tube of diameter d, the wall shear rate is given as

$$\gamma_w = \frac{8U_L}{d} \tag{81.16}$$

where U_L is the mean flow velocity. For rectangular channels of height h, the maximum or wall shear rate in developed laminar flow is

$$\gamma_w = \frac{6U_L}{h} \tag{81.17}$$

where U_L is again the mean flow velocity.

The wall shear stress, that is, the maximum value, in a flow channel such as the riser of an airlift reactor is related to the pressure drop (ΔP), the length L of channel, and the hydraulic diameter (24); thus,

$$\tau_w = \frac{d}{4L}\Delta P \tag{81.18}$$

Consequently, in turbulent flow, the wall shear stress is

$$\tau_w = \frac{1}{2}C_f \rho_L U_L^2 \tag{81.19}$$

where ρ_L is the liquid density and C_f is the Fanning friction factor. The latter is related with the Reynolds number as follows:

$$C_f = 0.0792\left(\frac{\rho_L U_L d}{\mu_L}\right)^{-0.25} \tag{81.20}$$

where d is the hydraulic diameter of the flow channel or pipe. From Equations 81.19 and 81.20, the wall shear stress can be shown to depend on Newtonian viscosity of the fluid: $\tau_w \propto \mu_L^{-0.75}$ (18). A typical variation of the wall shear rate and the isotropic turbulence shear rate (see a later section) during flow of a cell culture broth through a pipe is shown in Fig. 81.4. The wall shear rate greatly exceeds that in the bulk fluid; nonetheless, as discussed in a later section, conditions in the bulk volume are usually the relevant ones with regard to cell damage. Use of Equations 81.16 and 81.17 and similar others given later presupposes that the liquid velocity is known. This is normally the case in pipes and channels; however, with airlift vessels, the induced liquid circulation rate will often need to be estimated using available methods (24,25,33).

81.2.4.1.2 Non-Newtonian Power Law Fluids. Methods for calculation of wall shear stress in laminar and turbulent flow of power law fluids with and without dispersed gas have been discussed by Chisti (25) and Chisti and Moo-Young (46). For a non-Newtonian pseudoplastic medium flowing through a tube such as the riser or the downcomer of an airlift bioreactor, the flow is laminar when (47)

$$Re \leq 2300\frac{3n+1}{4n} \tag{81.21}$$

where the Reynolds number is calculated using the equation

$$Re = \frac{8\,U_L^{2-n}\,d^n\,\rho_L}{K\left(\frac{6n+2}{n}\right)^n} \tag{81.22}$$

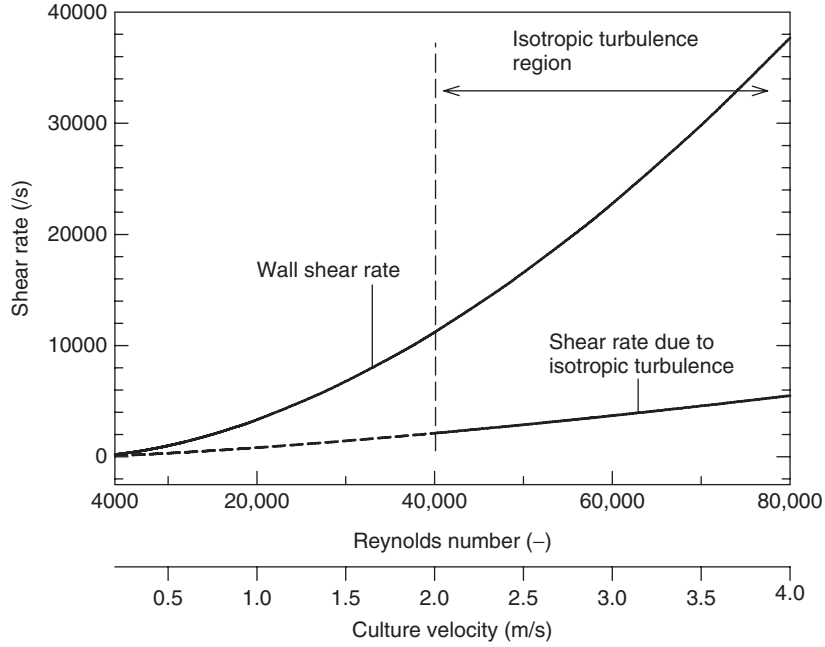

Figure 81.4. Variation of shear rate at pipe wall and in the bulk culture during turbulent flow through a 0.02 m diameter smooth pipe at various Reynolds numbers. The culture velocity is also shown. Density and viscosity of the culture fluid were 10^3 kg/m^3 and 10^{-3} Pa s, respectively. Turbulence was considered to be isotropic when the length scale of the terminal microeddies was smaller than or equal to a thousandth of the diameter of the pipe. The latter was taken as the scale of the primary eddy.

In the laminar regime, the wall shear stress for flow of a gas-free liquid has been expressed as (48)

$$\tau_w = \frac{8\,\rho_L\,U_L^2}{Re} \tag{81.23}$$

When the flow is turbulent, that is, the Reynolds number exceeds the value calculated with Equation 81.21, the wall shear stress in a gas-free liquid is (47,48)

$$\tau_w = \frac{0.316n^{0.121}\rho_L U_L^2}{8Re^{2/n(x-1)+2}} \tag{81.24}$$

In presence of a gas, the shear stress is a complex function of τ_w, the gas holdup, the properties of the liquid (ρ_L, K, n), and the superficial velocities of the gas and the liquid phases as discussed elsewhere (25,46). In Equations 21–24, d is the channel diameter, U_L is the superficial liquid velocity, K is the consistency index, and n is the flow behavior index. The parameter x in Equation 81.24 is given as

$$x = 0.70n^{-0.591} \tag{81.25}$$

as reported by Chisti and Moo-Young (46) based on data of Sokolov and Metkin (47).

81.2.4.2 Turbulent Submerged Jets. Submerged jets are encountered wherever a pipe or nozzle discharges a fluid beneath the surface of the same fluid in a larger reservoir. For example, culture broth recirculating from a tank to an ultrafiltration module and back to the tank could form a submerged jet. If the cross-sectional area of the discharge nozzle is less than about 25% of that of the reservoir, the wall effects can be neglected, and the jet is said to be "free". In a stable, submerged, turbulent jet, the maximum shear stress occurs in the direction of discharge, six to seven nozzle diameters downstream from the orifice. This shear stress is given as

$$\tau_{max} = 0.018\rho_L u_o^2 \tag{81.26}$$

where u_o is the velocity at the orifice.

A turbulent jet consists of two regions (Fig. 81.5). A conical core of fluid next to the orifice retains the discharge velocity of the orifice. This region of potential flow extends about six nozzle diameters from the discharge orifice, and within this region shear stresses are minimal. The potential core is surrounded by an expanding zone of developed turbulence. Quiescent fluid surrounds the turbulent flow field (Fig. 81.5). The total mass flow rate at any cross-section in the turbulent flow field of a jet increases linearly with

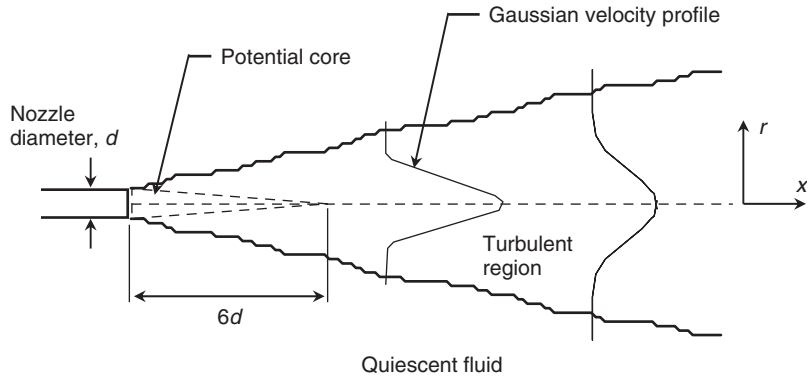

Figure 81.5. A submerged turbulent jet.

distance from the orifice, as the surrounding quiescent fluid is entrained in the jet. The velocity profile in the turbulent region is Gaussian and it is described by the equation

$$\frac{u_1}{u_{max}} = e^{-\beta(r/x)^2} \tag{81.27}$$

where β is about 75.2, r/x is the dimensionless radial distance (Fig. 81.5), u_1 is the local velocity at position r, and u_{max} is the maximum or the centerline velocity. The Gaussian profile persists until the centerline velocity declines to that of the surrounding flow. The maximum velocity, u_{max}, depends on the exit velocity at the nozzle and the axial distance:

$$\frac{u_{max}}{u_o} = C\left(\frac{d}{x}\right) \tag{81.28}$$

In Equation 81.28, d is the orifice diameter, x is the axial distance, and the constant C is about 6.06. The constants β and C may be influenced by the operating conditions.

If the nozzle discharge velocity is the same as in the pipe, the maximum shear stress at the pipe wall is always less than in the jet. The ratio of these shear stresses is given as

$$\frac{\tau_{max\,J}}{\tau_w} = 0.455\left(\frac{\rho_L U_L d}{\mu_L}\right)^{0.25} \tag{81.29}$$

The ratio τ_{maxJ}/τ_w increases with increasing velocity of discharge as shown in Fig. 81.6 for discharge of a cell culture fluid from a 0.02-m diameter pipe. Consequently, damage to fragile cells may occur during transfer operations such as inoculation of a bioreactor, even though the velocity in the transfer pipe may be relatively low. These effects

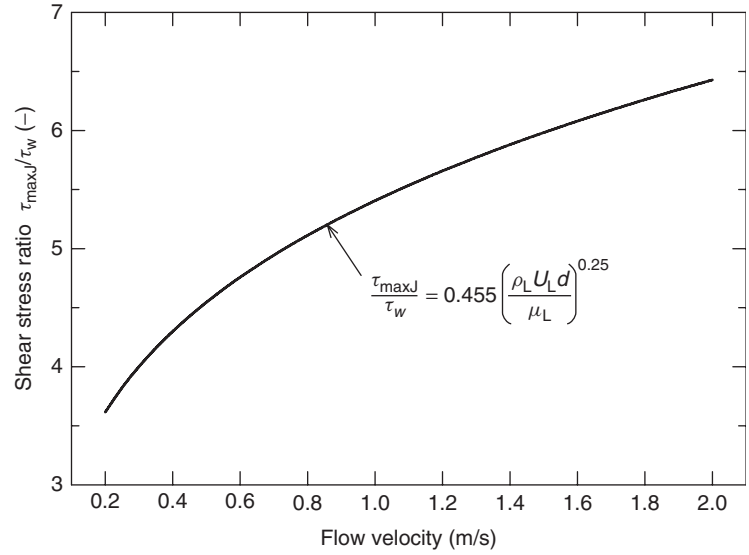

Figure 81.6. Ratio of the maximum shear stress in the jet to that at pipe wall for flow of animal cell culture fluid (density = 10^3 kg/m^3, viscosity = 10^{-3} Pa s) from a 0.02-m diameter pipe ending in same diameter opening to form a free jet.

may be avoided by discharging the jet above the level of the receiving fluid such that the liquid flows down the vessel wall.

Energy dissipation rates in turbulent jets are nonuniform. Dissipation is greatest near the axis of the jet and declines radially outward, becoming negligible at dimensionless radial distances (r/x) of greater than 0.2. In the fully developed turbulent region, the radially averaged energy dissipation rate E declines with axial location as follows:

$$E = \eta \left(\frac{d u_o}{x^{4/3}} \right)^3 \tag{81.30}$$

where the constant η is about 50 (49,50).

81.2.4.3 Centrifugal Pumps. Centrifugal pumps are commonly employed in bioprocessing; hence, knowledge of the shear rate in these devices is essential to assessing their suitability for a given use. The shear rate in a Newtonian fluid adjacent to the rotating impeller of a centrifugal pump depends on the radial position. The local shear rate at any position has been expressed as

$$\gamma = 6.30 N Re_L^{0.5} \tag{81.31}$$

where the local Reynolds number at the local diameter d_L is

$$Re_L = \frac{N d_L^2 \rho_L}{\mu_L} \tag{81.32}$$

Equation 81.31 is based on theoretical considerations, but it has closely correlated with the measured shear rate data over the range $10^2 \leq Re_L \leq 2 \times 10^6$ in a centrifugal pump with the impeller rotating in a standard volute casing (51). Over the approximate impeller rotational speed range of 0.01–100 s^{-1}, the shear rate values ranged over 1–10^5 s^{-1} in aqueous electrolyte solutions (51).

As a general guideline, centrifugal pumps may be used to transfer most low viscosity microbial broths and enzyme solutions so long as gas–liquid interfaces are rigorously excluded. Centrifugal pumps should not be used for animal cells, biofilm-supporting particles, soft immobilized enzyme supports, suspensions of nematodes and protozoa, protein precipitates, and plant cells. These pumps will be satisfactory for some microalgae, but not for others.

81.2.5 Shear Rate in Isotropic Turbulence

Irrespective of the bioreactor configuration, a turbulence field is deemed isotropic when the size of the primary eddies generated by the turbulence-producing mechanism is a 1000-fold or more compared to the size of the energy-dissipating microeddies. The length scale of the primary eddies is often approximated as the width of the impeller blade or the diameter of the impeller in a stirred tank. In bubble columns and airlift bioreactors, the length scale of primary eddies is approximated as the diameter of the column (or the riser tube) or the diameter of the bubble issuing from the gas sparger.

Shear stress, shear rate, the dimensions of microeddies, and other characteristics of flow are linked ultimately to the energy input and dissipation rates in the fluid. The local shear rate in the vicinity of an eddy in an isotropically turbulent field may be estimated as the ratio of the velocity and the length of the eddy; hence,

$$\gamma_i = \frac{u}{\ell} = \frac{\mu_L}{\rho_L \ell^2} \tag{81.33}$$

where ρ_L and μ_L are the density and the viscosity of the fluid, respectively. The mean length ℓ and the velocity u of the microeddies are related with the energy dissipation in the turbulence field; thus,

$$\ell = \left(\frac{\mu_L}{\rho_L} \right)^{3/4} E^{-1/4} \tag{81.34}$$

and

$$u = \left(\frac{\mu_L E}{\rho_L} \right)^{1/4} \tag{81.35}$$

where E is the rate of energy dissipation per unit mass of fluid. In most cases, all the energy input to the fluid is dissipated in fluid eddies, and E equals the rate of energy input. Equations 33–35 apply when local isotropic turbulence prevails.

For single-phase pipe flow, the specific energy dissipation rate is

$$E = \frac{U_L \Delta P}{\rho_L L} \tag{81.36}$$

where ΔP is the pressure drop over the tube length L, and U_L is the mean flow velocity. The pressure drop may be computed using Equations 18–20. The energy dissipation rate in bubble columns and airlift vessels is a function of the superficial aeration velocity (24,25); thus

$$E = g U_G \qquad \text{(bubble columns)} \tag{81.37}$$

and

$$E = g \frac{U_{Gr}}{1 + \dfrac{A_d}{A_r}} \qquad \text{(airlift bioreactors)} \tag{81.38}$$

Methods for calculating the specific energy dissipation rate in stirred vessels have been discussed elsewhere

(43,52). The energy dissipation varies greatly from the mean value in a stirred tank. The maximum energy dissipation occurs in the vicinity of the impellers. This maximum value can be calculated using the equation:

$$E = \frac{PoN^3 d_i^2}{\rho_L} \tag{81.39}$$

where Po is the power number, d_i is the diameter of the impeller, and N is the rotation speed (s^{-1}). In developed turbulent flow in stirred vessels, that is, when the impeller Reynolds number ($Nd_i^2\rho_L/\mu_L$) exceeds 10^4, the power number is generally constant for a given type of impeller and tank geometry. The constant power number values are noted in Table 81.3 for some common types of impellers in baffled stirred tanks. The energy dissipation rate in presence of aeration is generally less than in the equivalent ungassed state. The extent of reduction depends on the aeration rate used. In typically aerated conditions in microbial culture, the energy dissipated is generally 50–60% of the nonsparged case; however, in animal cell culture the aeration rates are so small that power number is barely affected by aeration.

Equation 81.39 assumes that dissipation occurs in the volume around the impeller; but it disregards flow through that volume. If the volume flowing through the impeller zone in 1 s is taken into account, the maximum specific energy dissipation will reduce by a factor that depends on the rotational speed and the geometry of the impeller.

As noted in Fig. 81.7, the same relationship exists between the isotropic turbulence shear rate and the specific energy dissipation rate in various culture devices; however, because the different devices operate in different ranges of specific energy dissipation rates, the shear rates experienced by cells are different under typically used culture conditions.

TABLE 81.3. Turbulent Power Number (Po) in Baffled Stirred Tanks

Impeller	Po
Propeller (square pitch, three-bladed)	0.32
45° Pitched blade turbine (six blades, pumping down)	1.90
Lightnin' A310 hydrofoil	0.31
Turbine (six-bladed)	6.30
Turbine (six curved blades)	4.80
Flat paddle (two blades)	1.70
Scaba agitator	1.45
Prochem impeller (five blades, $d_i = d_T/2$)	1.0

Source: Ref. 43.

Generally, if the dimensions of the biocatalyst particle are much smaller than the calculated length ℓ of the microeddies, the particle is simply carried around by the fluid eddy; the particle does not experience any disruptive force. On the other hand, a particle that is larger than the length scale of the eddy will experience pressure differentials on its surface, and if the particle is not strong enough it could be broken by the resulting forces.

In addition to turbulence within the fluid, other damage-causing phenomena in a bioreactor include interparticle collisions; collisions with walls, other stationary surfaces, an the impeller; shear forces associated with bubble rupture at the surface of the fluid; phenomena linked with bubble coalescence and breakup; and bubble formation

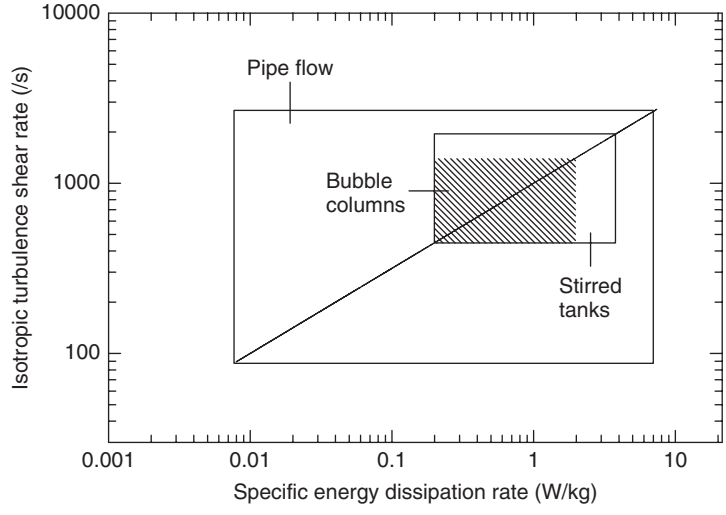

Figure 81.7. The relationship between isotropic turbulence shear rate and the specific energy dissipation rate is the same (solid line) in various culture devices, but the devices operate in different ranges of specific energy dissipation rates (boxes) along the diagonal line. The plot is for a waterlike culture fluid (10^3 kg/m^3 density, 10^{-3} Pa s viscosity).

at the gas sparger. Some of these aspects are discussed elsewhere in this chapter. Summarizing, several possible shear rate values may be calculated for a given situation in a bioprocess device. Not every calculated value is appropriate or relevant to the problem at hand. For pneumatically agitated bioreactors, when the turbulence characteristics in the bulk fluid are the relevant ones, the preferred approach is to use Equation 81.33 for shear rates in the vicinity of eddies. The same applies to mechanically stirred tanks. In some cases, the relevant shear rate may be that at the interface of a rising bubble unless turbulence is so intense that bubbles do not rise freely. Other situations would be controlled by the bubble rupture events as discussed later. In some other cases, the fluid eddy shear rate and the maximum shear rate at the impeller will need to be taken into account. Factors such as the frequency of passage of a sensitive biocatalyst through high shear regions may need consideration. Shear rates in the vicinity of particles and bubbles may be greatly accentuated by the presence of ultrasound (53).

81.3 RESPONSE TO SHEAR

Response to shear has been characterized using various indices, including growth rate (54–56), cell viability (57), and regrowth potential (58); release of intracellular material (54,59,60); changes in oxygen uptake rate, adenosine triphosphate (ATP), productivity of metabolites, and biochemical composition of the cells; and alterations in morphology of cells and cell aggregates (2,58,59).

Most studies of shear response of cells have utilized batch culture with or without aeration. Such cultures contain cells at different stages of growth; hence, the size and metabolic state of cells are nonuniform. In contrast, continuous culture is time consuming (54), differs substantially from the culture methodologies that are typically employed commercially, and, through natural selection, the cells in continuous culture adapt to shear fields, hence masking the effect of shear. For example, Wu *et al*. (61) noted for insect cells that the beneficial effect of shear-protective agents (serum, methyl cellulose, Pluronic F68) were not as important as the effect of passage number. Similar results have been alluded to for plant cells (54). To overcome problems associated with cell growth and shear adaptation, Zhang *et al*. (59) recommended the use erythrocytes for comparative evaluation of the hydrodynamic environment in bioreactors. A nongrowing, well-defined, and shear-susceptible cell population such as those provided by erythrocytes can help identify suitable regimes of operation of a given reactor. In addition, shear damaging potential of different bioreactor configurations can be assessed on a common basis using cells such as erythrocytes. Specific information on shear susceptibility of animal, plant, and various microbial cells is discussed in the following sections.

81.3.1 Bacteria, Yeasts, and Mycelial Microfungi

Yeasts, bacteria, and mycelial microfungi are generally quite robust and not easily damaged under typical processing conditions; however, even the most robust cells are broken when subjected to suitable combinations of high stress and exposure time (1). Often, genetically modified strains of an otherwise robust microorganism are less shear tolerant (1,10,62–64). With microorganisms, the composition of the growth medium and the specific growth rate used for the culture are known to influence the robustness of the cell (1). Cells grown in fully defined media that may lack one or more component essential for the synthesis of normal cell wall are often less robust (1). Growth at a higher specific rate will often produce weaker cells (1). When the shear field is not intense enough to damage cells, it may still affect product formation and characteristics (9,10). In one case, properties of a shear-sensitive polymer were affected, but not the producing bacterial cells (10). Cells experiencing physiological stress—for example, starvation—are more susceptible to shear stress–related damage (60).

Fragmentation of fungal hyphae and filamentous bacteria by mechanical agitation in stirred fermenters has been widely reported (55,56,65–69). Reports cited by Märkl *et al*. (60) document increasing release of intracellular material from mycelium of *Rhizopus javanicus* and *Mucor javanicus* as the stirrer speed increased. Increasing release of nucleotides was noted with increasing speed of agitation or with increasing agitation time at a constant agitation speed. Effect of Rushton turbine tip speed on performance of a process for converting cellulose to protein-enriched microbial biomass was clearly demonstrated by Moo-Young *et al*. (55). The process utilized the filamentous microfungus *Neurospora sitophila* for the conversion. Increasing impeller tip speed from 2.35 to 3.29 m/s reduced the specific protein production rate and the final yield (Fig. 81.8). In addition, a distinct lag phase was observed at the higher agitation rate (Fig. 81.8) when the inoculum grown in a more quiescent environment was transferred to the fermenter. At the highest tip speed shown in Fig. 81.8, the specific protein production rate was only 55% of that at the lowest tip speed. Similarly, the yield of crude microbial protein was reduced to ~67% of the value obtained at the lowest agitation speed used (55). Further work revealed that agitation-associated damage could be reduced substantially by replacing the Rushton turbines with axial flow hydrofoil impellers (55), thus confirming that different types of impellers generate very different shear fields at identical tip speeds. For equal or lower power draw, hydrofoil impellers are typically better bulk mixers than Rushton turbines (43,52).

In *Penicillium chrysogenum* fermentations performed in turbine impeller–agitated vessels of 0.005–1 m^3 working volumes, operated at impeller tip speeds of 2.5–6.3 m/s, the specific penicillin production rate and the mean length

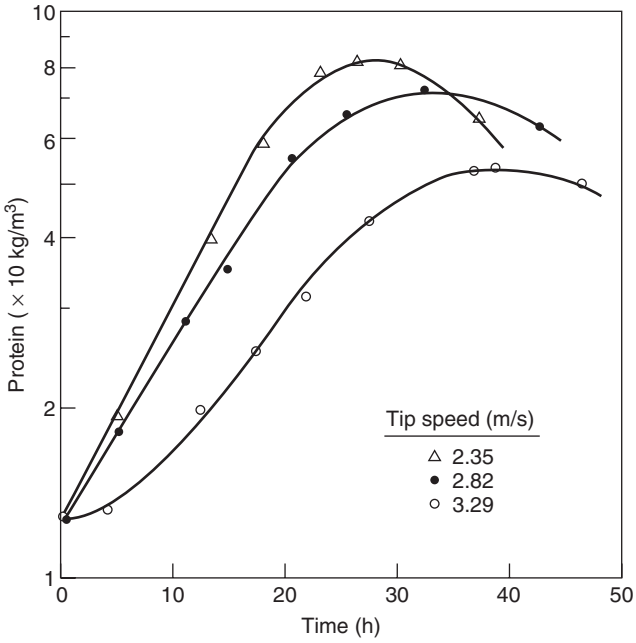

Figure 81.8. Effect of Rushton turbine tip speed on protein production by the mold *N. sitophila*. *Source:* Refs 55 and 56.

of the main hyphae were lower at high agitation intensities (2). High agitation speeds affected the fungal morphology, promoting mycelial fragmentation and a greater frequency of branching (2). The behavior of the fermentation at various scales correlated poorly with the impeller tip speed, but correlation was superior in terms of a parameter that took into account the frequency of passage of the culture through the intensely agitated zones around the impellers (2). This behavior suggests that the degree of hyphal damage in stirred bioreactors depends on a combination of the shear intensity in the impeller zone and the cumulative time of exposure of the microbial solids to the shear field.

Sometimes, especially with certain mycelial microfungi, the biomass yield may not be affected by agitation rate, but the cell morphology and production of metabolites may be influenced greatly. Using different strains of citric acid-producing *Aspergillus niger*, Ujcova *et al*. (3) showed that the yield of citric acid first increased with increasing agitation rate presumably because of improved oxygen supply, but the yield declined because of cell damage if the agitation speed was increased further. The yield maxima occurred at different agitation rates for different strains, and the sensitivity to agitation differed among strains. Other morphological effects of non-damaging shear levels include changes in growth form, whether pellet or pulplike; changes in the degree of branching; the extent of entanglement; whether growth occurs in filamentous or spherical cell form in certain dimorphic species; as well as others.

Evidence suggests that even a supposedly robust cell such as *Saccharomyces cerevisiae* (1,11) is susceptible to mechanical shear damage in fermenters (70–72). In one study, *S. cerevisiae* suspended in isotonic saline lost viability at increasing rate over a 25-h period, as the agitation speed of the paddle impeller was increased (71). At 1.43 m/s impeller tip speed, >90% of the cells were dead over 25 h. In contrast, at 0.66 m/s tip speed, only about 15% of the cells died over the same period (71). Excessive shear has been alleged to also influence the productivity of ethanol in fermentations employing *S. cerevisiae* (70). Shear stress in stirred fermenters has been claimed to affect production of thuringiensin by the bacterium *Bacillus thuringiensis* during stationary phase of culture (73).

Among methane bacteria, *Methanobacterium thermoautotrophicum* with rodlike cells that exceeded 2 μm in length was highly resistant to shear stress (60). In contrast, and surprisingly, the relatively smaller (<2 μm) spheroidal cells of *Methanococcus vaniellii* were quite sensitive to shear stresses (60). Supplementing the medium with carboxymethyl cellulose viscosity enhancer increased the extent of the cell damage (60). Failure to provide an essential nutrient, selenium in this case, also enhanced shear susceptibility of the culture (60). Although many authors have successfully correlated cell damage with the tip speed of the impeller, Märkl *et al*. (60) believe that power input per unit culture volume is a superior correlating parameter, which is also suitable for comparing the cell damage effects of mechanically stirred and other nonmechanically agitated bioreactors. A constant power input per unit culture volume has also been suggested as a bioreactor scaleup criterion for fragile biocatalysts (60). This recommendation notwithstanding, average power input alone cannot be a universally satisfactory determinant of cell damage; as noted in an earlier section, the maximum shear rate and the frequency of passage (or cumulative exposure) through the high shear zone need to be taken into account, especially when the shear rate in a given device is strongly position dependent. Several studies confirm that frequency of passes through high shear environment has a clear impact on biocatalyst survival (1,2,11,12,20,24,74). Effects of variously intense shear fields on microbial cells are further discussed by Thomas (5,75), Prokop and Bajpai (76), and Chisti and Moo-Young (1). Shear effects on microbial flocs and pellets are treated in a separate section of this chapter. Table 81.4 summarizes the damaging threshold values of impeller tip speed and specific power input for some microorganisms.

81.3.2 Microalgae and Cyanobacteria

Cell fragility has been referred to as the key problem of culture of microalgae in photobioreactors (77); however, the real situation is not quite as bad. Among microalgae, the sensitivity to shear varies greatly with the species. Algae

TABLE 81.4. Damaging Threshold Values of Impeller Tip Speed or Specific Power Input for Some Microorganisms

Stirred fermenters	**Impeller tip speed** (m/s)
Saccharopolyspora erythraea	>1.07
Methanococcus jannaschii	>2.35
Microalga *Ochromonas malhamensis* (8–20 μm average diameter cells)	≤1.4 with low level sparging
Ciliated protozoan *Tetrahymena pyriformis* (~80 μm cell diameter)	≤0.5
Saccharomyces cerevisiae suspended in isotonic saline	<1.43
Recombinant *Aspergillus oryzae*	Power inputs between 2.2 and 12.6 kW/m^3
Penicillium chrysogenum	>2.5
Neurospora sitophila	~2.35
Trichoderma harzianum	~0.4
Airlift bioreactors	**Power input** (W/m^3)
Microalga *Phaeodactylum tricornutum*	~270
Bubble columns	**Power input** (W/m^3)
Microalga *Dunaliella tertiolecta*	98

such as *Dunaliella* are indeed extremely fragile, but many other species will tolerate high levels of turbulence and sparging with gas. Thus, gas sparged airlift devices are commonly used to circulate algal cultures through solar receivers of photobioreactors (24,78–80). Similarly, relatively low shear positive displacement rotary pumps have been successfully employed. High shear centrifugal pumps have also been used; however, at least in some cases, the centrifugal pumps are known to be more damaging than the other fluid moving systems. In one case, for otherwise equivalent conditions, replacement of the centrifugal pump with a positive displacement device doubled the productivity of *Porphyridium cruentum* (77), a producer of phycoerythrin and polyunsaturated fatty acids. Irrespective of the method used to circulate the culture, the culture flow velocities through tubular solar receivers typically range over 0.3–0.5 m/s in tubes up to 0.06 m in diameter. These conditions have been used with a variety of algae.

Damage to cells of the marine microalgae *Skeletonema costatum* and *Haslea ostrearia* has been reported during passage through pumps and valves (81). The extent of damage depended on the characteristics of the device and the operational parameters such as the opening of the valve (i.e. the pressure drop and hence the energy dissipation rate) and the rotational speed of the pump. *H. ostrearia* is a single-celled diatom, whereas *S. costatum* grows as chains of connected cells. Both centrifugal and positive displacement rotary vane pumps reduced the chain length of *S. costatum*. Centrifugal pump was more damaging than the positive displacement device. Larger algal filaments were the most susceptible to damage. The rate of decrease in chain length was greater for chains with a longer initial length (Fig. 81.9). In the positive displacement pump, the percentage cell damage D_p correlated (81) with the number of passes N_d through the pump and the initial length L_i (μm) of the algal filaments as follows:

$$D_p(\%) = 2.54 N_d^{0.21} L_i^{0.55} \tag{81.40}$$

Equation 81.40 applied to filaments with initial modal lengths of 37.1, 65.5, and 77.8 μm. In a monoscrew pump, the percentage cell damage increased (81) with

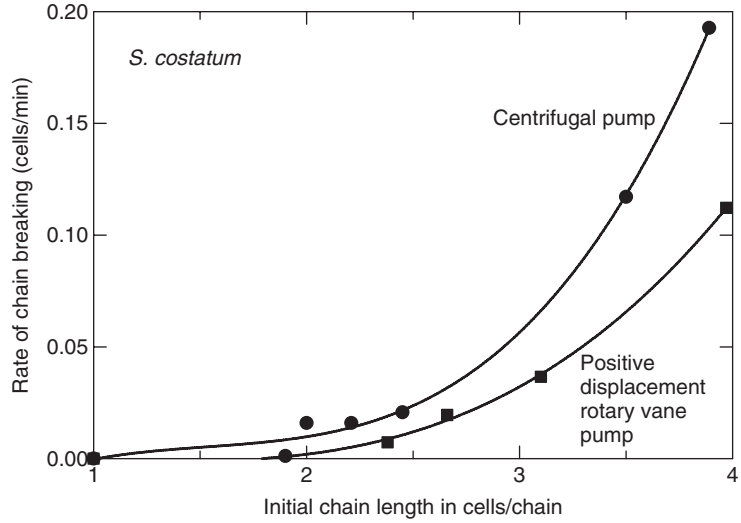

Figure 81.9. Rate of breakage of *S. costatum* chains as a function of the initial chain length (number of cells) for two types of pumps. The flow rate was 12 L/min in both cases. *Source:* Ref. 81.

increasing frequency of passes through the device; for a given frequency F, the damage increased with cumulative exposure time t as follows:

$$D_p(\%) = 1.8\,(Ft)^{0.64} \qquad (81.41)$$

For similar number of passes and taking into account pump leakage, the monoscrew pump was less damaging than the centrifugal device (81). Similarly, for *H. ostrearia*, the monoscrew pump was less disruptive than both the centrifugal and the positive displacement rotary vane machines (81). In other similar work with the highly motile microalga *Tetraselmis suecica*, Jaouen *et al*. (82) observed a loss of motility on passage of culture suspension through centrifugal and rotary vane positive displacement pumps but not through a peristaltic pump.

In cultures of *Haematococcus pluvialis*, a producer of astaxanthin, early onset of the stationary phase has been associated with turbulence-induced deflagelation of the cells (77). Fragility of species such as *H. pluvialis* depends also on the phase of growth; thus, tailoring the bioreactor operational regime to the growth phase can improve overall productivity (77). The stationary phase red cysts of *H. pluvialis* are significantly more robust than the green vegetative cells (77).

The cyanobacterium *Spirulina*—a health food and source of the food colorant phycocyanin—is another species that is susceptible to damage by excessive shear forces. Shear stress applied to optically dilute cultures of *Spirulina platensis* and *Chlorella vulgaris* in a Couette flow device, affected the rate of photosynthesis of the cells (83). Depending on the temperature and the intensity of irradiance, the increasing shear stress over the range of 0–0.6 Pa initially enhanced the rate of oxygen evolution by *Spirulina*; but beyond a "critical shear stress," the rate of photosynthesis plateaued and declined. The initial enhancement was apparently due to better illumination of the helically coiled bacterial trichome because of rotation in the flow field. Microscopic observations confirmed a shear stress–dependent reduction in the "straightened" trichome length of the bacterium, as shown in Fig. 81.10. The critical shear stress declined with increasing test temperature over the range of 25–40°C, suggesting a loss of mechanical strength of trichome with increasing temperature (83). In view of the short duration (16 min), the test temperature could not have altered the composition of the cell wall, only its strength. The growth temperature had little effect on shear susceptibility of the cells (Fig. 81.10). Shear stress values of 0.4 Pa and greater did not further affect the final trichome length (~50 μm), presumably because the trichome size had become too small to be further affected by the prevailing eddies.

In contrast to observations with *Spirulina*, increasing shear stress did not enhance the rate of photosynthesis in *Chlorella* (83); the rate of photosynthesis declined consistently with increasing shear stress, irrespective of the illumination intensity used (Fig. 81.11). *Chlorella* is known to be a relatively robust alga, so the results in Fig. 81.11 cannot be attributed to physical destruction of the cells. Indeed, the loss in photosynthesis was substantially reversible upon removal of the shear stress stimulus (83). A lack of any shear-induced enhancement in photosynthesis was apparently because a small spherical cell of *Chlorella* could not shade itself; hence, in an optically dilute suspension, increasing shear stress (turbulence) may have produced no

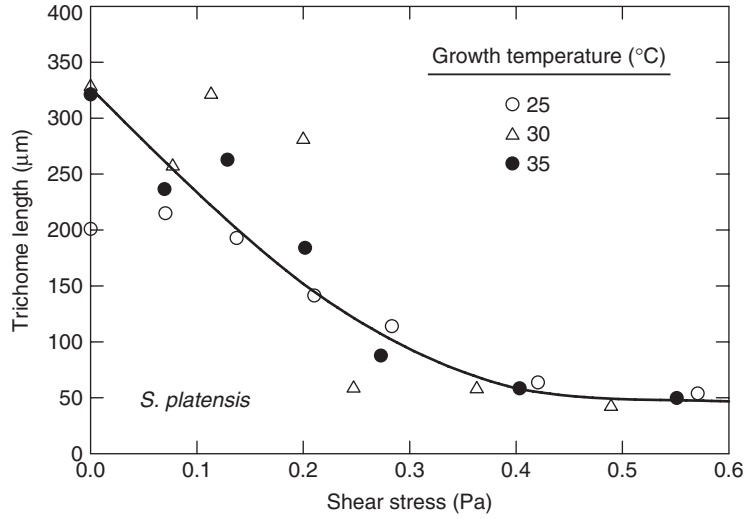

Figure 81.10. Effect of shear stress on average straightened trichome length of *S. platensis*. The shear stress was applied for 16 min at 30°C on cultures grown at various temperatures. *Source:* Ref. 83.

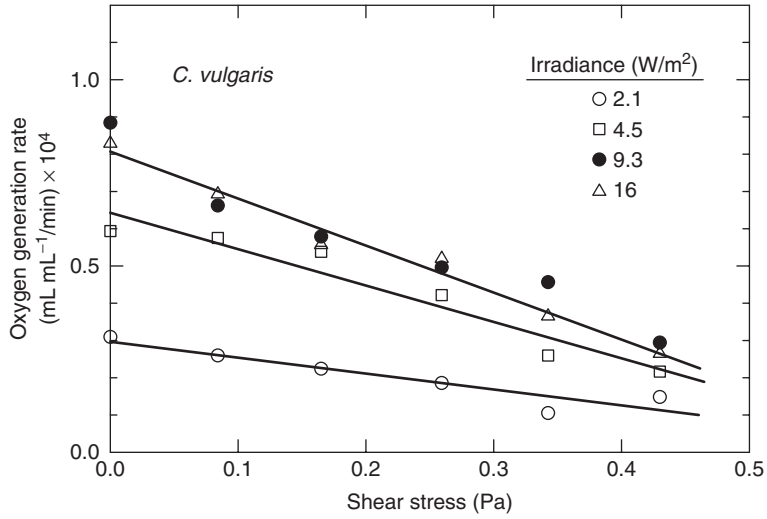

Figure 81.11. Rate of oxygen generation declines with increasing shear stress in Couette flow of *C. vulgaris*. Data are shown for various intensities of irradiance at 30°C test temperature. *Source:* Ref. 83.

improvement in light availability. Also, the 5–6 μm spherical cells of *Chlorella* are much smaller than the 50 μm stable trichome size attained by *Spirulina* trichomes exposed to shear stress (Fig. 81.10). In view of all this, the data in Fig. 81.10 have only one plausible explanation; at least in some species, the sublethal shear stress stimulus affects the photosynthetic capability of the cell.

The marine alga *Dunaliella* is particularly fragile: the cell lacks a ridged wall; only a thin cytoplasmic membrane encloses it. *Dunaliella* is a good source of natural β-carotene; hence, it is commercially useful. The cell also produces glycerol. Silva *et al*. (84) showed that *Dunaliella* was susceptible to damage by gas bubbles as well as by turbulence in the liquid. Supplementing the culture with carboxymethyl cellulose or agar improved cell survival.

In one study with *Dunaliella tertiolecta*, culture in a bubble column was quite successful; but when the bubble column was converted to an airlift device by inserting a vertical baffle, the productivity declined (85). Under conditions that were earlier identified as optimal, no growth was observed in the airlift reactor whereas good growth occurred in the bubble column. Microscopic examination showed significant disruption of the cells in the airlift device (85). This was associated with the hydrodynamic stresses generated as the culture flowed over the upper edge of the baffle into the downcomer (85). This effect could have been avoided, or at least minimized, by hydrodynamic smoothing of the upper and lower parts of the baffle to prevent flow separation (24). In the bubble column, the growth was sensitive to aeration rate: growth rate increased with increasing superficial gas velocity up to a velocity of about 0.6 m/min. Further increase in aeration rate reduced growth, apparently because of hydrodynamic stresses in the fluid (85). Under nongrowth conditions (no light), the specific death rate in the bubble column was shown to increase with superficial gas velocity for velocities exceeding 0.6 m/min (85). At a fixed aeration velocity ($U_G = 1$ m/min), the specific death rate decreased with increasing height of the culture fluid in the column (85), probably because the specific power input and, hence, the turbulence intensity declined (24). Similar behavior has been reported with animal cells in bubble columns (86–90).

For otherwise fixed conditions, increasing the number of aeration nozzles—that is, decreasing the gas jet velocity—caused a marginal reduction in the specific death rate of *D. tertiolecta* (85). This led to the conclusion that the events at the gas sparger did contribute to cell death (85), although the effect was minimal. Unlike Suzuki *et al*. (85), others (79,80) have quite successfully cultured various microalgae in pilot-scale airlift devices. Continuous culture of the green alga *Chlorella pyrenoidosa* in a rectangular airlift device with multiple light-emitting diodes was reported by Matthijs *et al*. (91). With a relatively robust photosynthetic organism such as *Chlorella*, increasing turbulence within limits improves productivity in photobioreactors because of enhanced fluid interchange between the dimly lit interior and the better illuminated exterior parts of a photobioreactor.

In addition to an organism's morphology, the biochemical composition of the cell wall has been associated at least qualitatively with the cell's susceptibility to hydrodynamic stresses. The microalga *C. vulgaris*, which is shear tolerant, has a thick (100–200 nm) cell wall composed of cellulose, pectin, and sporopollenin (60). The somewhat more sensitive alga *Chlamydomonas reinhardii* has only glycoproteins in its relatively thin (40 nm) cell

wall (60), whereas a highly sensitive cell wall–defective mutant of *C. reinhardii* is devoid of cell wall (60). Similarly, the cyanobacterium *Synechococcus* with murein-containing cell wall and the methane bacterium *M. thermoautotrophicum* with pseudomurine-containing wall are noticeably more resistant than methane bacteria such as *M. vaniellii*, which has a protein-based wall.

Although earlier work with the mold *M. javanicus* showed a reduced extent of damage to mycelia as the viscosity was increased at constant agitation rate, and similar reports exist with animal cells (92,93) and the halotolerant alga *Dunaliella* (84), Märkl *et al*. (60) observed an opposite effect: with a highly shear-sensitive strain of *C. reinhardii*, even a slight increase in viscosity enhanced cell damage (60). The viscosity was increased by adding carboxymethyl cellulose to the culture broth. With a relatively less shear-sensitive strain of *C. reinhardii*, increasing the viscosity reduced the impeller agitation speed at which the damaging effects were first discerned (60). Apparently, at least with the less sensitive strain, supplementing the medium with the viscosity enhancer caused the cells to grow in clumps, and aggregation supposedly was an effective shield against cell damage (60). Increasing shear damage with increasing culture viscosity has been seen before with a protozoan (94). These apparently contradictory results are easily explained: whether changes in viscosity increase or reduce shear damage depends on the peculiarities of the mechanism causing the damage. For a given impeller tip speed, increasing viscosity will not affect the tip speed-associated shear rate, but the turbulence will be reduced; hence, the shear rate in the fluid should be lower. However, the shear stress around a particle may increase if the fluid eddy length scale remains comparable to the dimensions of the particle. In other cases, increased viscosity may reduce both shear rate and shear stress; only eddies that are larger than the particle may survive and there may be little or no relative motion between the fluid and the particle. In other cases, the frequency of passage through high shear zones may decline with increasing viscosity.

Dinoflagellates are a group of microalgae. Biotechnological potential of dinoflagellates has been discussed by Garcia Camacho *et al*. (95). Small-scale turbulence is known to affect the growth rate and morphology of dinoflagellates (96–99). Agitation, shaking, aeration, and stirring have inhibited growth in laboratory cultures (100–105). The shear stress levels that dinoflagellates may withstand are generally one or two orders of magnitude lower than the levels that generally damage most animal and plant cells. The shear stress threshold of some dinoflagellates is even lower than that of erythrocytes (0.029 N/m^2). For example, a continuous laminar shear stress level of only 0.0044 N/m^2 (equivalent to a shear rate of 2.2 s^{-1}) has proved lethal to the dinoflagellate *Gonyaulax polyedra* Stein (103–105). Like animal and plant cells, *G. polyedra* responds differently to laminar and turbulent shear stresses. The observed response depends also on the intensity, duration, and frequency of exposure to shear field. Growth phase during which exposure occurs, prevailing irradiance level, and light–dark cycling also appear to influence shear tolerance. Other dinoflagellate species behave similarly (106,107). Shear stress levels can influence the production of dinoflagellate toxins (106).

Engineering problems of dinoflagellate culture notwithstanding, dinoflagellates can potentially contribute to improved understanding of shear stresses and other turbulence phenomena in bioreactors. For example, many morphologically diverse dinoflagellates are bioluminescent (e.g. *Lingulodium polyedrum*, *Ceratocorys horrida*, *Pyrocystis fusiformis*, *G. polyedra*), and turbulence appears to stimulate bioluminescence. Dinoflagellate bioluminescence is easily visualized and quantified (108). This provides a powerful tool for flow visualization under conditions not amenable to conventional methods (108–111). Bioluminescence stimulation and suppression under different conditions of turbulence may assist in establishing mechanisms of cell damage in bioreactors (112). Potentially, dinoflagellates can be used to map regions of high shear in biomedical devices such as prosthetic heart valves. Bioluminescence response of dinoflagellates to developed and developing turbulent flow in pipes has been discussed (113,114). Similar work in Couette flow devices has been reported (115,116).

Effects of hydrodynamic forces on microalgae and protection of the cells against damage are further discussed elsewhere (117–121).

81.3.3 Plant Cells

Cultured plant cells are a potential source of numerous high value compounds, although few production processes have been commercialized (17,122). Low culture productivities continue to be the primary limitation. Investigational culture in large bioreactors has been carried out since at least 1959. A variety of reactors have been used, including bubble columns, airlift devices, stirred vessels, rotary drum reactors, and immobilized cell systems (17). Airlift bioreactors have proved especially effective for large-scale culture of heterotrophic, photomixotrophic, and photosynthetic plant cell suspensions (24,123). Relatively low values of pneumatic power inputs have given satisfactory results during cultivation of plant cells. For example, Fischer and Alfermann (123) obtained good results with about 13 W/m^3 specific power input during culture of *Chenopodium rubrum* cells in a concentric draft-tube airlift device. Similarly, Ballica and Ryu (124) obtained maximum biomass and product yield at an approximate power input value of 35 W/m^3, also in a draft-tube airlift

reactor while culturing *Datura stramonium* cells. In the latter case, power inputs above ~60 W/m^3 caused large declines in biomass and product yields. The size of the cell aggregates declined with increasing specific power input (124). Reinhard *et al*. (125) described culture of *Digitalis lanata* in a 300-L airlift bioreactor for producing β-methyldigoxin.

Plant cells in suspension tend to be large: 20–50 μm in diameter and 100–500 μm in length. The cells have a cellulose-based wall. Most of the cell's volume is taken up by a vacuole that may occupy >95% of the available space. The fluid in the vacuole is much less viscous than the cytoplasm; hence, a cell with a large vacuole is likely to be less resistant to certain types of deformations than one with a smaller vacuole. Cells frequently occur as aggregates of up to a hundred cells. The aggregates settle easily. Plant cells grow slowly with doubling times of the order of 20–100 h. Cells may secrete extracellular polysaccharides, producing non-Newtonian broths. Also, the biomass concentration may be high, up to 70 kg/m^3. Heterotrophically growing plant cells require oxygen, but demands are low, of the order of 10^{-6} kg O_2/kg cell/s. Critical dissolved oxygen concentration generally tends to be ≤20% of air saturation. The polysaccharide-containing cultures tend to foam a lot when aerated. Also, excessive aeration may reduce productivity by stripping carbon dioxide and other essential volatiles produced by the cells themselves (5,122).

As has been demonstrated with some microorganisms (1), the composition of the culture medium, the culture conditions, and the specific growth rate of cells may affect the wall strength of plant cells also. For otherwise identical conditions, agitation intensity is reported to influence the composition of plant cell walls. Thus, the relative amounts of pectin, cellulose, and hemicellulose in walls of *Catharanthus roseus* were affected by the intensity of agitation in one case (126). In another case, cited by Doran (17), the mass ratio of cell wall relative to the whole cell increased with increasing intensity to shear, suggesting adaptation of the cell to the prevailing environment even over short periods. Even though the turbulence level may be insufficient to affect individual cells, aggregates may be affected; hence, a shear-related metabolic response may occur because of altered cell–cell interactions (122) and changes in nutrient supply (127). This indirectly affects metabolism.

On the basis of laminar flow viscometric measurements, a critical shear stress level of 80–200 N/m^2 has been suggested for *Morinda citrifolia* cells. For suspended cells of the same species exposed to turbulent shear stress, a damage threshold energy dissipation rate of 50 W/kg broth has been reported (128), while for *Daucus carota* a shear stress level of 50 N/m^2 has been associated with cell damage. In another study, carrot cells in a laminar flow Couette viscometer lost the ability to grow and divide in the shear stress range of 0.5–100 N/m^2 (76). The intracellular enzyme activity was impaired at shear stress levels above 3000 N/m^2, but significant lysis did not occur until a shear stress level of 10,000 N/m^2 applied over a prolonged period (≥1 h) (76). In contrast to the behavior in laminar flow, the cells were quite sensitive to turbulent impeller agitation. Impeller tip speeds of ~1.1 m/s lysed a significant proportion of the cells within 40 min (76).

In studies with *Perilla frutescens* cell suspensions, Zhong *et al*. (129) noted that the cell viability declined with increasing shear rate (constant exposure time) or increasing shear time at a constant rate of shear in a concentric cylinder shearing device. A constant shear rate of about 140 s^{-1} produced a noticeable loss of viability within 20 min. At a higher shear rate of ~860 s^{-1}, less than 75% of the cells were viable after 20 min (129). In marine propeller agitated fermenters, the impeller tip speed affected the specific growth rate and the yield of the cells (129). Tip speeds of >0.6 m/s reduced the specific growth rate and the cell biomass yield (129). In other cases, impeller tip speeds as low as 0.35 m/s have extensively lysed certain plant cells.

With *M. citrifolia* cells subjected to 25–350 N/m^2 turbulent shear stress in a capillary, the viability decline followed first-order kinetics in which the rate constant increased with the applied shear stress (130). The culture was circulated through the capillary by a peristaltic pump, which also contributed to cell damage (130). The specific death rate constant was linearly related with the cumulative energy dissipated (130). Cell aggregates subjected to shear were reduced in size. For the same species, damage was reported when cells grown in a quiescent environment were subjected to turbulent jet flow through 1- and 2-mm nozzles (74). Cells lost viability with increasing number of passes through the nozzles. The viability loss was of first-order in the number of passes (74). For a fixed number of nozzle passes, increased nozzle flow velocity enhanced the death rate constant. Similarly, the maximum and the mean aggregate size reduced when the suspension was subjected to jet flows (74). The average aggregate size was lower for higher jet velocities. The average energy dissipation rates in the jet ranged over 10^3–10^5 W/kg (74).

Meijer *et al*. (54) assessed the hydrodynamic stress sensitivity of *C. roseus*, *Nicotiana tabacum*, *Tabernaemontana divaricata*, and *Cinchona robusta* in a 3-L Rushton turbine-stirred vessel. Effects of stress were quantified in terms of culture growth rate, respiration rate, and release of organic compounds from the cells. Cultures of *C. roseus* carried out at 0.59 m/s and 2.36 m/s impeller tip speed showed identical behavior in terms of biomass growth rate and glucose consumption rate; hence, it was concluded that hydrodynamics-associated stress did not affect the cells over the ranges examined (54). Similarly, *N. tabacum* was little affected by different agitation rates, although the growth rate and the final yield were noticeably

greater at the lower agitation speed. Cells of *C. robusta* responded differently: at 0.59 m/s impeller tip speed, the cells grew and there was little release of intracellular protein; however, at 2.36 m/s, there was no growth and the specific protein concentration increased with culture time, indicating leakage from damaged cells (54). The *T. divaricata* cells also were damaged at 2.36 m/s, but less than the cells of *C. robusta*. The damage to *T. divaricata* was reduced at a lower impeller tip speed of 0.59 m/s. In separate experiments, cells of *N. tabacum* that had earlier withstood higher shear stress levels were shown to be more susceptible to damage after a prolonged period (10 days) of starvation (54). This effect is similar to that noted with other cells (60).

Increasingly, plant tissue is being cultured as hairy roots (131). Growing tips of hairy roots are damaged by elevated shear stress level, but can be acclimatized to tolerate relatively high shear forces (132,133). In column cultures (Fig. 81.12), superficial velocity of flow affects the rate of elongation and the viability at tip meristems (132). In studies that varied the medium flow velocity from 2 to 28 m/h, optimal growth occurred at a velocity of 15 m/h in column culture of red beet hairy roots (132).

Table 81.5 is a summary of the damage thresholds levels—either impeller tip speed or the specific power input due to aeration—noted for various plant cell suspensions in stirred fermenters and airlift bioreactors. The studies referenced earlier clearly affirm that the susceptibility to shearing forces varies a great deal with cell line. Moreover, for the same cell line, cultivation history (e.g. prolonged starvation) and age of cell affect the cell's response to shear fields (54,60,122), which is consistent with similar findings for microorganisms (1). That plant cells adapt to shear fields is also well known—cells cultured in high shear environments better withstand hydrodynamic forces after many generations. Shear sensitivity can depend on the age of the cell (134). Shear sensitivity of plant cells has been further reviewed by others (13,58,86,122,135–137).

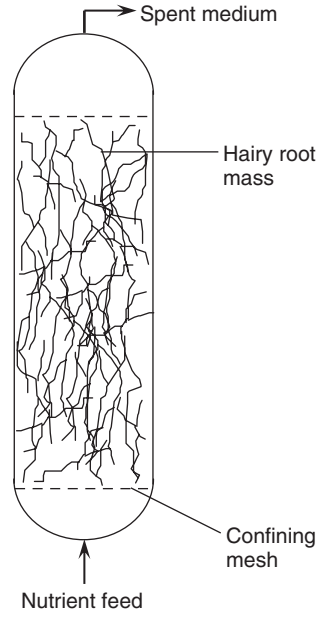

Figure 81.12. In hairy root culture the growth of root mass is confined within a column, and a nutrient medium flowing past the biomass supplies oxygen and other nutrients.

TABLE 81.5. Damaging Threshold Values of Impeller Tip Speed or Specific Power Input for Some Plant Cells

Stirred fermenters	**Impeller tip speed** (m/s)
Catharanthus roseus	≥2.36
Nicotiana tabacum	~2.36
Cinchona robusta	<2.36
Daucus carota	<1.10
Tabernaemontana divaricata	~0.59
Perilla frutescens	0.60
Others	≤0.35
Airlift bioreactors	**Power input** (W/m^3)
Chenopodium rubrum	≥13
Datura stramonium	~60

81.3.4 Protozoa

Strong shear fields have long been known to damage large protozoa. The ciliated protozoan *Tetrahymena* is certainly sensitive to high intensity shear forces (94), with and without gas–liquid interfaces. Low density cultures appear to be damaged by gentle agitation (138) and static gas–liquid interfaces (139). Higher density cultures can be more shear tolerant, and resistance to shear can be increased by using suitable protective additives in the culture medium (138,140).

In agitated suspension of *Tetrahymena pyriformis* (~80 μm cell diameter), lysis correlated with impeller tip speed (94), and most of the cells were destroyed once the tip speed equaled or exceeded 0.5 m/s. In a Couette viscometer, the critical shear stress for incipient lysis was ~24 N/m^2 (94). Eighty percent of the cells lysed within the first minute when exposed to a shear stress of 10^3 N/m^2. The damage increased with shear stress level and exposure time. At a given shear rate, increasing the broth viscosity made the protozoan more susceptible to shear damage, implying that the damage was associated with shear stress rather than with shear rate (94). The cells were more sensitive to turbulent shear stress: an average turbulent shear stress of ~10 N/m^2 lysed over half the population within 10 min. In contrast, in laminar flow, a similar level of damage occurred at shear stress levels of almost 300 N/m^2. Note that *T. pyriformis* cells are larger than most animal cells, but smaller than most cultured plant cells.

Low density ($<10^4$ cells/mL) cultures of *T. pyriformis*, *Tetrahymena thermophila*, and *Tetrahymena pigmentosa* in Erlenmeyer flasks were adversely affected by gyratory shaking (138). Also, air sparging of the flasks increased the doubling time of the cells. The damaging effect of gyratory agitation disappeared once the cell concentration exceeded 10^4 cells/mL (138). The damaging effect of agitation could be reduced by supplementing the broth with dextran (138), Pluronic F68 (141), and certain fatty acids (140). The protective effect of fatty acids such as 9 μM oleic acid and 140 μM linoleic acid appeared to be biochemically based rather than being purely physical (140). *T. pyriformis* cells under gyratory shaking undergo ultrastructural changes. These changes are not suppressed by supplementation of the culture with fatty acids, even though a protective effect occurs. Cell protective effect has also been observed with ergosterol and cholesterol supplementation, but not with octanoic acid, palmitic acid, and palmitoleic acid (140).

Surprisingly, even a static gas–liquid interface has been associated with lysis of *T. thermophila* cells (139). Lysis is suppressed by adding a small amount of a surfactant (e.g. Sodium dodecylsulfate (SDS), Pluronic F68, Tween 80) to the culture medium (139). The damaging effect of a static interface certainly cannot be ascribed to shear phenomena and biochemical factors must play a role. Indeed, the lytic effect of a static surface is abolished if the medium is simply diluted or reformulated without added surfactants (142). Apparently, certain constituents of a poorly formulated medium make the cells unduly susceptible to a gas–liquid interface.

Despite a claimed low tolerance for shear (138), *T. thermophila* has been successfully cultured in a 15-L stirred tank and a 1.5-m^3 airlift bioreactor (143). Cell concentration values of up to 3×10^6 mL^{-1} were easily attained in the stirred tank that was agitated with three, six-bladed paddle impellers (~7 cm diameter, 50–150 rpm, 0.05 vvm aeration rate, 13 L working volume). In the airlift device, the maximum cell concentration attained was 2×10^6 mL^{-1}, when the specific power input during cultivation ranged from 50 to 250 W/m^3 (143). Stepwise increases in the agitation speed and the aeration rate to maintain dissolved oxygen at ~50% of air saturation caused no obvious change in the growth profiles, as shown in Figs 81.13 and 81.14. Mass cultivation of another protozoan, *Paramecium tetraurelia*, has been reported (144).

81.3.5 Animal Cells

Animal cells are among the most shear-susceptible of biocatalysts. Animal cells are relative large—typically 10–20 μm in diameter—and they lack a protective cell wall. Osmotic shock is often sufficient to lyse animal cells. Other than blood cells, most normal animal cells are anchorage dependent. Cancerous cells, hybridomas, and established lines will normally grow in suspension. Because of these distinct growth characteristics, two types of culture methods are employed in industrial practice: free suspension culture in which cells are freely suspended in a nutrient broth and microcarrier culture in which anchorage-dependent cells grow on surfaces of solid carriers that are suspended in a culture fluid. Irrespective of the culture method, the suspending fluid is invariably directly sparged with air or other gas mixtures to supply the cells with oxygen. Although other aeration alternatives are available (145), direct sparging with a gas is likely to remain the dominant method of providing oxygen to animal cells (146). Both stirred tanks and airlift devices have been successfully employed for commercial processing of animal cells (147–149). Anchorage-dependent cells may also be cultured on surfaces of large static particles held

in packed beds (150,151), but this method is uncommon. Devices used in generation of implantable tissue typically grow normal cells supported on stationary surfaces or within a static matrix of gel or woven fabric (152). The supporting surface may be flat or variously shaped.

Cells in bioreactors are subject to two main kinds of fluid mechanical forces: (i) those due to turbulence within the liquid and (ii) forces associated with the gas–liquid interface. The latter category includes effects of bubble formation, rise, and rupture. In addition, in microcarrier culture, collisions among carriers and carrier–impeller (or carrier–wall) interactions may play a role. Furthermore, in tall bioreactors, cells may be subjected to substantial changes in hydrostatic pressure as they circulate with the fluid. Cells in tissue regeneration bioreactors experience the same kind of forces as occurring in flow past a flat plate, wall, or other submerged object. The specific considerations relevant to the various culture methodologies are treated in the following sections.

Resistance to shear stress is determined at least partly by the cytoskeletal structure of the cell. Cytoskeleton determines a cell's mechanical properties, its shape, and movements such as those that occur during phagocytosis. Cytoskeleton is made of protein filaments, mainly of actin. The filaments interact closely with the cell membrane by anchoring to specific membrane proteins. A cell exposed to mechanical forces undergoes cytoskeletal reorganization. Cytoskeleton-mediated stress signal transmission to intracellular organelles (Fig. 81.15) has been associated with various biochemical, physiological, and gene-level responses in vascular cells (4). Some cells are known to have surface stress receptors (e.g. Ca^{2+} ion channels) that have been implicated in biochemical responses (4,153,154) independent of cytoskeletal mediation (Fig. 81.15). Cytoskeletal properties are known to affect shear tolerance of hybridomas. Effects of turbulence on cytoskeleton and other biological responses have been treated by several authors (4,76,155). The work cited by Al-Rubeai *et al*. (156) suggests that inhibitors of actin polymerization decrease a cell's resistance to shear forces, while inducers of polymerization make the cells more robust. Thus, supplementing the culture medium with actin polymerization inducers may be one way of improving performance of bioreactor-cultured animal cells so long as the requisite production biochemistry is not adversely affected.

Plasma membrane fluidity (PMF)—a measure of the degree of packing of the membrane and its constituent's freedom to move about laterally through the bilayer membrane, to rotate about their major axes, and to oscillate in the plane of the membrane—is another factor that appears to influence shear susceptibility of cells (57). Increasing membrane fluidity correlates with increasing shear sensitivity (57). PMF increases with increasing temperature and can be manipulated in both directions using various additives. In studies with a freely suspended mouse–mouse hybridoma in a laminar shear stress Couette flow device, conditions that yielded higher membrane fluidity produced more fragile cells (57). For example, cells sheared at elevated temperatures showed greater loss of viability than unsheared controls at the same temperature (57). Effects of shearing of insect cells in a Couette flow device have been discussed by O'Connor and coworkers (157).

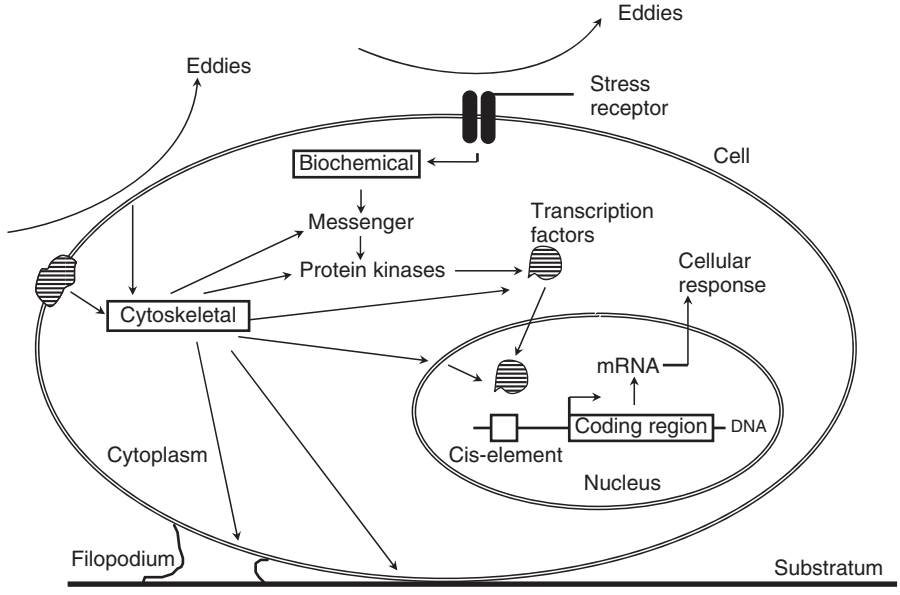

Figure 81.15. Stress signal transmission and transduction via cytoskeletal and biochemical routs in an anchored cell. Adapted from Ref. 4.

81.3.5.1 Shear Effects in Bubble-Free Environments

81.3.5.1.1 Suspended Cells. Freely suspended cells in bubble-free bioreactors are not damaged by mechanical agitation even at intensities much greater than the ones used in typical processing. Exceptions occur in extensional or elongational flow in certain high shear devices even when the flow is laminar. Extensional or elongational flow occurs whenever the cross-sectional area of the flow channel reduces, for example, at an orifice on the wall of a tank or at the entrance of a capillary connected to a larger reservoir. The fluid elements undergoing extensional flow stretch and thin. Suspended particles also experience elongational forces in the direction of flow and compression perpendicular to the flow streamlines. Drops subjected to extension flow can rupture. Similarly, extensional flow through orifices of high pressure homogenizers contributes to rupture of even the very robust microbial cells (1). Rupture of erythrocytes at entrances to capillaries is well known (158). Shear effects on suspended erythrocytes are discussed in detail in a later section. Shear susceptibility of suspended marine sponge cells has been discussed by García Camacho *et al*. (159). Shear-associated damage during cross-flow filtration (160) and centrifugation (161) of suspended mammalian cells have been discussed.

For a hybridoma line, Born *et al*. (162) reported that exposure to laminar shear stress (208 N/m^2) in unaerated flow in a cone-and-plate viscometer led to substantial loss in cell count and viability within 20 min. At a constant 180 s exposure, increasing shear stress over 100–350 N/m^2 linearly enhanced cell disruption, with >90% of the cells being destroyed at 350 N/m^2 stress level (162). Shear stress levels associated with bubble rupture at the surface of a bioreactor may range over 100–300 N/m^2 (17). These values are remarkably consistent with shear rates that damaged hybridomas in *unaerated* laminar flow experiments (162).

For a suspended mouse myeloma line in turbulent capillary flow, McQueen *et al*. (22) noted a threshold average wall shear stress value of 180 N/m^2, when lysis first commenced. Although the flow caused lysis, it had no effect on viability (22), suggesting that cells at various growth stages were equally affected. The sudden flow contraction at the entrance to the capillary may have contributed to cell lysis, but the residence time in the capillary also had an effect at otherwise constant average wall shear stress level. The rate of lysis was first-order in cell number. Above the threshold shear stress value, the specific lysis rate increased with increasing level of shear stress (22). The growth rate and the DNA synthesis rate of the cells exposed to the shearing environment were unaffected when the surviving cells were returned to a normal quiescent growth environment (22). In other studies cited by McQueen *et al*. (22), the shear stress threshold for damage has been reported as 0.87 N/m^2 for a mouse hybridoma and 1.5 N/m^2 for insect cells. Higher shear sensitivity of another mouse cell line relative to a human carcinoma has been reported (20).

For human cervical carcinoma HeLa S3 and mouse abdominal fibroblast L929, Augenstein *et al*. (20) observed lysis of suspended cells in turbulent flow through stainless steel capillaries. Cell death could be correlated with the average wall shear stress level or the power dissipation within the capillaries. The L929 line was more sensitive than the human cell. Control experiments showed that the positive displacement pumps used to circulate the cells through capillaries contributed little to cell lysis (20). Average wall shear stress levels of $0.1–2.0 \times 10^3$ N/m^2 were sufficient to induce cell inactivation for the two lines. According to Shiragami (21), the mean shear stress acting on cells suspended in capillary flow is 4/3 the shear stress at the capillary walls, so long as the ratio of the cell's diameter to that of the capillary is <0.08.

For a hybridoma examined by Shiragami (163), the specific rate of monoclonal antibody production in a surface-aerated spinner flask depended on the agitation speed. In a 250-mL spinner vessel an agitation rate of ~180 rpm gave the highest specific antibody production rate. The specific productivities were reduced at higher or lower values of agitation speed. The increased antibody production with increasing agitation was associated supposedly with enhanced secretion in a more turbulent environment (163). Oxygen transfer effects may have better explained the observations (see Chisti 145), but no data were reported on this aspect.

Damage to murine hybridomas was observed by Jan *et al*. (45) in stirred tanks equipped with marine impellers agitated at sufficiently high speeds that vortexing occurred and gas entrained into the medium. Even at these high speeds damage could be prevented by baffling the tank, which suppressed vortex formation. Usually though, vortexing is not a problem in large-scale cell culture. Unbaffled, marine impeller-stirred tanks were successfully used by Chisti (148) in industrial culture of several hybridoma lines. Effects of agitation on hybridoma culture in the absence of sparging or surface entrainment were further examined by Smith and Greenfield (164). Culture growth was unaffected by agitation intensity (100 or 600 rpm) in the RPMI medium supplemented with fetal bovine serum (FBS) (10% vol/vol). However, in PFHM II medium supplemented with Pluronic F68, FBS, or BSA, and agitated at 600 rpm (impeller tip speed = 1.6 m/s, power input = 1 kW/m^3), the results were different: the agitation intensity did not affect the exponential growth rate, but once growth had ceased, the decline phase was substantially faster than in control experiments (164).

A certain level of hydrodynamic shear is generally beneficial to culture processes, especially in intraparticle immobilized culture where mass transfer limitations can be severe. In producing engineered tissue of smooth muscle

cells/polymer matrices (biodegradable 2-mm diameter fibers of polyglycolic acid assembled into a nonwoven matrix), Kim *et al*. (151) noted that seeding of the matrix under agitation led to significantly higher intramatrix cell densities than when cell were seeded under static conditions. Moreover, the higher cell densities were attained more rapidly than the lower densities of static culture. In addition, the relative rates of synthesis of elastin and collagen were significantly greater in seeded matrices cultured with agitation than in ones grown statically (151). A lower possible supply of oxygen or other nutrients may have reduced the performance of static seeding methodology.

In view of the studies referenced earlier and similar others, sufficiently intense fluid mechanical forces other than those associated with aeration do affect cells. In culturing animal cells in stirred bioreactors, the average energy dissipation rate should not exceed about 50 W/m^3, even when low shear impellers are used.

81.3.5.1.2 Adherent Cells. Quite low shear stress levels—for example, between 0.25 and 0.6 N/m^2 in laminar flow (165)—can interfere with the process of cell attachment to surfaces; however, once the cells are attached and spread out, they may tolerate higher stresses. Laminar shear stress of the order of 0.5–10 N/m^2 may remove adherent cells from surfaces (166), but even lower values, for example, 0.1–1.0 N/m^2, are known to affect cellular morphology, permeability, and gene expression (166). Sublethal shear stress levels cause no obvious physical damage, but are known to produce various biochemical and physiological responses (4,153,154,167). In studies with rat aortic endothelial cells anchored on internal walls of glass capillaries, laminar shear stress was shown to affect the cytosolic pH because of preferential leakage of certain ions out of the cells into the buffer saline (154). This reversible permeability enhancement occurred even at stress levels as low as 0.05 N/m^2 applied over short durations ($\sim$2 min). Similar effects were noted with human aortic endothelial cells, but not with human skin fibroblasts or rat intestinal epithelial cells exposed to shear stress levels of up to 1.34 N/m^2 (154). With rat aortic cells, the flow-induced cytosolic acidification could be maintained for at least 30 min at 1.34 N/m^2 shear stress level, but the cytosolic pH returned to unstressed levels within about 15 min, when the sustained shear stress was $\leq$0.027 N/m^2 (154).

In studies with anchorage-dependent cells attached to the flat glass walls of a rectangular flow channel, Shiragami and Unno (168) observed increased activity of lactate dehydrogenase (LDH) in cells that had been exposed to a steady state shear stress of 0.5 N/m^2 for 12 h: the activity was fourfold greater relative to controls. The LDH activity correlated with the transmission of energy from the fluid to the attached cells (168).

In vivo hemodynamic forces have been implicated in various physiological and pathophysiological processes (4). Atherosclerotic lesions in humans tend to develop in zones of flow separation (4) such as regions of arterial branching and sharp curvature. Arteries adapt to chronic changes in blood flow, increasing in circumference under high flow and declining under reduced flow (4). Shear stress signals transmitted throughout the vascular cell via cytoskeletal and biochemical elements result in changes to structure, metabolism, and gene expression (4).

Moderate shear intensities can benefit virus production from some anchorage-dependent cells but not from others. For example, moderate shear levels improved the productivity of Japanese encephalitis virus (JEV) in microcarrier-supported Vero cells but not in similarly supported BHK-21 cells (169).

Shear effects need to be considered also in perfusion devices that retain cells over long periods in continuous culture (170). Shear effects on adhering erythrocytes and leukocytes are treated separately.

81.3.5.2 Erythrocytes and Leukocytes. Mammalian erythrocytes or red blood cells are among the best studied of animal cells. Properties of erythrocytes and other blood cells are relevant to various pathologies and biomedical processes. Erythrocytes and leukocytes being suspended cells *in vivo* likely experience the kind of stresses encountered in bioreactors and various other industrial processing devices; hence, these cells may provide a broad general insight into mechanical behavior of other cells of mammalian origin. The normal lifetime of a human erythrocyte in circulation is 121 days. The normal daily destruction rate is about 2×10^{11} cells (158). Some cells lyse during circulation; most are destroyed in the spleen. Aging cells resist deformation more than the younger ones. All cells unable to deform in the 3-μm openings of the splenic circulation are delayed and ultimately phagocytized (158).

Erythrocytes are highly deformable cells that orient in laminar flow so that the least possible surface area of the disc-shaped cell is perpendicular to the flow. Cytoplasm of erythrocytes is a viscous Newtonian fluid (171). The cell membrane behaves as an elastic solid: the cell deforms but almost instantly recovers its shape when the deforming force is removed. The membrane has little resistance to bending, but substantially resists increase in area (171). Erythrocytes suspended in turbulent isotonic saline (viscosity $\sim 1 \times 10^{-3}$ Pa s) have been observed to undergo elongation and deformation; however, the cell appears to be less vulnerable to turbulent shear stress than a cell at the same stress level in a viscous suspending medium (158). On the basis of measurements in turbulent jets, a critical lytic shear stress level of 4000 N/m^2 has been reported for very brief exposures ($\sim 10^{-5}$ s) (158). Measurements on erythrocytes of different mammals reveal that the critical

shear stress increases dramatically as the cell volume declines.

According to Blackshear and Blackshear (158), "Areal change occurs when the cell membrane is subjected to stress; hemolysis occurs when the area increases by approximately 6.4 percent." Hemolysis is associated at least in part with physical factors and flow, which produce the hemolysis threshold strain in membranes of erythrocytes (158). Once the threshold strain is exceeded, membrane pores open and the membrane eventually tears (158). A briefly (e.g. 10 ms) imposed uniaxial tension of 0.058 N/m is a sufficient criterion for lysis (158). When the cell is subjected to biaxial stress, a tension of about 0.029 N/m may produce lysis. In viscometric stressing for prescribed periods, time to lysis declines as the imposed stress is increased. However, it has been conclusively shown that shear stress alone is not a sufficient predictor of hemolysis rate or thresholds (158); cell shape and tumbling also play a role. Membrane shear appears to be far lower when the cells are suspended in higher viscosity media in viscometric studies.

Erythrocytes allowed to adhere to a glass surface and then subjected to a fluid shear commence movement when the fluid shear force exceeds about 10^{-11} N (171). During this process the cell gradually moves downstream, but the membrane may remain attached to the surface (171). The membrane can be deformed permanently when the deforming force persists for more than a few minutes (171). Shear elasticities of nonnucleated mammalian red cells are generally similar, but elasticities are about an order of magnitude greater for cells of nucleated species. Small amounts of thiol reagents are known to decrease the elongation of human red cells suspended in a shear field (171), presumably by producing some sort of cross-linking. Potentially, this methodology may improve survival of any fragile cell with significant amounts of cross-linkable protein in the membrane. Other additives may render the cell more susceptible to shear damage. Certain chemical lysins and some antigen–antibody reactions cause perforation of cell membrane and leakage of intracellular material (158). Cholesterol enrichment or depletion of the human erythrocyte membrane does not affect its viscosity.

Hemolysis of red cells is known to occur intravascularly *in vivo* as well as in various *in vitro* flow systems (158). A number of studies have correlated hemolysis to flow in pumps, valves, heart–lung machines, blood dialyzers, and transfusion filters. In flow through tubes, wall roughness of the scale of erythrocyte correlates with hemolysis (158). Bubbles trapped in surface imperfections appear to aid lysis. In flow through tubes, hemolysis correlates with the shear rate and the surface-to-volume ratio (158). This type of lysis occurs at shear stress thresholds lower than the ones required to produce lysis in a fluid shear field. Wall contact-associated lysis has been observed to depend on the chemical nature of the wall material. Lysis may decline with time as surfaces become passivated by prolonged contact with plasma proteins (158).

In capillaries of ~1 mm diameter, an upper limit on the mean tube velocity of 6 m/s has been suggested for capillaries with sharp-edged entrances and blood with a viscosity of 4×10^{-3} Pa s (158). This corresponds to a Reynolds number of 1500 inside the capillary and an average wall shear rate of about 4800 s^{-1}. Velocities as high as 17 m/s may be employed inside capillaries with carefully flared entrances (158). As with other animal cells, erythrocytes subjected to bubbling are susceptible to bubble rupture–associated damage (59). Agitation in the absence of gas sparging can damage erythrocytes. In surface-aerated shake flasks, increasing shaker platform speed over 100–400 rpm increased the specific cell lysis rate (Fig. 81.16). The slight decline in lysis rate at 100 rpm (Fig. 81.16) was associated with improved surface aeration relative to static flask. Because erythrocytes do not multiply *in vitro*, the effects of cell damaging forces are not masked by growth-associated adaptation, changes in cell size, and stages of growth; hence, suitably chosen erythrocytes provide a well-defined cell population for comparative assessment of the damaging potential of various hydrodynamic environments (59).

In comparison with erythrocytes, the cytoplasm of leukocytes has markedly different rheological properties (172), but the properties of its membrane are similar to those of the red cells. Leukocytes adhering to vascular endothelium detach when the shear stress is between 26.5 and 106.0 N/m^2 (172). According to work cited by Prokop and Bajpai (76), a shear stress level of 60 N/m^2 applied over 10 min should lyse about a quarter of a leukocyte population. In another study, sublethal shear stresses of 10 and 20 N/m^2 applied over 10 min in a Couette viscometer affected the biochemical response of human T cells relative to unsheared controls (153). It seems, therefore, that cells

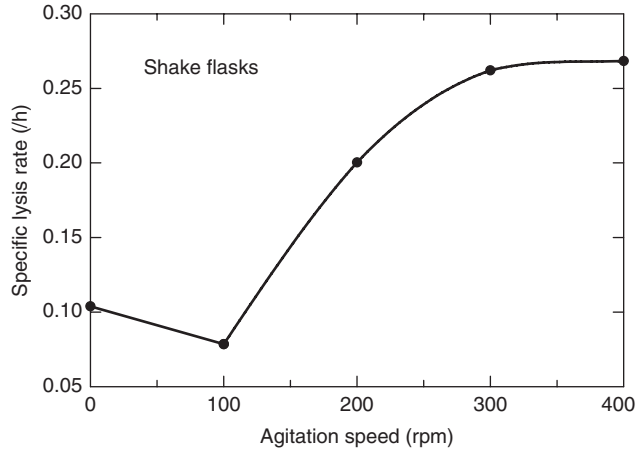

Figure 81.16. Effect of shaker platform agitation speed on specific lysis rate of suspended porcine erythrocytes in surface-aerated shake flasks. *Source:* Ref. 59.

in *in vivo* circulation are apparently more shear resistant than ones studied *in vitro*.

81.3.5.3 Microcarrier Culture. Both stirred tank and airlift bioreactors (173) may be used for suspended microcarrier culture. Microcarrier-supported cells likely experience hydrodynamic forces of greater magnitude than do freely suspended cells. This is because in highly agitated or aerated systems, the length scale of fluid eddies can be of the same order as the dimensions of microcarriers, resulting in high local relative velocities between the solid and the liquid phases (19,148,174). Furthermore, the carriers have greater inertia than free cells; hence, collisions among microcarriers, and between the impeller and microcarriers likely damage attached cells. Similarly, the fluid eddy impact and shear stress forces on a high inertia particle are greater than on free cells.

Resistance of a cell to rupture by impact, that is, burst resistance, is a possible measure of the cell's survivability in culture environment. Measurements of burst force are potentially useful also for comparative assessment of cell strength and in establishing culture conditions that give rise to more robust cells. It may eventually be possible to correlate the sensitivity to shear of a cell to its resistance to mechanical rupture (175). Burst strength may be directly relevant in microcarrier culture where impact-associated damage is likely; however, in view of the cytoskeleton-mediated pressure signal transmission to internal parts of a cell, a more likely scenario is that the force required to cause impact-associated damage is far lower than the rupture threshold. These issues notwithstanding, resistance to rupture of a mouse hybridoma grown in continuous serum-containing culture has been measured by squeezing single cells between flat surfaces of micromanipulator arms (176). The bursting strength increased with cell size (177). The bursting force correlated with the initial cell diameter as follows:

$$S = 0.2d_c - 0.1 \times 10^{-6} \tag{81.42}$$

where the intercept was not significantly different from zero (176). The cell diameter ranged over $\sim(10-17) \times 10^{-6}$ m. Other similar data (177) have been correlated (175) as follows:

$$S = 0.27d_c - 0.86 \times 10^{-6} \tag{81.43}$$

where the burst strength S is in newtons and the hybridoma cell diameter d_c is in micrometers. The calculated bursting tension had a mean value of $(1.8 \pm 0.5) \times 10^{-3}$ N/m, which was essentially independent of cell size (176). Because the bursting tension was size independent, the bursting pressure fell with increasing cell diameter. At $(0.8 \pm 0.3) \times 10^{-3}$ N/m, the calculated mean compressibility modulus of the cells was roughly independent of cell diameter (176).

Sinskey *et al*. (178) advanced the concept of "integrated shear factor" (ISF)—a measure of the strength of the shear field between the impeller and the spinner vessel walls—to correlate shear damage to mammalian cells. The ISF was defined as

$$ISF = \frac{2\pi N d_i}{d_T - d_i} \tag{81.44}$$

or effectively the laminar shear rate between the impeller tip and the walls. For a range of stirred vessels (0.25–2.0 L, $0.032 \leq d_i$ (m) ≤ 0.085), cell damage occurred once the *ISF* value exceeded about 18 s^{-1}, during culture of microcarrier-supported human fibroblasts (179). Damage could also be correlated with the impeller tip speed, but unlike the ISF, the damaging value of the tip speed depended on the size of the culture vessel (179).

Relying on earlier work of Nagata, Croughan *et al*. (179) arrived at the following expression for a time-averaged shear rate

$$\gamma_{av\,T} = \frac{112.8 r_i^{1.8} \left(r_T^{0.2} - r_i^{0.2}\right) (r_c/r_i)^{1.8}}{r_T^2 - r_i^2} \tag{81.45}$$

where r_i and r_T are the impeller and the tank radii, respectively. The radius r_c of the formed vortex zone would need to be estimated using Nagata's expression:

$$\frac{r_c}{r_i} = \frac{Re_i}{1000 + 1.6Re_i} \tag{81.46}$$

The impeller Reynolds number in Equation 81.46 is calculated as follows,

$$Re_i = \frac{N d_i^2 \rho_L}{\mu_L} \tag{81.47}$$

Equation 81.45 was developed for unbaffled stirred tanks operated in the turbulent regime (179). For human fibroblasts on microcarriers in various stirred vessels, cell damage occurred when the time-averaged shear rate exceeded about 2.5 s^{-1} (179). For chicken embryo fibroblasts, also on microcarriers, the damage threshold was 6 s^{-1} time-averaged shear rate (179). Cell damage correlated also with the Kolmogoroff eddy length scale (ℓ); for human fibroblasts the cell damage occurred when the length scale declined to approximately below 125 μm, whereas for the chicken embryo cells damage was observed when the ℓ value declined to below 100 μm (179).

Analyzing data from several sources, Croughan *et al*. (179) further showed that the specific death rate correlated with the average energy dissipation rate per unit mass;

thus,

$$k_d \propto E^m \tag{81.48}$$

where m was 0.72, 0.76, and 0.82, respectively, for microcarrier-supported Vero cells, similarly supported human fibroblasts, and a freely suspended protozoan. For attaining a more homogeneous shear field in stirred culture vessels, that is, for the minimum value of the maximum-to-average shear rate ratio, Croughan *et al*. (179) noted an optimal vessel geometry corresponding to $r_i/r_T = 0.74$.

Damage to microcarrier-supported Chinese hamster ovary cells during an abrupt contraction in laminar flow began to be detected at the energy dissipation value of 10^4 cm^2/s^3 (180). This value of energy dissipation is orders of magnitude lower than the values reported to cause damage to suspended animals cells (180).

In microcarrier culture, collisions between microcarriers and interactions between carriers and internals of a reactor are other possible causes of cell damage, particularly in stirred bioreactors (19,181,182). Cherry and Papoutsakis (174,181,182) advanced the concept of "severity of collision" to account for at least some of the damage to cells in suspended microcarrier culture in stirred vessels. Severity of collision combined collision frequency and energy of the impact. Two collision severities were defined: a "turbulent collision severity" (TCS) for turbulence-associated particle-to-particle impacts and an "impeller collision severity" (ICS) for particle-to-impeller collisions; thus,

$$TCS = \left(\frac{E\rho_L}{\mu_L}\right)^{3/2}\left(\frac{\pi^2\rho_S d_p^5 \varepsilon_S}{72}\right) \tag{81.49}$$

and

$$ICS = \frac{9\pi^4\rho_S n_B N^3 d_i^4 d_p^4}{512 V_L} \tag{81.50}$$

where E is the energy dissipation rate per unit liquid mass, ρ_S and d_p are the density and diameter of the microcarriers, ε_S is the volume fraction of the carriers, n_B is the number of impeller blades, N and d_i are the impeller rotational speed and diameter, and V_L is the volume of the liquid in the vessel. Improved cell growth was observed with smaller microcarriers as predicted by Equations 81.49 and 81.50. The specific cell death rate increased with increasing values of TCS and ICS (181,182); however, the influence of hydrodynamic forces on culture performance correlated also in terms of the ratio of Kolmogoroff eddy scale to bead diameter: the specific death rate declined as ℓ/d_p increased. As culture viscosity was raised, damage to cells declined in conformance with Equation 81.51 and in agreement with interpretations based on the ℓ/d_p ratio (182).

Unlike in stirred tanks, animal cell microcarriers suspended in airlift bioreactors under typical operating conditions do not significantly interact with each other or with the walls of the vessel (183); instead, the microcarrier particles follow the laminar streamlines of the fluid (183). Consequently, in airlift reactors at least, the effects of particle–particle or particle–wall collisions on monolayers of cells may be disregarded. Observations of Ganzeveld *et al*. (183) spanned microcarrier loadings of up to 30 kg/m^3, with carriers of 150–300 μm diameter, and 1030–1050 kg/m^3 density. The observations covered a power input value of up to 33 W/m^3, which is about the upper limit for cell culture in pneumatically agitated bioreactors. These results applied to a split-cylinder airlift bioreactor with an aspect ratio of 7.6, which would not normally be exceeded in large-scale cell culture systems. As an additional design constraint, the Reynolds number in the riser and the downcomer should not exceed about 3000, or the flow will be more chaotic (183).

Numerical analysis of forces exerted by laminar flow on anchorage-dependent cells attached to flat surfaces suggests that shear stress between 0.25 and 0.6 N/m^2 is sufficient to detach round cells, but much higher values are needed to dislodge spread out cells (165). These observations are relevant to microcarrier culture where, during inoculation, the round cells must first attach to microcarriers before spreading on the solid surface. During proliferation, bead-to-bead transfer of cells may also require a level of turbulence that is not so high as to hinder the reattachment process, yet not so low that bead-to-cell encounters are few.

Typically, the shear rate values in airlift bioreactors range over 250–4000 s^{-1} for operational conditions that are relevant to animal cell culture (18). These shear rates are substantially lower than $\sim 10^5$ s^{-1} that would be needed to damage cells if a 100-N/m^2 shear stress value (17,162) is taken as the threshold of mechanical damage. However, based on the shear stress data of Olivier and Truskey (165), during the process of attachment of cells to microcarriers, shear rate levels of 250–600 s^{-1} may well be detrimental. Thus, during initial attachment of cells, the reactor would need to be operated at reduced aeration rates—a practice that is well established through empirical experience, but previously explained only intuitively (18).

Under conditions typical of microcarrier culture in airlift bioreactors, the specific energy dissipation rates are different in different zones of the vessel. The specific energy dissipation rates increase in the order: downcomer < riser < bottom, for any fixed value of the aeration rate (18). The dissipation rates in all zones decline with increasing loading of microcarriers; however, the prevailing shear rates are not particularly sensitive to the density or the diameter of microcarriers within the ranges that are relevant to anchorage-dependent cell culture.

In one case, typical shear rates ranged over 250–4000 s^{-1} in microcarrier-containing systems, but much higher values, up to 12,000 s^{-1} could occur in solids-free media (18). These values compare favorably with shear rates of $\sim 10^5$ s^{-1} that have been reported as the threshold of damage to cells. Cells in airlift bioreactors would experience a substantial increase in the riser shear rate only when the fluid eddy length-to-microcarrier diameter ratio declines to ~1 (18).

Effects of shear stress on adherent cells are further discussed by Kretzmer (184). Effects of mixing intensity on cell seeding and proliferation in three-dimensional fibrous matrices have been discussed (185). Many adherent cells *in vivo* are known to be affected by shear stress (186).

81.3.5.4 Hydrostatic Pressure. As the scale of operation increases, suspended animal cells will inevitably experience substantial hydrostatic pressure changes as they move with fluid elements in a large bioreactor. At least for hybridomas, artificially imposed pressure cycling of up to 1.2 atm (18 psig) has shown no harmful effect (149). This level of pressure fluctuation will be encountered in bioreactors that are about 12 m tall; hence, for a 2:1 aspect ratio, an animal cell culture vessel could be scaled up to about 340 m^3. If, as recommended for airlift and bubble column bioreactors (24,25), an aspect ratio of 5:1 is employed, a maximum vessel volume of about 50 m^3 should be feasible. Suspension cell culture vessels in current commercial use do not generally exceed 10 m^3, or about 20% of the feasible volume based on hydrostatic pressure considerations.

81.3.5.5 Bubble-Associated Damage. That sparging damaged cells has been known since the 1960s; however, the specific events responsible for the damage—whether bubble formation at the sparger, bubble detachment, rise through the fluid, or events at the disengagement surface—and the mechanism(s) of damage remained unclear until recently.

The growth rate, viability, and antibody productivity of a mouse hybridoma in a surface-aerated stirred vessel were not affected by the agitation rate, but damage occurred when gas was sparged through the culture (187). In surface-aerated operation, the average and the maximum shear stress values varied over the respective ranges of 0.001–0.4 N/m^2 and 0.06–6.4 N/m^2. Subsequent work showed that bubbles larger than 5 mm were significantly less damaging to cells than smaller bubbles (188). Furthermore, placing the sparger below the impeller enhanced cell damage presumably because the impeller-associated bubble breakup gave rise to the more damaging smaller bubbles (188).

Cell lines differ tremendously in sensitivity to aeration as was demonstrated by Handa *et al*. (189). At constant aeration rates in geometrically identical bubble columns, smaller diameter bubbles (0.2 mm diameter) were shown to be significantly more damaging to a hybridoma than larger bubbles (1.62 mm diameter). In industrial scale culture of several hybridomas, Chisti (148) preferred even larger bubbles (10–20 mm diameter) for aeration. Similarly, Tramper *et al*. (89) observed that smaller bubbles were more damaging to insect cells than larger ones. However, the effect of bubble size may not be prevalent across cell types. Thus, in another study, baby hamster kidney (BHK-21) cells were not sensitive to the size of gas bubbles (190). Over a superficial gas velocity range of (0.42-8.5) $\times$ 10^{-4} m/s, higher velocities led to faster decline in cell viability of a hybridoma (189), which is consistent with other similar observations (87).

In commercial stirred tank culture of several hybridoma lines at up to 0.3 m^3, Chisti (148) employed submerged aeration with bubbles of 0.01–0.02 m diameter. Because of high rise velocities and mobile interfaces, such bubbles did not carry many attached cells to the surface. In contrast, during aeration with sintered metal spargers that produced slower rising bubbles of ~0.002–0.003 m diameter, the cells were rapidly carried into a persistent foam layer at the top by a froth floatation mechanism (148). The foam produced by larger bubbles collapsed soon after the bubbles rose to the surface. The reactors employed were agitated by magnetically coupled agitators with support bearings submerged in the culture. Reactors with submerged mechanical seals were also used. No loss in culture performance occurred relative to roller bottles. The impeller tip speeds >1 m/s produced no ill effects. Under typical operating conditions, the length scale of the microeddies was about 130 μm, or about 10-fold greater than the dimensions of the cells (148).

On the basis of energetics of bubble-associated damage to freely suspended cells, Wang *et al*. (191) concluded that the principal determinants of cell damage were cell-bubble encounter rate, the rate of bubble breakup within the fluid, and the bursting rate at the surface. Cell death correlated linearly with specific gas–liquid interfacial area, with the proportionality constant being 0.0125 m/h for a murine hybridoma (191). For a bubble larger than about 7 mm, microeddies in the wake of the rising bubble are incapable of damaging freely suspended animal cells (192).

Using an elegant mechanistic analysis, Tramper *et al*. (88,89) related the first-order rate constant for cell death due to all causes to aeration rate in a bubble column; thus,

$$k_d = \frac{24 Q V_k}{\pi^2 d_B^3 d_T^2 h_L} \tag{81.51}$$

where k_d is the first-order death rate constant, Q is the volumetric aeration rate, h_L is the height of fluid, d_T is the column diameter, and V_k is a hypothetical killing volume associated with the bubbles. The latter is actually the total

volume of fluid associated mainly with the bubble wakes; the cells entrapped in the circulating wake are carried with the bubble to the surface where most of the damaging events take place. According to Equation 81.51, the specific cell death rate is proportional to the frequency of bubble generation or $6Q/\pi d_B^3$. Alternatively, because at hydrodynamic steady state the bubble generation frequency equals the frequency of rupture at the surface, the death rate may be interpreted as being dependent on the frequency of bubble rupture and the killing volume associated with the bubbles.

On the basis of Equation 81.51, the death rate constant should decline with increasing height of fluid as experimentally confirmed. For otherwise fixed conditions, increasing liquid height in bubble columns improved survival of insect cells (88,89), myelomas, and hybridomas (86,90,190), supporting the view that cell death occurred predominantly in the bubble disengagement zone at the surface (189,190). For a myeloma grown in serum-supplemented medium, the minimum culture height that provided a performance equivalent to that of surface-aerated flasks, was ~0.7 m, corresponding to a bubble column aspect ratio of ~14 (90). The 0.05 m diameter column was aerated through a sintered disc sparger (150–250 μm pore size). The aeration rate was 5 mL/min (90), corresponding to a specific power input of about 0.42 W/m^3.

If bubble rise were to predominantly contribute to cell death, then the specific cell death rate should be independent of the height of fluid (193). Because this is contrary to experimental observations, the rise events may be disregarded as principal contributors to cell damage (193). If gas entry at the sparger contributed predominantly to cell damage, then at a given gas flow rate in the reactor, decreasing the number of sparger holes should enhance the specific cell death rate constant (193). In bubble columns, Jöbses *et al*. (193) noted that increasing the sparger hole gas velocity over 0.6–2.5 m/s at a constant volumetric gas flow in the reactors had no effect on the first-order rate constant for cell death; hence, events at the sparger could be disregarded as contributing to cell damage. This process of elimination identified bubble breakup at the culture surface as the principal cause of damage to suspended cells in sparged bioreactors such as bubble columns (193). Equation 81.51 applies also to airlift devices (87), especially ones in which gas is not carried into the downcomer. Because most agitated tanks used in animal cell culture operate at quite low mechanical power input and the impeller does not usually serve as a bubble breaking device, Equation 81.51 should provide a lower limit on k_d also in such tanks.

Using a hybridoma culture van der Pol *et al*. (86) showed that the first-order death rate constant increased with increasing $1/d_T^2$ in bubble columns as expected from Equation 81.51. Equation 81.51 suggests that cell damage increases in direct proportion to the superficial gas velocity in the column, or in direct proportion to the specific power input. Note that increasing the liquid level at constant aeration rate in a column of fixed diameter decreases the specific power input (18,24,25). Equation 81.51 further suggests that for a given V_k, larger bubbles should be less damaging than smaller ones. This agrees with substantial empirical evidence (88,89,148,188,190,194).

That the death rate increases linearly with increasing aeration rate has been proved (88,89,194). Also, the killing volume V_k has been shown to be independent of the aeration rate and the height of fluid, so long as the bubble diameter is not affected (88,89). The killing volume apparently depends on bubble diameter, increasing with diameter but in such a way that the ratio V_k/d_B^3 declines as the bubble diameter increases. This has been confirmed by Wu and Goosen (194) using *Spodoptera frugiperda* insect cells in bubble columns that were sparged with bubbles of different mean diameters while maintaining a constant volumetric gas flow rate. Increasing bubble diameter reduced the specific death rate as shown in Fig. 81.17. In view of the numerous contrary observations, analyses suggesting lesser cell damage with smaller bubbles are clearly flawed.

The dimensionless specific killing volume, or $6V_k/\pi d_B^3$ in Equation 81.51, depends on the concentration of serum in the culture medium. Van der Pol *et al*. (86) showed that the dimensionless killing volume declined as the serum concentration was raised over the range 0–2.5% (vol/vol); the dimensionless killing volume in the absence of serum was ~2.7-fold compared to that at 2.5% serum in a hybridoma culture (86). This and other similar observations (86) at least partly explain the well-known protective effect of serum. Cell-protective effects of other proteins may be similarly explained. Serum-free media with 1 g protein/L—equivalent to supplementing the medium with 2% vol/vol serum—are commercially used in sparged airlift culture vessels (149).

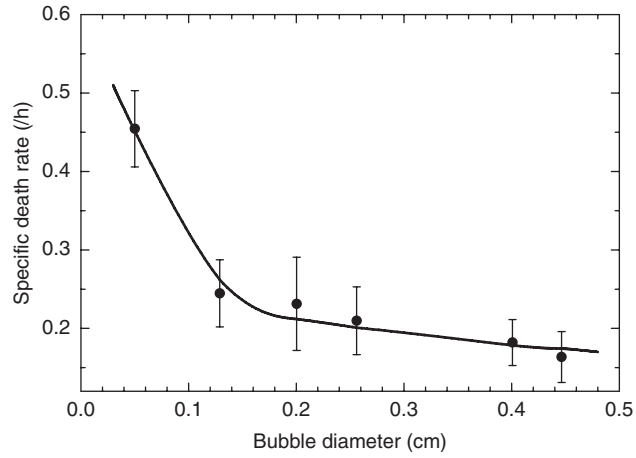

Figure 81.17. Effect of bubble diameter on the specific death rate of *S. frugiperda* insect cells in bubble columns aerated at a constant volumetric gas flow rate of 10 mL/min. Adapted from Ref. 194.

The reason for rupture of larger bubbles being less damaging to cells than breakup of smaller ones has become clear through analyses of mechanics of rupture (195,196). Numerical simulations and experimental observations of bubble rupture at air–water interface confirm that smaller bubbles rupture much more violently than larger ones (195,196). A bubble reaching the surface rises to different heights above the flat liquid surface before rupturing. For a bubble that is stationary at the surface, a part is always submerged below the flat surface of the liquid. The degree of submergence is generally greater for smaller bubbles.

During rupture, the liquid drains from the film between the raised liquid surface and the bubble (197,198). As the film thins, a hole develops in the center of the dome and the film rapidly retreats into the bulk liquid (Fig. 81.18). The rupture of the film and consequent elongational and accelerational flow have been postulated to damage cells in the film and those adhering to the bubble cavity (197). A cell on the surface of a rupturing film would apparently not experience any motion until struck by the toroidal ring of fluid at the receding edge of the film (197). The force experienced by the cell will depend on the film thickness at the instance of rupture (197). Rupture of thinner films is likely to be less damaging than when a thicker film breaks.

Once the bubble ruptures, fluid rapidly accelerates and moves down the interior walls of the bubble cavity (Fig. 81.18). The flow from around the walls impacts at a stagnation point located immediately below where the bubble had been (Fig. 81.18). The high pressure produced by the impacting streams forces a jet of fluid upward into the gas phase above the liquid surface (Fig. 81.18). A second opposing jet is forced into the fluid below the stagnation point. Intense accelerational flows around the bubble cavity and formation of liquid jets occur mostly during rupture of small bubbles. Bubbles larger than about 6 mm rupture much less violently.

According to Boulton-Stone and Blake (195), "...one of the most important factors determining the motion following film rupture, in terms of the energy released, is the height of the top of the bubble above the equilibrium free-surface" of the liquid. Bubbles rupturing from a lower position beneath the equilibrium surface of the liquid release more energy because of their higher internal pressure. The energy is released as high-speed liquid jets. Bubbles larger than about 6 mm bursting at the surface do not form significant jets (195), which is consistent with numerous observations dating from the 1950s and earlier. When a jet is produced, the speed of the jet declines as the size of the rupturing bubble increases: for example, for air bubbles rupturing on water, a maximum jet speed of 6.4 m/s has been calculated for rupture of a 1-mm bubble; for rupture of a 6-mm bubble, the maximum jet speed declines to 0.94 m/s (195). In addition to a liquid jet rising into the atmosphere above the liquid, a second liquid jet moves down into the fluid from the region which had been below the base of the bubble. The maximum pressure produced during bursting of bubbles of various sizes declines with increasing bubble diameter as illustrated in Fig. 81.19. The maximum energy dissipation rate occurs just beneath the bubble, immediately before the jet forms (195). The calculated maximum energy dissipation rates for the smallest bubbles are equivalent to a stress of about 10.4 N/m^2 (195). The maximum energy dissipation rates

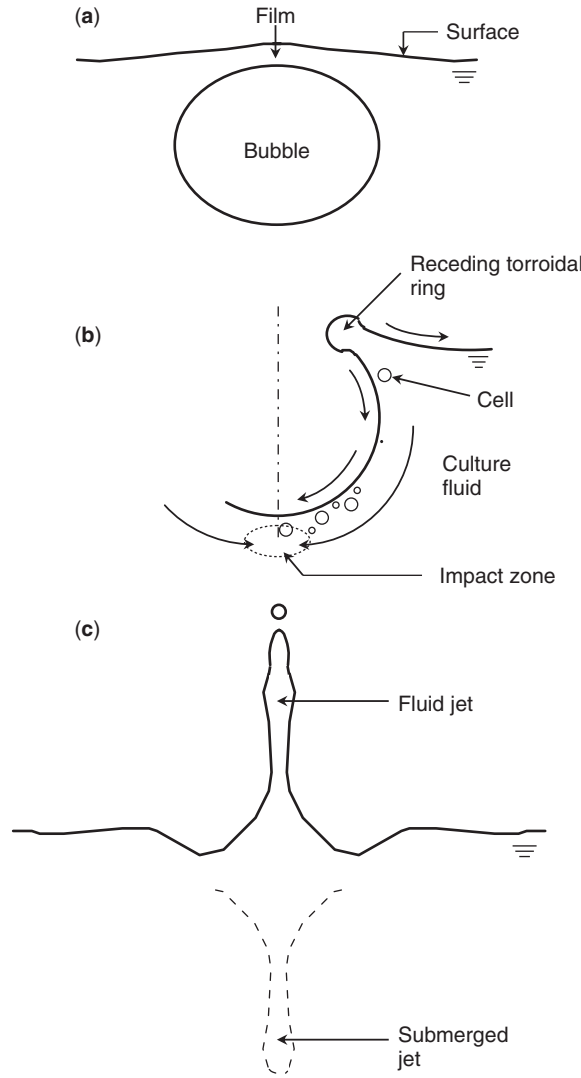

Figure 81.18. Events during the rupture of a bubble. (a) Bubble arrives at the surface and rises so that the film between the bubble and the surface thins. The height of the rise and the film thickness depend on the bubble size; smaller bubbles rupture deeper. (b) A hole develops in the film and the toroidal ring of the rupture vent expands and recedes into the bulk fluid. Streams of fluid draining into the bulk fluid impact beneath the bubble, generating intense local turbulence and creating a jet of fluid (c); a similar jet is produced underneath the liquid surface. When produced, the jet might rupture near the top to form droplets.

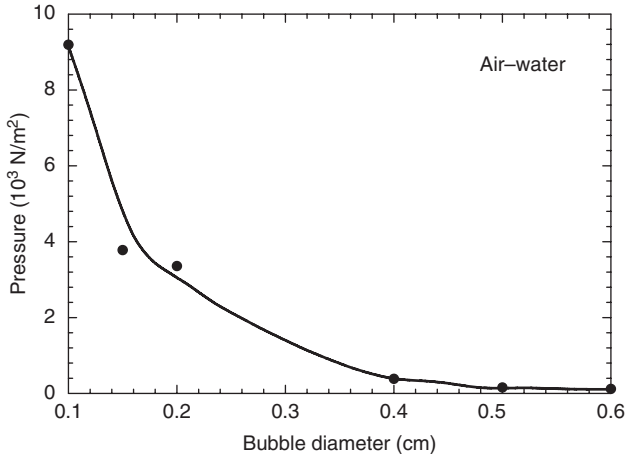

Figure 81.19. The maximum pressure produced during bursting of air bubbles of various sizes on the surface of water. Adapted from Ref. 195.

decline with increasing bubble diameter as depicted in Fig. 81.20.

Even a violent bubble rupture event would be inconsequential if there were no cells in the vicinity. Unfortunately, cells attach to rising bubbles and the fluid behind bubbles is especially rich in cells. That some animal cells will attach to rising bubbles has been shown with *Trichoplusia ni* and *S. frugiperda* insect cells (197,199). The cells adhered to rising microbubbles (diameter $\leq$ 3 mm) of the type used commonly in froth flotation. Hydrophobic interactions are apparently responsible for cell attachment—a mechanism observed also with ore particles attaching to bubbles during foam flotation. Although very small bubbles are generally not suited to aeration of cell cultures (148), larger bubbles also transport cells to the surface, but not predominantly as

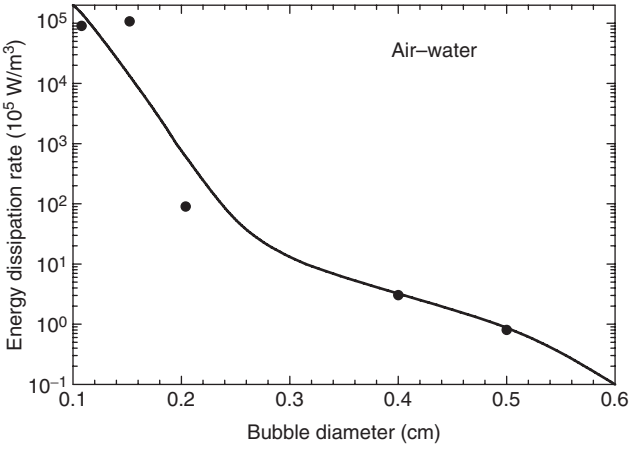

Figure 81.20. The maximum energy dissipation rates produced during bursting of air bubbles of various sizes on the surface of water. Adapted from Ref. 195.

adhering cells. Instead, the cells are trapped in the circulating wake carried behind large bubbles. The fluid associated with the wakes is known to be richer in particles than the bulk fluid.

More than 95% of the cells in the liquid ejected as a jet during rupture of bubbles have been shown to be nonviable even when the cells in the bulk culture contained fewer than 10% dead cells (196). Clearly, the cells carried in the bubble wake are destroyed by the rupture event. On the basis of simulations of rupture of bubbles with diameters of 0.77, 1.70, and 6.32 mm, Garcia-Briones *et al*. (196) calculated maximum energy dissipation rate values of 9.52×10^7, 1.66×10^7, and 9.40×10^4 W/m^3, respectively. Comparing these values with energy dissipation rates that have damaged cells in various unaerated flow devices (capillaries and viscometers), Garcia-Briones *et al*. (196) noted that values of the order of 5.81×10^2 W/m^3 did not damage the cells significantly, whereas appreciable damage occurred when the energy dissipation rate exceeded about 2.25×10^4 W/m^3. Clearly, therefore, a 6.32-mm bubble still has a significant potential to damage cells, and smaller bubble would produce instantaneous damage. For example, in gas-free capillary flow in experiments reported by Augenstein *et al*. (20), more than 80% of the cells died within 0.3 s of exposure to energy dissipation rates of about 4.80×10^7 W/m^3 (196). Interpreting data from several sources, Garcia-Briones *et al*. (196) further note that average energy dissipation rates of the order of 2990–29,000 W/m^3 have generally produced a significant decline in growth rate in impeller agitated bioreactors. These dissipation rates are average values; the cells probably experienced much higher local energy dissipation rates in the vicinity of the impellers.

If stable foam is not allowed to form, and relatively large bubbles (diameter $\approx$ 10–20 mm) are used for aeration so that the energy dissipated during rupture remains below the cell-damaging threshold, then the cells carried in the wake will not be damaged or removed into a foam layer. For bubbles of a given size, the volume of the circulating wake can be reduced by increasing the viscosity of the culture broth. Small increases will reduce the rise velocity of the bubbles and the circulation in the wakes will be slowed down. Consequently, slight enhancements in viscosity could reduce the transport of particles in the wake. This may indeed be one explanation of why viscosifying additives have been frequently observed to reduce cell damage. Also, for a given volumetric aeration rate, use of larger bubbles reduces bubbling frequency; hence, the frequency of bubble rupture is reduced.

On the basis of the studies reviewed, several important observations can be made regarding freely suspended animal cells in sparged and agitated bioreactors: (i) the aeration rate should be kept as low as possible; (ii) the mean bubble size should larger than 7 mm, preferably about 10–20 mm;

(iii) the location of the sparger should be such that the rising bubbles do not interact with any impellers; (iv) with small airlift and bubble column reactors the aspect ratio should be about 14; however, in larger columns where the sparged portion of the cross-section can be a small fraction of the total cross-sectional area, more realistic aspect ratios of about six or seven are satisfactory; (v) when an impeller is used, the average energy dissipation (input) rate should remain below about 1.0×10^3 W/m^3. Observations (i)–(iii) are consistent with industrial practice (148). The sole purpose of the impeller should be to suspend the cells and mix the fluid gently so that the oxygen transferred from the bubbles is distributed throughout the vessel. Consistent with this purpose, the impeller should be of a kind that does not produce excessively high local rates of energy dissipation. For example, relatively large axial flow hydrofoils are the preferred impellers (43,148). In addition, a suitably selected additive such as Pluronic F68 should be used whenever feasible.

81.3.5.6 Mitigation of Shear Damage. Various approaches have been used to reduce bubble rupture-associated damage to cells. Some common approaches are the use of cell protective additives as noted here; compartmentalization of the culture into cell-free and cell-containing zones with sparging confined to cell-free regions (150,151); use of bubble-free oxygenation through microporous or diffusion tubing made of silicone rubber or other polymers (145); use of liquid oxygen vectors such as perfluorocarbons (145); and surface aeration (145). Alternatives to bubbling are suited typically only to specific cases; direct sparging remains the predominant method of aeration of cell cultures and it is not likely to be displaced in the foreseeable future (146).

One adaptation of submerged aeration is the "bubble bed" bioreactor that can substantially reduce surface rupture of bubbles in short-term batch culture (200). The bubble bed device (Fig. 81.21) is similar to a concentric draft-tube airlift bioreactor, but a downward pumping axial flow impeller located in the draft-tube circulates the fluid. The downward liquid flow in the draft-tube is sufficiently fast that gas bubbles injected into the draft-tube cannot escape; hence, the bubbles do not rupture at the surface of the culture. Pure oxygen or oxygen-enriched gas is used to reduce the needed gas injection rate to very low values. The gas holdup in the downcomer increases during batch operation and a noncirculating bed of bubbles develops. The cross-sectional area of the draft-tube increases downward (Fig. 81.21) so that the superficial velocity of the liquid declines as it moves down; consequently, the downflowing liquid cannot drag the bubbles out of the draft-tube and into the bubble-free annular zone. According to Sucker *et al*. (200), the cell growth and antibody production in bubble bed devices is comparable to values

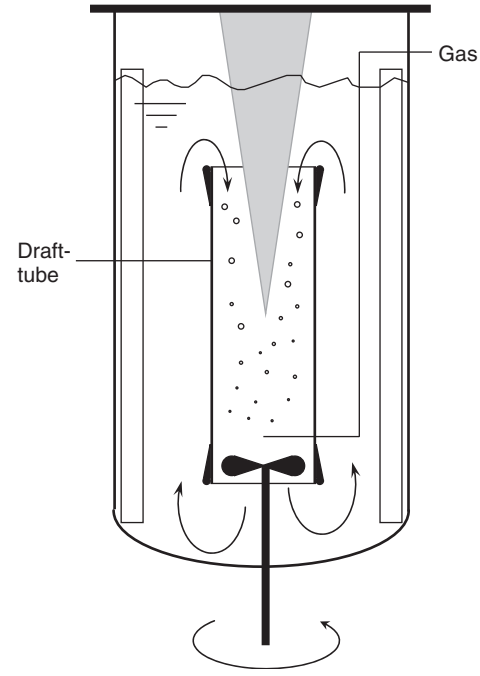

Figure 81.21. A bubble bed reactor.

obtained in surface-aerated spinner flasks even when the sparged culture in the bubble bed units is not supplemented with serum, Pluronic F68, or other protective additives.

81.3.5.6.1 Shear Protectants. Bubble-associated damage can be significantly reduced by adding shear protective substances to the culture medium. Many additives have been examined for shear protective function (201). Some of the protective additives are noted in Table 81.6. The protective effect depends on the properties of the specific additives, the concentration used, the type of cell, and the mechanism(s) of protection. Some common protective agents and their mechanisms of protection are discussed in the following text.

81.3.5.6.1.1 Serum. A concentration-dependent protective effect of fetal calf serum, horse serum, and others has been widely observed in aerated and bubble-free suspension cultures of many types of animal cells (57,86,87,92,190,201–203). Typically, protection increases

TABLE 81.6. Media Additives Associated with a Cell Protective Effect

Serum	Pluronics
Proteins (e.g. serum albumin)	Polyvinyl alcohols
Derivatized celluloses (e.g. methyl cellulose)	Polyvinyl pyrrolidone
Derivatized starches (e.g. hydroxyethyl starch)	Polyethylene glycols
Dextrans	

with increasing serum concentration up to about 10% (vol/vol) serum. In one study reduction in fetal calf serum level from 2.5% to 0% substantially increased the death rate constant of a hybridoma in aerated culture (86). Investigations revealed that serum had no long-term biological effect, but only a direct nonspecific physical protective effect (86). Thus, cells growing in low serum medium were immediately protected upon transfer to a medium with 2.5% serum. A physical protective effect of serum has been claimed to originate in its ability to reduce PMF (57,202). According to Martens *et al*. (87), serum has an immediate physical protective effect, and also a physiological protective effect that takes longer to become effective. The latter finding concurs with Michaels *et al*. (203). In bubble-free experiments in a Couette viscometer (shear rate = 5000 s^{-1}, shear stress = 5 N/m^2), prolonged exposure of cells to FBS reduced their shear sensitivity in laminar flow studies (203); however, shorter (30–120 min) exposure to FBS did not affect shear tolerance of cells. On the basis of these results, the protective effect of FBS was claimed to have both physical and biological (biochemical) origins (203).

The precise nature of the physical protective effect of serum is not clear. Supplementation with serum enhances the viscosity of the culture medium, but the effect is small (166,204). Nevertheless, Croughan *et al*. (92) and others (93,181) have associated the observed protection to the turbulence dampening effect of serum. In contrast, other evidence suggests a lack of relationship between the amount of protection afforded by the serum and enhancement of viscosity (205,206). In addition to dampening turbulence, the serum proteins may coat the cells so that the fluid eddies no longer penetrate to the vicinity of the cell membrane (92). In one study, increasing concentration of FBS over 0–10% (vol/vol) reduced PMF of a hybridoma line, making the cells more resistant to shear damage (57,202).

81.3.5.6.1.2 Pluronic® F68. Another well-known shear protectant is the nonionic surfactant polyol Pluronic® F68, a block copolymer of poly(oxyethylene) and poly(oxypropylene). Highly pure Pluronic F68 is added to cell culture media, typically at 0.5–3 kg/m^3 (166,189,190,193,201,203). The protective effect of the surfactant is concentration dependent, increasing with concentration, but leveling off at ~0.5 g/L (Fig. 81.22).

The protective effect of Pluronic F68 is commonly associated with its ability to suppress attachment of cells to bubbles (190): in presence of the surfactant fewer cells are carried to the surface where much of the cell damage occurs in aerated culture. However, evidence exists for other protective mechanisms. For example, a cell protective effect of Pluronic F68 has been observed even in unaerated culture (57,193). In one case, this effect was observed in a strongly agitated culture sample (193). Although no bubbles were present, a deep vortex was drawn into the fluid by the marine impeller used. Extensive cell damage occurred, but the damage was significantly reduced when the culture was supplemented with Pluronic F68. On the basis of these observations, Jöbses *et al*. (193) concluded that the protective effect of Pluronic F68 was due to its direct influence on cells and due to some effect of the surfactant on the gas–liquid interface. One possible explanation for the protection observed by Jöbses *et al*. (193) in the absence of the bubbles follows: the damage may have been occurring at the rapidly moving surface of the vortex (207) and supplementation of the culture with Pluronic F68 may have reduced surface adherent tendency of the cells; hence, fewer cells may have attached to the surface during its formation at the periphery of the vessel.

Using flow cytometry, Al-Rubeai *et al*. (156) showed that leakage of a positively charged dye, fluorescein diacetate, from murine hybridomas increased with rising intensity of agitation, hence suggesting a possible link between permeability of cell membrane and shear rate. However, because intense agitation was accompanied by entrainment of gas bubbles into the culture (156), the observed leakage could not be conclusively associated with fluid turbulence. The authors noted that for otherwise fixed agitation conditions, the leakage of the dye reduced when the culture medium was formulated with 1% Pluronic F68. The protective effect of the surfactant was apparently linked at least partly with its biochemical association with the cell membrane. The agitation- and vortex-associated hydrodynamic forces were reported to also affect the antigen receptors embedded in the membrane of the hybridoma (156). The number of active surface receptors declined with increasing intensity of agitation and the accompanying increase in the size of the vortex; however, the viability of the cells

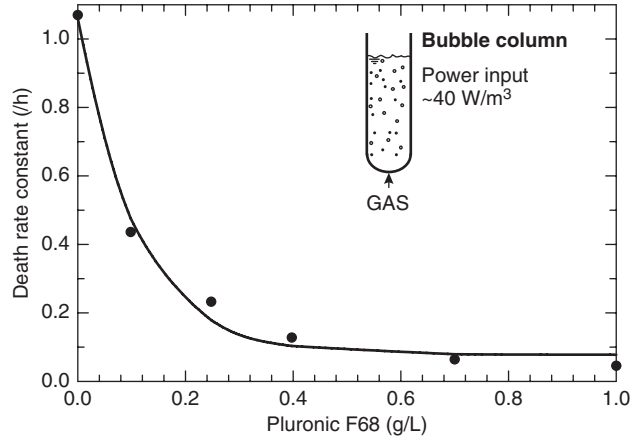

Figure 81.22. Cell protective effect of Pluronic F68 in a bubble column. The specific first-order cell death rate constant is plotted as a function of the concentration of Pluronic F68 in the medium. All data were obtained at a constant specific power input of ~40 W/m^3. Adapted from Ref. 193.

was unaffected. Pluronic F68 had a protective effect on the receptors.

Pluronic F68 is known to reduce the PMF of cells and this has been suggested as a possible mechanism of protection (57,202). Other additives that affect PMF also affect a cell's shear tolerance; for example, in one case, cholesterol enrichment of the culture medium reduced membrane fluidity and enhanced the shear resistance of hybridomas, whereas supplementing the culture with benzyl alcohol increased PMF and made cells more shear sensitive relative to controls (57,202).

Other protective mechanisms speculated for Pluronic F68 include its stabilizing action on the gas–liquid interface and consequent slower film drainage during bubble rupture (190), improved nutritional transport because of a reduced cell–fluid interfacial tension, and incorporation of the surfactant into the cell membrane accompanied with membrane-stabilization (208,209). Although the protective effect of Pluronic F68 is said to be solely due to physical factors (203), the surfactant is known to produce other physiological and biochemical effects in some cases at least. Growth suppressory and stimulatory effects of Pluronic F68 have been seen even in some static cultures. Such effects are sometimes associated with impurities in Pluronic F68 samples. Pluronic F68 affects permeability of some cells. Exposure of *S. cerevisiae* to 0.2% (wt/vol) for 30 min at 20°C made the cells more permeable and they became susceptible to otherwise nonlethal doses of certain antibiotics (210). The mean activity of alcohol dehydrogenase in permeablized cells was more than 3.5-fold of that in normal cells. Although Pluronic F68 could permeablize the yeast cells, it did not inhibit growth or affect cell viability relative to controls when added to culture media at up to 1% (wt/vol), which was the highest concentration tested (210).

Other data suggest that the cell-protective effect of Pluronic F68 may not be quite general (59). For porcine erythrocytes suspended in isotonic buffer, Zhang *et al*. (59) noted that addition of Pluronic F68 actually increased cell lysis in agitated environments relative to results in the surfactant-free medium. Whether Pluronic F68 incorporates into erythrocyte's membrane is not known; however, cholesterol enrichment or depletion of erythrocyte membrane is reported to not affect its viscosity and presumably, therefore, its fluidity. In addition to Pluronic F68, several other pluronics are known to have a shear protective capability. Shear tolerance of plant cells is improved in presence of Pluronic F68 (211).

81.3.5.6.1.3 Poly(ethylene glycol) (PEG). Poly(ethylene glycol) (PEG) supplementation of the medium has a protective effect on some cells but not on others. In one study (212) that employed different PEGs of molecular weights of 400–35,000 Da in the concentration range of 0–2 kg/m^3, the polymer had a protective effect in sparged cultures when the molecular weight and the concentration exceeded 1000 Da and 0.25 kg/m^3, respectively. The extent of protection afforded depended on the molecular weight and the concentration used. Under the best conditions, the PEG supplementation reduced the first-order cell death rate constant to 0.5% of the value in the PEG-free medium (212). The PEG additives affected the surface tension of the culture medium; however, in extreme cases the surface tension varied only over $\sim$(60-70) $\times$ 10^{-3} N/m (212). The pattern of variation (but not the magnitude) in surface tension with the addition of PEG was similar to the pattern of change in the death rate constant. This led the authors to suggest that the presence of PEG at the gas–liquid interface was somehow related to the protective mechanism.

Michaels *et al*. (203) showed that in sparged bioreactors supplementing the culture medium with Pluronic F68, FBS, or PEG (8000-Da molecular weight, 1 kg/m^3) protected cells irrespective of whether the CRL-8018 hybridomas were grown in the presence of the additive or the additive was added after the damaging levels of agitation were imposed.

81.3.6 Composite Particles and Cell Aggregates

81.3.6.1 Microbial Biofilms on Suspended Particles. Gas–liquid–solid three-phase suspension reactors are increasingly being used in wastewater treatment (24,213). The suspended solid phase (usually sand, glass beads, or carbon particles) supports a biofilm of waste-degrading microorganisms (214). The hydrodynamic environment of such systems must be tailored to control the biofilm thickness without dislodging it altogether (24). Biofilm slurry reactors are conceptually similar to microcarrier-supported suspension culture of animal cells, but there the similarity ends. Unlike animal cell microcarrier suspensions, the biofilm reactors are much more turbulent, the solids loading is generally higher, the density difference between the solid and the liquid phase is much greater, and the biofilm is typically four or five times thicker than the monolayer of cells on microcarriers.

In studies of degradation of naphthalene-2-sulfonate by *Pseudomonads* immobilized as biofilms on sand particles suspended in an external-loop airlift bioreactor, Wagner and Hempel (215) noted that at solids loadings of 20–30 kg/m^3, only about 15–20% of the particles were covered with biofilm, but high solid loadings were necessary to control the film thickness at 75 $\pm$ 10 μm by providing a high attrition environment (215). These observations were for particles about 200 μm in diameter, covered with $\sim$75-μm thick biofilm, suspended in the reactor under fairly turbulent conditions (230–440 W/m^3

specific power inputs). Even when oxygen limitation is not an issue, diffusion of other substrates limits the useful thickness of microbial biofilm to less than 400 μm in most wastewater treatment operations (213).

The development of microbial biofilms on static surfaces and carriers suspended in airlift bioreactors has been investigated quite extensively (6,7,214,216–222). In one case, 21 carriers were tested at a constant carrier loading of 125 kg/m^3 (214). The superficial gas velocity was constant at 0.038 m/s. The hydraulic retention time of wastewater was 1 or 2 h. On the basis of the tests, carrier diameter and surface roughness were the major factors that influenced biofilm formation (214). Smaller particles, 0.1–0.3 mm in diameter, tended to show better biofilm development. This was said to be due to more frequent collisions among larger particles causing biofilm detachment (214); however, with larger particles, a greater *severity* of collisions would have been a better explanation (24). For equal mass loadings of solids in two systems, the system with larger particles should have fewer particles per unit volume and, therefore, a lower frequency of particle–particle collisions. Cell disruption experiments in agitated slurries of glass beads confirm this (11). The explanation for the impact of surface roughness on biofilm formation lies in the fact that a rough surface provided many relatively protected, low shear sites where microbial colonies could take hold in the process of gradually spreading over the whole surface. On the basis of the criteria of surface roughness, particle size, cost, and the requirement of a high density carrier for ease of separation, basalt ($\rho_S = 2900$ kg/m^3) was the best carrier (214).

Irrespective of carrier type, biofilm formation is favored at relatively high dilution rates when any detached cells are rapidly washed out (214,218). Tijhuis *et al*. (218) have shown that during start-up at high dilution rates, the concentration of bare carriers declines as an increasing number are covered with the biofilm. The total amount of the biomass in the reactor increases, but the amount per carrier remains constant until most of the carriers are covered. With few bare carriers remaining, the extent of abrasive loss of film declines and the film thickness begins to increase until a stable thickness is reached (218). These observations suggest that varying the reactor operation to suit different stages of film development may be worthwhile (24).

In other similar work, detachment of biomass from nongrowing biofilms supported on carriers suspended in four configurations of draft-tube sparged internal-loop airlift reactors was examined (221). The superficial aeration velocity in the riser varied over the approximate range 0.03–0.09 m/s. The detachment of biomass from biofilm-covered carriers in presence of bare solids was dominated by collisions between bare carriers and the covered particles (221,222). The concentration of bare solids and the particle roughness strongly influenced the detachment rate (221). For otherwise identical conditions, biofilm detachment due to bare carriers increased in the order: glass, sand, basalt. The glass particles were the most round and smooth; the basalt carriers were the roughest. While biofilms develop more easily on rough surfaces (214), once developed, the film is readily damaged by biofilm-free rough carriers. Gjaltema *et al*. (221) observed that a "change in flow regime from bubbling to slug flow considerably increased the detachment rate." This change apparently occurred at a U_{Gr}-value of ~0.06 m/s. The "slug flow" regime noted by Gjaltema *et al*. (221) was more likely the highly chaotic churn turbulent regime in which particle-to-particle collisions are more frequent and severe than in the bubble flow regime. The bottom clearance of the draft-tube had no effect on detachment rate (221), but only a small range of the A_d/A_b ratios was investigated. The volume fraction of carriers was 3.3–3.8% and other properties were basalt, $d_p = 0.32$ mm, $\rho_S = 3010$ kg/m^3; sand, $d_p = 0.31$ mm, $\rho_S = 2606$ kg/m^3; and glass, $d_p = 0.28$ mm, $\rho_S = 2887$ kg/m^3 (221). Another similar study focused on the effects of particle shape, structure, and concentration on biofilm detachment (222).

Strategies for development of biofilms with nitrification activity on carriers suspended in draft-tube sparged internal-loop airlift reactors were investigated by Tijhuis *et al*. (220) and van Benthum *et al*. (223). The development of the nitrifying films was similar to what had been reported for heterotrophic biofilms (216–219); however, the nitrifying films were more robust (223). This suggests that biofilms formed by different microorganisms can have markedly different physical properties and strength of attachment to substrate (24); hence, the operating regime of the reactor and, in extreme cases, the design peculiarities are likely to be affected.

In further studies of the dynamics of biofilm detachment from carriers suspended in airlift reactors, Tijhuis *et al*. (217,218) noted that the common assumptions of uniform growth and detachment of biomass over the surface of the film under fixed hydrodynamic conditions were inconsistent with observations. Instead, nonuniform local detachment of biofilm with formation of cracks and fissures on its surface and rapid filling of the spaces formed with new growing biomass was proposed as a more realistic picture of film dynamics (217).

During development of mixed bacterial biofilm on static glass surface in a rectangular turbulent flow cell, Stoodley *et al*. (7) noted that parts of the biofilm sloughed off at a wall shear stress level of 1.32 N/m^2. In the region of detachment, pieces of the biofilm were still attached to the surface, suggesting that the glass-to-biofilm bond was stronger than the biofilm structure (7). Relative to the clean flow cell, the pressure drop through the channel was higher in presence of the biofilm (7) presumably because a patchy development of the film increased the effective surface roughness.

81.3.6.2 Flocs and Agglomerates. Microbial flocs are encountered in several commercially relevant processes, especially in wastewater treatment and beer fermentation with autoflocculating yeasts. Similarly, agglomerates of protein precipitates form during certain recovery operations. The size of flocs and agglomerates often needs to be preserved or increased during processing. The stable size of aggregates and flocs and whether the flocculated mass further increases in size or breaks up depend on the level of turbulence in the suspending fluid. Turbulent stress levels below about 0.75 N/m^2 are generally too mild to break aggregates (224). Physical disruption of aggregates commences at stress levels of ~2.6 N/m^2 and especially when the stress level exceeds about 5 N/m^2 (224). In a turbulent field, aggregates may deform or breakup because of the influence of instantaneous velocity differences acting on different parts of the floc (225). Also, turbulent drag forces originating from the local motion of the fluid relative to the aggregate may contribute to fragmentation (224). The shear force across the aggregate due to instantaneous velocity difference is related to the energy dissipation rate in the fluid and the size of the aggregate (224); thus,

$$F_s = \frac{\pi}{4}(\rho_L \mu_L E)^{1/2} d_F^2 \tag{81.52}$$

The dynamic pressure fluctuations acting on opposite sides of the floc create a normal stress. Assuming that the eddy size is in the Kolmogoroff microscale range and that the particle dimensions are similar to those of the eddies, the normal force can be expressed as follows (224):

$$F_n \propto \left(\frac{E}{\mu_L}\right) \rho_L^2 d_F^2 \tag{81.53}$$

The turbulent drag force acting on an aggregate may be calculated using the following expression (224):

$$F_D \propto \frac{C_D}{2}\left(\frac{d_F}{2}\right)^3 (\Delta u d_F)^2 \rho_L \tag{81.54}$$

where Δu is the difference in velocities of the particle and the fluid, and C_D is the drag coefficient. For low density particles in the Stokes regime ($Re < 1$), the drag coefficient equals $24/Re$, where Re is the Reynolds number, or $(\rho_L \Delta u d_F)/\mu_L$. Reynolds shear stresses—that is, turbulent stresses associated with the fluctuating component of the mean velocity—may be calculated using the equation (226):

$$\tau = 0.37 \rho_L \left(\frac{E \rho_L}{\mu_L}\right) d_p^2 \tag{81.55}$$

which applies to stresses around a spherical particle. Reynolds stresses are independent of viscosity.

The maximum stable size of the aggregate in a turbulent field can be established by a force balance on a particle: at stable size the instantaneous turbulence force accelerating the particle just equals its mechanical strength (224). In the inertial subrange of turbulence when the eddy size is greater than the Kolmogoroff scale (ℓ),

$$d_{F\,max} \propto \left(\frac{\rho_L \sigma_M}{\mu_L}\right)^{1/3} E^{-1} \tag{81.56}$$

whereas in the viscous subrange of turbulence when the eddy size is $\leq \ell$, we have

$$d_{F\,max} \propto \left(\frac{\sigma_M \mu_L}{\rho_L^2 E}\right)^{1/2} \tag{81.57}$$

where σ_M is the mechanical strength of the aggregate. In practice, the maximum stable floc size has correlated with the energy dissipation per unit mass of fluid as follows:

$$d_{F\,max} \propto \Gamma E^{-m} \tag{81.58}$$

where the coefficient Γ depends on the nature of the particle and m is usually between 0.2 and 0.4 (227).

In stirred tanks, the maximum floc size for particles of uniform composition has been theoretically and experimentally correlated with the rotational speed of the impeller (225); thus,

$$d_{F\,max} \propto N^{-1.5} \tag{81.59}$$

which applies to particles smaller than the microscale of turbulence. The dependence shown in Equation 81.59 can be expressed in terms of the energy dissipation per unit mass; hence,

$$d_{F\,max} \propto E^{-0.5} \tag{81.60}$$

Expression (81.60) is consistent with that reported by Thomas (225), but the exponent on E is somewhat stronger than the values noted by Gregory (227) (see Eq. 81.58). In precipitation vessels, shear rate values of ~80 s^{-1} appear to be a damaging threshold for soy protein precipitate particles of 20–30 μm initial size (5). Particles exposed to approximate shear rates of ≥80 s^{-1} over 10–12 min would be reduced to 5–8 μm. The shear rate numbers were calculated from the specific energy dissipation rates in the vessels, as follows:

$$\gamma = \left(\frac{\rho_L E}{\mu_L}\right)^{0.5} \tag{81.61}$$

Protein precipitates are easily damaged by pumping. Moyno screw pumps, centrifugal pumps, and gear pumps all damage precipitates to similar levels (5). Peristaltic pumps are

apparently the only suitable ones. Shear-induced break up of protein precipitates during acceleration in a centrifugal field can greatly (>10-fold) reduce the recovery capacity of centrifugal separators (228). In the entrance region of a disc stack centrifuge, the shear rate can approach 10^5–10^6 s^{-1} (229). Effects of agitation during precipitation and processing of α-lactalbumin enriched whey protein precipitates have been discussed by Byrne and Fitzpatrick (230).

Size, morphology, and density of mycelial pellets depend on agitation intensity (231–235). Fragmentation of mycelial pellets of the molds *Lentinus edodes* and *A. niger* in a standard Rushton turbine-stirred tank was examined by Taguchi *et al*. (236). Two types of pellet fragmentation patterns were noted: (i) decrease in diameter by erosion of surface; and (ii) direct rupture of the spherical pellet. The rates of these processes were expressed as

$$-\frac{\mathrm{d}d_\mathrm{p}}{\mathrm{d}t} = k_\mathrm{j}\,(N d_\mathrm{i})^{5.5}\, d_\mathrm{p}^{5.7} \qquad (81.62)$$

for pellet surface erosion, and

$$-\frac{\mathrm{d}N_\mathrm{p}}{\mathrm{d}t} = k' N_\mathrm{p} = \alpha \left(d_\mathrm{p}^{3.2} N^{6.65} d_\mathrm{i}^{8.72}\right)^{5.5} N_\mathrm{p} \qquad (81.63)$$

for rupture of the particle. In Equations 81.62 and 81.63, d_p is the pellet diameter at time t, N is the rotational speed of the impeller, d_i is the impeller diameter, N_p is the concentration of unbroken pellets at time t, and k_j, k', and α are constants. The rates of pellet erosion and rupture depend strongly on the agitation intensity–associated factors (i.e. on N and d_i) and on the dimensions of the pellet. As shown in Fig. 81.23, the pellet diameter declined with increasing agitation speed and with increasing elapsed time at a given speed. The decline slowed as the pellet attained a stable size with respect to given conditions of agitation (Fig. 81.23).

In submerged stirred tank culture of the filamentous fungus *Aspergillus awamori*, Cui *et al*. (237) correlated the pellet size with the specific energy dissipation rate; thus,

$$d_\mathrm{p} \propto E^{-0.16} \qquad (81.64)$$

The E values varied over 0.2–5.7 W/kg (237), whereas the pellet diameter ranged roughly over 1–2 mm. The length of the "hairy" hyphal extensions from the well-defined surface of the denser pell*et al*so correlated with the specific energy dissipation rate (237); thus,

$$L_\mathrm{h} = 1.17 \times 10^{-4} E^{-0.25} \qquad (81.65)$$

where L_h (m) is the length of the hairy extensions.

In studies with aggregates of *Corynebacterium glutamicum* in a stirred tank and a capillary loop shear device, Illing and Harrison (238) correlated the break up of cell aggregates with the magnitude of the turbulent

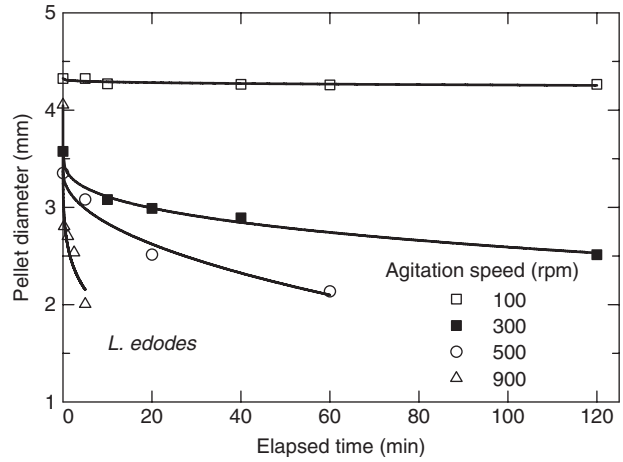

Figure 81.23. Effect of impeller agitation speed and elapsed time on pellet diameter of *L. edodes*. Pellets were 3.4–4.3 mm in initial diameter. A conventional stirred tank with a Rushton turbine ($d_\mathrm{i}/d_\mathrm{T} = 3$) was used for agitation. *Source:* Ref. 236.

forces and the total duration of the force event. Effects of hydrodynamic stresses on particles are further discussed by Henzler (239) and others (240). Shear sensitivity of activated sludge flocs is discussed by Mikkelsen (241).

81.3.7 Nematodes

Nematodes or round worms are the most abundant multicelled animals that occur widely in soil. Many nematodes are free living, thriving on bacteria and fungi, but some are parasites. Insect parasitic (or entomopathogenic) nematodes are potentially useful for biocontrol of insect pests (242). Entomopathogenic nematodes are generally quite small (e.g. 0.5 mm in length). Nematode preparations for use as molluscicide for control of garden slugs have been developed (243). Nematodes lack well-defined circulatory and respiratory systems and oxygen is absorbed directly through the body surface in contact with the surrounding medium.

Nematodes for use in insect control can be mass produced using solid-state culture techniques (242), but these methods are labor intensive and submerged culture is preferred for large-scale propagation. For use in biocontrol, a submerged culture needs to generate a large quantity of the "infective juvenile" stage of the worm's life cycle. Infective juveniles are highly sensitive to shear forces (243,244). Shear sensitivity and other process-relevant properties of nematode broths depend on the species being cultured (243). Methods for large-scale submerged culture of various species have been described (243,245–247).

81.3.8 Bioactive Proteins and Polymers

The biological activity of large molecules such as proteins, enzymes, and antibodies is a function of the molecular

structure, and any change to structure can produce irreversible loss of bioactivity. Large molecules are susceptible to structural disruption by hydrodynamic and other physicochemical forces. In general, the likelihood of a molecule being affected by shear forces increases with molecular size. Also, hydrodynamic forces can greatly affect the physical characteristics of some physiologically inactive biopolymers by influencing their synthesis by the producing organisms, although the organisms themselves may remain unaffected (9,10). For example, the morphology of bacterial cellulose produced in cultures of *Acetobacter* sp. is affected by mechanical agitation (10,62,248). Cellulose microfibers produced under intense agitation tend to be shorter because they break off earlier from the surface of the producing cell (10).

Bioactive proteins consist of one or more polypeptide chains that are folded into a globular shape. Molecular dimensions of globular proteins in solution depend mainly on the molecular weight, that is, the number and the lengths of the polymer chains contained in the globule. Globular protein molecules are typically 3–10 nm in diameter and the dimensions of the fluid microeddies do not approach that size in most realistic processing situations. Solution properties such as ionic strength and water activity are other factors that affect protein size by affecting the tightness of the globule. Because the hydrodynamic diameter of a protein globule is affected by the properties of the solvent, the globule's resistance to shear damage is also affected. Under given conditions of intense turbulence, damage is more likely in solvents that force the protein to adopt a loosely folded configuration with a large hydrodynamic diameter. Most eukaryotic proteins also have large carbohydrate groups attached and these groups can influence or modulate bioactivity (249). Certain proteins are associated with membranes, for example, with the endoplasmic reticulum, mitochondrial folds, and lamellae of chloroplasts, and functionality depends on maintaining the necessary association.

A seemingly minor alteration of the protein structure can greatly affect its ability to withstand hydrodynamic shear. For example, normal hemoglobin is relatively shear tolerant but the variant form found in patients with inherited sickle cell anemia is sensitive to shear. This shear sensitivity is clinically manifested in the denaturation of the protein and consequent hardening of the erythrocytes (250).

Shear-associated inactivation has been reported for numerous enzymes including catalase, rennet, carboxypeptidase, fibrinogen, urease, cellulase, ribulose-1,5-biphosphate carboxylase, lipase, yeast alcohol dehydrogenase, and horse liver dehydrogenase. Generally, the activity loss was irreversible and could be correlated with the dimensionless product of the shear rate and the time of exposure. Many of these studies did not rigorously suppress the formation of gas–liquid interfaces and the observed shear effects were really the effects of shear in presence of a gas–liquid interface (5). The apparent shear damage can be greatly reduced or prevented if a gas–liquid interface is not allowed to form in the shearing device, as demonstrated by various authors (251–254). Proteins adsorb and unfold at the gas–liquid interface and such unfolded proteins are susceptible to damage. Development of gas–liquid interfaces cannot be completely suppressed in most processing scenarios, and therefore, some loss of protein activity is inevitable. Protein inactivation at interfaces has been reviewed by Sadana (255).

Most enzymes withstand the shear rates that are commonly encountered during processing including high shear operations such as cell disruption (1). Exceptions occur when shear stresses are applied in presence of gas–liquid interfaces (1,8,256,257) or liquid–liquid interfaces (258,259), or when the bioactivity of the enzyme is linked with its association with a membrane or organelle. Membrane-associated proteins are more prone to shear damage (1). The globular structure of proteins unravels at least partly at gas–liquid interfaces and other hydrophilic–hydrophobic boundaries. Such unfolded proteins are especially susceptible to irreversible damage by aggregation and other mechanisms. Some protein solutions become turbid when shaken vigorously. This phenomenon is caused by protein aggregation that is facilitated by the enhancement in the gas–liquid interfacial area that occurs during shaking (260,261). In addition to processes such as high pressure homogenization and pumping, high shear processing of proteins occurs during liquid–liquid emulsification, which is used to produce microencapsulated proteins for drug delivery systems (262). Shear and interface-associated damage to proteins in delivery devices such as implantable pumps for insulin (263) can be a problem. Stability problems can also arise during parenteral administration of proteins by needleless injectors.

For *Trichoderma reesei* cellulase solution in a stirred reactor, agitation-related enzyme inactivation was observed in presence of surface aeration and also when the surface was eliminated; however, denaturation was much faster in gas-entrained operation (264). In both cases, the rate of enzyme denaturation increased with increasing speed of agitation. Under given conditions of agitation, increasing the concentration of the dissolved enzyme reduced the rate of inactivation in both surface-aerated and gas-free systems (264). This contrasts with several earlier observations and suggests that aggregation of the unfolded protein was not a major contributor to the observed denaturation. The activity loss was influenced by the pH of the solution (264). Also, the type of buffer used at a given pH value affected the enzyme stability in the agitated reactor (Fig. 81.24). The agitation-associated activity loss could be reduced by increasing the ionic strength (buffer concentration) of the enzyme solution (264). Nitrogen sparging of the enzyme

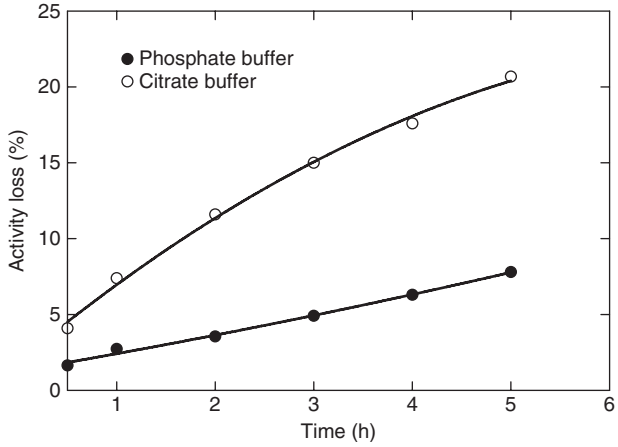

Figure 81.24. Cellulase activity loss by agitation (six-bladed turbine, ~1.6 m/s impeller tip speed) in a surface-aerated vessel using different buffer systems at pH 4.8 and 50°C. *Source:* Ref. 264.

solution enhanced the deactivation rate compared to the nonsparged (surface-aerated) reactor. The denaturation rate depended on gas holdup and, therefore, on the impeller speed (264).

Effects of extremely high shear rate levels ($>10^5$ s^{-1}) on recombinant human growth hormone (rhGH) and recombinant human deoxyribonuclease (rhDNase) were examined by Maa and Hsu (262). The rhGH and rhDNase had respective molecular masses of 22.13 and 32.74 kDa. The shearing was done at a controlled temperature of 20°C. The aggregation and the bioactivity of the two proteins were not significantly affected at shear rates greater than 10^5 s^{-1} applied over 60 min in the absence of gas–liquid interfaces (257,262). Thermodynamic properties of the proteins were determined before and after shearing using scanning microcalorimetry (SM). Alterations in secondary and tertiary structure of a protein are manifested in its scanning calorimetry data. The SM thermograms of rhDNase were not significantly affected by shearing; however, for rhGH, the SM indicated possible conformational changes (262). The silver-stained sodium dodecylsulfate-poly(acrylamide) gel electrophoresis (SDS-PAGE) gels of rhGH showed no significant differences in the high molecular weight region, but low molecular weight fragments were observed in the sheared sample, which suggested some clipping of rhGH in the intense shear field. No significant changes were noted in the SDS-PAGE gels of sheared and unsheared rhDNase (262). If a globular protein's molecular weight is assumed to indicate its size, the rhDNase molecule should be larger by a factor of approximately $(32.74/22.13)^{1/3}$, or 1.14 relative to the rhGH. It seems, therefore, that the molecular size is not the sole determinant of a protein's susceptibility to damage; the specific structure or morphology also appears to play a role.

The damaging effect of shear in presence of gas–liquid and solid–liquid interfaces may be reduced by supplementing the protein solution with a surfactant. Added surfactants tend to reduce gas–liquid interface-induced aggregation and precipitation of rhGH (257). Proteins adsorb also on hydrophobic solid surfaces. Adsorption of insulin at hydrophobic surfaces accompanied by denaturation is well known. Similarly, tPA is known to adhere to solid surfaces (249), but the surface adherent tendency is reduced in the presence of surfactants such as Tween-80 (polyoxyethylene sorbitan monooleate) added at 0.01% typical concentration (249). Shear susceptibility of proteins is further discussed elsewhere (5,265).

Plasmids (229,266) and linear double-stranded DNA (267–273) are susceptible to damage by shear forces. Consideration of shear effects is necessary in the processing of DNA, for example, during microencapsulation for making DNA vaccines (273). Plasmids being evaluated for use as vaccines and in gene therapy are generally obtained from recombinant bacteria, typically *Escherichia coli*. For isolating the native undamaged supercoiled circular plasmid DNA, the cells are lysed by thermal or chemical methods, as mechanical means of cell disruption tend to damage the DNA (226,274).

Damage to a 10.4-kb plasmid was observed during recovery from the *E. coli* host by various methods of mechanical disruption of the cell (226). The methods tested included several variants of high pressure homogenization, ultrasonication, and bead milling (1,226). Homogenization and ultrasound were the most destructive to the plasmid. Although sonication fully lysed the cells within 2 min under the conditions used, no intact plasmid was obtained in the lysate (226). Bead milling was relatively less damaging and more than 95% of the plasmid in the cells could be recovered intact under relatively mild processing conditions. The conditions for maximum recovery were a nominal bead loading of ~84% of the volume of the grinding chamber; 0.5-mm diameter glass beads; 1910-rpm agitation with a six-bladed polyurethane impeller; and six passes through the mill with an average residence time of ~1 min per pass (226).

A plasmid is of course substantially larger in size than the protein it codes. Also, unlike globular proteins, plasmids adopt stringlike shapes with an average hydrodynamic diameter of 150–250 nm for 5- to 10-kb plasmids (274). For larger plasmids, the hydrodynamic diameter may potentially exceed 1 μm (274). As a consequence of the size, plasmid and other DNA are susceptible to hydrodynamic shear forces (274). Compared to the plasmid DNA, the much larger chromosomal DNA (e.g. 4000–4500 kb for *E. coli*) is even less shear tolerant, and this has important implications for recovery of the plasmid; overzealous processing can reduce the size of chromosomal DNA compared to that of the plasmid, making separation difficult (274).

Even short-duration exposure to sufficiently intense shear fields will undesirably convert the native supercoiled circular plasmid DNA to the open circular and linear forms (274). A plasmid's susceptibility to shear forces is critically dependent on its size and the ionic strength of solution (274,275). Plasmids of 13, 20, and 29-kb size are prone to shear degradation (229). Shear sensitivity increases rapidly with increasing plasmid size (Fig. 81.25). For plasmids $\geq$20 kb, degradation is observed within a few seconds of exposure to shear rates of $>1 \times 10^6$ s^{-1} generated by a rotating disc (274,275). At a shear rate of 1×10^6 s^{-1}, more than 80% of the native plasmid structure may be lost within 5 s for a plasmid of $\geq$30 kb. The degradation typically obeys first-order kinetics. Degradation occurs in the absence of gas–liquid interfaces, but is accelerated by such interfaces. In Fig. 81.25, the 13-kb plasmid is relatively shear tolerant in the absence of a gas–liquid interface; however, much smaller plasmids are damaged when sheared in presence of a gas. Damage has been reported during nebulization of a 6.5-kb plasmid (276). The rate of degradation is lower in media with a high ionic strength, presumably because the ionic strength affects the hydrodynamic diameter of the plasmid. DNA adopts a more compact shape in media with high ionic strengths. Also, the ions may interact with the plasmid DNA to increase its resistance to uncoiling. In studies with a 20-kb plasmid, increasing ionic strength to a physiological value (equivalent to ionic strength of 150 m*M* sodium chloride) reduced the damaging effect (229,275). This protective influence of the ionic strength was observed only at relatively high shear rate values ($\sim 1.2 \times 10^6$ s^{-1}). Shear damage to a 20-kb plasmid was independent of the plasmid DNA concentration over the concentration range from 0.2 to 20 μg/mL (229).

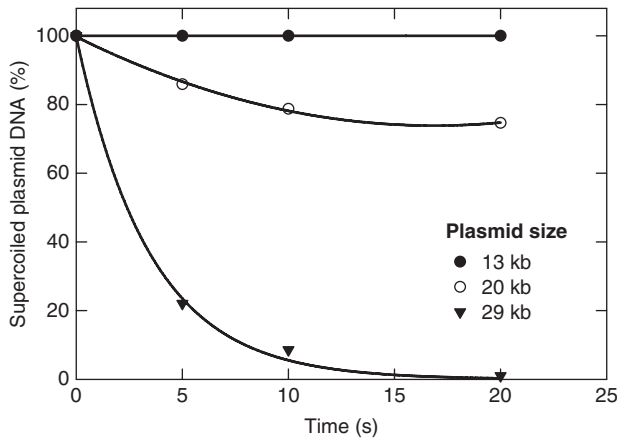

Figure 81.25. Percentage of initial native supercoiled plasmid DNA remaining after various periods of exposure to an average shear rate of $\sim 1.2 \times 10^6$ s^{-1} in a rotating disc chamber. The measurements were at room temperature. *Source:* Ref. 229.

Damage to plasmid DNA has been reported also during centrifugal clarification of the flocculated cell lysate. This damage is apparently associated with the acceleration of the fluid entering the rotating bowl of the centrifuge (274).

In drug delivery formulations, the shear susceptibility of the plasmid DNA can be reduced by formulating with complexing additives (e.g. polylysine, lipids) that cause compaction of the molecule into relatively shear-tolerant particles (274). Effects of shear stress on linear double-stranded DNA are similar to those discussed here for the plasmid DNA.

81.4 CONCLUDING REMARKS

Biocatalysts, especially molds, filamentous bacteria, certain microalgae, and plant and animal cells are susceptible to damage by hydrodynamic and mechanical forces encountered in bioprocessing. Typically, recombinant strains are more prone to shear damage than equivalent wild types. Extent of damage depends on the cell and the specific damaging mechanism operating. Often, the damage may be reduced by one or more of several approaches: adaptation of cells, supplementing culture media with shear protectants, modification of processing operations and equipment, as well as other methods. In many cases, the mechanisms of protection and damage are not entirely clear, but multiple mechanisms seem to operate. As noted throughout this chapter, some sound guidance is available for engineering and operation of fragile culture processes; nevertheless, *a priori* quantitative prediction of culture behavior is not reliably possible. Empirical approaches must continue to be relied upon in engineering practice.

NOMENCLATURE

A_b	Cross-sectional area under the baffle or draft-tube (m^2)
A_d	Cross-sectional area of the downcomer (m^2)
A_r	Cross-sectional area of the riser (m^2)
ATP	Adenosine triphosphate
a	Parameter in Equation 81.2
BSA	Bovine serum albumin
C	Parameter in Equation 81.28
C_D	Drag coefficient
C_f	Fanning friction factor
C_{fmax}	Maximum value of friction factor
D_p	Percentage cell damage (%)
d	Diameter or hydraulic diameter (m)
d_B	Bubble diameter (m)
d_c	Cell diameter (μm)
d_F	Floc diameter (m)
d_{Fmax}	Maximum stable diameter (m)

d_i	Impeller diameter (m)
d_L	Local diameter (m)
d_p	Microcarrier or particle diameter (m)
d_T	Tank or column diameter (m)
E	Energy dissipation rate per unit mass (W/kg)
F	Frequency (s^{-1})
FBS	Fetal bovine serum
F_D	Turbulent drag force on a particle (N)
F_n	Normal force on a particle (N)
F_s	Shear force across the aggregate due to instantaneous velocity difference (N)
g	Gravitational acceleration (m/s^2)
h	Channel height (m)
h_D	Height of dispersion (m)
h_L	Height of liquid (m)
ICS	Impeller collision severity defined by Equation 81.50 (kg/m^2s^3)
ISF	Integrated shear factor defined by Equation 81.44 (s^{-1})
K	Consistency index (Pa s^n)
k	Parameter in Equation 81.2 (m^{-1})
$k\prime$	Constant in Equation 81.63 (s^{-1})
k_d	Death rate constant (s^{-1})
k_i	Constant in Equation 81.12
k_j	Constant in Equation 81.62 ($s^{4.5}/m^{10.2}$)
L	Channel length (m)
LDH	Lactate dehydrogenase
L_h	Length of hairy extensions from pellet surface (m)
L_i	Initial length of filament (μm)
ℓ	Mean microeddy length (m)
m	General exponent
N	Rotational speed (s^{-1}) or cell concentration (m^{-3})
N_d	Number of passes through pump
N_o	Initial cell concentration (m^{-3})
N_p	Concentration of unbroken pellets at time t (m^{-3})
n	Flow behavior index
n_B	Number of impeller blades
PEG	Poly(ethylene glycol)
PMF	Plasma membrane fluidity
Po	Power number
ΔP	Pressure drop (Pa)
Q	Volume flow rate of gas (m^3/s)
Re	Reynolds number
Re_i	Impeller Reynolds number defined by Equation 81.47
Re_L	Local Reynolds number defined by Equation 81.32
r	Radial distance (m)
r_c	Radius of the vortex zone defined by Equation 81.46 (m)
rhDNase	Recombinant human deoxyribonuclease
rhGH	Recombinant human growth hormone
r_i	Impeller radius (m)
r_T	Tank radius (m)
S	Burst strength (N)
SDS-PAGE	Sodium dodecylsulfate-poly(acrylamide) gel electrophoresis
SM	Scanning microcalorimetry
TCS	Turbulent collision severity for particle-to-particle collisions (kg/m^2s^3)
t	Time (s)
U_B	Bubble rise velocity (m/s)
U_G	Superficial gas velocity (m/s)
U_{Gr}	Superficial gas velocity in riser (m/s)
U_L	Average liquid velocity (m/s)
u	Mean velocity of the microeddies (m/s)
Δu	Difference in velocities of the particle and the fluid (m/s)
u_l	Local velocity at position r (m/s)
u_{max}	Maximum velocity at centerline (m/s)
u_o	Jet velocity at orifice (m/s)
V_k	Dimensionless hypothetical specific killing volume
V_L	Volume of liquid (m^3)
W	Width of the impeller blade (m)
x	Parameter in Equation 81.24 or axial distance (m)

GREEK SYMBOLS

α	Constant in Equation 81.63 ($s^{35.575}/m^{65.56}$)
β	Parameter in Equation 81.27
Γ	Coefficient in Equation 81.58
γ	Shear rate (s^{-1})
γ_{av}	Average rate (s^{-1})
γ_{avT}	Time-averaged shear rate (s^{-1})
γ_i	Isotropic turbulence shear rate defined by Equation 81.33 (s^{-1})
γ_{max}	Time-averaged maximum shear rate (s^{-1})
γ_w	Wall shear rate (s^{-1})
ε_S	Volume fraction of microcarriers or solids
η	Constant in Equation 81.30
μ_{ap}	Effective or apparent viscosity (Pa s)
μ_L	Viscosity of liquid (Pa s)
π	Pi
ρ_L	Density of liquid (kg/m^3)
ρ_S	Density of microcarriers or solid (kg/m^3)
σ_M	Mechanical strength of aggregate (N/m^2)
τ	Shear stress (N/m^2)
$\tau_{max\ J}$	Maximum shear stress in submerged free jet (N/m^2)
τ_w	Wall shear stress (N/m^2)

STERILIZATION AND DECONTAMINATION, BIOPROCESS EQUIPMENT

PETER L. ROBERTS
R&D Department, Bio Products Laboratory, Elstree, Hertfordshire, United Kingdom

82.1 INTRODUCTION

Sterilization and decontamination methods are used during the development and manufacture of biological and other pharmaceuticals in order to remove microbiological agents. For instance, in the case of biologicals products derived by fermentation in bacterial or cell cultures, this involves ensuring that all components that are added to the culture, for example, the growth medium and all items of equipment that the cells come into contact with, are sterile. In addition, in the case of animal cells, the possibility of the presence of endogenous viruses needs to be considered. The classical sterilization methods used in hospitals and the pharmaceutical industry, for example, autoclaving and sterile filtration, are able to inactivate or remove microorganisms very effectively. However, it may be necessary to accept a lower degree of sterility assurance with cell culture or human derived material, or when the specific clinical application is taken into account.

In the case of cell culture systems, the presence of microorganisms can lead to gross and obvious destruction of the cells or difficulties in their culture, although contamination may not be obvious or easily detectable. Increasingly, cells have been recognized as being a potential source of endogenous infectious agents, for example, persistent/latent viruses such as retroviruses or herpesviruses. Moreover, viruses may be used for the immortalization of primary cell lines and for engineering cells to produce biological products using recombinant DNA technology. Thus, biologicals pose a threat to the recipient of any such product as well as to all those that handle such material, whether in a laboratory or on an industrial scale. In addition, consideration must be given to the disposal of potentially contaminated waste materials. All these safety aspects are becoming increasingly subject to legislation by governments.

The range of microbial agents that may potentially contaminate a cell culture include protozoa, fungi, bacteria, mycoplasma, and viruses. The range is further extended by the so-called unconventional agents that cause prion-associated diseases in animals and man, for example, bovine spongiform encephalopathy (BSE), Creutzfeldt–Jakob disease (CJD), and scrapie, that is, the spongiform encephalopathies. These infectious agents are unusual in that they are considered to be infectious proteins, that is, prions (1,2). The sensitivity to inactivation of all these microbiological agents varies widely, although, in general all can be inactivated by heat treatment using a standard autoclave or dry heat oven, or they can be removed by filter sterilization. Exceptions to this include highly resistant prions (3) and bacterial endospores, for example, the *Bacillus* and *Clostridium* species. Also, smaller microorganisms, that is, mycoplasma and small viruses, can pass through conventional bacterial retentive filters. Further general background on this topic can be found in Refs 4–9.

82.2 STERILIZATION BY HEAT

The use of heat, either in the form of dry heat treatment in an oven at about 160°C or by treatment with steam

Upstream Industrial Biotechnology: Equipment, Process Design, Sensing, Control, and cGMP Operations, Volume 2, First Edition. Edited by Michael C. Flickinger.

at about 121°C, that is, autoclaving, are two of the most commonly used methods of sterilization (10,11). In general, autoclaving is the more severe of the two methods, but to be performed successfully requires an efficient, well-maintained, and validated machine. It may not be possible to use these standard sterilization methods for some materials due to their heat sensitivity. Less effective conditions may be acceptable, for example, treatment with boiling water or steam at about 100°C. For instance, cell culture incubators are commonly fitted with the ability to be heated at about 80°C for decontamination purposes. The recommended procedure in this case is to repeat the heat treatment on several successive occasions. It is preferable to keep the incubator in a humid state to maximize the sterilizing effect. Heat treatments such as these can be very effective, but fall short of conditions that are accepted as true sterilization. In particular, agents such as bacterial endospores or even standard vegetative bacteria may not be inactivated at these temperatures.

82.2.1 Autoclaves

Almost all microorganisms, apart from some bacterial endospores and prions, are readily inactivated by moist heat at about 121°C, such as that generated in an autoclave (Fig. 82.1). Various standard cycle conditions may be used, for example, 115°C for 30 min, 121°C for 15 min, 126°C for 10 min, or 134°C for 3 min. These times and temperatures are those that should be actually found in the load during the sterilization phase and exclude the machine and load warm-up phase. These standard cycles are not strictly equivalent, with that at 115°C being the least effective and that at 134°C being the most effective. The efficiency of these cycles is tested by determining the survival of highly heat-resistant endospores of *Bacillus stearothermophilus* at a given temperature after various time intervals. The cycle of 121°C for 15 min is most commonly used and is capable of inactivating 1×10^8 cfu of *B. stearothermophilus*. While it is possible to use other cycles with a similar sterilizing capability, these would in fact be either excessively long, for example, 115°C for 60 min, or excessively short, for example, 126°C for 5 min or 134°C for 1 min. In practice, cycles of 115°C for 30 min, 121°C for 15 min, 126°C for 10 min, and 134°C for 3 min have become the accepted standard cycles. These cycles are capable of killing in the order of 1×10^4, 1×10^8, 1×10^{17}, or 1×10^{32} cfu of *B. stearothermophilus*. For routine cell culture applications, the 121°C for 15 min cycle is commonly used. A more severe cycle is currently recommended for the inactivation of prions, 132°C for 1 h, or 134°C to 138°C for 18 min (12). This latter cycle is only applicable if an adequate porous load cycle can be used. Even these extreme cycles may not be fully effective for certain strains/types of agents. To operate the autoclave, steam must be generated either in the equipment itself, as in the case of a small bench top model, or from an external boiler in the case of a large capacity machine as used in industries, hospitals, or microbiology departments. It is critical to operate these machines correctly to ensure that a sterile load is produced. In addition, due to the use of high pressure and high temperature in the equipment, appropriate safety precautions must be followed, as directed by the manufacturers.

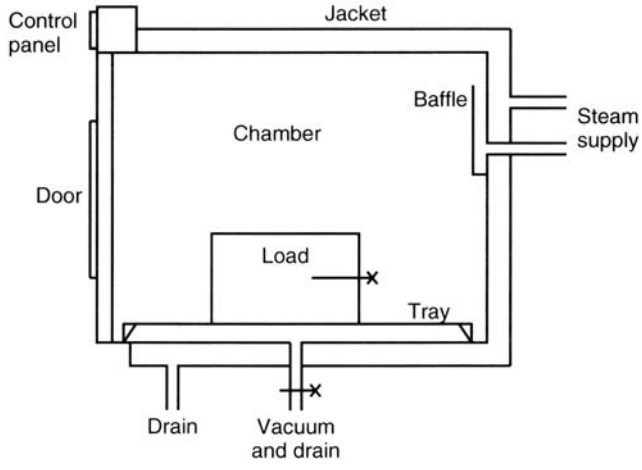

Figure 82.1. Diagrammatic representation of a multipurpose laboratory autoclave. The sterilization phase of the cycle is controlled by thermocouple probes placed in the chamber drain or in the load. The control panel contains temperature and pressure and cycle stage indicators as well as various recording instruments such as a chart recorder or printer. A filter is usually placed on the vacuum line to prevent any microorganisms from leaving the chamber.

82.2.1.1 Laboratory Autoclaves. At their most basic, these are simply small domestic pressure cookers with a capacity of about 0.01 m^3. To operate such a machine, open the lid and fill with water to the required depth. The items to be sterilized are then placed in the machine on shelves or in a basket as appropriate. The lid is then closed and tightly sealed. The water is heated to boiling point and the steam, which is generated, is allowed to purge the chamber for several minutes before the pressure valve is closed. This pressure valve may close automatically in some models. The timer is started when the required pressure/temperature is reached. At the end of the cycle, the heater is turned off and the pressure allowed to fall. When a temperature of about 80°C and atmospheric pressure is reached, the door is opened and the sterilized items are removed. Horizontal models of portable bench top autoclaves are often more sophisticated and have additional controls and safety features. They may have more than one cycle, for example, 121°C and 134°C, a drying option at the end of the sterilization process,

and safety features such as a temperature lock to prevent access during the process. In addition, an automatic timer and various cycle stage indicators may be present.

There are various limitations associated with using such small bench top machines. Generally, they lack adequate air removal methods and are therefore not suitable for porous loads, such as wrapped items, or laboratory discards. If they do not possess an adequate drying stage after sterilization, items may be wet. Because the temperature/pressure in the load is not monitored and there is no printed cycle record, documentation and assurance of sterility may be difficult to demonstrate. In addition, because of the absence of a cooling phase the load may cool slowly and the cycle may take excessively long to complete. There may also be concerns about the safety of the operator using the more basic models of such equipment. In conclusion, their use in the cell culture laboratory is limited to small items that have not been wrapped and bottled fluids. They should not be used for very critical applications, wrapped or difficult items, or contaminated laboratory discards.

82.2.1.2 Large Capacity Autoclaves. Larger autoclaves have a chamber size of at least 1 m^3 and use an external steam supply. In the case of a single cycle gravity displacement autoclave, air is displaced from the bottom of the chamber by the steam of lower density that enters at the top. A system for cooling the load at the end of the cycle via a jacket or spray cooling system is included. There is often a drying stage, using vacuum and heat, at the end of the run. This type of autoclave is useful for items that are easily exposed to steam, that is, not wrapped, and for bottled fluids. However, they are not really suitable for porous loads and wrapped items because air removal is probably not adequate to ensure complete steam penetration, and thus, sterilization. To overcome these limitations and to ensure maximum flexibility in use, a multicycle porous load autoclave is preferable in a cell culture laboratory. It is essential that such a machine includes a porous load cycle, in which air is removed from the load and chamber using vacuum and pressure pulsing stages. The basic steps in such a cycle generally include air removal, sterilization, cooling, and drying using heat and vacuum. The precise details of the stages involved depend upon the exact type of cycle and machine as each is dedicated to a specific type of load. A standard gravity displacement cycle is also included for bottled fluids. Examples of various cycles are given in Fig. 82.2. In contrast to the standard gravity displacement cycle (Fig. 82.2d), the use of a vacuum pump and steam pressure to produce pulses of pressure in the chamber is a more effective method for removing air from difficult loads and wrapped items. There are a wide range of cycles specifically dedicated for this purpose and examples are given in Fig. 82.2a–c. The inclusion of a single high vacuum step at the start of the cycle (Fig. 82.2a) is the simplest approach; however, other methods are generally more effective. The use of a cycle that includes a number of pulses at negative and/or positive pressure is preferable (Fig. 82.2b and c) for ensuring effective air removal. Such cycles should be used for sterilizing/decontaminating critical loads such as contaminated laboratory discards and well wrapped items. Relevant aspects of each cycle programme are generally predetermined by the manufacturer.

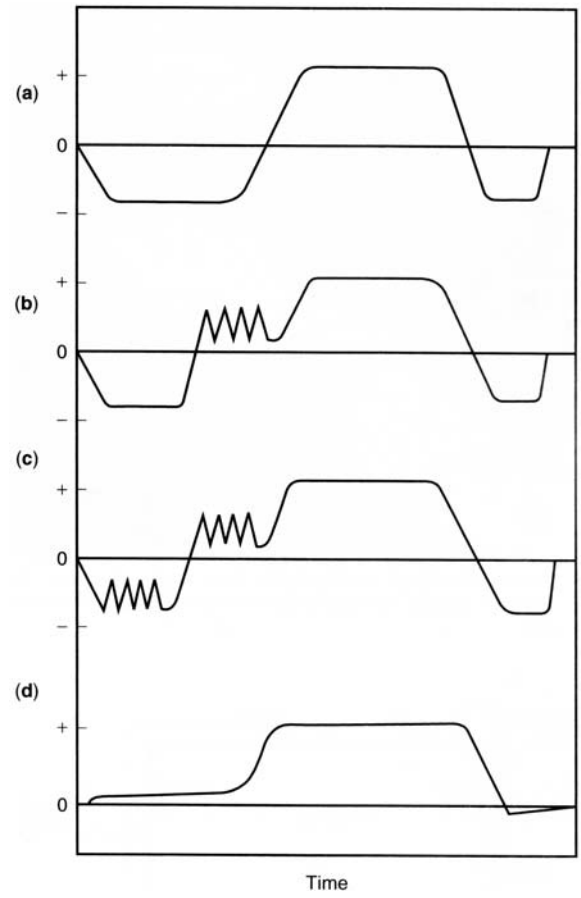

Figure 82.2. Autoclave cycles available on a multipurpose laboratory autoclave. For difficult porous loads, wrapped items, or laboratory discards, a cycle using air removal must be used. Various different methods are available for achieving this and some of these are illustrated. Positive (+) and negative (–) pressure conditions are indicated. In the simplest approach a single initial vacuum pulse is used at the start of the cycle (a). However cycles with a combination of negative and positive pressure pulsing stages as shown in (b) and (c) are generally more effective for air removal. A combination of both negative and positive pulsing stages as shown in (c) is particularly effective. A cycle in which the air is simply removed by gravity displacement and steam flow is shown in (d). This type of cycle is only suitable for bottled fluids and unwrapped items. At the end of the sterilizing phase, a vacuum is created, while the load is still warm in order to dry porous loads. The exact details of pressures, times, and resulting temperatures depend on the specific nature of the cycle.

Dials and/or digital meters on the equipment indicate the stage of the cycle and the current operating conditions in terms of pressure and temperature. This information is also recorded via a printer or chart recorder. An air detector is usually fitted and this monitors the efficiency of air removal from the load and chamber. The cycle will not start unless this is adequate. There are many advantages in using a multicycle autoclave with a porous load cycle. For instance:

- there is good steam penetration into wrapped items, thus ensuring sterility;
- several cycles are available allowing flexibility of use;
- the equipment has a large capacity;
- items will be free of moisture at the end of the cycle.

In general, large capacity/industrial-scale autoclaves are tailored to the customer's specific requirements. They are used in hospitals, the pharmaceutical industry and are preferable for cell culture and microbiology.

After the machine has been installed and initial tests carried out, it may be necessary to conduct further tests and validate critical loads. The heat sensitivity of items should be considered and tested if necessary. Most plastics can withstand the standard 121°C cycle, although polystyrene will not. Only a relatively few cell culture media or supplements are capable of being autoclaved. Autoclavable formulations of some media do exist and these have glutamine omitted, because of its heat sensitivity. The suppliers of cell culture reagents should be consulted for further information.

It is best to add temperature indicators to every item in the load. This is essential where autoclaves do not have a temperature recorder. Autoclave-sensitive tape, autoclave tubes (Browne's tubes) or indicator strips can be used. Such indicators only provide an approximate indication that sterilization conditions have been met. Items of equipment to be sterilized are usually placed in paper sterilization bags or wrapped in aluminum foil or paper. The wrapping is sealed by folding and taping; however, care must be taken not to completely seal the package in order to ensure that satisfactory air removal and steam penetration is accomplished. In the case of empty bottles/containers with caps, the cap should be loosened. Although some autoclave bag manufacturers claim that steam can penetrate directly into sterilization bags, it is best to completely open the neck of the bag prior to autoclaving to ensure adequate air removal and effective steam penetration. Bottled fluids are best autoclaved with the lids tightly closed in order to prevent any possibility of the fluid boiling over. Suitable bottles should be used that can withstand the autoclave cycle when used in this way; alternatively, the lids can be loosened. The ability of the container or bottle/cap combination to withstand autoclaving should also be checked. The manufacturer's/sterilization engineer's instructions and Standard Operating Procedures (SOP) should always be followed. These are different for each autoclave. Logbooks on the servicing, testing, and use of the machines must be maintained.

82.2.1.3 Testing. While in theory it may be possible to directly confirm the sterility of every autoclave load, by for example, incubating the complete batch of product or by inoculating suitable culture media in the case of critical therapeutic products, this is rarely done in practice. Instead, the performance of the autoclave is confirmed by a comprehensive programme of routine testing and validation by autoclave engineers. Testing should be carried out on a regular basis and records kept. This is essential to ensure efficient and safe operation of the machine and to meet regulatory requirements, for example, Health and Safety; Good Manufacturing Practice (GMP) and Good Laboratory Practice (GLP) guidelines. The user should record details of all the runs in a logbook and a leak rate test should be carried out at least weekly. At the end of every run, the autoclave recorder should be checked to ensure a satisfactory cycle, for example, pulsing profiles, temperature, and time. A steam penetration test into a standardized load of towels or cotton sheets, that is, the Bowie–Dick Test, is usually done daily or weekly (13). Servicing must be carried out at regular and agreed intervals, for example, every 3–6 months. Before the machine is first used, the testing of critical worst-case loads should be validated by thermocouple studies. The types of load to be tested might include a mixed load of contaminated laboratory discard. To ensure the worst case is tested, the autoclave should be filled to capacity and thermocouple probes placed in those items where steam will have difficulty penetrating. When carrying out a testing programme, a standard test pack of towels, as used in the Bowie–Dick Test, should be monitored with a thermocouple placed in the center of the test pack. The temperature should be maintained at an acceptable limit, for example, 0–2°C above the target temperature throughout the cycle. The temperature indicated on charts and displays should correspond with this. Important critical loads are best tested using the worst-case situations and critical or difficult items, for example, filters used in sterilization, must also be specifically validated. The operation of the door lock, which prevents entry into the machine until the load has cooled to a safe level, that is, 80°C, should be checked. In the case of liquids, a similar testing procedure is used and the temperature of all bottles within the load should agree to within set limits, for example, ±1°C. Full details of the current requirements for sterilizers are given in various published standards and guidelines (9,14,15).

82.2.2 Hot Air Ovens and Incineration

Heating in the dry state by incineration or treatment in a hot air oven is an alternative method of sterilization (10,11,14). In general, higher temperatures and longer times must be used, compared to autoclaving. Incineration may be used during routine aseptic techniques, for example, the mouth and lids of bottles may be briefly flamed directly in a Bunsen burner. Metal items and scissors, as used during the preparation of primary tissue cultures, can be sterilized in ethanol and subsequently flamed. Waste that is contaminated with microorganisms is considered as clinical waste. This is also true for biological materials, which include cell cultures. Various guidelines control the safe disposal of such waste (12,16). Incineration of microbiologically contaminated material is best carried out after the material has been made safe by autoclaving or chemical treatment directly in the laboratory. The waste material can then be sent for incineration. Where incineration is the only means of decontamination and is outside the user's control, health and safety issues regarding the use of contractors will need to be considered. Incineration is effective when a temperature of about 350°C is reached and thus the operation and type of incinerator is important. The incinerator used must be effective and able to ensure that no unburned material remains or escapes in the smoke.

Ovens are simple and cheap alternatives to the use of autoclaves. They are routinely used to sterilize glassware and metal objects; however, they are generally unsuitable for plastic items. In an oven, heat may be distributed by convection or more effectively by the use of a fan. A filter can be fitted to the air vent to prevent any recontamination of the load by air gaining access to the chamber during the cooling process. The actual time of the load at sterilizing conditions is the critical factor for ensuring effective sterilization. The timer fitted to the oven may start either when the machine is switched on or when the interior of the chamber reaches a predetermined temperature. In more sophisticated cases, thermocouple probes placed in the load provide the controlling parameter for the sterilizing phase. Where this is not the case, an estimate for the load warm-up period must be included when setting the timer. The treatment process can be monitored by chart or digital recorders. In the pharmaceutical industry, tunnel sterilizers may be used to increase capacity. In these, items of equipment, for example, bottles, are continuously fed through the oven on a conveyor system. This type of equipment requires extensive validation to ensure effective sterilization.

The most common heat treatment cycle is 170°C for 1 h, however alternative combinations are 160°C for 2 h or 180°C for 0.5 h. In all cases, this represents the actual temperature within the load during the sterilization phase. Other cycles exist, for example, 150°C for 2.5 h, 140°C for 3 h, and 120°C for 18 h, but these are less effective. These are much less commonly used but may be suitable for less critical applications or where the material is heat-sensitive, for example, plasticware. The basic steps involved in using an oven for sterilization are relatively straightforward and much simpler than for an autoclave. Care must be taken not to overfill the oven, so as to ensure good air circulation. As with autoclaves, suitable indicators can be included to confirm that items have been heat-treated. Heat-sensitive tape is available, which changes color at 160°C to reveal dark stripes. Other strip indicators are available, which indicate that other temperatures have been reached.

Because of their simplicity, the need for extensive engineering maintenance and validation is reduced. However, it is wise to test the performance of the instrument as part of the commissioning process. Further, ongoing testing on a routine basis will be required for critical use in pharmaceutical and hospital applications. Testing may include the use of thermocouples placed in the oven, next to the oven temperature probe, to confirm that the warm-up phase and any temperature overshoot is not excessive, for example, warm up <135 min, overshoot <2°C. Slight fluctuations during the sterilization phase and the general drift in temperature must also be within acceptable limits, for example, 1°C and 2°C respectively. Thermocouples placed around and within the load should confirm that the load temperature agrees with the oven temperature indicator, for example, within 5°C. The appropriate guidelines for sterilizers should be checked for details of the exact current requirements (14,17).

82.3 FILTRATION

Filtration is used in the cell culture laboratory to remove cellular microbial agents from liquids and gases (18–20). Special filters are also now available for removing viruses (see the section on Virus Filtration) and are commonly used for the sterilization of cell culture media and additives, because of the heat sensitivity of such items. With filtration there is the added risk of recontamination between the actual filter sterilization step and dispensing the sterile material into the sterile final container. Because of the critical nature of this process, commercial sterile filtration/final filling operations need to be closely monitored and controlled, and there are extensive regulatory and GMP requirements, which must be complied with. In practice, many of the commonly used materials in cell culture are filter-sterilized. Standard filtration processes commonly use filters with a pore size of 0.2 μm, which are suitable for removing bacteria, yeast, and fungi. There are essentially two types of filters—membrane filters that trap microorganisms on their surface, and depth filters with a less defined pore size that trap microorganisms in the depth of the matrix. Both types are considered in more detail below. Membrane filters are preferred for critical

sterilizing applications, because they have a defined pore size and mode of action, that is, trapping bacteria on the surface. However, the use of depth filters is often very useful for prefiltering a product and thus, reducing the bioburden of microorganisms present, prior to the final sterile filtration step. Recently, filters with a pore size small enough to remove viruses, that is, about 15 nm, have become available (21–26). However, this is a relatively new area and its application in cell culture and bioproducts has thus far been limited. This technology is being used by some manufacturers of calf serum–based products, as well as for treatment of bioproducts for therapeutic use. Recently, plasma-derived products that use this technology have become available (26). In addition to removing conventional microbial agents, filtration may be a useful method for removing prions (27). This is because these agents normally exist in a highly aggregated state and even the minimal infectious unit comprises a large number of individual prion protein units. The range of filters and filtration equipment available is very large. However, the manufacturers produce a range of technical literature and are happy to provide technical advice. In some cases they are willing to optimize/test filtration systems for a specific user's application in their own testing laboratory.

82.3.1 Depth Filters

This type of filter is often made of glass fiber, but other materials may be used. Depth filters operate by trapping microorganisms in the depth of the filter matrix. This may involve physical trapping or be due to electrostatic, or other, interactions. It is possible, at least in theory, to saturate the capacity of this type of filter with regard to microbial binding. For this reason, membrane filters are normally used for situations where the absolute sterilization of liquids is critical. However, with extensive validation it may be possible to justify the use of specific depth filters/product combinations. Depth filters are more commonly used for reducing the microbial content/bioburden, both at various stages in a manufacturing process, for example, prior to specific purification stages, and immediately prior to the final sterile filtration step. The efficiency of the purification process and the capacity of the final sterile filtration step can thus be enhanced.

Depth filters are commonly used for filtering gases (28). The simplest example of the use of this type of filter is the cotton wool used for plugging pipettes used in liquid transfer. In addition, micropipette tips, tubes, and flasks are available with integral depth filters. One type of depth filter that is extensively used in cell culture situations is the so-called HEPA (high efficiency particulate air) filter. These are used to filter air in laminar airflow or microbiological safety cabinets, as well as sterile rooms. In addition, they can be used as vent filters on cell culture fermentation equipment or to filter gases supplied to cell cultures. They remove particles of 0.3 μm or larger at >99.97% efficiency. They are effective for all types of microorganisms, including viruses, even though these agents are much smaller than the nominal filter pore size. This is by virtue of the fact that these agents exist in the atmosphere, attached to liquid droplets in aerosols or attached to dust particles. For pharmaceutical use, there are standards for the quality of air permitted for any particular class of clean room or cabinet. For filter sterilization and aseptic filling there should be no more than 3500 particles/m^3 (29). Relevant standards/classifications should be consulted for the current requirements.

82.3.2 Membrane Filters

Membrane filters are preferable to depth filters for critical sterilization applications where a high level of assurance regarding sterility is required. Membrane filters are made from a range of materials, including cellulose (acetate, nitrate or a mixture), nylon, polysulfone, polyvinylidene fluoride, or polycarbonate. Filters made with low protein-binding properties such as polyvinylidene fluoride, may also be useful in some circumstances. In the case of polycarbonate filters, the pores are of a particularly discrete size because they are produced by a radiation etch method. Because membrane filters act exclusively by retaining microorganisms on their surface due to the pores being of a defined size, there is no risk of exceeding the capacity of the filter and allowing microorganisms to pass through.

Filters with a nominal pore size of 0.2 μm are the current standard for sterilizing liquids and removing cellular microorganisms. If the effective removal of mycoplasmas is essential, the use of membrane filters with a pore size of 0.1 μm should be considered. These are now commonly used by most manufacturers of serum-based additives for cell culture. Such filters may also help by removing any large animal viruses that may be present. Low residual levels of the chemicals used during the filter manufacturing process, for example, detergent, ethylene oxide if used as the sterilizing method, can affect cell growth (30,31). Filter manufacturers can usually provide data on the levels of extractable chemicals as determined using standard solutions/solvents. In the case of pharmaceutical products, such data may not be sufficient and product-specific testing may be required by the regulatory agencies. For cell culture applications it is preferable to use filters with low extractable levels, which have been sterilized by gamma irradiation or autoclaving rather than by ethylene oxide. In critical applications, the first volume of liquid through the filter can be discarded. Membrane filters can also be used for filtering the gases, that is, CO_2 or air that may be used when culturing cells that is, with incubators or

fomenters. Cell culture flasks are available with integral membranes, which allow gaseous exchange without having to leave the cap partially open. For sterilizing gases, it is possible to use a filter with a pore size of 0.02 μm (32), which is small enough to remove viruses. Membrane filters may also be used to protect pipette-handling devices from contamination.

A wide range of types of apparatus for filtration are available. In the simplest systems, a filter of 11 or 25-mm diameter can be attached to a syringe. On a larger scale, cartridges of various sizes (which may be pleated to maximize filtration area with a given device) are used for filtering large volumes of at least several liters. Filter units, comprising the filter membrane in a plastic housing, often come presterilized or may be autoclavable. The unit is designed for single use. In some cases, the filter cartridge must be inserted into a metal housing to produce the complete unit. In the case of filter discs, these need to be assembled in metal or plastic holders prior to sterilization. Complete preassembled and presterilized filter units have the advantage that they are convenient and pretested by the filter manufacturer, whereas filters that require assembly in housings, particularly filter discs, are more prone to failure.

82.3.3 Using Filters

Although filtration can be carried out using positive or negative pressure, it is best carried out using positive pressure. This is because in some situations, for example, when filtering buffers/medium with bicarbonate, the pH may rise during filtration. In addition, frothing and protein denaturation may occur if protein solutions are filtered under negative pressure. On a small scale, the apparatus may simply involve the use of a syringe, but on a larger scale air or nitrogen at positive pressure can be used. An alternative approach is to use a peristaltic pump (Fig. 82.3a). Metal vessels dedicated for filter applications and which can be pressurized are commercially available.

The exact details for using filters vary widely and are dependent upon the type of filtration system used. In the case of commonly used stainless steel filter housings and filter discs (Fig. 82.3b), the method used is as follows.

Disassemble the unit and place the filter on top of the metal grid. Care must be taken to ensure that the filter is used in the correct orientation. To increase the capacity of the filtration system, appropriate prefilters (depth or membrane) can be included with the use of appropriate separators between the layers. The assembly of the unit is a critical process and the manufacturer's instructions must be carefully followed in order not to damage the filter. The assembled unit, along with any associated plastic tubing, is then autoclaved. The standard conditions for this are 121°C for 15 min, although some types of filter are able to withstand higher temperatures. The manufacturer's instructions must be consulted. The filtration process itself is carried out in a laminar airflow cabinet or sterile room using appropriate aseptic procedures. The liquid to be filtered may be placed in a pressure vessel or alternatively a peristaltic pump may be used. An air vent may be present on the housing to allow any air bubbles present in the system to be bled off at the start of the filtration process.

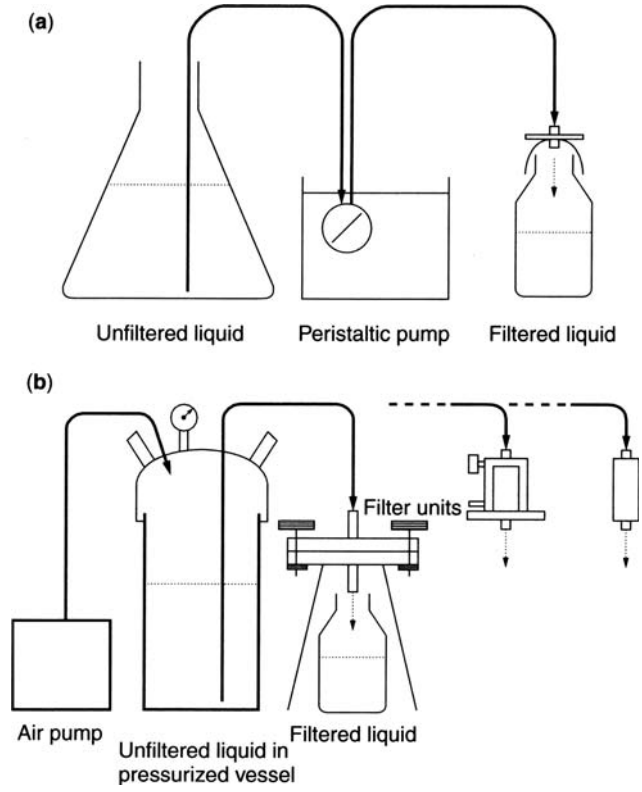

Figure 82.3. Methods used for sterilizing liquids by filtration. The systems shown are designed to filter volumes of a minimum of 1 L, but are usually used for volumes of 5 L or more. In system (a), a peristaltic pump is used to force the liquid through a disposable sterile disc filter. In system (b), a pump is used to pressurize the vessel holding the liquid to be sterilized. This can then be filtered in one of several ways, for example, disc filter, cartridge filter in a stainless steel metal housing that has been autoclaved by the user. Alternatively a presterilized cartridge filter or disc filter that requires no special housing can be used.

82.3.4 Integrity Testing

The manufacturer of the filter will confirm its integrity prior to release. In addition, it is possible for the user to test the integrity of filters. This monitoring is essential in the pharmaceutical industry for sterile filling operations. It must be carried out after using the filter, but may also be performed before use. There are various methods available, including the bubble point, diffusion airflow (or forward flow), or pressure hold tests. The filter manufacturers have

correlated these tests with filter performance for removing microbial agents and provide acceptance limits for the test. The industry standard for this is the use of a particularly small bacterium, for example, *Pseudomonas diminuta* in the case of 0.2-μm filters, which provides a severe test of the filter's efficiency. The test method used should preferably confirm the integrity of the complete filter system, that is, with the housing where relevant. The different integrity test methods are considered below:

1. *Bubble Point Test.* Relatively simple tests may be sufficient, for instance, testing the bubble point by trying to force air forwards or backwards through a wet filter unit attached to a syringe. If air passes through unhindered, then the filter is damaged. During the filtration operation itself, the presence of backpressure also provides some assurance of filter integrity. More sophisticated quantitative procedures can also be used. The manufacturers provide appropriate values for the pass/fail limit which are dependent on the exact filter type and size and the filter system in use.
2. *Diffusion Airflow (Forward Flow) Test.* An alternative approach is that based on determining the airflow across the filter. This method is known as the *diffusion airflow* or *forward flow method* and involves testing the airflow across the wet filter at a specified pressure, usually at about 80% of the bubble point pressure.
3. *Pressure Hold Test.* A third method is the pressure hold test. For this, the filter is pressurized and the pressure decay against time measured.

In addition to all these methods, the actual sterility of the final product can be tested directly, simply by incubating the final product at an appropriate temperature and inspecting for microbial growth. This may be carried out on the complete batch or samples can be taken and inoculated into appropriate microbiological growth media. The sensitivity of such methods will depend on the sample size and use of suitable growth media. This approach is routinely carried out in critical applications such as with therapeutic products. This is because the sterilization step itself is not carried out on the product in its final container, as with for example, autoclaving, and thus, there exists the risk of contamination during the final sterile filling operation itself. Testing for viruses is not generally carried out due to the wide range of virus types in existence. Instead, these agents are usually controlled by testing and controlling the start materials, that is, the cell cultures and growth media.

For critical applications in the pharmaceutical industry, there may be a requirement to test the filter performance with the specific product in use. While this may not be essential for filters that remove bacteria, product-specific testing is likely to be required to confirm the effectiveness of virus filters. This is because virus removal systems have only recently been developed and experience in their use is limited. In contrast, bacterial filters have been in use for a long period of time and so an extensive knowledge of filter performance in relation to a wide range of specific types of test products has been built up. This is sometimes referred to as the *matrix approach* and may be used to justify the efficiency of a specific product/filter combination without recourse to specific bacterial challenge testing with a particular new product. In the case of the HEPA filters used in microbiological safety cabinets and the filtration of air in sterile rooms or containment rooms, smoke challenge tests are used. For this, dioctyl-phthalate particles of about 0.3 μm diameter are used. Testing should be carried out approximately every year.

82.4 FUMIGATION

An alternative sterilization method involves the use of disinfectants in the gaseous state, that is, fumigation. Either formaldehyde gas or ethylene oxide are commonly used (5,9,33). They are, in general, effective against most types of microorganisms although bacterial endospores are somewhat more resistant. These agents are more effective at temperatures over 37°C and high humidity levels, for example, 75–100%. Fumigation is less effective if conditions reduce the accessibility of the microorganisms to the gas, for example, being dried in organic or inorganic material. Fumigation is not used for decontaminating general laboratory waste due to the difficulty in penetrating the load and the presence of organic materials.

82.4.1 Formaldehyde

Formaldehyde gas is commonly used to decontaminate or sterilize laminar airflow cabinets and rooms used for handling cell cultures (6,9). It can also be used for sterilizing items of equipment. Formaldehyde gas is toxic and appropriate safety precautions must be observed and it may be necessary to use breathing apparatus.

Before fumigating a sterile room, all unnecessary items must be removed, particularly those items, which would or might be harmed by exposure to the gas, for example, cell cultures and sensitive electrical or electronic equipment such as computers. The room must then be cleaned to minimize the level of microbial contamination and to remove substances that may hinder penetration of the gas. In the laboratory a dedicated formaldehyde-generating kettle can be used. A simpler method involves filled a pan with formaldehyde and placing this on a hot plate connected to a timer. For this, formalin solution (20 mL/m^3 room volume) is used. Alternatively, paraformaldehyde (10 g/m^3 room volume) can be heated. Formaldehyde

gas can also be generated directly by mixing formalin solution, or paraformaldehyde and water, with potassium permanganate. However, caution must be exercised when using this method as the reaction can be very rapid and may be violent. Equipment that generates a mist of formaldehyde droplets can also be used. With the environmental air handling system for the room turned off, the formaldehyde generator is turned on and the room is evacuated. The door is then locked and fully taped up and sealed and a safety warning notice placed on the door. The room should be left until the next day. Before entering the room, the total exhaust cabinet and/or air extracting system, operating in total exhaust mode, should be turned on remotely. If this is not possible, the room should be entered by someone wearing breathing apparatus that can turn on the cabinet and air handling system. The room should be left until the formaldehyde reaches an acceptable safe level. Testing equipment can be used to monitor the level of formaldehyde. It may be necessary to clean the room to remove deposits of paraformaldehyde that will emit formaldehyde gas. It may take several days to fully remove residues of the formaldehyde gas from the area. In view of the safety implications, fumigation is considered as a fairly specialist procedure and as a last resort, for example, for major spills of high risk microbial agents and in sterile filling rooms in the pharmaceutical industry.

Microbiological laminar airflow/safety cabinets used for handling cell cultures should be decontaminated on a regular basis or after it has become apparent that contaminated cultures have been handled. The use of appropriate respiratory protective clothing is not necessary for this procedure. Only cabinets that can be sealed and, which are ducted to the outside can be decontaminated using formaldehyde. The cabinet must first be thoroughly cleaned before fumigation, particularly if spillages of cell culture media or reagents are likely to have occurred. This should include the area below the removable work surface. In some cases, the cabinets may have integral formaldehyde generators that can be filled from outside the cabinet; otherwise a small dedicated portable formaldehyde generator can be placed inside the cabinet. The generator should be filled with about 25 mL of formalin solution; however, this will depend on the size of the cabinet. Where appropriate, follow the manufacturer's instructions. The cabinet door should be closed and sealed with masking tape. The generator should be turned on and a warning notice placed on the cabinet. The cabinet should be left overnight for the fumigant to act. The next day, the air-exhaust system should be switched on while gradually opening the door to the cabinet. The cabinet should be left running for about half an hour to remove residues of formaldehyde gas. Deposits of paraformaldehyde should preferably be cleaned from the cabinet. However, the operator must take care not to be exposed to formaldehyde when carrying out this task, as residual levels can remain high for a considerable period of time. Full cleaning of the cabinet, involving removal of the work surface and opening of the glass front panel are preferably carried out several hours later.

Items of equipment can be conveniently sterilized at the time the room or cabinet is fumigated by leaving them inside the room/cabinet. An alternative procedure is to place the items in a suitable plastic bag or box together with some formalin liquid. Items used very regularly for cell culture procedures such as pipette aids and micropipettes should be treated on a regular basis and prior to their return to the equipment manufacturer for calibration or servicing.

82.4.2 Ethylene Oxide

Ethylene oxide is used for sterilizing items of clean equipment in so-called cold-temperature autoclaves or in combination with steam, particularly in the hospital environment (33). It is not commonly used in the laboratory. However, it is possible to buy some items of plasticware, which have been presterilized with ethylene oxide, for example, syringes and filters. However, this method of sterilization can leave behind toxic residues; so items sterilized by alternative methods, for example, gamma irradiation, may be preferable. As with formaldehyde, it is also important to remember that ethylene oxide gas is very toxic and operator exposure needs to be minimized.

82.4.3 Hydrogen Peroxide

As an alternative low temperature sterilization agent, hydrogen peroxide is becoming more commonly used. This has the advantage that it will inactivate endospores, leave no toxic residues or significant moisture, and is relatively rapid that is, 2 h versus 14 h for ethylene oxide. This method is routinely used for sensitive items of hospital equipment, as well as for sterile isolators. However, it has been reported that the penetration of the gas into difficult loads can be a problem (34), and thus suitable validated sterilizing cycle must be used.

82.5 GAMMA IRRADIATION

Gamma irradiation is a very common method of sterilization (35). Most presterilized items of equipment are treated in this way, for example, tissue culture flasks, filters, plastic pipettes, pipette tips, and syringes. It is frequently used to sterilize items that cannot be heated. It has good penetrating powers and thus, has the advantage that items can be completely sealed and packaged before being sterilized. Items are exposed to 2.5 Mrad, the accepted standard dose, in a ^{60}cobalt plant. Some chemicals can also be purchased that have been sterilized in this way, for example, antibiotics.

This level of exposure has been in industrial use for a considerable time and has been found to be acceptable as long as there are only low levels of contamination by microorganisms. It is thus suitable for items that are essentially sterile before final irradiation, that is, items made in a factory environment. This method may not eradicate the more resistant bacterial spores and viruses. Both γ and ultraviolet (UV) irradiation have almost no effect on prions (2,3), an observation suggesting they either have no nucleic acid or have a very small and highly resistant genome.

82.6 ULTRAVIOLET LIGHT

UV light at a wavelength of about 260 nm will inactivate microorganisms and viruses (35). However, its usefulness as a method of sterilization is limited because of its poor powers of penetration. UV light can be used to sterilize the air in cell culture cabinets and rooms and to sterilize surfaces once they have been cleaned. The power of UV lamps decreases with use; so, they must be checked regularly. Bacterial spores and prions are highly resistant and bacteria possess DNA repair mechanisms, which can overcome limited damage. Irradiation with UV light is used in some high purity/pyrogen-free water systems to keep the level of viable microorganisms to a low level. This approach can also be used in combination with other chemical methods to decontaminate water, for example, in swimming pools. Recent developments using high intensity visible/UV light sources have allowed this method to be used for sterilizing simple pharmaceutical products such as water or saline. However, more complex bioproducts may be too sensitive to allow this method to be used.

82.7 LIQUID DISINFECTANTS

Many types of liquid disinfectants are available and play a useful role in the cell culture laboratory (4,5,9). A summary of common disinfectants, their effectiveness and use is given in Table 82.1. Disinfectants can be either prepared using laboratory reagents or purchased in the form of proprietary formulations. Various factors should be taken into account when using or selecting a suitable disinfectant. The use of disinfectants is not considered an absolute method of sterilization compared to such methods as autoclaving. They have limitations in terms of their spectrum of antimicrobial activity (Table 82.1). All disinfectants, some more than others, are less effective in the presence of organic matter. Although the concentrated stock disinfectant is stable, the stability of the working dilution varies with the type of disinfectant. Nevertheless, diluted disinfectants are used in the laboratory for the routine disinfection of equipment and surfaces in rooms and cabinets, routine hygiene within the laboratory, disinfection of cell culture items after use and before washing and resterilizing for recycling, for example, glassware, and treating used or contaminated cell culture media before disposal. However, care must be taken to ensure that they are effectively used. For instance, when treating items by immersion, care must be taken to fully immerse the equipment and to prevent pockets of air being trapped, which can prevent all surfaces being exposed to the disinfectant. For this reason, and to ensure that all organic material is removed, exposing the item to the disinfectant in two separate steps is a preferable approach to ensure effective decontamination in more critical situations. Disinfectants can be applied to surfaces using a cloth or by a hand-held sprayer. Paper towels should be used to cover liquid spills and then disinfectant applied. This must be allowed to act for the recommended time before disposal and the surface must then be retreated with the disinfectant. Some disinfectants are available in powder form, which can be directly applied to liquid spills so that they can be contained, absorbed, and treated in one step.

Disinfectants can be used to disinfect clean rooms on a routine basis prior to fumigation. For this a "knapsack" or large volume sprayer with a long lance is used. Appropriate safety precautions must be taken to avoid exposure of the face, eyes, and lungs to the disinfectant.

TABLE 82.1. Use of Common Disinfectants

	Recommended Conditions[a]		Effective Inactivation[b]			
Type of Disinfectant	Concentration	Time (min)	Bacteria	Bacterial Endospores	Fungi	Viruses
Alcohol	70%	30[c]	+	–	–	±
Phenolics	2–5%	30	+	–	+	±
Hypochlorite	10,000 ppm	30	+	+	+	+
Aldehydes	2–4%	30	+	+	+	+

[a] The specific manufacturer's recommendations should be followed for proprietary products.

[b] Agents that are inactivated at the recommended concentration are indicated by (+). In the case of viruses, the agent may be effective against enveloped viruses, but its effect on nonenveloped viruses may be only partial (±).

[c] In practice, it may require repeated applications to achieve a sufficient exposure time.

82.7.1 Formaldehyde and Glutaraldehyde

Formaldehyde and glutaraldehyde can both be used as liquid disinfectants, although glutaraldehyde is more commonly used and is probably more effective. Their advantage is that they are relatively insensitive to the presence of organic matter and are both able to inactivate bacterial endospores. However, there are health and safety implications regarding their use. For glutaraldehyde, in particular, there is pressure to limit exposure. Formaldehyde is used at about 4% and this is easily prepared by diluting the commercially available solution, that is, 40% formaldehyde solution (formalin). Glutaraldehyde is used at 2% and this is available as a component of many commercial formulations. The typical treatment time is at least 30 min, but longer times are advised to obtain full sporicidal activity. Proprietary glutaraldehyde-based disinfectants need the addition of an activator before use and then have a recommended life of about 7 days. Aldehyde vapors are considered to be relatively toxic because they are able to sensitize and also have mutagenic and carcinogenic properties. Steps to limit exposure must therefore be taken by for example, the use of a fume cupboard or appropriate microbiological safety cabinet.

82.7.2 Hypochlorite

Hypochlorite has a relatively low cost and is readily available, for example, household bleach and Chloros. Its disadvantage is that it is not so effective in the presence of high levels of organic matter. It corrodes metals and therefore, must not be used to sterilize centrifuge rotors or cell culture cabinets. Although the concentrate is stable, dilute hypochlorite is not and should be changed after 24 h. The recommended concentration when high levels of organic matter are present or for critical situations when contamination is known to be present, is 10,000 ppm available chlorine. Lower concentrations of 2500 ppm are recommended for routine hygiene. The recommended exposure time is at least 30 min, although overnight exposure may be preferable. Extended exposure to hypochlorite at 20,000 ppm available chlorine is currently a recommended procedure for inactivating prions. Sodium dichloroisocyanurate powder can be used for treating spills by absorbing the liquid and rapidly releasing high levels of chlorine.

82.7.3 Phenolics

Clear phenolic disinfectants such as Hycolin, used at a concentration of 2–5%, are effective against most common microorganisms; although, they are less effective against bacterial endospores. They are largely unaffected by the presence of organic matter and are commonly used in bacteriology laboratories. One disadvantage is that they tend to leave sticky residues when used for cleaning surfaces.

82.7.4 Alcohol

Alcohol, usually in the form of ethanol, is frequently used for disinfecting surfaces, protective gloves, and hands. For optimal effect it should be used at a concentration of about 70%. It can be readily applied using a hand-held sprayer. Surfaces must be fully saturated to ensure that the exposure time is sufficient. The ethanol/water mixture is then left to evaporate off naturally. Its rapid rate of evaporation, enhanced in a cabinet due to the airflow, may make it difficult to ensure an adequate exposure time. In such situations, more than one application of the alcohol may be preferable. Its advantage is that it has low toxicity, is convenient, easy to use, and leaves no residue. However, it is not very effective against fungi, bacterial endospores, and nonenveloped viruses. Also, care must be taken when handling it due to its flammability. It is therefore best used as a cleaning agent or disinfectant for less critical applications. In the case of cell culture procedures, it can be used as a precautionary measure for treating work surfaces and the exterior of cell culture flasks prior to and during work. For critical use or where contamination is suspected, it is best to decontaminate first with a more effective disinfectant and then to treat or spray surfaces with an alcohol solution as an additional precautionary measure.

82.7.5 Others

There are many other useful disinfectants, which can be prepared in the laboratory or purchased as commercial formulations. Some examples are hydrogen peroxide at 5–10%; acids or alkali; ethanol (70%) mixed with 4% formaldehyde or 2000 ppm hypochlorite; ethanol/propanol/aldehyde mixtures. The proprietary disinfectant Virkon has been shown to inactivate a wide range of viruses and other microorganisms, and is made up of three components: an oxidizing agent (peroxide), acid at pH 2.6, and detergent. This is used as a 1% solution and requires an exposure time of at least 10 min. In the pharmaceutical industry, chemical "clean in place" systems are used to clean and disinfect pipe systems and vessels. This procedure usually involves wash cycles with sodium hydroxide (0.5 *M*), followed by an acid rinse, and extensive washing with water. Final sterilization is usually accomplished using steam.

82.8 VIRUS TESTING AND ELIMINATION FROM BIOLOGICAL PRODUCTS

The presence of viruses is a common problem in biological products. Due to their small size, conventional sterilizing filters cannot easily remove viruses. The approach used is a combination of testing and the incorporation of specific virus reduction steps in the manufacturing process.

82.8.1 Virus Screening

The range of viruses that may potentially be present in biological material is extensive. This is made more difficult by the ability of some viruses to exist in a latent/persistent state without any obvious cytopathic effect. Thus, retroviruses such as the human immunodeficiency viruses (HIV-1 and -2), the human T-cell lymphotropic viruses (HTLV-1 and -2), or mouse retrovirus should be tested for. Similar considerations apply to herpesviruses such as herpes simplex virus (HSV-1 and -2), Epstein–Barr virus, cytomegalovirus, varicella zoster, and human herpes virus 6 (HHV-6). In the case of rodent cells, viruses that are potentially pathogenic to man that may be present include rat rotavirus, reovirus type 3, Sendai virus, lymphocyte choriomeningitis virus, and hantavirus. For bovine cells or those that have been grown with bovine serum, tests are commonly performed for viruses such as bovine viral diarrhea, infectious bovine rhinotracheitis, parainfluenza, bovine parvovirus, and bovine adenovirus. Various strategies may be employed in virus testing, including detection in animals, eggs, or cell culture. The induction of virus-specific antibodies in animals in the so-called mouse, rat, or hamster antibody production tests, are also commonly used. Increasingly, molecular techniques based on the detection of viral nucleic acid by the polymerase chain reaction (PCR) are used. Master and extended cell banks produced at the end of the manufacturing run are tested. In order to assure the worst-case situation, a passage number well in excess of that which is likely to be used in the final full-scale manufacturing process should be tested. The sensitivity of detecting certain latent viruses, such as herpesvirus and retroviruses, can be increased by the inclusion of appropriate chemical agents that induce virus replication.

82.8.2 Virus Elimination Methods

A complementary approach to screening and testing for viruses is to treat the product in order to physically remove or inactivate any viruses that might be present (36–39). A virus reduction step may be part of the standard purification process for the product, that may fortuitously remove viruses, or alternatively, a specific or dedicated step may be added.

The minimum level of virus elimination that is considered effective for any given virus elimination step is about 10^4-fold (4 logs). Enveloped viruses are in general more susceptible than nonenveloped viruses. The incorporation of more than one step is needed in order to provide a sufficient level of assurance with regard to virus safety. When several steps are included in a process, elimination figures of around 10 logs for resistant viruses and 20 logs or more for viruses of low to medium resistance can be expected. Quantitative risk assessment taking into account the level of virus that is likely to be present in the start material, can be used to determine if the level of virus reduction is sufficient. Because of the limitation of any particular removal or inactivation method with regard to the range of viruses affected, there has been pressure to include two or more specific virus reduction steps in a purification process. In addition, the methods used should be complementary in that they act by different mechanisms, for instance, the combination of a physical step such as virus filtration and a chemical inactivation step such as solvent/detergent. The inclusion of several virus elimination steps also has the advantage that in the unlikely case of one step failing, there should still remain an adequate margin of virus safety. The use of specific virus elimination steps, rather than simply relying on the standard manufacturing process steps, is preferred. This is because dedicated steps are generally more readily controlled, can be specifically optimized for virus reduction, and can be more readily validated. Virus elimination values for a range of viruses by various steps in a typical manufacturing process are given in Table 82.2.

In addition to the inclusion of effective virus reduction steps, it is essential to ensure that virus safety is not subsequently compromised by recontaminating the product by exogenous viruses during the manufacturing process. The various precautions taken to prevent recontamination are part of the GMP and include the use of closed processing systems and/or physical separation in different rooms or areas. Effective cleaning and sterilization procedures for equipment are also used as described previously.

A major factor that must be considered with any virus removal/inactivation method is the possibility that the step may have adversely affected the product. Most effective virus inactivation methods are relatively severe, and a compromise between maximum virus elimination and minimum product yield/activity loss must be reached. Even in the case of virus filtration, which is a very gentle procedure, product losses on the filter membrane can be high if the size of the protein is too near to that of the filter pores.

Some of the most commonly used virus elimination techniques are considered below. However their effectiveness may be dependent on the specific conditions in the material in question. For this reason product-specific virus elimination studies are necessary (see section titled Validating Virus Reduction Steps).

82.8.2.1 Downstream Processing. The purification steps used during the manufacturing process may provide some degree of virus elimination. Filtration steps using a pore size of 0.2 μm, used for removing cellular microorganisms and debris, will remove larger viruses to some degree. Filters of a smaller pore size, for example, 0.1 μm, used for removing mycoplasma and particulates, are capable of removing larger viruses even more effectively as well as removing

TABLE 82.2. Example of Virus Elimination During the Purification of a Monoclonal Antibody

Step[b]	Virus Reduction (log_{10})[a]					
	Sindbis	SFV	HSV-1	Vaccinia	MLV	Polio-1
Solvent/Detergent[c]	>5.7	>6.7	>5.7	nd	>3.6	0[d]
Protein-G Chromatography[e]	6.0	nd	7.1	nd	nd	3.1
Ion-Exchange Chromatography	nd	nd	5.5	nd	nd	2.4
Size-Exclusion Chromatography	nd	nd	2.7	nd	nd	1.2

Total Reduction	>18.4	>13.4	>28.6	6.8	>3.6	7.7

[a] All are enveloped except polio-1. Sindbis and Semliki Forest viruses (SFV) as representative enveloped virues, and models for the hepatitis C virus and the West Nile virus (WNV). Herpes simplex as a representative herpes virus. Murine leukemia virus as a retrovirus, a common endogenous contaminant of rodent cells. Polio-1 as a representative nonenveloped virus.
[b] Purification of human anti-D monoclonal antibody BRAD-3 (39).
[c] 0.3% tri-*n*-butyl phosphate/1% Triton X-100 for 1 h at 20°C.
[d] Nonenveloped virus, thus not susceptible to solvent/detergent treatment.
[e] Step includes column elution at acid pH, which contributes to virus elimination by inactivation
[f] Ultipor DV-50 (Pall) was used. Alternatives such as Viresolve-180 (Millipore) or Planova 35 (Asahi) should be equally effective. Filters with a smaller pore size will be effective for removing small viruses such as polio-1 and encephalomyocarditis (EMC).
nd, not determined.

some smaller viruses. Precipitation methods used to concentrate the product from the bulk harvest will, in some cases, separate virus into the waste material. For instance, this occurs during the cold-ethanol fractionation steps that are used during the preparation of albumin and immunoglobulin from plasma (41,42). The chemical reagents that are used may themselves inactivate viruses (43). In view of the variables associated with the process, this is generally not considered a robust elimination step. However, it almost certainly contributes to the safety of the product.

Chromatographic methods used in the preparation of high purity products also make a significant contribution to the virus safety of the product (44). Affinity or ion-exchange methods have been reported to give significant virus reduction in some manufacturing processes (45–47). However, for any given chromatographic system, the degree of virus elimination cannot be predicted. Reduction values ranging from 2 to 7 logs have been reported for different viruses in different chromatography systems. This variation is not surprising in view of the diversity of surface characteristics associated with different viruses and the column resins involved. Virus reduction during chromatography is largely due to virus removal, and procedures that enhance this, such as extensive washing or the use of buffers of varying ionic strength and pH, can enhance virus elimination. In addition, virus inactivation by chemicals used during washing or elution for example, low pH or isothiocyanate can occur during the process.

82.8.2.2 Virus Filtration. Virus filters have now become widely used in the pharmaceutical industry for eliminating viruses from biological products. This is due to the development of filters that have a sufficiently small pore size that they are effective for virus removal (48–52). Ultipor VF (22,53,54), Planova (23,26,55–58), and Viresolve (25,59–61) filters have been used (Table 82.3). These filters are available in a range of formats and have been shown to remove viruses in a size-dependent fashion. Some of these filters can be used in either a dead-end or recirculating mode. The filter types come in a range of pore-sizes

TABLE 82.3. Examples of Virus Filters

Manufacturer	Filter Type	Grade	Pore-Size[a]	Material	Mode of Use[b]	Mechanism	Integrity Testing
Asahi	Planova	15N 35N	15 nm 35 nm	Regenerated Cellulose	T or D	Depth	Liquid–liquid intrusion
Millipore	Viresolve	70 180	70 kDa 180 kDa	PVDF[c]	T	Membrane	Gold particle
Pall	Ultipor VF	DV-20 DV-50	70–160 kDa 160–200 kDa	PVDF	E	Membrane[d]	Forward flow

[a] Nominal pore size or molecular weight cutoff alone is given.
[b] T, tangential or D, dead-end.
[c] PVDF, polyvinyl deoxyfluoride.
[d] Triple layer membrane.

and the most appropriate type that gives the highest virus reduction without affecting product yields should be used. When filters of the smallest size are used, viruses ranging from the smallest of ca. 20 nm that is, parvoviruses to the largest of ca. 150 nm that is, herpes virus, can be used. If it is necessary to use filters with a medium pore size in order to ensure the passage of product through the filter, then virus removal will be limited to only those of medium to large size that is, >50 nm.

As with sterilizing filters that are designed to remove bacteria, it is essential that integrity testing is carried out on virus filters. Different test methods are available depending on the type of filter involved. The filter manufacturer may also use supplementary test methods for the quality control and release of the product. In all cases, the performance of the filter in the integrity tests has been correlated with the removal of a representative virus, which has been selected to have a size close to that of the filter pore size. The filter manufacturers have generally used bacteriophages such as PR772 (53 nm) as size models for this purpose. The filter manufacturer provides an acceptable pass limit, which correlates with the removal of about 4 log of virus.

The integrity of virus filters is tested by various types of integrity tests, depending on the filter manufacturer. In the case of the Planova filters, a gold particle tester is used. This test involves evaluating the removal of gold particles, slightly larger than the pore size of the filter, from a solution. The optical absorbance of pre- and postfiltration samples are measured on a spectrophotometer and their ratio calculated. This method is destructive, and thus can only be performed after filter use and allows no possibility of retesting the filter. In the liquid/liquid intrusion test, the filter is first treated with a liquid, for example, polyethylene glycol 800, to lower the pressure required to force a second immiscible liquid, for example, ammonium sulphate solution, through the filter. The second immiscible liquid is then introduced and the pressure increased to a specified level. The flow-rate under these conditions is then determined. The forward flow test is a variation on the familiar bubble point method. It involves treating the filter with isopropanol in order to reduce the pressure required to force air through the filter. The pressure is then increased and the pressure needed to force air through the filter is measured.

82.8.2.3 Solvent/Detergent Treatment. The most widely used method for virus inactivation is the solvent/detergent procedure. This involves treatment with a mixture of an organic solvent tri-n-butyl phosphate (TNBP) and a nonionic detergent in order to destroy enveloped viruses (62–65). Polysorbate 80 (Tween® 80) or Triton® X-100 at 1% are the detergents most commonly used at present. It should be noted that polysorbate 80 may be manufactured from bovine sources, but the use of vegetable-derived polysorbate 80 is equally effective, (66) and is to be preferred in view of concerns over prions (see section titled Prions). Solvent/detergent treatment is best carried out early in the standard purification process, so that subsequent purification steps, particularly those involving chromatography, may be sufficient to remove the chemicals to acceptably low levels. Initial treatment with soybean oil is sometimes used for the partial removal of TNBP, and specific chromatographic resins are available to remove the detergent if needed. The solvent/detergent procedure is gentle, generally having no apparent effect on structure, activity, or immunogenicity of proteins. The rate of virus inactivation is dependent on the particular nonionic detergent used and increases with temperature. The inactivation of >9–11 log of virus has been demonstrated. The method is robust and relatively insensitive to small changes in manufacturing conditions such as temperature, solvent/detergent concentration, pH, ionic strength, and protein concentration (67).

82.8.2.4 Pasteurization. Heat treatment in solution at 60°C for 10 h in the final container has long been used as a virus inactivation method (68). In the case of albumin, the fatty acid caprylate (octanoate) and/or acetyl tryptophan is used at low concentration as a stabilizer and does not need to be removed after treatment. In other cases it may be necessary to treat the product in bulk solution, often after the addition of a general stabilizer such as a sugar, amino acid, or salt. These are generally added at a high concentration and need to be removed after treatment. During pasteurization, the inactivation of most viruses occurs rapidly, that is, within 10–30 min. However, inactivation can be slower or incomplete for the heat-resistant viruses such as hepatitis A virus or some parvoviruses. There is evidence that the composition of the product can effect virus inactivation for such viruses as parvovirus B19.

82.8.2.5 Dry Heat Treatment. Products that are freeze-dried and treated at 80°C for 72 h have a good safety record with regard to virus transmission (69–72). Higher temperatures, for example, 100°C (73–75) have also been used. Some virus elimination also occurs during the freeze-drying process, a necessary prelude to the virus inactivation step itself. Several factors may influence virus inactivation by this method, particularly residual moisture content (72). However, a loss of product activity due to denaturation may occur. Also, there is the possible production of neo-antigens in the product by such extreme heating conditions. This may lead to the induction of an immune response against the product in recipients.

82.8.2.6 Extreme pH. Treatment at low pH, usually of about pH 3.5–4 for 30 min–2 h, has been used for virus

inactivation in various biological products (40,76–81). Virus inactivation is more effective at a lower pH and a higher temperature. Even a pH as high as 5.0 can be very effective, provided a long incubation period is used. Some nonenveloped viruses such as hepatitis A and parvoviruses are relatively resistant to acid conditions and may not be inactivated by this method.

82.8.2.7 Irradiation. Irradiation with UV light can be used as a method for virus inactivation (82–87). Because of the poor penetrating power of UV light, it is necessary to use a system that ensures all the liquid is effectively exposed to the light. This may involve the use of a thin film of liquid or a static mixer. Light in the UV-C wavelength that is, of 200–290 nm appears to be the most effective and is able to inactivate both enveloped and nonenveloped viruses. Damage or alterations to proteins by free radicals and reactive oxygen species can be a problem. However, this can be prevented by the inclusion of a quencher such as the flavonoid rutin (88,89).

γ irradiation has also been used for virus inactivation. Irradiation from a cobalt-60 γ irradiation source, as available in commercial irradiation facility is used. A loss of protein activity may occur at the high doses required for effective virus inactivation (90,91). However, if the dose-rate and total exposure dose are well controlled, effective virus inactivation can be achieved with only a limited effect on the product (80). The inclusion of protectants, such as the antioxidant ascorbate, to removes the free radicals and reactive oxygen that can damage the product, can improve the process (92–95). Freezing or lowering the moisture content of the product by freeze drying prior to irradiation maybe necessary to further prevent damage to the product.

82.8.2.8 Validating Virus Reduction Steps. While published information on the effectiveness of any virus elimination procedure is useful, product-specific studies are also required. This is in order to confirm and optimize the virus reduction step and to satisfy the requirements of regulatory agencies (96).

This involves the deliberate addition of virus to a small-scale version of the purification process, and following the virus through the process. The laboratory model must be demonstrated to be an exact scaled-down model of the full-scale manufacturing process. The product intermediate is then spiked with the virus and the process step performed. The amount of virus present at the start and end of the process is quantified by assaying infectivity or by detecting viral nucleic acid by PCR as appropriate.

Various viruses can be used for spiking studies including those that are of particular concern in the product. In addition viruses that are related to any viruses of concern are also included for example, bovine viral diarrhoea (BVDV) virus or Sindbis is a specific model for hepatitis C virus (HCV). In addition, other general model viruses are used in order to increase the range of virus types being tested and to include viruses with particular properties, for example, enveloped or nonenveloped, small or large size, or high resistance to physicochemical damage. Possible model viruses have been suggested by regulatory authorities (96).

While an estimate of the total virus reduction capability of the manufacturing process can be made. This is only really practical for processes with relatively low virus reduction capabilities. However, adding up the individual reduction values for each stage of the process can give an estimate for the total process. Although this approach is only strictly applicable where the individual steps are orthogonal, that is, based on different principles, this method has become widely used. Also, the effect of various parameters on the process, for example, protein concentration, residual moisture content, stabilizer concentration, pH, ionic strength, temperature, and chromatographic parameters, should be investigated. From such studies, an idea of the robustness of the inactivation process can be obtained and suitable limits set for relevant process parameters.

82.9 PRIONS

Screening for prions is not generally carried out on biological products at present. However, current concerns over prions and evidence that lymphocytes are involved in their spread and pathogenesis, may lead to routine testing for such agents in the future. At present, the most sensitive detection methods for prions are based on infectivity; however such testing may take at least 1 year to be completed and are very expensive to conduct. An alternative approach is to screen for the abnormal form of the prion protein, which appears to coexist with infectivity. This can be done by Immuno Western blotting or immunoassay; but these are less sensitive than infectivity assay. However, further developments in this area are likely, given public and regulatory concerns over BSE and its possible human derivative, the new variant Creutzfeldt–Jakob disease (vCJD). Prions are extremely stable to many physical and chemical inactivation procedures. However, they are removed by many manufacturing processes including filtration, chemical precipitation, and chromatography. At present, the screening and/or sourcing of the biological start material is the standard approach recommended for controlling such agents and preventing their presence in therapeutic products (104). Where it is essential to use bovine-derived material, such as fetal-calf serum, source material should be obtained from countries where BSE is absent. In addition, manufacturing procedures themselves have been shown to eliminate prions (98).

82.10 REGULATORY AND SAFETY ISSUES

The safety of individuals involved in manufacturing biological and other products is controlled, for example by the Control of Substances Hazardous to Health (COSHH) regulations in the United Kingdom. Codes of practice are published, which provide practical guidance on how to meet such legal requirements, covering hazards from both chemical as well as biological agents that may pose a safety risk, for instance chemical agents that are used as disinfectants, for example, glutaraldehyde and formaldehyde, as well as cells, microorganisms, and viruses. Detailed guidance on these aspects is given in such documents as the Categorisation of Biological Agents According to Hazard and Categories of Containment, which is regularly updated. More specific guidance may exist for specific groups of agents such as HIV and prions. From a legal point of view, the COSHH regulations put the onus for safety on the employer. From a practical point of view, this means that the manager of those individuals involved is responsible for their safety. This involves assessing the associated risks, developing and implementing safe working practices and ensuring these are followed. In turn, the worker himself must ensure that such safe working procedures are followed and must also ensure the safety of other individuals.

Appropriate guidelines for the sterilization and decontamination of equipment and contaminated waste materials must be followed in order to protect individuals receiving products, to protect the environment and to ensure safe practice. This also applies to the effective operation of equipment designed to sterilize and decontaminate, that is, autoclaves and ovens. Such aspects are covered by documents including Health Technical Memorandum 2010 (14) and appropriate British Standards (15).

The manufacturers of sterile pharmaceutical products are required by regulatory authorities to follow GMP guidelines (29). GMP is defined by regulatory bodies such as the Medicines and Heathcare products Regulatory Agency (MHRA) in the United Kingdom, the European Medicines Agency (EMEA) in the European Union, the Food and Drug Administration in the United States, or equivalent bodies in other countries. These regulators are required to ensure that products are safe and effective to the public. They must therefore be free of bacteria and other microorganisms and, in addition, the risks from viruses and prions must be reduced to an acceptable minimum. Guidelines have been issued and are regularly updated on the testing of cell lines for viruses and other infectious agents (99–101), methods for the removal and inactivation of viruses from cell culture and other biological products, and the validation of such procedures (96,98).

The use of the principles of GLP may also be relevant when developing biological products. In the case of the safety studies required for new pharmaceutical products, their use may be mandatory. Details of the approaches to be followed have been published (102,103). The use of the principles of GLP is designed to ensure the quality and integrity of scientific data generated in the laboratory. They are designed to ensure that all the methods used are adequately described, the results accurately recorded and fully traceable. All aspects of the study are covered, including the planning, performance, recording, and independent monitoring and archiving of the data generated. SOP can be used for routine activities. In the context of sterilization in the laboratory, this may include sterile filtration, the use of disinfectants, and the operation of ovens/autoclaves. There must also be an independent Quality Assurance programme. A Study Director is required to take overall responsibility for any particular safety study. It is also a requirement that all the equipment, such as autoclaves and ovens, used must be well maintained, regularly serviced, and calibrated at suitable intervals and records kept. In addition to official documents on GLP, practical guidance on its interpretation in the context of the cell culture laboratory has been published (104). Working to GLP is only mandantory in limited situations such as studies designed to ensure the safety of therapeutic products; these include animal toxicity testing of cell lines and products, the screening of cell lines for viruses; and the evaluation of virus inactivation/removal methods used in biological products. However, many or all of the principles involved may be usefully applied in the research or R&D laboratory, particularly, if for instance a cell line is subsequently used for manufacturing a therapeutic product.

analysis, 1539
clinical analyzers, 1539–1540
enzyme linked immunoassays, 1539
unspecific assays, 1539
precipitates, 1752–1753
protein disulfide isomerase (PDI), 200
protein expression, in bacteria, 557
altering growth conditions to increase soluble expression, 558
induction conditions, 561–562
lowering growth temperature, 558–561
medium composition, 561
altering protein sequence for solubility, 566
inclusion bodies, formation of, 566
mutation to increase solubility, 567
role of proteolysis, 566–567
cell free expression systems, 565–566
growth conditions and variables that affect yields of soluble protein, 568
inoculum preparation and storage, 568
maintaining solubility during harvesting and cell lysis, 569–570
protecting your cultures from contamination, 568–569
selection stress, stability of, 569
shaker flask versus fermentor cultivation, 569
trouble shooting protein producing recombinant bacteria, 568
host strain, choice of, 562
coexpressing other proteins, 562–563
E. coli, alternative hosts to, 563
low protease strains and those with better redox characteristics, 562
strain choice for expression versus transformation, 562
vector, altering, 563
altering the gene sequence of protein, 565
choice of promoter, 563–564
cold shock vectors, 564
selecting signal sequences/fusion partners, 564–565
protein expression kinetics and cell growth, 85
batch culture kinetics
experimental data, 85–86
model simulation comparison with experimental data, 87–88
unstructured kinetic models, 86–87
continuous culture kinetics
cell cycle models, 91–92
experimental data, 88–90
segregated models, 92
structured kinetic models, 90–91
fed-batch and perfusion cultures
model simulations, 92
monoclonal antibody production optimization, 92
suboptimal growth-associated production kinetics, 92–93
protein expression vectors, 216
protein glycosylation, 489
bioinformatics resources for glycans analysis and assignment, 506
deglycosylation methods
chemical methods, 498–499
enzymatic methods, 499–500
effects, 493
activity, 495–496
immunogenicity and biological clearance, 496
structure and stability, 493–495
glycans analysis and characterization strategies
capillary electrophoresis, 504
chromatographic profiling, 501–504
detection methods, 504–505
electrophoresis, 505
mass spectrometry, 500–501
monosaccharide composition analysis, 506
sequential enzymatic digestion, 505
sialic acid analysis, 505–506
glycosylation sites identification, 497–498
LC–MS of glycopeptides, 497
lectin affinity capture, 496–497
overview, 489–490
glucosylphosphatidylinositol (GPI) anchors, 492
less common forms, 492–493
N-linked glycosylation, 490
O-linked glycosylation, 490, 492
of recombinant therapeutics, 506–507
genetic engineering, 515–520
glycosylation control modeling, 520
host cell selection effects, 507–515
process condition effects, 520–526
protein hydrolysates, 424–425
protein immobilization, on mesoporous silicas and carbons
adsorption on surfaces, 1155–1156
biocatalysis, 1162, 1165–1173
enzyme immobilization on ordered materials, 1157–1162
materials, 1147–1154
protein posttranslational modification, effect of culture medium osmolality on, 602–603
protein production, cell types for, 9–10
protein release model, 39–40

proteins, biotechnological production of, 635
Protein Sciences Corp., 319
protein toxicity overcoming, 202
protein transient production, cell lines for, 10
proteolysis, role of, 566–567
proto-oncogenes and genomic instability, 619
protoplast fusion and cell, 236
protozoa, 1736–1737
provirus, 237
pseudohomogeneous matrix, 1399
